

II.3. FIRE Command

The FIRE command fires enables all enabled subtasks, and then fires a specified number of tokens into the \$IgnitionBuffer. A typical user interaction is as follows (defaults are given in square brackets) :

```
-PEGASUS- fire
  How many Ignition Tokens ?? [1] ==> <CR>
  Start the Event Generator ?? [N] ==> <CR>
-PEGASUS-
```

If the user desires to start the Message Event Generator, the FIRE command communicates appropriately with the Message Event Generator module. The pseudo code for the command is as follows :

```
BEGIN
  FOR AllUserSubtasks DO
    BEGIN
      IF (Subtask Enabled) THEN
        Enable(Subtask)
      END ;
      Number = AskUser("How many Ignition Tokens ") ;
      IF (AskUser("Start Event Generator") = True) THEN
        Signal(StartEventGenerator) ;
        ClockReset ;
        INCR I FROM 1 TO Number DO
          Fire($IgnitionBuffer) ;
          IF (AutomaticMode = True) THEN      ! in AUTOMATIC mode
            Block(on $TerminationBuffer) ; ! waits for the end of
        END ;                                ! the experiment.
```

II.4. MSGEVENT / GENSTOP Command

The MSGEVENT command permits the user to vary the time interval between successive messages to the buffers associated with a MSGEVENT variable. The variation of the time interval can be either by associating a constant with the MSGEVENT variable or by associating a table object with it. In the latter case the Message Event Generator fires off the specified buffer at time intervals that are successive values of the table. A typical user interaction for a constant inter-message time interval is as :

```
-PEGASUS- msgevent
  Name Of Message-Event ==> AEvent
  Name Of Table Object  ==> constant
  Value -- (BASE 10)   ==> 20.
```

-PEGASUS-

The GENSTOP command permits the user to stop the message event generator and thus control the duration of his external stimulus in the experiment.

II.5. STATUS / TOTIME Command

The STATUS command gives the status of the various subtasks in the user task force. Status information includes information such as whether the subtask is running, what is its location with respect to the hardware, and other operating system specific information. The TOTIME command gives the user access to the start time, the end time, and the total time taken by the latest execution of all subtasks. A typical user interaction is as follows :

```
-PEGASUS- totime
(      TIME -- Minutes : Seconds      )
Subtask ID      Subtask      Start Time      End Time      Total Time
-----
  1      ASubtask      00 : 00.002      00 : 12.346      00 : 12.344
  2      BSubtask      00 : 02.879      00 : 13.999      00 : 11.120
```

-PEGASUS-

The STATUS, TOTIME, and GENSTOP commands can be used while an experiment is in progress. This is unlike the rest of the commands which are recommended for use on a per-experiment basis.

II.6. ENABLE / DISABLE / TFINIT Command

The ENABLE / DISABLE commands permit the user to enable or disable a particular subtask. Disabling a subtask essentially makes the subtask unavailable for the current experimental run. This allows experimentation with a different number of servers for a node in a given execution of a graph. A typical user interaction is as follows:

```
-PEGASUS- disable
Name Of Subtask ==> CSubtask
Name Of Subtask ==> BSubtask
Name Of Subtask ==> r6
```

-PEGASUS-

The TFINIT command initializes the task force for the next experimental run.

II.7. RUNTIME Command

The RUNTIME command allows the user to associate a given table object and a delta-time with the specified RUNTIME variable (Section 4.3.1.3). A typical user interaction is as :

```
-PEGASUS- runtime
Name of Subtask ==> ASubtask
Name of RUNTIME variable ==> AVar
Value of Delta-Time (milliseconds) [175] ==> 100
Name of Associated Table Object [BTable] ==> ATable
```

-PEGASUS-

Appendix III

The B-language Grammar

This appendix describes the B-language grammar in reasonable detail. The objective is to give the user a formal introduction to the language. The description, however, is not exhaustive.

```

5. The Cm* Test Bed

Edward F. Gehringer, Anita K. Jones, Zary Z. Segall

5.1. Introduction

Interest in multiprocessor architecture has grown steadily over the past ten to fifteen years. VLSI technology offers the potential for building multiprocessors which are substantially larger than present computers to solve problems that cannot be solved today. A substantial number of multiprocessor designs exist, yet only a few multiprocessors have been built with a high degree of parallelism, say thirty or more processors.

Although multiprocessors appear to have cost/performance and reliability benefits, the computing community has relatively little experience in the actual use of multiprocessors. Consequently, little is known about how well the potential of multiprocessors can be realized in practice. This is exactly the thrust of the Cm* research project. This paper presents our experience in two important aspects of multiprocessing: first, the structure and organization of a multiprocessor test bed, and second, a collection of experimental results acquired from it.

A distributed system can be seen as being composed of an architectural component and a behavioral component. The first component consists of hardware, firmware, and software elements, and the relationships between them. The behavioral component is characterized by the way the architecture acts in the presence of a workload. The architectural component should be flexible, and the behavioral component should provide a controllable and measurable behavior.

These two goals have been emphasized in the Cm* test bed. Hardware-architecture flexibility has been realized by a programmable interconnection network. The two operating systems STAROS and MEDUSA provide adaptable mechanisms and policies for running experiments with application programs. The workload, the measurement tools, and the experimentation control are integrated into an experimentation environment. This environment complements the other support programs such as compilers and loaders with facilities for the specification, monitoring, and analysis of experiments.

The Cm* project has successfully constructed a 50-processor multiprocessor and two operating systems, thus demonstrating the feasibility of several aspects of multiprocessing. This paper explores some of those aspects, beginning with the Cm* hardware. Next, it focuses on the software—operating systems, utilities, and the higher-level software used to control experiments and gather data from them. Section 5.3 uses these experimental results to investigate how well various algorithm structures exploit the

Figure 20: Five-Cluster Cm* Configuration

potential parallelism of Cm*. Finally, the results of extended measurements on the hardware itself are presented.

5.2. The Cm* Experimentation Environment

5.2.1. The Cm* Hardware

The Cm* hardware consists of a number (currently 50) processor-memory pairs, called Cm's, connected by a hierarchical, distributed switching structure. Cm* is partitioned into several (currently 5) clusters of up to 14 Cm's each; the Cm's in an individual cluster are connected via a *map bus* to a mapping processor, called a *Kmap*, through which they communicate with each other (Figure 20). The clusters themselves are connected via *intercluster busses*. For a Cm to communicate with a Cm in a *remote* cluster, it first sends a request to the Kmap in its cluster, which forwards it to the Kmap in the remote cluster, which in turn passes the request to the target Cm.

Consequently, any Cm can reference memory anywhere in the system; the memory appears to be a

single large memory. Nevertheless, the communication paths are of different length and induce a performance hierarchy: references by a Cm to its local memory take about 3 μ sec.; references to another Cm in the same cluster require 8.6 μ sec.; and intercluster references take about 35.3 μ sec. [31].

Each Cm is a Digital Equipment LSI-11 with 64K or 128K bytes of memory, modified by the addition of a local switch, or *Slocal*, which examines each memory reference generated by the processor. Using its internal mapping tables, the *Slocal* decides whether the reference is to the processor's local memory (in which case the reference takes no longer than a memory reference by an unmodified LSI-11), and if not, passes the reference on to the Kmap. The Kmap is a high-speed microprogrammable communication controller with a cycle time of 157 nanoseconds, a control store of 4K 80-bit words and a data RAM of 4K 80-bit words. Since the Kmap is programmable, it is possible to experiment with different processor-memory and interprocessor communication strategies. Further, the border between software and firmware is fluid, and can be moved to investigate different operating-system implementations. For example, important operating-system functions can be placed in the Kmap to improve performance or to protect them from user programs.

Each Kmap has two bi-directional ports which may each be connected to a separate intercluster bus. This permits the clusters to be connected in many different ways. At present, there are two intercluster busses to which all five Kmaps are attached; hence there is a direct path between each pair of Kmaps, and messages need never be forwarded via intermediate Kmaps. All communication between Kmaps and from Kmap to Cm is performed by packet switching rather than circuit switching to avoid deadlock over dedicated switching paths. The Kmap is provided with eight process-state *contexts* so that it can service up to eight requests concurrently by switching from one context to another. Typically, it switches away from a context while awaiting completion of a memory access emanating from that context.

A major advantage of the Cm* structure is its extensibility. Because the switching structure is not centralized, it does not grow more complicated as the number of processors is increased. By contrast, C.mmp [83], an earlier multiprocessor constructed at CMU, employed a 16-by-16 crosspoint switch to route memory references to its sixteen processors. The complexity of such a switch grows by a factor of n^2 as n , the number of processors, is increased. Cm* is built from clusters of limited size, which may be interconnected arbitrarily. Thus there is no inherent limit to the number of processors or the amount of shared memory. Because intercluster messages need not pass through a central switch or bus, there is also no architectural limit to the overall intercommunication bandwidth. Indeed, it has been estimated [74] that a Cm* structure of up to 10,000 processors could be built.

5.2.2. Flexibility of the Switching Network

Multiple-processor computer systems vary along a continuum from shared-memory multiple-ALU machines like the ILLIAC IV [5], to multiprocessors in which each processor may access any portion of memory though it is directly connected to one portion of memory, to computer networks where each processor may directly address only its own memory. Cm*'s Kmaps can be microprogrammed to emulate either of the latter two structures, or other interconnection structures such as rings and cubes.

For example, if the Kmap is loaded with microcode which cannot map an address generated by one processor to the memory of another, Cm* becomes, in effect, a network of LSI-11's. It is useful to compare the performance of a multiprocessor with a network, as it seems intuitively true that a network should be cheaper than a multiprocessor with the same processor-memory pairs, due to the relative simplicity of the interconnection hardware.

Levy Raskin [55] performed two experiments comparing Cm* as a multiprocessor with Cm* as a network. His results showed that, at least for some practical multiprocessing algorithms, a network can be competitive with a multiprocessor. The first experiment used an integer-programming application which exhibited rather low communication traffic:

Set-Partitioning Integer Programming The set-partitioning algorithm implemented for Cm* uses an enumeration algorithm which performs an n -ary tree search in a large, relatively sparse binary matrix for a minimum-cost solution. The matrix is two dimensional; its size is usually on the order of hundreds by thousands. The problem is to solve

$$\min(\underline{c} \cdot \underline{x}) \quad A \underline{x} = \underline{e}, \quad x_j = 0 \text{ or } 1 \text{ for } 0 \leq j \leq N$$

where A is an $M \times N$ binary matrix, $\underline{c}$ is a vector of length N , and $\underline{e}$ is the identity vector of length M .

As an example, consider the airline-crew scheduling problem. The rows of the A matrix correspond to a set of flight legs to be covered during a specified period, and the columns of A correspond to a possible sequence of tours of flight legs made by one crew; $\underline{c}$ is a vector containing the cost of each tour. A feasible solution consists of a set of tours that satisfy all the flight legs (one and only one crew makes a flight leg). The algorithm seeks the solution with the lowest cost.

The integer-programming algorithm was run on both Cm* configurations. In the network configuration, all interprocessor communication must be via messages (transmitted by value) rather than shared memory. The shortest message could be transmitted in 85 μ sec. The algorithm was tested on five sets of data. When the matrix and other read-only global variables were replicated in each processor, the communication overhead was moderate, about 1.3 Mbits/second. Nonetheless, the network configuration

Figure 21: Comparison of Integer Programming on Network and Multiprocessor Configurations, Cases 1 and 2

Figure 22: Comparison of Integer Programming on Network and Multiprocessor Configurations, Cases 3 through 5

actually performed better than the multiprocessor configuration (Figures 21 and 22), perhaps because its microcode is simpler.

The second network experiment involved a speech-recognition task with complex and intense communication demands. It was an application of HARP, a speech-recognition system developed at CMU [39, 18]. It implemented a voice-input "desk calculator" with a 32-word command vocabulary. Despite the fact that the algorithm was carefully tuned to minimize interprocessor communication, the optimal number of processors in the network configuration was only three; as additional processors were added, execution time increased due to the high message rate. By contrast, the multiprocessor configuration could achieve performance gains with up to seven processors.

To implement large programs on Cm*, it is necessary to expand the LSI-11's sixteen-bit address space. Here, too, the Cm* architecture provides considerable latitude. Each Slocal has one *map bit* and one relocation register for each 4K-byte *page* of its Cm's address space. The map bits can be selectively set by the Kmap to cause various portions of the Cm's address space to be mapped, via the Kmap, to remote Cm's or remote clusters. References which are not mapped to other Cm's can be relocated within the local memory of the same Cm. The Slocal relocation registers too can be updated by the Kmap microcode. Hence a running program can be given access to different portions of Cm* memory at different times. The Kmap's data RAM can be used to cache recently accessed mapping information. Different Kmap microcodes have employed very different strategies for mapping addresses and managing the cache.

5.2.3. External Control of Experiments on Cm*

There are several reasons why Cm* needs to communicate with other computers. When multiple groups are using Cm* simultaneously for operating-system development, some external machine must keep track of who has what resources so that the groups do not interfere with each other. When large multiprocessor experiments are performed, perturbation is minimized if performance data is archived by an external computer. It is occasionally desirable to perform an application cooperatively between Cm* and other computers. Finally, as a research computer, Cm* does not warrant a fully developed set of utilities. Software development can be streamlined if the compilers and editors on other machines can conveniently operate on Cm* code.

Some of these functions are provided by a PDP 11/10 known as the Cm* Host. Anyone who wishes access to Cm* first logs into the Host from a terminal anywhere in the Computer Science Department. Then he reserves some set of resources. These usually consist of individual Cm's, or entire clusters. To

Figure 23: The Cm* Hardware Environment

use a pre-loaded Cm* operating system, the user need reserve only a single serial line attached to one Cm. To load an operating system, one or more entire clusters are required. During the daytime, two different operating systems are normally running in two different partitions of Cm*.

The Host can be used to start, stop, and single-cycle Cm's. It can also be used to "listen to" serial lines selectively, so that if several processors are sending him output simultaneously, the user can temporarily "gag" all but one of them to look at output from the other uninterrupted. Should he choose to listen to all his processors, he can have each line of output prefixed by the name of the processor which sent it.

Through the Host, one gains access to the three *Hooks processors*, which are special microprocessors attached to the Kmaps. The Hooks run a powerful debugging tool known as *KDP*, which can load, start, and stop and single-step a Kmap, and examine its registers or RAMs. With KDP, microcode can be debugged on Cm* itself, rather than on a software simulator. This is important, because in a multiprocessor, microcode bugs are often timing dependent and incapable of re-creation in a simulator.

The *diagnostic processor* is a PDP 11/10 connected to the Host. It runs diagnostic programs on unused Cm's and to maintain an error log. These records are important for the management of a large multiprocessor.

Cm* communicates with other general-purpose computers over the Computer Science Department's ETHERNET. Files, particularly object-code files, are transferred over this link to Cm*. The data-aggregation facilities of the *SIMON* monitor [70] run on a Vax and gather data which is shipped in packets from the resident monitor running on Cm*. Commands are sent to the resident monitor from the Vax, making it possible to control Cm* experiments from an external machine. Figure 23 is a diagram showing how Cm* is interfaced to other devices and computers.

5.2.4. Experimentation-Environment Software

Cm* provides a flexible, layered experimentation environment. The experimenter may use as many of the layers as he deems appropriate for his application—from the "bare" hardware to sophisticated experiment-management tools. We shall mention the components of this environment, then return to describe them in detail.

An operating system is the foundation of any software environment. Cm* has two: STAROS and MEDUSA. They are instrumented with sensors to allow monitoring. The utilities run as user programs on top of an operating system. On Cm* they are heavily oriented toward providing facilities for creating and controlling sets of concurrent processes. The top level of the experimentation environment consists of three components, a schema manager, a monitor, and a workload generator. These allow speedy construction of synthetic tasks to exercise various portions of the multiprocessor.

5.2.4.1. Operating Systems

STAROS [29] is an operating system for the support of *task forces*: collections of processes cooperating toward the achievement of a single goal. These processes are usually small, with less responsibility than the average process which runs on a uniprocessor, and they proceed in parallel to take advantage of the multiprocessor architecture. STAROS strives to make processes cheap enough that many functions which are ordinarily accomplished by procedure calls—requests for operating-system services such as memory allocation, for example—can be performed instead by separate concurrent processes.

In addition, STAROS is an *object-oriented* operating system: every action performed by the system is the application of some function to one or more objects. STAROS objects include basic objects, which are similar to segments in ordinary virtual-memory systems; stacks, deques, and mailboxes, whose semantics

are implemented in microcode; and abstract objects of user-defined types. The representation (e.g. data) of an abstract object is protected from being accessed or modified except by the small set of procedures which constitute its *type manager*. This facilitates the construction of software in terms of modules which have small and well protected interfaces.

Finally, STAROS is a *message-based* operating system. Message primitives, which are efficiently implemented in Kmap microcode, furnish support for interprocess communication and synchronization and function invocation.

MEDUSA [50], another Cm* operating system, has been strongly influenced by the underlying Cm* hardware. The goal of the MEDUSA project is to create an operating system with three attributes: *modularity*, *robustness*, and *performance*. Two aspects of the architecture influence how these goals are attained: Cm*'s memory is uniformly addressable—processes on different processors can reference the same memory; and the hardware is distributed, with a time penalty for accessing distant words of memory.

An examination of these issues resulted in an operating system with three properties. Functions of the operating system are performed by disjoint utilities that are physically distributed; each utility implements some abstraction for the rest of the system. Utilities are organized as task forces, which are similar to STAROS task forces, except for the degree of sharing: memory may not be shared among an arbitrary set of processes; rather each segment is either global to the task force, or private to a particular *activity*—the MEDUSA term for a component process of a task force. Third, utilities communicate via messages, as in STAROS.

As in STAROS, the MEDUSA message operations are microcoded for the sake of efficiency. The main difference is that MEDUSA messages are byte streams sent through pipes, similar to pipes in UNIX. A pipe can be nearly 4K bytes long, so a rather long message can be sent, providing there is room in the pipe. On the other hand, STAROS messages consist of only one word, or one *capability* (a protected pointer to an object). Consequently, STAROS message communication is generally done by reference—a pointer to the data is passed—while MEDUSA messages are passed by value.

In order to promote an efficient implementation, MEDUSA has attempted to adhere more closely to the Cm* hardware structure than has STAROS. For example, STAROS supports a full capability-based addressing scheme. An address names a capability, which indirects through a descriptor to a segment of memory. A MEDUSA address names a descriptor directly, avoiding one level of indirection, but affording less flexibility in sharing.

Many of the differences between the designs of the two systems can be explained as follows. STAROS views Cm* basically as a multiprocessor. Task forces consist of processes that share global data. Hence it is convenient and efficient for processes to communicate by passing references. All physical movement of data is explicitly requested by some process. Processes may migrate from one processor to another.

MEDUSA views Cm* basically as a tightly coupled network. Messages are passed by value. Transmission of a message physically relocates that message from one memory to another as in a network. Block movement of data is integrated into the message primitives. As on a network, a process remains associated with a specific processor. Recall, however, that MEDUSA does permit processes in the same task force to share memory independent of its physical location.

5.2.4.2. Support Software

Few existing languages offer comprehensive facilities for defining the many components—code, data, processes, and mailboxes—that constitute a task force. Objects must be created and named, and placed in appropriate physical memories. Both operating systems have provided support software to deal with these issues. MEDUSA has built its own linker, known as MEDLINK. Its directives allow the task-force author to control how resources are utilized by the activities that make up a task force.

The STAROS project has developed a separate language for the specification of task forces. Called TASK [33], it provides inter-process naming and resource-allocation mechanisms. It can be thought of as an extension to the BLISS language [84], in which STAROS modules are written. TASK provides a way to declare names which can be shared among the STAROS modules in a task force. It generates loader directives for constructing the task force. TASK can specify the objects and processes which are to be created when a task force begins execution. Its resource-usage directives can state, for example, that a process should execute on the same Cm which contains its code; that two processes should share the same Cm; or that two other processes should execute on different Cm's or in different clusters—to decrease contention, for instance.

5.2.4.3. Support for Experimentation

Several elements make up Cm*'s *Integrated Instrumentation Environment* (IIE).

- First there is the software which *manages* the experiment—takes a description of the experiment, causes the experiment to be run, and then stores its results. This is called the *schema manager*.
- Second, the SIMON monitor [70] gathers resource-utilization data while the experiment is running. It gets its information from sensors embedded in the operating system. Each sensor records the state of a resource.

Figure 24: The Integrated Instrumentation Environment

- Finally, there is the task force which is to be measured, called the *stimulus*. It may be either an application program or a synthetically generated workload. Cm*'s workload generator is PEGASUS [61].

Figure 24 shows how these components fit together. Active at experiment run time are the instrumented stimulus; the instrumented operating system; and the resident monitor, a process which enables and disables the sensors and collects data from them.

A *schema* is a complete experiment description, consisting of a task force to be measured, monitoring directives, system configuration information, and experiment directives written in the workload-generator language. The results of an individual experiment are captured in a *schema instance*. Schemata are archived by the *schema manager*. They may be created either from scratch with a conventional text editor, or generated automatically during a series of runs, by having the schema manager record the commands which are used. The schema manager scans the schema and sends directives to the run-time system. These include global initialization commands for the entire experiment along with commands to set up, start, and terminate each run.

SIMON is a high-level multiprocessor monitoring program. The user asks a high-level question, which SIMON attempts to map into low-level questions. For example, if asked for the utilization of a particular processor, SIMON would consult its relational database to discover where the resource was located, and what kind of sensor existed to record usage of the resource. Then it would enable the sensor. Some of

Figure 25: A Node Corresponding to a Subtask

the entries in the database tables contain information which does not vary much with time, for example, the list of processors in the system. Other entries instead contain descriptors for sensors embedded into the operating system. If one of these entries is read, the corresponding sensor will be activated. SIMON itself runs on a Vax and communicates with the resident monitor on Cm* under STAROS. A compatible resident monitor will soon be built for MEDUSA.

The final component of the IIE is the workload generator PEGASUS. Some measurements can best be made with synthetic workloads which exert precise loads on particular components of the system. In addition, it is usually quicker to compose directives for a workload generator than to write an application program with the same characteristics.

PEGASUS represents a task force as a graph. The nodes of the graph are the subtasks (i.e. processes or activities), and the arcs are buffers (e.g. mailboxes) that can queue data variables flowing from one subtask to another. The firing rules are boolean expressions that state which arcs must contain tokens (input firing rule) before the node fires and places tokens on which output arcs (output firing rule). The output firing rule can be expressed probabilistically. For example, it can state that an output token will be placed on arc B_3 with a probability of 40%, or on both arcs B_1 and B_2 with a probability of 40% (see Figure 25).

The subtasks themselves are programmed in terms of simple statements and control constructs. A

simple statement says that a particular action is performed a given number of times. For example, $\langle a_i, r_j \rangle$ says that action a_i is performed r_j times. An action consists of a memory reference or the firing of a token. Simple statements may be arranged sequentially, or they may be encapsulated in loops. The *Select* statement allows one of the branches of a case-like statement to be chosen probabilistically. There is another statement which varies the values of parameters each time a loop is performed. This allows an experiment to be repeated automatically under slightly different conditions each time. PEGASUS has been interfaced to MEDUSA, and a STAROS implementation is in progress.

5.3. Research in Distributed Systems

A multiprocessor like Cm^* is an versatile test bed. Algorithms can be tested to see how efficiently they decompose for multiprocessing. Interprocess communication systems—such as the STAROS and MEDUSA message systems—can be compared. Experiments can be performed with different ways of organizing task forces. The hardware can even be evaluated, to decide which components are performance bottlenecks and deserving of close attention in future multiprocessor designs. We will describe some of the results which have been obtained using Cm^* .

One important question is whether multiprocessors can be cost-effective computational engines; in other words, is there a substantial amount of computing that they can perform more efficiently than alternative architectures—say, fast uniprocessors or networks of smaller computers? Germane to this question is the issue of *speedup*.

5.3.1. Speedup

At first glance, it might seem that most algorithms would run faster on a multiprocessor. Few algorithms, after all, are strictly sequential by nature. But offset against the potential parallelism is the overhead of creating, synchronizing, and communicating with additional processes. These are pitfalls on which many algorithms falter. The question thus becomes: Are there algorithms for important classes of problems which can effectively exploit the parallelism offered by a multiprocessor?

Speedup is a useful measure of whether an algorithm succeeds in harnessing the potential parallelism of a computer like Cm^* . It is defined as E_u / E_m , the ratio of the elapsed time required by a uniprocessor algorithm to the elapsed time taken by a multiprocessor algorithm for the same computation. If n processors are used, the speedup is generally between 1 and n . Sometimes when a multiprocessor algorithm is run on a one-processor configuration, the speedup will be less than one; an expressly uniprocessor algorithm would have been faster. Occasionally one encounters a speedup of more than n . We take up this topic in Section 5.3.1.5. For most algorithms, the speedup curve is convex in the number

of processors; speedup rises as processors are added, up to a certain point. Then the speedup begins to fall, meaning that adding more processors actually slows down the computation. Thus, another interesting question is, What is the optimal number of processors for executing each algorithm?

During the past few years, we have measured the speedup of several algorithms on Cm*, under widely varying conditions. Early experiments were performed with only a 10-processor Cm* system, precluding realistic multicluster investigation. In later experiments, the number of Cm's per cluster has changed from time to time. Some experiments have enjoyed the full support of an operating system; others have been built from scratch, using only rudimentary Kmap microcode. Among these algorithms are a quicksort, a partial differential equation solver, a railway-network simulation, and the integer-programming algorithm first mentioned in Section 5.2.2. We shall describe them as we consider particular speedup issues.

5.3.1.1. Theoretical and Practical Speedup

Some algorithms lend themselves to more speedup than others. We say that the algorithm exhibits a *linear* speedup if the time taken by an n -processor version is one- n th the time required by the uniprocessor version. Two of our algorithms, partial differential equations and integer programming, have a theoretical possibility of nearly linear speedup. On the other hand, the theoretical speedup s of the quicksort algorithm is only

$$\frac{1}{s} = \frac{1}{p} + \frac{2 - \frac{\log_2 p}{p} - \frac{2}{p}}{\log_2 n}, \quad (1)$$

where p is the number of processes and n is the number of elements sorted.

Linear speedup is the maximum normally obtainable by multiprocessor algorithms. Computations which fail to attain it suffer a *decomposition penalty* [75], which has two components, algorithm penalty and implementation penalty.

The *algorithm penalty* arises from the nature of the algorithm itself, and it also has two components [9]. One of these is the synchronization penalty imposed by the algorithm; in other words, the amount of time that some processors are idle while waiting for other processors to deliver results. The other is the complexity of the reconstitution computations; in other words, the time required to combine the results generated by the individual processors into an overall result for the entire computation. This component is insignificant in the algorithms presented in this paper, but not for all algorithms, for example, the power-systems simulation implemented on Cm* by Dugan, Durham, and Carey [15, 16, 9, 76].

The *implementation penalty* is a consequence of executing the algorithm on a particular hardware and system-software configuration. It is also made up of two components. The first is the degree of coupling between the parallel processors. It reflects the overhead of the interprocess communication (e.g. via global data or message passing) required by the algorithm. This penalty diminishes, for example, as the message-communication microcode is optimized. The other component is the impact of process and data placement: Cm*'s memory-reference hierarchy slows down processes which need to reference non-local data.

Algorithms with little decomposition penalty show the most speedup. This implies little synchronization or communication, few references to large global data structures, and simple reconstitution computations: in short, processes which are relatively small and independent.

5.3.1.2. The Influence of Synchronization

How much does synchronization cost? As a case in point, consider the partial differential equations algorithm:

Partial Differential Equations. The objective is to solve Laplace's partial differential equation (PDE) with given boundary conditions (Dirichlet's problem) by the method of *finite differences*. The equation

$$\frac{\partial^2 z}{\partial x^2} + \frac{\partial^2 z}{\partial y^2} = 0 \quad (2)$$

is solved for points of an m -by- n rectangular grid, where only the values at the outer edges of the grid are given. The solution is found iteratively. On each iteration the new value of every element is set to the arithmetic mean of the values of its four adjacent neighbors. Each process runs on its own dedicated processor; it performs the iteration for a fixed, continuous subset of the grid array, which will be called a *task*. Thus, the processes are distinguishable. The algorithm was implemented on the 10-processor Cm* by Levy Raskin [55], and updated by Jarek Deminet [13] for the 50-processor system.

Several different variations [6] of this algorithm have been implemented on Cm*. All methods use one process per processor, so these terms can be used interchangeably. The processors iterate on equal-sized partitions of the grid.

1. *Jacobi's method.* At the beginning of each iteration, a processor retrieves its partition from a global array. New values are computed for each element of the partition, then stored back into the global array. This storing is performed inside a critical section. The processor then checks its error vector (computed from the difference of the new and old values in its partition). If the error vector is smaller than a pre-specified limit, the processor reports that it has finished. Otherwise it blocks, until the other processors have completed the current

Figure 26: Comparison of Speedup for Different Methods of PDE

iteration. Iterations are performed until all processors have finished.

2. *Asynchronous Jacobi Method.* This method is the same as method 1, except that a processor does not wait for the other processors to finish before starting on the next iteration.
3. *Asynchronous Gauss-Seidel Method.* This method is similar to method 2, except that the processor uses newly computed values as soon as they are available, instead of the values known at the beginning of the iteration.
4. *Purely Asynchronous Method.* To compute new array values, this method uses the most recent values of all components by reading them directly from the global array and writing the updated values back to the global array (without any critical sections or synchronization). It uses a critical section only for a processor to report that it has finished.

Raskin compared these algorithms using a 21×24 array (504 elements) on a one-cluster Cm* system with a maximum of eight processors. His results are shown in Figure 26. With eight processors, method 1 yields a speedup of just over 5.0; method 3 gives a speedup of better than 5.3; method 2 yields 6.4; and method 4, almost 7.3.

An apparent anomaly in these figures is the lower speedup of method 2 compared to method 3, though the values used in asynchronous Gauss-Seidel iteration are nominally more up-to-date. However, the

uniprocessor Gauss-Seidel algorithm is almost twice as efficient as the uniprocessor Jacobi algorithm. Because it cannot quite maintain this advantage as the number of asynchronous processes increases, the speedup of the asynchronous Jacobi algorithm is greater. In fact, all of the asynchronous algorithms take more iterations as the number of processors increases [6]; but the rate of increase with method 3 is greatest, followed by method 2 and then method 4. (The number of iterations taken by the synchronous Jacobi algorithm is independent of the number of processors.) Nonetheless, method 3 is still faster than method 2 for eight processors, by a margin of 38 percent. Beware of confusing speedup with speed; a slower algorithm may display a better speedup.

Note that the asynchronous Jacobi and Gauss-Seidel algorithms are the only two which demand precisely the same amount of synchronization (critical sections at the beginning and end of an iteration, no waiting for other processors). Regardless of execution time, each time the synchronization requirements are decreased—from method 1 to methods 2 and 3, and then again to method 4—speedup improves. Hence, the degree of synchronization seems to be the dominating factor affecting the speedup of the algorithm.

The cost of synchronization is also illustrated by a comparison of two methods of simulating the structure of liquids.

Simulation of Molecular Motion. Given the microscopic interactions between particles, we want to predict the static and dynamic properties of a collection of such particles. Macroscopic quantities are obtained by an averaging according to one of two methods—either ensemble averaging or time averaging. The Metropolis method [44] employs ensemble averaging. To generate each new configuration, a single particle is moved. The bottleneck of the calculation for each move is the computation of the binding energy for each particle, which involves $O(N)$ calculations. The parallel algorithm uses K processors in an attempt to reduce the complexity of this step to $O(N/K)$. The interactions can be evaluated in parallel without interprocessor communication, but the contributions calculated by each processor must be added together. The complexity of this step is $O(N)$. In addition, the computation must be synchronized at each move.

The molecular-dynamics algorithm [80] uses time averaging. First, an initial set of velocities for the particles is calculated. Given an initial set of coordinates, the velocities can be used to predict a set of coordinates at a later time. A summation is again performed to find the binding energy, but with this algorithm, the summation can be reordered to allow a processor to sum its subset of binding energies *locally*, with the global summation being required only once at the end of the computation.

These simulations are described by Ostlund, Hibbard, and Whiteside [49]. This problem is representative of the general problems involved in the theoretical study of molecular

Figure 27: Speedup of Molecular-Motion Simulation

motion. The results shown in Figure 27 are for a system of 50 particles.

The molecular-dynamics algorithm shows better speedup than the Metropolis algorithm. One factor is that the molecular-dynamics algorithm avoids summing of shared variables. In addition, since particles move simultaneously rather than one at a time, the $O(N^2)$ serial computation of the binding energy is converted to an $O(N^2/K)$ parallel computation using K processors. A processor computes $O(N^2/K)$ interactions between synchronizations, instead of $O(N/K)$ interactions as in the Metropolis algorithm.

Both graphs exhibit a zig-zag pattern because the particles are parceled out among the processors as evenly as possible. Each time that there is a decrease in the number of particles handled by the "busiest" processor, speedup increases markedly. Note, for example, the large jump in going from 24 to 25 processors; in the latter case, no processor need handle more than two particles.

Both of these algorithms for molecular motion are synchronous, requiring lock-step iteration; no asynchronous molecular dynamics equation is known. Significant hurdles stand in the way of developing an asynchronous algorithm; for molecular dynamics, it would require averaging the interactions between particles occupying different positions in space and time. In general, even when an asynchronous algorithm exists, it is more difficult to prove its convergence. It must reliably attain the same final state each time it is repeated, yet it passes through a sequence of intermediate states which is unpredictable due to slight variations in processor speeds.

5.3.1.3. The Placement of Processes

On a multiprocessor like Cm* with a non-uniform reference time to different portions of memory, the placement of processes and data can have a major impact on algorithm performance. What factors need to be taken into account in deciding how they are to be distributed? The first is *locality of reference*. To expedite memory references, data should be local to the processor which references it. Although this is not feasible for shared global data structures, it still pays to minimize the distance between processors and their data.

For example, Raskin's version of the PDE assigned processors to array partitions essentially at random. But not all of the processors had the same amount of work to perform. Those that operate on partitions in the "middle" of the grid require more iterations than the ones that are close to the boundary, so ideally they should be solved by the fastest processes. When Deminet re-implemented the algorithm for the multicluster STAROS, he created a version that satisfied this criterion; we will call it the *improved processor selection version*.

Figure 28: Effects of Improved Processor Selection

Figure 28 displays the effect of improved processor selection. It is significant when the number of processors is larger than 16, meaning that more than two clusters are involved. At thirty-five processors, the improvement is about 20%.

5.3.1.4. The Distribution of Data

While thoughtful placement of processes can greatly improve locality of reference, it does little to reduce *memory contention*. If a global data structure is deposited in the local memory of a single Cm, then many processors will compete for access to the same Slocal and memory, so response will deteriorate. The impact can be substantial because many multiprocessor algorithms, such as the PDE, make a large fraction of their memory references to a single shared data structure.

Deminet performed an experiment to determine the effects of data placement. Method 4 of the PDE was run on a 150-by-150 grid. In one case, the data was centralized in the memory of a single Cm. In the other, the pages of the array were distributed between clusters to maximize cluster locality of reference. Figure 29 displays the results. The centralized-data version achieved a maximum speedup of 16, while the distributed-data version yielded a speedup of 28 with 37 processors (the most processors for which it was run), apparently without reaching its maximum. It is also illustrative to consider the degradation of an

Figure 29: Effects of Distribution of Data

individual processor's performance: in the distributed-data version, all processors ran at least 68% as fast as the fastest processor, while in the centralized-data version, the slowest processor ran at only 28% of the speed of the fastest.

There is a tradeoff between locality of reference and memory contention. When data is too centralized, many processors are contending for the same memory. When data is too widely distributed, processors have to make too many expensive intercluster references. Consider again the PDE. When processors are added to the experiment, the strategy is to fill up one cluster before beginning the next. The curve in Figure 30 first shows a dropoff in speedup between 20 and 21 processors, just as the experiment moves into its third cluster. The explanation is that data is now distributed between three clusters instead of two. All but one of the processors need to perform intercluster accesses to access data in the third cluster. The extra intercluster references slow down the entire experiment. Notice the additional, and more pronounced, drops in performance as the experiment crosses into its fourth and fifth clusters. Deminor called this the *crossover phenomenon*.

As we have seen, many factors must be taken into account when deciding how to distribute data. There is no straightforward way to estimate the interplay of these factors and determine how to place the data objects in the most desirable location. Cm*'s operating systems provide no automatic distribution

Figure 30: The Crossover Phenomenon with the PDE

algorithms. The TASK language permits the programmer to specify constraints on object placement, and uses heuristics to attempt to satisfy them, but it cannot guarantee optimality.

The Cm* quicksort is another algorithm which operates on a large shared data structure:

Quicksort. In the multiprocessor quicksort [60], a number of indistinguishable processes, one per processor, take part in sorting a global array of integers. The processors share a *stack*, which contains descriptors for continuous subsets of the array which have yet to be sorted.

On each pass, a processor tries to pop a descriptor for a new subset from the shared stack. If successful, the processor partitions the subset into two smaller ones, consisting respectively of all elements less than, and greater than, an estimated median value. After this partitioning, a descriptor for the shorter of the new subsets is pushed onto the stack, and the longer subset is further partitioned in the same way. This algorithm was implemented on the 10-processor Cm* by Levy Raskin [55]. Jarek Deminet [13] adapted it to the 50-processor configuration, modifying the algorithm to cut down on references to the shared stack.

Placement decisions are simpler to make if an algorithm has a predictable pattern of reference, for

Figure 31: Speedup of Quicksort

example, if each process is statically associated with a partition of data which is known at compile or load time. The PDE is such an algorithm; hence it is possible to arrange for the data to be close to the processor, and it displays an increasing speedup even for relatively large numbers of processors. On the other hand, the quicksort's processors dynamically choose subsets of the global array from a shared stack; it is not known *a priori* which processor will manipulate which data. The quicksort (see Figure 31) reaches maximum performance at a relatively small number of processors.

5.3.1.5. Greater Than Linear Speedup?

Is it ever possible for a multiprocessor algorithm to exhibit greater than linear speedup? Intuitively, the answer is no, because such an implementation would do less total work than its uniprocessor cousin. By simply turning its independent processes into coroutines, one could produce a faster uniprocessor version of the same algorithm. This assumes, of course, that as much memory was available to the uniprocessor version as to the total multiprocessor version; otherwise more frequent swapping would retard its execution speed. Also, if process switching were much slower than synchronization primitives, the multiprocessor version might gain a more-than-linear advantage over the coroutine version, but this could not properly be called speedup.

Nonetheless, we do occasionally encounter a particular algorithm execution with more-than-linear

Figure 32: Speedup of Integer-Programming Computation

speedup. One such case occurred with the integer-programming algorithm first mentioned in Section 5.2.2, which was implemented by Raskin for the 10-processor Cm*. This is a search algorithm. Its initialization phase puts a large number of possible solutions in a global stack, from which all the processors choose their work. As the search proceeds, a global variable holds the cost of the best solution found so far by any processor. All processors compare their current cost value to it, and begin to backtrack in the search when the global cost is lower.

It is possible for the multiprocessor version to be "lucky". If one of its processors encounters a near-optimal solution at the outset, none of the processors will have very much work to do. The uniprocessor version, which does not encounter the near-optimal solution until later, has the disadvantage of having done a more complete search over the earlier possible solutions. But the opposite can also happen. Suppose the near-optimal solution turned up, say, first of all. Then the uniprocessor and multiprocessor versions would encounter it at the same time. But before its cost could be determined, the other processors in the multiprocessor version would have wasted processing time on their initial

solutions.

Hence, the multiprocessor version cannot be "lucky" all the time. A search program can occasionally exhibit greater than linear speedup, but it cannot "on average" show greater than linear speedup, over all possible sets of input data. The results shown in Figure 32 illustrate this. Only one of the five integer-programming runs managed to surpass linear speedup.

5.3.2. Task-Force Organization

Implementations of the algorithms introduced in the previous section are quite simple. A single *master* process is responsible for setting up and starting each of the other processes, known as *slaves*. The slaves execute in parallel, perhaps synchronizing from time to time, until they have completed their portion of the computation, and then notify the master. When all of the slaves have completed, the master reports the results of the experiment.

Master-slave organization is one of the simplest task-force structures, and one for which it is meaningful to measure speedup, since the multiprocessor algorithms have a uniprocessor analogue which can be used for speed comparisons. Some algorithms have no uniprocessor version, for example, this simulation:

Railway-Network Simulation. The task force consists of a fixed number of processes (63 in this version), each of which represents a *station*. Two stations may be connected by a unidirectional *track*. For a given station *A* a set of *previous stations* includes each station *B* for which there is a track from *B* to *A*. The stations exchange messages representing *trains*. The route of each train is an attribute of the train, determined when the train is created. Each station serves the trains in the order in which they arrive.

Each process maintains its own simulated time. At any given moment, the simulated time will probably be different in different processes; thus the simulated time of sending a train from one station to another is unrelated to the real time when the message representing the train was created. Even the real-time order of events may be different from the simulated-time order. Suppose, for example, that station *A* sends a message to station *C* at real time 5. At this moment station *A*'s clock may show the simulated time 50. Station *B* may send a message to *C* at real time 7, but its clock may then show the simulated time 40. The second message should be serviced by *C* before the first one, since only the simulated time is relevant. In general, a station-process blocks until it knows the simulated time of the arrival of the next train from each station.

Unlike in the previous experiments, several processes may run on each processor. There exists one additional process, the *reporter*, which records data sent to it by the stations. As programmed, the application may not be run on a uniprocessor configuration,

Figure 33: Speedup of Railway-Network Simulation

since the reporter must be running throughout the experiment. In fact, this task force will fit in a minimum of four Cm's. The algorithm was programmed by Jarek Deminet in 1979.

It is very difficult to estimate speedup for this algorithm, because running time depends not only on the number of processors, but also on the distribution of processes among them. In the implemented version, processes may not move from one processor to another. If they did, it would probably be necessary to move their local data to avoid the penalty of remote references. To move data would itself impose an overhead. Thus the run time of the experiment depends heavily on the initial assignment of processes to processors. Figure 33 graphs the run time vs. number of processors. After an initially decreasing region where the average number of runnable processes is greater than the number of processors, there are apparently random fluctuations in the graph, perhaps due to variations in the suitability of the initial assignment of processes to processors.

5.3.3. Hardware Reliability Tests

Long-term reliability data for the components of Cm* has been obtained by the Auto-Diagnostic, a program which continuously exercised the hardware by running diagnostic programs on all otherwise idle computer modules. The diagnostics tested four distinct components: the memory, the instruction set, the traps and interrupts, and the Slocal and a small part of the Kmap. The memory test consists of thirteen

subtests including a gallop test, marching ones and zeros, and shifting ones. The instruction-set test and the trap-and-interrupt test check the functioning of the LSI-11 processor. The Slocal diagnostic tests the registers and data path of the Slocal, among other things.

Table 1: Distribution of Transient Errors on Cm*

Mode	Diagnostic Test Used				Total	% Total
	Memory	Instr.	Trap	Slocal		
Burst	5	1	1	13	20	31.2
Simultaneous	5	1	0	5	11	17.2
Isolated	13	3	2	15	33	51.6
Total	23	5	3	34	64	100.0
% Total	35.9	7.8	4.7	51.6		

In continuous measurements over a period of eight months, transient errors were noted more than twenty times as often as hard failures (permanent faults which reflect an irreversible change in the hardware. Of the transient errors, 83% of them were local, confined to only one Cm. Table 1 [78] reports the data. A *burst error* consists of multiple errors in the same Cm within a short span of time. *Simultaneous errors* affect more than one Cm; an *isolated error* is a single error in a single Cm. Transient errors followed a decreasing failure-rate Weibull distribution. This is in contrast to the usual assumption of exponentially distributed transient errors. Studies done on several other computers also reported a decreasing failure rate [42].

5.4. Summary

We have tried to make general observations about the cost effectiveness of multiprocessor computation, based on a variety of experiments on Cm*. These are only a sample of the work that has been done with Cm*. Aided by the experimental support provided by the Cm* test bed, a flexible hardware/software architecture, we are continuing to broaden the range of our investigations. The long-range issue is not whether Cm* itself, with its relatively primitive microprocessors, is a useful vehicle for solving large problems, but whether multiprocessor architectures in general have an important role to play in providing computational power.

Multiprocessors have some important advantages over uniprocessors. Since simple processors are becoming quite inexpensive, multiprocessors of substantial size may prove significantly less expensive than uniprocessors of the same power. Their total processing power is not so constrained by fundamental physical constants as is the case for uniprocessors. Their cost advantage leads to another benefit: they

can be cost effective without very high processor utilizations; they can afford to lose some computational cycles to synchronization, for example.

We are optimistic that the benefits of multiprocessing can be realized in practice. Many algorithms have a theoretically linear speedup, including the asynchronous partial-differential equation solver and the molecular dynamics algorithm presented in this paper. Other algorithms, such as the quicksort and the power-systems simulation, do not decompose so effectively. There may be some *problems* for which there is no good multiprocessor algorithm; for example, those that converge only with a high degree of synchronization, or those that have memory-access patterns so unpredictable that data cannot really be localized. In between these extremes, much more work is necessary to refine and automate the techniques for decomposing algorithms and distributing processes and data. Our approaches have often been heuristic, but they can provide the basis for more extensive and rigorous investigation.

Cm* is a large project. The authors wrote the paper, but performed only a fraction of the work. Even this list of contributors is of necessity very incomplete. Richard Swan, Sam Fuller, and Dan Siewiorek were major instigators of the hardware design. John Ousterhout was involved in the software effort from the start, and along with Pradeep Sindhu, was primarily responsible for the MEDUSA operating system. Anita Jones, Bob Chansler, and Ivor Durham, along with Karsten Schwans, Steve Vegdahl, Mike Kazar and Joe Mohan, designed most of the STAROS system. Zary Segall, Rick Snodgrass, and Ajay Singh were the driving forces behind the IIE. Levy Raskin was the first experimenter, and he was followed by Jarek Deminet, Neil Ostlund, and Bob Whiteside. Sarosh Talukdar oversaw the power-systems simulation work.

The Status Monitor

6. The Problem

R. Snodgrass

The cause is hidden, but the result is known.

-- Ovid, from *Metamorphoses* IV

6.1. The Cause and the Result

In the realm of programming computers, as in all analytic endeavors, one must first understand the behavior before one can understand the underlying reasons for that behavior. As the computational structures employed in programs tend toward greater complexity, computer system designers, implementors, and users find it increasingly rare that they can agree with Ovid that "the cause is hidden, but [at least] the result is known." Monitoring is a necessary first step in understanding a computational process, for it provides an indication of *what* happened, thus serving as a prelude to ascertaining *why* it happened.

The realization that monitoring is a difficult task, one that deserves study, has come only recently to the computing community. The reason for this slow awakening is, again, the increase in complexity. When computing systems (both hardware and software) were simpler, it was possible to adequately understand the system's behavior with rather unsophisticated monitoring tools and the (considerably more sophisticated) modeling techniques then available. Many aspects, such as characterizing the control flow or determining execution times, were so straightforward as to not even being considered issues. Times have changed, and many of these "non-issues" are now so problematic that systems often do not provide *any* solutions to them.

This chapter (and the thesis in general) is loosely organized around a sequence of problem and result statements. Implicit in each problem statement are the results generated by preceeding statements, since one benefit of acquired knowledge is the ability to ask further, more precise questions. Each result will bring about other questions, which will impact on the ensuing problem statement. At this point, the problem statement is annoyingly vague:

Problem 1: What is involved in monitoring distributed systems, and why is it such a hard problem?

The purpose of this chapter is to refine this problem statement into one which is more concrete and thus more approachable.

6.2. Definitions

The definition of monitoring employed in this dissertation is a rather general one: monitoring in the process of extracting dynamic information concerning a computational process as that process executes²

A *computational process* is simply anything that can be said to compute. Examples include the microprogram, a subroutine, a conventional process, a collection of processes, or even an operating system.

Computational processes differ primarily in the number of components to be monitored, from a single line on a bus to the entire system, and in the time frame in which the measurements take place, ranging from hundreds of nanoseconds to months. The granularity at which the monitoring takes place has a substantial effect on the methods used to collect data: different granularities demand radically different approaches.

Dynamic information may also be spread over a large range of granularity, from information concerning the sequence of microrinstructions executed during a particular time interval, to the average amount of time a routine executes, to some global statistic concerning the execution of a whole series of programs. This property goes hand in hand with the last part of the definition. If the information to be collected is not dynamic, there is no need to collect it as the process executes.

Defining a distributed system is more difficult. Although John Shoch has several arguments to support the contention that "there is nothing different about 'distributed' computing" [62], he also presents several distinctions between distributed and non-distributed systems (his widely-shared belief is that there *is* a difference). The two relevant to monitoring are

- Distributed systems seem to be characterized by a lack of central control.
- A quantitative difference in the number of system components (processors, memory, addressing domains, etc.) leads to a qualitative difference³. This will not be possible for distributed systems. How can we comprehend parts of the system without comprehending all

²There are at least two other definitions of *monitor* which should be mentioned. One use of the word monitor, prevalent in the 1960's and early 1970's, is as a synonym for *operating system* or at least the user interface to the operating system. The second refers to an arbiter of access to a data structure in order to ensure specified invariants, usually relating to synchronization [25]. Both definitions emphasize the *control*, rather than the *observational*, aspects of monitoring.

³At the same workshop [38], Richard Watson added several related attributes: more heterogeneity, distribution of state, and communication via messages. And David Reed offered perhaps the best argument for monitoring in his characterization of distributed systems: "In centralized systems, it has been possible so far for single persons to understand the entire system (even of the size of MULTICS

of it?).

These two aspects conspire to make monitoring a difficult (and thus interesting) task. A precise definition of 'distributed' is not important; the intent of the title is to include the attributes listed above in the problem domain.

The general definitions presented above allow concepts developed in this research to be applied to several previously unrelated domains. This section closes with a discussion of representative utilizations of monitoring information.

One use of monitoring is to facilitate the debugging of complex programs. Debugging proceeds in five stages: (1) observe the behavior of a computer program; (2) compare this behavior with the desired behavior; (3) analyze the differences; (4) devise changes to the program to make its behavior conform more closely to the desired behavior; and (5) alter the program in accordance with these changes [45]. Monitoring is concerned with the first (and somewhat the second) stage in this process. The third and fourth stages are still the province of the programmer (although the Programmer's Apprentice project [64] is making some progress in this area); the fifth stage is routinely accomplished using text editors, and could be automated given the automation of the fourth step.

Sophisticated monitoring tools are necessary to make efficient use of limited computing resources. Ideally, such optimization would be done analytically, but in general a priori determination of runtime efficiency is impossible. Thus it is necessary to tune the application once it is implemented. Tuning requires feedback on the program's efficiency, which is determined from measurements on the application while it is running⁴.

A third use of monitoring is to query the system, not for performance measures, but merely for status information, such as how far a computation has progressed, who is logged on the system (the *system status* command of most time-sharing systems), the state of certain files (the *catalogue* or *directory* commands), or the quantity and nature of hardware and software failures.

And finally, monitoring information may also be used internally by the application program for various purposes. For example, consider a program which varies the number of processes dedicated to a particular function based on the request rate for that function. Information concerning the hardware

⁴Robert Sproull called this tuning *performance debugging*: it's not enough just to show that a system works; you want it to work well [38]

utilization and the number of outstanding requests could be used by the program to determine whether to start up more processes to handle the current demand (if the utilization is low and the request rate high) [52]. Monitoring information is also valuable for programs which must be reliable; the fact that a processor (containing particular processes belonging to a program) has failed, for example, is important to the program if it must be able to recover from such failures⁵.

6.3. The Impact of Complexity on Monitoring

The previous section indicted that monitoring is difficult because of the complexity and decentralization of the process being monitored. The purpose of this section is to determine how increased complexity impinges on the task of monitoring. The impact of decentralization is reflected more in the specific algorithms and will be dealt with in later chapters. We will start by investigating the monitoring of the program counter, or PC, certainly an important aspect of the dynamic state.

In the (good old) days, a program consisted of a single program executing on a monolithic operating system on a single processor. The PC could be traced or sampled. Tracing, which involves storing the information each time some event occurs, is usually done at the procedure level, although it can be done at the statement level with greater overhead. At the beginning of each procedure (or statement), code is inserted by a preprocessor to increment a counter or generate a timestamp. A postprocessor is often used to correlate the data with the source text of the program.

Sampling involves storing information when requested, asynchronously with the execution of the program. Usually sampling is initiated by a clock tick, by an operating system call, or by a separate process. The information gathered by sampling is stochastic; for instance, it can indicate what percentage of execution time takes place within an individual routine, but it cannot reliably determine how many times a routine was invoked. Sampling does have the advantage that it requires less resources, and thus perturbs the system to a smaller degree than tracing.

In the past two decades the programming environment has changed radically. In some sophisticated systems being developed today, a program consists of many interacting processes running on many geographically distributed computers communicating over high bandwidth networks [Xerox]. These systems differ quantitatively with systems of the past: where there was one processor, there are now tens to hundreds; where there was one process, there are now many per processor; where there were a few

⁵Eric Rosen, in an article describing a particularly interesting instability which occurred on the ARPANET [57], concluded that "we need a better means of detecting that some high priority process in the Imp [a node on the ARPANET], despite all the safeguards we put in, is still consuming too many resources."

I/O devices, there are now complex communication media, sophisticated encoding formats, and powerful interprocess communication protocols, all supported by large software components; where there was a single contiguous address space, there are now many small, separately addressable objects, each containing code or a specific data structure.

Returning to the example of monitoring the PC, we must first determine what the PC is for this new environment. One possibility is to use the PC of each of the processes making up the program of interest. For the single process example, the routine name and statement number within that routine can be quite informative; a printout of, say, fifty routine names and statement numbers is rather overwhelming. This *quantitative* difference necessitates a *qualitative* change in the monitor, for there is one aspect that remains unchanged: the user (and especially the information capacity of the user) who must interpret the monitoring data.

The presence of the user has been implicit throughout this discussion. Fundamentally, the user is not interested in the PC at all; instead, the user wants an understanding of the *state* of the execution as it evolves through time. This state manifests itself in many forms: the changing values of the variables in the program, the input read by the program and the output produced, the constantly changing PC. All are valid indicators of the program state and each may be sufficient when monitoring a single process. Individually, however, they are woefully inadequate for monitoring distributed systems. Instead, the monitor must be able to express the system state (as well as other attributes of the system) in a form useful to the user.

As an example, suppose the monitor could provide this description of the program state:

Process A is waiting on process B to acknowledge the xxx request; process Y is sending process Z information concerning the object yyy; and process M has completed.

There are several aspects to note in this example. The information the monitor displayed is both less and more than a list of PC's. The monitor had to understand that a PC in a certain range meant that process A was waiting for something, yet the exact PC was unimportant. Conceivably, the PC could have been completely different and the monitor would have displayed the same information. In addition, the monitor had to be able to look inside the various queues and buffers maintained by the communication mechanism in order to be able to state that a process is waiting on another process to acknowledge a particular request. Names had to be associated with the various processes, objects, and requests in order to produce an intelligible state description. And finally, the monitor had to know that the user was interested in the current state in terms of interprocess communication. Another perhaps just as useful state description is

Process A has used 75% of its resources, while processes X, Y and Z have used only 20% of their resources.

The decentralization inherent in distributed systems also necessitates interpretation of the monitoring data by the monitor. The mention of several processes in the previous example implies a degree of logical decentralization; if those processes are on different processors, then there is also physical decentralization. To present a global view of the program state, the monitor must integrate data collected at geographically distinct sites. Simply determining what information to collect and where to acquire this information becomes a difficult task.

Result 1: The quantitative and decentralized aspects of the monitored system, coupled with the limited information handling capabilities of the user, demand an intelligent monitor.

At this point, the problem at hand is

Problem 2: What are the organizing concepts for a monitor which can collect information from a variety of sources, interpret this information, and present it in a series of high level views in a format comprehensible to the user?

6.4. Knowledge Representation

In its most general form, the process of monitoring is concerned with retrieving information from the monitored system and presenting this information in a derived form to the user. Viewing the monitor as the proverbial black box, it is fundamentally an information processing agent. As the previous sections have indicated, this activity is rather sophisticated. Looking inside this black box, there is some form of knowledge representation to direct the monitoring activity. Thus, there are at least two ways to abstractly view a monitor: as a knowledge representation system and as an information processing agent. As will be seen, both of these views are very fruitful. The rest of this chapter will investigate the knowledge representation issues; chapter 2 will pursue the information processing aspects of monitoring.

In an examination of the discussion of a possible high-level PC, one starts to notice phrases such as "the monitor had to understand." Now, in one sense, the monitor *can't* understand; it is, after all, only a computer program. However, computer programs are remarkably versatile and almost any type of desirable behavior can be programmed with the correct selection of data structures and algorithms. Hence, the process of "teaching the monitor" or "making the monitor understand" is transformed into the more intellectually manageable task of deciding what data structures and algorithms to employ within the monitor.

These data structures and algorithms encode the knowledge the monitor can apply to the task at hand. The majority of monitors did very little interpretation of the collected data, and thus used rather ad hoc

methods for determining what to monitor and how to perform the monitoring. Two recent systems have addressed the monitoring of complex systems; it is useful to analyze the character of knowledge each used to direct the data collection and interpretation.

Model's thesis [45], one of the first to systematically approach this topic, stressed the adoption of a uniform model of a complex activity for use in monitoring. His monitor was designed to be used with programs written in artificial intelligence languages such as KRL, which are themselves written in Lisp. Despite the sophisticated control and data structures provided by these high level languages, most debugging is still done in the implementation language. The complexity of programs written in these languages is seriously limited by the lack of adequate debugging tools. Model argued that of the five stages present in the debugging process (see section 6.2), monitoring has the most potential for improvement at this time.

The monitor collected events generated by the interpreter (the monitor had no control over which events were collected). These events were related to the program's data and control structures implicitly in the routines generating the events. However, some cross-referencing was done, so that the monitor knew, for example, that some events caused other events. The user could specify which events, as well as which fields in these events, were to be displayed. The knowledge utilized by the monitor was wired into the code.

Gertner's thesis [22] focussed on the flow of messages between processes in RIG [4], a distributed system constructed at the University of Rochester. In his system, Gertner described the computation using finite state automata, with the transitions being events (usually messages sent between two processes in the system). Associated with each message is a set of timestamps relating to the activity involved in processing the message. These timestamps allow the monitor to calculate processing intervals, message counts, overlapping periods, etc. A hierarchy of finite state automata can be defined, with elementary transitions at one level composed of multiple transitions at a lower level. This hierarchy allows monitoring information to be presented at the appropriate level of abstraction. Again, the knowledge of how to derive information from the timestamps was implicit in the monitor's code.

Unfortunately, these ad hoc approaches are simply inadequate for distributed systems. In Model's system, events capture only the notion of *state transitions*. The system state must be inferred by the user. Modelling all activity in terms of finite state automata, as in Gertner's system, while expressing to some degree the semantics of the periods between the events, is overly restrictive. Sampling data (as opposed to trace data) does not integrate easily into the scheme. The proliferation of extraneous states is also a problem which results from a total reliance on this model.

In order to construct a monitor which can apply substantial knowledge concerning the system being monitored, this knowledge must be organized in a coherent fashion. Thus a formalism is needed to describe this knowledge. The formalism must, to some degree, encode the following knowledge:

- what information the monitor collects concerning the system;
- how new information can be acquired by the system;
- what dependencies exist between various components of this information;
- how the information relates to the data and control structures within the programs, and to the data and control structures of the underlying operating system; and
- what information the user wants to see.

There are also three basic "notions" that must be characterized by this formalism. Two of these are the concepts of "entity" (or "object") and the concept of "relationship" between two or more entities. The monitor must understand that there are such things as processors, processes, memory, message ports, semaphores, etc. and that certain relationships exist between these things, such as a process running on a processor. In Model's thesis, for example, entities were the values of certain attributes, and the relationships were the events themselves.

The third notion that must be characterized by this formalism is the concept of time. The monitor must understand that facts are only true for a certain period of time, and that entities and relationships are temporally bounded. For instance, in Model's thesis, time was one of the fields in each event record, and queries could specify which time period the user was interested in. Also, Model's monitor understood that events were sequential, and thus that some events were after others. However, the concept of something being true for a period of time *between* two events is not represented within the monitor, and thus the user could not request such information. Clearly, a multiprocess monitor must have a better understanding of time.

The aim of this chapter has been to sufficiently refine the original problem statement into one which can be attacked in concrete terms. This chapter has argued that

Result 2: Monitoring in fundamental terms is concerned with knowledge representation and information processing.

This leads to the following problem statement:

Problem 3: What knowledge is necessary to adequately monitor a distributed system, and how is this knowledge represented within the monitor?

However, before we can address this question, we must investigate the information processing aspects of

monitoring.

I shall limit the scope of my investigation to the above problem. I will not deal in depth with the uniprocess aspects of monitoring; instead I will concentrate on monitoring process-process and process-operating system interactions (the distinction between these interactions is lessening in importance [53]).

7. A Low Level Data Collection Mechanism

R. Snodgrass

Data collection techniques have been at the center of attention in previous work in monitoring, to the exclusion of other areas such as representation and manipulation of the collected information. Most papers on the monitoring of user programs describe *profiling* in a variety of programming languages. This approach involves execution counts or timing at the procedure or statement level, using sampling or tracing. These papers are simply variations on a common theme; there have been few advances since the early 1960's, when sampling and tracing were first introduced. Data collection for monitoring of operating systems has also relied on sampling or tracing. Techniques for using special hardware have been more innovative: since additional logic imposes no overhead on the computation, capabilities such as event counters, combinational and sequential logic on events, comparators, and histogram generators can be provided. Network data collection has concentrated on performance evaluation issues and has been, in general, confined to techniques mentioned above. Recent systems have taken a more integrated approach to monitoring, attempting to reduce the great effort necessary when using the low-level tools previously available. A unified set of facilities for monitoring a packet radio network was developed at UCLA. Gertner's thesis, described earlier in section, allowed relatively painless monitoring of a distributed system at the message passing level. The Computer Network Monitoring System (CNMS), a rather ambitious system designed at the University of Waterloo, used a sophisticated combination of hardware and software to monitor a geographically distributed network.

In spite of these developments, an integrated approach to monitoring data collection founded on fundamental concepts, goals, and limitations is still lacking. One possible strategy for developing such an approach is to start with the relational model described in the previous chapter. Unfortunately, this strategy is insufficient. Data collection must be strongly tied to the primitive relations referenced by the user. The operationalization of a primitive relation, is a predicate which, when presented with a possible tuple, will query the system and determine whether the relation is satisfied for that tuple. This predicate provides a well-defined semantics for the relation, but does not allow a direct implementation.

Another possible strategy proceeds by developing a conceptual model of the behavior of the program to be monitored, and attempts to represent that behavior within the relational model. This strategy will be the one pursued in this chapter. The next section begins with a comparison of data collection as performed by a conventional data base system and by a monitor. A model of the environment where the data collection takes place is then presented, followed by a discussion of the properties an effective mechanism must have. The remainder of this chapter will present such a mechanism and examine how various aspects of

the environment impact on this mechanism. The discussion will be independent of any particular operating system. However, it is assumed that the monitor is partitioned into a *resident* portion, responsible for collecting the event records and interacting with the operating system, and a system-independent *remote* portion, responsible for analyzing and displaying the monitoring data. This separation is necessary when monitoring a distributed system, where a resident monitor would exist at each processor, sending collected data to the centralized remote monitor. The implementation follows this organization.

7.1. The Environment

Data collection in the monitoring domain differs from that in conventional database management systems in several ways. In most information processing systems, the emphasis is on information manipulation and retrieval, with minimal aids for data collection. Although some systems provide tools for key entry and point-of-sale data acquisition, data collection remains difficult to automate. The reason is that the highly-structured databases must interface with much less regimented mechanisms: written and oral communication, multiple incompatible data representations, psychological and societal constraints. The monitor, as an information processing system, has much more control over the collection of data, since that data is already available in digitized form, either resident on a bus line or network link, or stored in registers, main memory, or on disk, certainly in a most convenient format.

The availability of monitoring information results in a second distinction between data collection as performed by conventional information processing systems and by the monitor: rather than being constrained by insufficient data, the monitor must take dramatic measures to *reduce* the incoming flow of data. For example, suppose that the monitor receives a value-time pair for each change in the program counter. The monitor would have to run on a machine several orders of magnitude faster than the one being monitored merely to store the information. However, if only routine timings were desired, the grain of data should be much coarser. As another example, suppose that timings were desired only for a single routine. Unless the data collection mechanism supports *filtering*, where only data satisfying specified constraints is actually collected, the monitor will have to contend with data concerning all routines. Extraneous data is very expensive to collect, since computing resources are required to collect it and to decide to discard it. Thus, data collection for monitoring involves careful selection of data, rather than access and conversion to a more useful representation, as in conventional information processing systems.

In order to discuss the data collection mechanisms within the operating system or application program, it is necessary to characterize the environment in which the mechanism executes. The environment is defined to be a collection of *strongly typed objects*, both passive (e.g. data structures) and active (e.g.

processes). *Type managers* export functions to be applied to objects of the type(s) supported by the manager; all operations on an object are performed by the type manager supporting that type as requested through well-defined interfaces (implying the existence of a type-checking mechanism). This model thus identifies the *operation* being performed on the *object* by the *performer* (the type manager) as a result of a request by an *initiator*. The user can create new types by defining the representation of the object and specifying the operations which can be performed on objects of that type. The model applies to all levels of granularity; in particular, a type manager may be implemented in hardware, firmware, or software.

The model employed here has been used in several recent operating systems [27] and languages, although the model can be used to conceptualize program behavior in any system). The model is especially applicable to monitoring because it forces data structure state changes to be precisely specified: any change to the representation of a data structure (i.e., object) must occur within a function of the type manager as a result of performing a defined operation. Control flow can also be characterized in this manner: all changes in the execution state of a process can be accounted for by examining the sequence of operations performed by the process. Monitoring the model directly is difficult, due to the large differences in granularity involved. For instance, monitoring the add operation performed on an integer object by the hardware concerns significantly different issues than monitoring the file read operation performed on a file object by the file system.

There are several properties related to the typing model which should be satisfied by the data collection mechanism. The mechanism should support strong typing, in that typing violations are not necessary to perform the data collection. The mechanism should rely as little as possible on cooperation by the type managers, to allow additional data types and type managers to be monitored easily. The mechanism should be efficient, especially when disabled. The mechanism should be very flexible, allowing the monitor to specify exactly the information to be collected, thereby supporting filtering. And finally, the mechanism must exhibit good software engineering.

One property not listed above is simplicity. Often the attributes of efficiency and flexibility interact with simplicity; for instance, a mechanism supporting many modes of operation may be flexible but will probably not be simple. Also, while restructuring an algorithm can make it both less complex and more efficient, squeezing out the last bit of efficiency usually leads to more complex code.

Given that there are trade-offs, our approach is to place simplicity below the other properties in importance. This strategy is acceptable given an intelligent monitor which can take a high-level, non-procedural query and map it into a series of requests to the low level collection mechanism. Thus,

simplicity in the low level mechanism has only a second order effect on the complexity of the user interface. As was argued in chapter 1, monitoring distributed systems *is* complex; this complexity will be evident throughout the monitor, except at the level of the user interface. We assume that the higher levels of the monitor can contend effectively with the complexity (and flexibility) presented by the data collection mechanism.

7.2. The Mechanism

The data collection mechanism employed in the monitor is closely tied to the type model presented earlier. An *event* is simply an occurrence the user is interested in. Each event occurs in the context of an operation as defined in the type model. Information concerning an event is structured into an *event record*, which is potentially of variable length and which contains both system and user-defined fields. Event records are typed, with each event type being produced by a particular *sensor*, which determines that an event has occurred, collects the relevant information concerning that event, and sends the information to the remote monitor. Each sensor is found within a type manager, and is associated with an operation (or set of operations) provided by the type manager. For example, the file system (a type manager for the file object type) may have a ReadFile event sensor located in the code performing the read operation. Other sensors, such as OpenFile, ExtendFile, PhysicalBlockRead, and ModifyProtection, may also be present in the file system. Since state changes on a file object can only occur as the result of operations performed by the file system, sensors within the file system can monitor these state changes for all file objects.

Event records always contain the name of the type manager performing the operation (if the type manager is itself an object), the event type, the name of the referenced object, and the name of the initiator. Thus, all four components of a state change are recorded for later analysis.

Event records are stored in *receptacles*, which handle the enabling and synchronization of event records. Receptacles are abstract objects in their own right, whose type manager is the resident monitor. Events are *enabled* by the resident monitor by setting switches in the receptacle. Locks in the receptacle arbitrate simultaneous access and modification of the switches by the resident monitor and the sensors.

There are several operations on receptacles supported by the resident monitor. To install a receptacle in an object, the type manager for that object requests a receptacle from the resident monitor. The type manager then places the receptacle in the object at a location determined by the type manager, which has total control over the representation of the object. To enable (or disable) an event for an object, the resident monitor presents the object to the appropriate type manager with a request for the receptacle

contained in the object. The resident monitor then modifies the appropriate switch in the receptacle. Therefore, the minimum functionality a type manager must provide to support monitoring is the access receptacle operation, which can be implemented quite easily, and the install receptacle operation, which is also straightforward to implement.

Any sensor using the receptacle contained in an object must reside in the type manager for that object. When such a sensor is encountered during the processing of a requested operation, the event identification, object name, initiator name, performer name, and receptacle, as well as any additional information provided by the sensor, is passed to the resident monitor, and a store event record operation is performed by the resident monitor. First the appropriate enable switch in the receptacle is checked to ensure that the event is enabled for this receptacle. If so, an event record in the proper format is then sent to the remote monitor.

Placing the enable switches in the receptacle allows great flexibility in the enabling of events. Receptacles are associated with passive objects and processes (active entities). A receptacle associated with a passive object arbitrates the collection of monitoring information for that object. Enabling the file read event for the receptacle associated with a particular file causes event record to be collected for file reads *only for this file* by any file system process. On the other hand, enabling the file read event for the receptacle associated with a particular file system process causes event records to be collected for file reads on any file performed *only by this file system process*. An analogous selection applies to the initiator of a file read operation. The event records can thus be filtered at a fine grain along three dimensions: by object, performer, or initiator. Each sensor supports filtering of an event type in only one dimension. However, several sensors (and event types) can be associated with an event (such as file read), each designating a different receptacle to arbitrate event record generation by the sensor. Viewing the set of possible event records as a discrete four-dimensional space with axes consisting of event types, objects, performers, and initiators, the event records generated by a particular sensor form a two-dimensional plane, parallel to two of the axes, and intersecting the event axis and one other axis. The event records enabled by a particular receptacle form a series of two-dimensional planes, all parallel yet intersecting the event axis at different points⁶.

To achieve higher degrees of filtering (either a line or a point in the event space) requires either additional information be stored in the receptacle (and additional processing to determine if the event is

⁶ A point in this space may include several event records, each representing the same event, object, performer, and initiator, but occurring at different times. Of course, time could be considered as yet another dimension. Visualizing the event space is more difficult with such a change; the author finds four dimensions hard enough!

indeed enabled), or new receptacles representing component pairs (such as object-performer) or component triples (such as object-performer-initiator) to be created and associated with the participating objects. Both alternatives require super-linear space and/or time, and thus are unacceptable in an environment supporting many objects.

The typing model applies to all levels of abstraction, from the hardware (with objects such as memory locations, interrupt lines, device registers), the firmware, the language level (with objects such as variables, semaphores, procedures), to the process level and the program level (with objects such as servers, databases, users). The data collection mechanism can be used at all of these levels, presenting a consistent interface to the rest of the monitor: event records containing the event type, object, performer, and initiator, as well as other, event-specific, information. By associating receptacles with the objects defined at a particular level of abstraction, the full filtering capabilities can also be realized. However, the implementation will differ greatly from level to level, and there must be ways to transmit the information gathered at the lower levels, especially at the hardware and firmware levels, to the higher levels where they can be dealt with by the monitor.

7.3. Integrating Sampling and Tracing

In the preceeding discussion, the assumption was made that the event record is sensed and communicated to the remote monitor when the event occurs. Such event records are called *traced* event records, since their generation is *synchronous* with the event, and thus with the operation whose object, performer, and initiator is named in the event record.

Sampled event records, on the other hand, are generated at the request of the monitor, *asynchronously* with the event they are concerned with. As an example, a sensor located in the scheduler of an operating system could generate traced event records pertaining to context switching: process x started running at time t_1 , process y started running at time t_2 , etc. Another sensor located in the scheduler could generate sampled event records at the request of the monitor: process z is now running.

In the context of the type model, both sensors were executed as a result of an operation supported by the scheduler; the former by the dispatch operation, the latter by the report current process operation. The only distinction is the nature of the initiator--either a random process in the system, or the resident monitor. As far as the low level data collection mechanism is concerned, there is absolutely no difference between sampling and tracing: the sensor, when encountered in the course of executing the operation, checks the enable switch in the appropriate receptacle, and, if set, sends the event record to the remote monitor. Also, the resident monitor must now have the ability to invoke operations in other type managers,

but the added complexity is where it should be: in the monitor rather than in the user's (i.e., type manager's) code.

7.4. Interaction with the Remote Monitor

Since the remote monitor contains a large knowledge base concerning monitoring, it is important that it be system independent. Hence, the remote monitor's view of the world is an abstraction supported by the resident monitor interacting with a particular operating system with certain assumptions being made about the event records being generated. There is a tradeoff between strong assumptions, which are difficult to support by the resident monitor, and weak assumptions, which make the derivation of high level information from event records difficult. This section is concerned with the environment as seen by the remote monitor, and how this view is supported.

The format of the event record is one aspect to be standardized. Each event record is divided into a fixed and a variable part. The fixed part is identical in format in all event records, and included the event number, the (possibly nil) names of the initiator, performer, and object, and (possibly) a timestamp. The variable part contains the domains of the event record, i.e., the additional information provided by the sensor. Domains must be formatted in a defined external type (currently either a short integer, a long integer, a boolean, a variable length character string, or a remote name (see below)), with the sensor mapping values in an internal format to an external type. Names and timestamps are much harder to standardize; the rest of this section will describe our approach to these two issues in the context of data collection.

7.4.1. Naming

There are several name spaces within the monitor for operating system objects; this section is concerned with *internal names* (the operating system specific names), *remote names* (system independent names which are processed by the remote monitor), and the mapping between these two name spaces. Other chapters will deal with the remaining name spaces active in the monitor.

Internal names allow the resident monitor to gain access to the object in question. The internal name for a file may be the disk address of its directory entry, or the inode number in the case of Unix files [56]; the internal name for a process might be a memory address of a process control block, or an offset into the process table. Object-based systems allow a consistent naming scheme to be used; the operating system supports the addressing of *all* objects by using a name in a standard format. These names are usually protected, so that processes must acquire names, rather than being allowed to arbitrarily generate them. StarOS [27] and Medusa [51], the two operating systems the monitor was implemented on, are both

object-based systems; internal names are called capabilities and descriptors, respectively. A remote name is an integer which can be mapped to an internal name, thereby allowing the actual object to be referenced by the resident monitor.

It is helpful to examine briefly how names in these two name spaces are used by the monitor. When the monitor starts, it knows no names. The user issues a query, and the remote monitor instructs the resident monitor to find certain objects and to return the remote names of these objects. At that point, the remote monitor sends some of these names back to the resident monitor, instructing it to enable certain events on those objects. As these events subsequently occur, event records containing the remote names in their fixed parts are sent to the remote monitor.

In order for this interaction to occur successfully, several invariants concerning remote names must be guaranteed:

<i>Uniqueness</i>	Remote names must be unique (one remote name for each object (internal name)) for event records to make any sense at all.
<i>Injectivity</i>	Remote names must be unambiguous (one object for each remote name), for the same reason.
<i>Bidirectionality</i>	The mapping must be bidirectional; in particular, we must be able to find the object given a remote name.
<i>Completeness</i>	When an event record is sent to the remote monitor, the remote name for the object, the sensor, and the initiator must be available.
<i>Lifetime</i>	The mapping must allow operating system objects to be garbage collected.

Unfortunately, there is no mechanism for producing remote names which will satisfy all five invariants, although different mechanisms violate different invariants. Assume we have a remote name for an object. We can either

- not allow garbage collection, or
- allow garbage collection, and violate the bidirectionality invariant (if the object is deleted, we cannot map the remote name to an internal name), or
- violate the injectivity invariant (map the old remote name onto a new object which has the same internal name as the old, deleted object).

The second and third alternatives apply to operating systems that do not support a consistent, protected internal name space. For example, the disk address of a file may be a perfectly valid name for the file while it exists (assuming the directory is not reorganized). However, there is no guarantee that the file will not be

deleted and the entry replaced with that of another, newly created file.

The approach used here applies to object-based operating systems, and will support capability addressing at the expense of a slightly corrupted bidirectional invariant: sometimes the mapping from the remote name to the internal name will not work. To see how this is done, we must first explain the mapping between internal and remote names.

Remote names will be of the form $\langle \text{epoch} \rangle \langle \text{minor name} \rangle$. The $\langle \text{minor name} \rangle$ will be formed from the internal name in a system-dependent fashion (this does not circumvent protection, since the internal name may be *read*, but not *written*). Whenever an event record is constructed, the current $\langle \text{epoch} \rangle$ for each $\langle \text{minor name} \rangle$ in the event record will be concatenated with the $\langle \text{minor name} \rangle$, thereby forming a remote name.

The resident monitor will maintain a list of internal names it has collected from the event records it has sent to the remote monitor. Whenever a remote name is sent to the resident monitor, the associated internal name will be retrieved using the $\langle \text{minor name} \rangle$ field. Whenever an object is deleted, the $\langle \text{epoch} \rangle$ for the $\langle \text{minor name} \rangle$ for that object be incremented, to ensure that the next object created with this internal name will be mapped to a unique remote name. Note that interaction between the garbage collector and the resident monitor is required to keep the $\langle \text{epoch} \rangle$ values consistent.

The mechanism outlined above satisfies all of the invariants except the garbage collection invariant. As long as an internal name resides in the resident monitor, the object it refers to cannot be garbage collected. Having many internal names in the resident monitor imposes an unnecessary processing and memory burden on the system. Therefore the mechanism must allow internal names to be removed from the resident monitor.

Stated simply, an internal name should be removed if it will never be needed again⁷. Since it is impossible to predict when this will be the case, various approximations may be used:

- the object has an explicit destroy operation performed on it;
- there is only one internal name (the resident monitor's) referencing this object (and thus, the object is nonexistent as far as the rest of the environment is concerned);
- the remote monitor will never send the remote name to the resident monitor in a request;
- it has been a long time since an event record has been generated;

⁷Put another way, all the invariants can be satisfied given an omniscient resident monitor!

- the user has specified that this object is unimportant (or equivalently, has not specified that this object is important);
- the object is of an unimportant type (or equivalently, is not of an important type);
- the remote monitor doesn't have a remote name for this object.

The first alternative applies only to objects which have an explicit destroy operation on them which can be monitored. The semantics of the destroy operation from the monitor's point of view is that, after the operation has been performed, nothing interesting will ever happen to this object, i.e., no event records containing a name for this object will ever be generated. The second alternative depends on a garbage collector which can determine whether there is only one internal name extant; current garbage collectors do not have this capability < is this true? > The last four heuristics depend on psychological aspects, and can be shown to be appropriate only after experimentation with many users over long periods of time.

7.4.2. Time

Time is a difficult problem when monitoring a distributed system. There must be a mapping from the local time recorded in the event records to global time. Unfortunately, it is theoretically impossible to exactly synchronize imprecise physical clocks over a geographical network with indeterministic transmission times. A more practical constraint is keeping the overhead incurred in synchronizing the local clocks acceptably low.

7.5. Sensor Specification

During the initial development of the low level event collection mechanism, it became apparent that there were several procedural difficulties in the placement of sensors in the various operating systems. One difficulty was that the sensor routine (which stores the event records) was becoming quite cumbersome. One design required twelve parameters for a typical sensor involving three domains! Since the sensors were to be placed in critical portions of the operating system, there was little room for error in the specification of these parameters. A second problem was the assignment of event numbers; an incorrect event number in a sensor routine would result in the absence of event records of that type--a situation that might be difficult to detect by the user interacting with the remote monitor. Two sensors with the same event number would cause havoc within the remote monitor. A third problem is maintaining consistency between the remote monitor's view of the world and the world as it actually is. This is especially true during the early development of the monitor, when the collection of sensors inside the operating system, and the various attributes of those sensors, is changing frequently.

Finally, all these problems are exacerbated by the sheer number of sensors: we can easily envision

several *hundred* sensors in an operating system when it has been fully instrumented. The task of ensuring that all of these sensors, which are distributed across many source files, are correct and consistent, both between each other and with the data structures within the remote monitor, is unmanageable if it remains a manual one.

7.5.1. User-Defined Events

All of the issues mentioned above are also present when users are allowed to define events. Several, including the event number assignment and communicating the sensors' specifications to the remote monitor, become even more difficult in the presence of user-defined events.

In general, the less the user has to specify, the less that can go wrong with the specification. In a best case senario, the user would specify the interesting events and indicate where the sensors for these events were to be placed in the code. The sensor would be produced automatically from the specifications, and would be as efficient as one crafted by hand. When the program was run, the event types generated by these sensors would automatically be defined as relations with the full query language available for manipulating events generated by the sensor. In addition, enabling and disabling of the sensors in the user's program would be handled automatically as a side effect of evaluating queries referencing these relations.

The solution, described in this section, is to create a database, called the *sensor description file (SDF)* containing information on the sensors defined in a given taskforce (a *taskforce* is a collection of processes cooperating to perform a particular task [28]). The sensor description allows the above senario to be realized in its entirety: placing sensors in a program involves merely creating a sensor description file consisting of a few lines per event type and object type, adding the sensors to the program (one line per sensor), and running a program (called the *description file preprocessor (DFPre)*) with the SDF as input. All of the details are automatically taken care of by DFPre and by the monitor.

7.5.2. Syntax and Definitions

A sensor description file consists of a set of *objects* partitioned into *classes*. Each object is associated with a set of class-dependent *attributes*. There can be one or more *values* for each attribute, and some attributes can have objects as values. The syntax follows this description quite closely:

```
<description file>      ::= <objects>

<objects>                ::= <object> | <object> <objects>
<object>                 ::= "(" <class> <attribute list> ")"
```

```

<attribute list>      ::= <attribute> | <attribute> <attribute list>
<attribute>          ::= "(" <attribute name> <attribute values> ")"

<attribute values>    ::= <attribute value> | <attribute value> <attribute values>
<attribute value>     ::= <object> | <object name> | <atom> | <integer> | <string> | <list>

<class>               ::= <atom>
<objectname>          ::= <atom>
<attributename>       ::= <atom>

```

As an example, the following description file has one object with two attributes:

```

(event      (name Iteration)
            (timestamp true)
)

```

An SDF describes the sensors defined in a given taskforce. Since the operating system is itself a taskforce (or collection of taskforces), one SDF specifies the sensors embedded in the operating system. The **Taskforce** class includes attributes which hold for the task force as a whole. The **ObjectType** class describes the objects which can be monitored by sensors defined in the SDF. The **SensorProcess** class contains those attributes relevant to a particular process (i.e., a type manager). The **Event** class contains most of the attributes, including the following:

Location	the sensor process containing the sensor for this event;
Object	the object type this event refers to;
Timestamp	whether timestamps are to be included in the event record;
MinorType	how the event is to be triggered;
SpaceTimeRatio	the relative tradeoff between space and time efficiency in the sensor;
Domains	the domains included in the event.

The **Domain** class includes attributes relating to each domain, particularly the type attribute.

7.5.3. The Description File Preprocessor

The description file preprocessor (DFPre) reads in a description, performs syntactic and semantic checking, and outputs one or more files containing information derived from the input file. The position of DFPre in the program development process is illustrated in figure 34.

The *require* files contain routine definitions to be used by the sensors. For example, each event results

Figure 34: The position of DFPRE in the program development process.

in the definition of a sensor routine. If the SDF contained the following event class (a fragment of an actual SDF used to monitor a parallel partial differential equation (PDE) program):

```

(event      (name Iteration)
            (location PDESolver)
            (timestamp true)
            (domains (domain (name IterationNumber)
                             (type Integer)
                           )
            )
            ...
)
  
```

then the routine IterationSensor, with one parameter (IterationNumber) would be defined. To place a sensor for this event, the user would simply put the line

```
IterationSensor(ThisIterationNumber)
```

in the PDESolver code, where ThisIterationNumber is a variable containing the current iteration number. The require files contain virtually all the details necessary for the monitor to interact with this sensor.

The remote description is a specially-formatted file containing the information in the SDF of use to the remote monitor. This file is assembled and loaded with the user's program. When the resident monitor encounters the taskforce, it ships the remote description to the remote monitor as a series of event records. When this operation completes, the remote monitor is aware of the events, sensor processes, and object types defined in the task force, and knows how to enable and disable the events.

This mechanism also works for the SDF(s) associated with the operating system. When the remote monitor is started, it knows of no events, sensor processes, or object types. The resident monitor, when started, first establishes contact with the remote monitor, then sends over the remote description, thereby defining the events contained in the operating system.

In addition to rectifying the problems introduced on page 114, using SDF's has several other advantages. Since DFPre has detailed information on the structure of each event, the code for that sensor can be tailored precisely to that event. The spacetime ratio attribute is especially useful in this regard. DFPre can also collection aggregate information concerning, for instance, all events located in a particular process, in order to perform global optimization. The receptacles for each object type can also be configured quite precisely. And finally, the information in the remote description can be used to compensate for resources consumed during event collection, since the remote monitor will know what processing was involved in storing each event record.

7.6. An Example

To illustrate the actions of the monitor, we will examine how a particular program running on Cm* is monitored. The program solves Laplace's partial differential equation with given boundary conditions (*Dirichlet's problem*) by the method of finite differences. The equation

$$\frac{\partial^2 u(x,y)}{\partial x^2} + \frac{\partial^2 u(x,y)}{\partial y^2} = 0$$

is solved for points on an m by n rectangular grid, where only the values at the outer edges of the grid are given. The solution is found iteratively. On each iteration, the new value of each element is set to the arithmetic average of the values of its four adjacent neighbors.

Several processes and several processors work on the grid simultaneously. The grid is partitioned into regions, with one process responsible for each region. The configuration is shown in figure 34. Note that the solvers require access to adjacent regions to derive new values for points on the boundary of their region.

There are many possible ways to synchronize the processes. The most efficient is the purely asynchronous method. The processes are only synchronized at the beginning of the computation. This means that, due to differences in the scheduling and in the data that each process is working on, some processes may perform many more iterations than others.

The proposed experiment will investigate the relative synchrony of two of the processes operating on adjacent regions. If one of the processes (call it P_1) gets behind the other process (P_2), then the second

Figure 35: Configuration of the PDE task force

process will be using older values for the points on the boundary, possibly slowing the convergence for the entire grid. This experiment will focus on those periods of time when P_1 gets significantly behind P_2 (i.e., more than one iteration).

One sensor is needed, a traced event sensor which generates an event record each time the solver process begins a new iteration. The sensor descriptor file is shown in appendix PDESDF.

When the PDE program is loaded onto Cm*, the monitor is sent the information provided by the SDF. Since the Iteration sensor has a *minortype of sensortraced*, the events generated by this sensor are automatically converted into a primitive period relation by the monitor. Thus, when the remote monitor receives the SDF describing the Iteration sensor, the primitive period Iteration is defined, with two domains: Process, the name of the process generating the event record, and IterationNum, an integer designating the iteration which has just begun. Derived relations can now be specified using the Iteration relation, as will be described in detail in the next chapter.

7.7. Summary

This chapter first presented a model for the environment the data collection mechanism was to execute in, the type model, and then a mechanism which integrates well with this model. The occurrence of an event is tied to four components: the operation, the object being operated on, the performer of the operation, and the initiator of the operation. These components are recorded in the event record generated by the sensor, along with additional information germane to the event. A new type of object, the receptacle, was introduced to arbitrate the generation of event records, and great flexibility in filtering was

shown to be possible by associating the receptacles with the various entities participating in the event. We demonstrated that, from the point of view of the sensors, there was absolutely no difference between traced and sampled event records, the distinction lying instead in the identity of the initiator of the operation involving the sensor. Several issues involved with the interaction of the remote monitor, in particular naming and time, were discussed, and techniques were developed for coping with the problems inherent in those areas. Finally, the substantial software engineering issues involved in placing sensors were dealt with quite successfully by having the user create a database, the SDF, which allowed the monitor to aid in installing sensors by handling all of the details for the user.

At this point, it is possible to answer the query of chapter 2,

Problem 5: Is it possible to provide effective data collection mechanisms?

with a resounding Yes!

Result 5: The system-dependent aspects of data collection can be embedded entirely in the primitive relations. The user does not have to specify how the data is collected, or to worry about the details of collecting, formatting, and processing the event records. Sensors are efficient, and easy to install.

8. Simon: A Simple Monitor for StarOS

Richard Snodgrass

8.1. Introduction

This document specifies the user interface and overall design for an initial implementation of a monitoring system for StarOS. The reader should read my thesis proposal, which gives an overview of the relational approach to monitoring, before reading this paper.

8.1.1. Objectives

The objectives of this first implementation are three-fold: (a) to test my ideas on a significant set of monitoring tasks; (b) to delimit the various issues involved in monitoring; and (c) to get experience with the VAX and StarOS programming environments before attempting the design of a comprehensive system.

There were several limitations on the scope of this implementation in order to complete it in a reasonable amount of time. Although the thesis is based on the monitor supporting the conceptual model of a relational database, this implementation will concentrate on the more concrete issue of dynamic incremental updating of temporal relations. The following issues will *not* be included in this implementation:

- static relations; all computations will be done in "real-time"
- quel-like query language; a relational algebra will be used instead
- efficiency; no tuning of the relational operators will be done
- incomplete information, although a few aspects may be included if they are straight-forward

Chapter 8.5 examines how the implementation discussed below might be extended to incorporate the above issues.

8.1.2. A Paradigm for the Implementor

Incremental update algorithms for temporal relations accept information in the form of "this relationship between these entities became true at time t_1 " and "the relationship subsequently became false at time t_2 ", and use this information plus stored information concerning the current state of the relation to derive an updated relation. Relations thus evolve in time through tuples (rows of a relation) being added and removed. These changes cause relations derived from a relation to acquire or lose tuples of their own, a

process continuing until the new information has been completely assimilated by the relations defined in the system. It is thus natural to concentrate on the flow of tuples (both being added and being removed) among the relations that are associated with each other through derivation expressions. Examining the monitoring concepts of primitive relations, derived relations and relational operators from this viewpoint results in rather different conceptualizations of these fundamental notions.

It is important to remember that two radically different paradigms are at work in this design. One paradigm was introduced in my thesis proposal: the process of monitoring is profitably conceptualized by the user as the accumulation of monitoring information in the form of relations which can then be manipulated conveniently by the user. The paradigm introduced above is rather different: the process of monitoring is profitably conceptualized by the designer (implementor) of the monitoring system as the creation and execution of a network of nodes across which flows information collected by the monitor. The former paradigm was discussed to some length in my thesis proposal; this document will investigate the implications of the latter paradigm.

8.1.3. Overall Design

The monitor will provide a collection of *access nodes* and *generic operator nodes*, which the user will instantiate and link together in a tangled tree. Information in the form of tuples (a collection of domains, or, alternatively, a row of the relation) will flow out of the access nodes (which will communicate with the access module(s) on C_m^*) and up through the tree. Operator nodes will take tuples from one or two lower nodes and produce tuples which will be sent further up the tree. The entire hierarchy will be driven by tuples originating in the access nodes (these tuples can represent either events which occurred or samples which were automatically collected by the access module).

One might visualize this network by thinking of the nodes, both access and operator, as integrated circuits (ICs), having zero or more input pins, one or more enable pins, one or more output pins, and a data-out pin. Each pin represents a domain; a collection of input or output pins together with the enable or data-out pins signify a tuple arriving at the device or being generated by the device. For those operator ICs (nodes) requiring two tuple inputs, there would be two sets of input pins (with two enable pins). A network is constructed by selecting the appropriate ICs and ensuring that every pin of each IC is connected to at least one pin of another IC in a hierarchical fashion. Access ICs are somewhat unusual in that they are connected to the outside world. When something changes in the outside world (the "something" can be specified by the input pins) the access IC places a value on each of the output pins and raises the data-out pin, thus generating an output tuple. This triggers the IC(s) connected to this IC, causing them to place a tuple on their output pins and raise their data-out pins.

In the final design, the monitor will automatically construct the network given the high level queries specified by the user. In the meantime, the user will be provided with commands to manipulate the network (see chapter 8.4).

This network approach emphasizes the flow of information from the access module on Cm* to the user's terminal. Relations are not explicitly represented in the system; instead a relation consists of all the tuples which appear at the output pins of a particular IC (node) over the time period the node is in the network (see section 8.5.2.1 for a way to support static relations using this framework). The instantaneous snapshot of each relation is contained in the internal state of the node computing that relation. The algorithms contained in the operator nodes, while performing standard relational operations such as join and projection, are quite different from their database counterparts, since they are tuned for incremental update of temporal relations. Since relations are represented only implicitly, a mechanism for viewing a relation is vital. Among the collection of operator nodes is a display node, which merely displays the tuples it has received on its input pins.

8.1.4. A Series of Implementations

The design is evolutionary, in that it consists of a series of implementations, each extending the previous implementation and attacking a larger set of issues. The four implementations are listed below (the terms will be discussed in later chapters):

- Step 1: a truly minimal system
 - representation of tuples
 - a few generic operator nodes
 - debugging facilities, including pseudo-access nodes (which do not access StarOS but instead are used for debugging)
 - primitive constructors (create, link, unlink)
 - control mechanisms for moving tuples around the network
- Step 2: a minimal StarOS monitor
 - additional operator nodes
 - communication with StarOS
 - a few actual access nodes
- Step 3: add naming and improve the user interface

- defstruct
- full communication with StarOS
- a full complement of access nodes
- Step 4: round out the system (may never be done)
 - uncertainty considerations
 - display of multiple relations

I expect each step to take approximately two weeks.

The monitor will be written in Franz Lisp, running on the VAX, and the access modules will reside in a single process written in Bliss/11 and run under StarOS. The two processes will communicate over the Ethernet using the Pup protocol.

8.2. Access Nodes

The access nodes collect all the information accessible by the monitor. Each node conceptually takes zero or more input domains (pins) specifying an entity and augments these with additional domains describing that entity. Thus there is an output pin for every input pin, plus the output pins computed by the access node. Each domain is typed (unlike real ICs); see Appendix I for a discussion of the allowable types and their representations. Each access node is associated with an accessing mechanism which specifies how the information in the additional domains is to be computed. Access nodes can be instantiated by the create operation (see section 8.4.1) enabling several copies to exist simultaneously in the network.

The particular access nodes that are supported were chosen for several reasons. Naming is a basic facility which should be provided early in the implementation, since the other access nodes depend on names being associated with the entities involved in the relationships accessed by the nodes. Over half of the access nodes support naming either directly or indirectly. Since processes are so prominent when first monitoring a system, about one fourth of the access nodes involve processes. To support the proposed synthetic workload generator, the TimeStamp access node was provided. And finally, several access nodes provide general information concerning modules, processors, and capabilities. The access nodes listed below allow a full range of issues concerning the collection of monitoring information to be investigated.

The description of each access node consists of a signature (the node name and the domains), a

description of each domain, and the associated access mechanism for the node. Implicit in each description is the time domain (an output pin) and the enable and data-out pins. The underlined domains in the signature are both input and output pins (connected together inside the node); the domains which are not underlined are computed by the node and are thus only output pins.

8.2.1. CapaInfo (ThisCapa, Type, Cluster, Cm)

Domains:

ThisCapa	CAPA, specifies the capability pointing to the object described by this relation
Type	ENUMERATED: (BasicObject, KernelPO, UserPO, DeviceObject, ShadowObject, DataMailbox, CapabilityMailbox, DirectoryObject, DequeObject, StackObject)
Cluster	INTEGER, the cluster this object resides in
Cm	INTEGER, the processor this object resides in

Access Mechanism:

*** object manager request *** The type domain is computed using Basic.DFS.

8.2.2. GetMpx (Nucleus, Mpx)

Domains:

Nucleus	CAPA to the nucleus module
Mpx	CAPA to Mpx Basic status object

Access Mechanism:

Get the Mpx Basic status object via ***.

8.2.3. Library (Index, Module)

Domains:

Index	ENUMERATED index into StarOS Library
Module	CAPA of module

Access Mechanism:

Convert the index into an integer (using ModLib.DFS) and access the StarOSLibrary capa.

8.2.4. ModuleAttributes (Module, ModuleId, NumberOfFunctions, NumberOfProcesses)

Domains:

Module	CAPA to a module object
ModuleId	INTEGER
NumberOfFunctions	INTEGER
NumberOfProcesses	INTEGER, the total number for this module

Access Mechanism:

Sample when needed, using ABlock.DFS. Access the NumberOfProcesses using ProcessSetTotalCount in ProSet.DFS. Additional output domains will be added if necessary.

8.2.5. ModuleFunctions (Module, Function, NumberOfProcesses, InitStackSize)

Domains:

Module	CAPA
Function:	INTEGER
NumberOfProcesses	INTEGER, for this function
InitStackSize	INTEGER

Access Mechanism:

Sampled when needed, using function attribute block of module, one for each function, using ABlock.DFS. Access NumberOfProcesses using ProcessSetFunctionCount in ProSet.DFS. Additional output domains will be added if needed.

8.2.6. ModulesLoaded (UserInterface, Module, Name)

Domains:

UserInterface CAPA to user interface process

Module CAPA

Name STRING name of Module

Access Mechanism:

Sampled when needed, using data structures found in the UIModuleRock capa (User[x335ID20]); look up string in \$ModuleTable (UserCm.B11[x335ID20]). ***

8.2.7. ModuleProcs (Module, Function, Process)

Domains:

Module CAPA

Function INTEGER

Process CAPA

Access Mechanism:

Sampled when needed; grab first process of this function using ProcessSet (Modul.DFS, ProSet.DFS); for each process (next = EnvBrotherProcess in Enviro.DFS) assign to process.

8.2.8. MpxStatus (MpxObject, CurrentProc)

Domains:

MpxObject CAPA

CurrentProc CAPA

Access Mechanism:

Sample with high frequency, using ***.

8.2.9. ProcessAttributes (Process, IsActivated, RBRD, CPll, Cluster, Cm, FunctionNumber, Module)

Domains:

Process	CAPA
IsActivated	BOOLEAN
RBRD	ENUMERATED: (Ready, Blocked, Running, Done)
CPll	ENUMERATED: (Created, PartInitialized, Initialized)
Cluster	INTEGER
Cm	INTEGER
FunctionNumber	INTEGER
Module	CAPA

Access Mechanism:

Sample when needed, by accessing data and capa part of process object, using StatVe.DFS and Enviro.DFS. Access Cluster and Cm using ***.

8.2.10. ProcCapas (Process, Occupant)

Doains:

Process	CAPA
Slot	INTEGER
Occupant	CAPA

Access Mechanism:

Sampled, using UENVNameSpace (in Enviro.DFS).

8.2.11. ProcessorMpx (Mpx, Cluster, Cm)

Domains:

Mpx	CAPA to Mpx Basic object
Cluster	INTEGER
Cm	INTEGER

Access Mechanism:

Sampled when needed, using ***.

8.2.12. ProcessorUniverse (Configurator, Cluster, Cm, MemorySize, Status)

Domains:

Configurator	CAPA to module
Cluster	INTEGER
Cm	INTEGER
MemorySize	INTEGER ***
Status	ENUMERATED: (CmMissing, CmSuspect, PcDown, CmAvailable, BootCm)

Access Mechanism:

Sampled when needed, using Config.DFS.

8.2.13. TimeStamp (Type, SubType, Args)

Domains:

Type	***
SubType	***
Args	***

Access Mechanism:

Traced by receiving a message from the application.

8.2.14. UserId (UserInterface, Username)**Domains:**

UserInterface CAPA to user interface process

Username STRING

Access Mechanism:

Sample when needed, using ***.

8.3. Generic Operator Nodes

In order to derive new relationships that are in a more useful form than the relationships expressed by the access nodes, it is necessary to use operations that can be performed on the tuples from one or two relations to compute a new relation. The system provides a collection of *generic operator nodes* which can be instantiated by specifying the parameters associated with the node. In the descriptions that follow, the parameters syntactically follow the name of the node. An integer is used to specify a domain (domains are ordered, with the first domain being domain 1; the implicit time domain is always domain 0). Parameters make operator nodes more convenient than ICs, since they can specify which input pins will be used to compute the function and often which function is computed as well. The description of each generic operator node consists of a signature (the node name, the instantiation parameters in brackets and the output domains in parentheses) and an explanation of the computation performed by the node. Some nodes append new output domains computed from existing domains; the rest map the input domains to the output domains in some fashion. The names of the output domains not computed by the node are taken from the input domains they are connected to. Note that all of these operations rely heavily on the implicit time domain in their computations.

8.3.1. ApplyOp [Operation Domain₁ Domain₂] (Result); unary

Computes the domain Result whose value is the result of the specified operation on the specified domains. The operation can be any Lisp function which can be applied to two arguments. Special semantics are associated with arithmetic operations on temporal domains; see Appendix IV.

8.3.2. Constant [Constant] (Constant); no input tuples

Generates a constant on its Constant output pin. This constant can be of any type.

8.3.3. Count [MajorDomain MinorDomain] (Count); unary

Computes the count of the tuples having the same value for the MajorDomain after a projection on the MajorDomain and MinorDomain has been done (i.e., two tuples with the same MajorDomain and MinorDomain count only as one).

8.3.4. Display [Name₁ ... Name_n]; unary

Maintains a display of the argument relation on the screen. The instantiation parameters are column (domain) titles.

8.3.5. Duration (Duration); unary

Computes the TEMPORAL domain Duration whose value is the length of time (in milliseconds) the tuple was valid.

8.3.6. Join [Predicate Domain₁ Domain₂]; binary

The output tuple contains all the domains of the two input tuples which can contain a different number of tuples. Each time a tuple enters the left input, it is concatenated with all of the tuples that have entered into the right input. The predicate is then applied to the corresponding domain₁ coming from the left tuple and domain₂ coming from the right tuple. If the predicate returns non-nil, the concatenated tuple is placed on the output pins. An analogous process occurs each time a tuple enters the right input.

8.3.7. Projection [NumDomains Domain₁ ... Domain_{NumDomains}]; unary

The projection node is conceptually a parameterized cross-point domain switch. The values of a particular subset of the domains in the input tuple are selected and placed in the specified order on the output pins. An example is

Projection [6 4 3]

which takes the third and fourth input pins and connects them to the second and first output pins, respectively. Input pins 1, 2, 5, and 6 get connected to output pins 3, 4, 5, and 6 respectively. Note that the first NumDomain input pins are connected to a like number of output pins and that the information from the rest of the input pins is discarded.

8.3.8. Selection [Predicate Domain₁ Domain₂]; unary

If the predicate returns non-nil, then the input pins are copied to the output pins.

8.3.9. SelectConstant [Predicate Domain Constant]; unary

Similar to the Selection operator, except that the third argument is a constant rather than a domain index.

8.3.10. Sum [MajorDomain MinorDomain] (Sum); unary

Similar to Count, except the sum of the values in MinorDomain (which must be an INTEGER or TEMPORAL domain) is computed, rather than the number of distinct values.

8.4. Node Interconnection

In previous chapters the access nodes and generic operator nodes supported by the system were described. The access nodes provide all the information the monitor knows about the application running on Cm*; the operator nodes are used to convert this information into a form more useful to the user. This is done by combining the nodes into a *tangled tree* with the links corresponding to paths over which individual tuples flow.

The analogy between nodes and integrated circuits breaks down somewhat when one examines how the nodes are interconnected. Ideally (?) one would like to specify all connections between pins in the network. The difficulty lies in the fact that the pins represent domains of the relation, yet the implementation deals only with *tuples*, which are collections of domains. This is natural, since we are still dealing with relations. A second difficulty with the analogy is that each instantiated node has a unspecified number of input pins which are connected directly to an equal number of output pins (unlike standard ICs!). The exact number of pins is determined when the node is connected into the network. The reason is that a node should take as arguments relations containing an arbitrary number of domains, rather than having, say, a generic operator node called Duration1 which computes the duration of all one domain relations, another node called Duration2, etc. One way to deal with this problem is to include the *number of domains* as an instantiation parameter. Instead, the manner in which the pins are connected is constrained. The set of output pins of each device is grouped together into either a single tuple or a left and right tuple (the nodes can have 0, 1, or 2 input tuples). The link command is provided to connect the output tuple of one device to an input tuple of another device. The projection operator node, which maps a number of input domains (the input tuple) into a (possibly smaller) number of output domains (the output tuple), provides some of the flexibility that the link command removes.

8.4.1. Primitive Constructors

There are three primitive constructors. The first creates an instantiation of an access or operator node. The second creates a link between two nodes, and the third destroys an existing link. Given the predefined nodes and these constructors, it is possible to specify arbitrarily complex computations on monitoring data.

8.4.1.1. (Create name newname (arg₁ ... arg_n))

This operation creates an instantiation of the node *name* with the specified instantiation parameters and associates the name *newname* with it. For example,

```
(Create 'ApplyOp 'Add12 '(+ 1 2))
```

creates the node *Add12*, which will add the values of the first two domains and append the result as an additional domain of the tuple. Instantiation parameters are only allowed for operator nodes. The instantiated node is assigned to *newname* and the create operation returns nil. Note that the number of pins has not yet been determined (although some restrictions may have been placed on them; for instance, *Add12* has at least two input and three output pins).

8.4.1.2. (Link fromnode tonode)

This operation connects the output tuple of the node *fromnode* to an input tuple of *tonode*, which must have at least one input tuple. For binary operator nodes, use

```
(Link fromnode tonode left)
```

or

```
(Link fromnode tonode right)
```

The link operation must be able to determine how many output pins there are on *fromnode* (how this is done will be seen in a moment). It then connects all the output pins of *fromnode* (the output tuple) to the selected input pins (the input tuple) of *tonode*. At this time, the number of output pins on *tonode* can be determined by adding the number of domains computed by *tonode* (which appear after the output domains connected directly to the input domains) to the number of input pins coming from the output tuple of *fromnode*. Note that this requirement forces the network to be a fully connected dag, or tangled tree. This property is satisfied by all networks which can be derived from relational queries.

Once the number of input and output pins has been determined, the link operation merely links them together in the order in which they occur (output pin 1 of *fromnode* is connected to input pin 1 of *tonode*, etc.)

8.4.1.3. (Unlink fromnode tonode)

If these nodes have been connected using the link command, then this link is removed. Otherwise, this operation has no effect.

8.4.2. Two Examples

To illustrate the link operation, suppose that

```
(create C Constant (1))
(create A ApplyOp (+ 1 1))
(create L Library)
```

had been executed. The instantiated node C has at least one output domain (called Constant); A has at least one input domain and two output domains (one called Result); and L has at least one input domain and at least two output domains (one called Module). All nodes have one input tuple and one output tuple. After executing

```
(link C A)
```

C has no input domains and one output domain (called Constant); A has one input domain called Constant and two output domains, Constant and Result. Proceeding further,

```
(create P Projection (2 2 1))
(link A P)
(link P L)
```

P simply interchanges the Constant and Result domains, so that the Result domain can be used as an Index to L. L has two input domains, Result and Constant, and three output domains, Result, Constant, and Module. Note that the input domain specified in the signature for Library was assumed by the Link command to be the first input domain.

As a more extended example, suppose we wanted a list of all the processes owned by any given user. Informally, this list can be derived by getting the user interface module out of the StarOS library, going down the user interface processes accessible from this module until we find the user's user interface process, getting all the modules loaded by the user, and then getting all the processes which are invoked functions of those modules (whew!!). This process is illustrated below:

First a few comments on the notation will be given. Instantiation parameters are enclosed in square brackets; output domains are enclosed in parentheses. The vertical lines between domains indicate the connection of those domains; the rest are eliminated by projection nodes, which are not shown. Vertical lines between nodes indicate *all* of the output domains of the upper node are connected to input domains of the lower node. To express this network in terms of the operations given above, the projection nodes and the connections must be made explicit:

(Create UI Constant (UserInterface))	;UserInterface is ENUMERATED
(Create Lib1 Library (UserInterface))	;get the user interface module
(Link UI Lib1)	
(Create Proj1 Projection (1 2))	;the module domain
(Link Lib1 Proj1)	
(Create MP1 ModuleProcs)	;get the user interface procs
(Link Proj1 MP1)	
(Create Proj2 Projection (1 3))	;the process domain
(Link MP1 Proj2)	
(Create User1 UserID)	;get the user ids
(Link Proj2 User1)	
(Create SC1 SelectConstant (EQ 2 RS41))	;UserName = RS41
(Link User1 SC1)	;find correct interface proc
(Create Proj3 Projection (1 1))	;user interface process domain
(Link SC1 Proj3)	
(Create ML1 ModulesLoaded)	;get the modules loaded by
(Link Proj3 ML1)	;this user
(Create Proj4 Projection (1 2))	;the modules domain
(Link ML1 Proj4)	
(Create MP2 ModuleProcs)	;get the processes of these
(Link Proj4 MP2)	;modules
(Create Proj5 Projection (2 1 3))	;the process and
(Link MP2 Proj5)	;module domains
(Create D1 Display (Modules Processes))	;display them
(Link Proj5 D1)	

There are several problems with this notation. First, it is quite verbose. Although there are only seven "useful" nodes (as illustrated before), constructing the network requires twenty-five separate operations. Second, it necessitates inventing names for the instantiated nodes (one way to get around this would be to have the create operation automatically invent a name for the newly instantiated node). Third, it ignores the names of the input and output pins, instead relying on the implicit ordering enforced by the link operation and the use of integer constants for domain indices. Finally, there is no way to parameterize the entire subnetwork, or to remove it conveniently. In short, the notation is at too low a level. Although it provides the abstraction from pins to collections of pins (tuples), it constructs a network rather than specifying operators that take relations as arguments. The next section discusses a notation which solves most of these problems.

8.4.3. Defining Structures

The *defstruct* operation translates a higher-level description of a network structure to an internal form which an extended create operation then transforms into a list of create and link operations. It makes certain assumptions concerning the form of the network to be constructed, and thus is less general than the create and link operations themselves. The *defstruct* operation is intended to fit between a high level calculus-based query language such as Quel and the low level create and link operations just discussed. The transformation from a query to a *defstruct* specification should be relatively straightforward; the same

can be said for the transformation performed by defstruct. Thus the defstruct syntax is designed to appear as much as possible to be relational operators (in the form of generic operator nodes) operating on relations (in the form of output tuples of nodes at the top of trees within the network) to produce relations.

The overall syntax of the operation is

```
(defstruct newname (param1 ... paramn) (domain1 ... domainn)
  source)
```

The defstruct operation creates a *structure* which is similar to a generic operator node with no inputs in that it is instantiated with a create operation with zero or more instantiation parameters. The list of domains specifies the names of the output pins for the structure. The source is an expression which states where the information that is routed to the output pins comes from. It has the following syntax:

```
(node (param1 ... paramn) (domain1 ... domaink)
  leftsource rightsource)
```

The node specifies an access or generic operator node (not one that has been created). The list of domains specifies which domains will be provided by this source. Conceptually, the domains provided by leftsource (and rightsource if the node is binary) are linked to the node (after it has been created) as input tuples in the order they are specified in leftsource and rightsource. The names of these domains are also given to the names of the output domains to which they are connected. These output pins are connected to a projection node which selects the domains named in the domain list. Thus each source specification is translated into an operator or access node-projection node pair, with generated names for the instantiated components. To illustrate, the following structure

```
(defstruct UserProcess (UName) (UName ModuleName Process)
  (ModuleProcs (Module Process)
    (ModulesLoaded (Mods)
      ((Select (EQ Id Name)) (Module)
        (UserID (Module Id)
          (ModuleProcs (Procs)
            (Library (Module)
              Constant (UName)
            )
          )
        )
      )
    )
  )
]
```

is identical to the one specified earlier when

```
(create UserProcess (RS41))
```

is executed.

Note that the syntax for source bears a strong resemblance to the defstruct syntax. The primary difference is that the arg_i in defstruct are the *names* (i.e., the formals) of instantiation parameters which are used within the structure being defined, whereas the arg_i in source are the *values* (i.e., the actuals) of the instantiation parameters which are provided to the node. This correspondence allows the source to be the name of a structure (which appears in an earlier defstruct) followed by the values of the instantiation

parameters and the names of the domains (nothing should follow the list of domains when a structure instantiation is used as a source). Using a structure as a source in another structure implies either that defstruct be able to treat this structure as a special case or that the link operation be able to handle structures. The latter change will be made, with the added provision of allowing unlink to undo the changes caused by the corresponding link operation.

8.5. Conclusion

This report has outlined an evolutionary (as opposed to revolutionary?!) approach to implementing a system supporting incremental updating of temporal relations.

8.5.1. Abstraction

The facilities provided by the monitor has been presented starting at a very low level of abstraction and moving up to a middle level of abstraction: The initial conceptual view was one of ICs (nodes) connected in a network. Each IC had a number of input, enable, and output pins, and one enable pin. This view allowed the primitive nodes provided by the monitor to be defined. After the various generic operator and access nodes were listed, a set of three primitive constructors were described which perceived the network from a more abstract level. These constructors viewed a node in the network as an instantiated generic or access node (with bound instantiation parameters) which had zero, one or two input tuples and one output tuple. Two operations were described which connected and disconnected nodes together at the tuple level. At that point a third level of abstraction, that of structures, was introduced. A structure is a portion of a network with certain constraints on the manner in which the components of that structure could be connected. Structures could be instantiated similarly to generic operator nodes. The defstruct operation viewed a node in the network as an operator which took one or two input tuples consisting of named domains and which provided an output tuple also consisting of named domains, with a convention of connecting domains of similar names. The final level, that of relational queries, is discussed below.

8.5.2. Extensions

To be relevant to the thesis, this approach must allow extension to a general monitoring system supporting the relational model. This chapter will illustrate a few ways that the system can be extended into a general system. Once the initial system has been implemented, these ideas can be investigated further.

8.5.2.1. Static Relations

Static relations can be stored by providing a *Store* operator node which would store incoming tuples in an external relational database in a relations specified by one of its instantiation parameters. Queries on stored relations could be handled with a *Retrieve* access node which would generate the tuples of a specified relation in chronological order.

8.5.2.2. Calculus-based Query Languages

The mapping of Quel statements into algebraic operator trees is well-understood, although temporal operators may introduce some complexity. The *defstruct* operation provides an example of compiling an algebraic specification into a network. It should be possible to extend this mechanism to handle Quel-like statements.

8.5.2.3. Efficiency

One of the motivations for an initial implementation is to determine how much of a problem efficiency will be. If it is indeed a problem, there are several possible areas for improvement. The queries presented to *defstruct* are in an appropriate format for transformations to improve efficiency. Such transformations sometimes provide exponential speed-ups in execution time. The algorithms within the operator nodes is another such area.

8.5.2.4. Incomplete Information

This topic was discussed briefly in my thesis proposal. The approach was to divide periods into portions which are known and portions which are possibly invalid. Each portion would be represented by a tuple with an additional implicit domain (probably a boolean value) specifying how definite the tuple was. The access nodes would initialize this domain and the operator nodes would use the domain in their update algorithms.

8.5.3. Unresolved Issues

There are many additional issues which must be resolved during the implementation of this design. A few of the more important ones are listed below:

- | | |
|--------------------------|--|
| Duplicate tuples | Should they be removed by each node, or should there be a special operator node whose only job it is to remove them? Should this node be automatically linked in by the <i>defstruct</i> operation? Which operator and access nodes are sensitive to duplicate tuples? |
| Monitoring errors | Should there also be <i>compensation links</i> between various access nodes which describe the impact one access mechanism has on the validity of the information returned by a second access mechanism? |

- Triggering** Some nodes (such as ApplyOp) should trigger on the leading edge of a tuple (i.e., when it becomes true), other nodes (such as Duration) should trigger on the trailing edge (when it becomes false), and a third set of nodes (such as Join) should trigger on both edges. How is this variation handled?
- Initialization** What sorts of activity should take place when a node is created or linked into the network? For instance, operator nodes must initialize their internal data structures and access nodes should establish contact with the access module on Cm*.
- Naming within defstruct** How are access and operator node domain names known to defstruct? How does defstruct handle domains which may or may not be input domains (such as the Function domain of ModuleProcs)? How should constants be handled?
- Type checking** Should the link and defstruct operations do type checking on the pins that are connected?
- Sampling** How does the monitor determine when to start sampling and the frequency to sample?

Appendix IV Representation Issues

IV.1. Tuples

Tuples are represented by a list of domains. Each domain has a type-dependent structure. The domains are referenced by index: domain 0 is the implicit time domain, and domain 1 through domain n are the explicit domains. The time domain is a list containing the begin time and the end time using a global clock.

IV.2. Domain Types

<u>Type</u>	<u>Representation</u>
INTEGER	Integer
BOOLEAN	Either the atom True or the atom Nil
CAPA	Integer index into access module's capa list (256 entries)
ENUMERATED	Symbolic value created by access node
STRING	Lisp string
TEMPORAL	List containing the slope and the intercept (initial value); the range is time

An example of an ENUMERATED domain is the type domain for the CapaInfo access node, which can have the symbolic value *BasicObject*, *CapabilityMailbox*, etc., each of which is a symbolic value within Lisp. An example of a TEMPORAL domain is the duration domain of the Duration operator node, which consists simply of a slope equal to 1 and an intercept equal to 0.

IV.3. Arithmetic Operations on Temporal Domains

<u>Operation</u>	<u>Result</u>
Temporal [+ /-] Constant	$\text{intercept}' := \text{intercept} [+ /-] \text{constant}$
Constant [+ /-] Temporal	$\text{intercept}' := \text{constant} [+ /-] \text{intercept}$
Temporal [+ /-] Temporal	$\text{intercept}' := \text{intercept}_1 [+ /-] \text{intercept}_2;$ $\text{slope}' := \text{slope}_1 [+ /-] \text{slope}_2$

Temporal * Constant	$\text{intercept}' := \text{intercept} * \text{constant};$ $\text{slope}' := \text{slope} * \text{constant}$
Constant * Temporal	$\text{intercept}' := \text{constant} * \text{intercept};$ $\text{slope}' := \text{constant} * \text{slope}$
Temporal / Constant	$\text{slope}' := \text{slope} / \text{constant}$
Temporal / Temporal	$\text{intercept}' := \text{slope}_1 / \text{slope}_2;$ $\text{slope} := 0$ (i.e., no longer a temporal domain)
all other operations	illegal

9. A General Monitoring Mechanism

Richard Snodgrass

9.1. Introduction

This document describes a very general monitoring mechanism for multiprocessors which was designed by Bob Chansler, Ivor Durham, Anita Jones, Zary Segall, and Richard Snodgrass. The fundamental approach was to design a single mechanism which could handle the majority of monitoring tasks yet be relatively simple to implement.

The intent of this document is to review the basic design, enumerate the various issues which must be considered when implementing the mechanism and then present a system-independent specification of a minimal (stage 1) monitoring mechanism. A brief discussion of the implementations of the stage 1 mechanism under two operating systems, StarOS and Medusa, completes the document.

The mechanism, like the operating systems it will be implemented on initially, is object-oriented. Monitoring actions are associated with the objects supported by the operating system and with the active entities which perform operations on these objects. The mechanism can be configured along several dimensions, allowing the user to specify quite precisely the aspects (s)he is interested in. In addition to being very flexible, the mechanism presented here is simple and efficient. The processing of monitoring data is divided into two portions, one synchronous with the occurrences the user is monitoring, and one asynchronous, with some coordination between the two. The synchronous portion is designed to be as efficient as possible, with the asynchronous portion being less critical in a multiprocessor environment.

This mechanism borrows heavily from the Hydra Kernel Tracer, which turned out to be very useful for monitoring both the operation system and user processes.

9.2. The Basic Design

The monitoring mechanism developed here records information concerning events, which are simply occurrences the user is interested in. Given this general definition of events, the mechanism can be used to support both tracing and sampling. There are several components to the mechanism:

- *events*, which are actions performed by an *initiator* to an object
- *event types*, which partition events into useful categories
- *sensors*, which detect that an event has occurred

- a *storage mechanism* for event information
- a *receptacle* for holding event information
- a *notification mechanism* for performing auxiliary actions when event information is stored
- a *sensor enable mechanism* for turning on and off the sensing of events
- a *storage enable mechanism* for turning on and off the storage of event information
- a *notification enable mechanism*
- a mapping between sensors and event types
- a mapping between event types, initiators, and receptacles
- a mapping between event types, objects, and receptacles
- a *compensation mechanism* to aid in calculating the effect the monitoring action had on the data in the collected information

In order to achieve maximum generality, it is useful to consider each of these components as a separate entity. This approach will be taken here, with the eventual implementation enforcing certain assumptions concerning these components.

9.2.1. EventSets

For each type of object to be monitored, there is an *eventset* of event types concerning objects of that type. The following is a list of possible eventsets:

- Process EventSet
- Task Force EventSet
- Multiplexor EventSet
- Memory Management Table EventSet
- Image Slice EventSet
- Module EventSet

Each eventset contains several sources of monitoring information for the event types contained in the set. The events and information sources for the Process EventSet include:

- Assign event - scheduler

- Block event - multiplexor
- Create event - process creator
- Preempt event - multiplexor
- Wakeup event - multiplexor

9.2.2. Receptacles

Receptacles are used to store the information associated with an event. Each Receptacle contains

- internal state, and
- a circular queue of event records.

Intuitively, an eventset is a collection of sources of monitoring information concerning the object type the eventset is associated with, and a receptacle is a container for this information. Receptacles contain an enable boolean in their internal state which specifies whether event records are to be stored in the receptacle.

The implementation determines the *grain* of events which can be monitored. Clearly, if the monitoring mechanism is to not greatly perturb the system, the grain of events to be monitored must be significantly larger than the combined storage and notification mechanisms.

9.2.3. Event Records

Event records contain

- event information,
- an optional timestamp, and
- optional monitoring error compensation information.

9.2.4. The InitiateMonitoring Operation

To associate an event type, an object, and a receptacle, the

InitiateMonitoring (Object, EventType, Receptacle)

operation is provided by all eventsets. There is also an analogous TerminateMonitoring operation. As an example which will be referred to throughout this document, the

InitiateMonitoring (AProcess, Block, ThisReceptacle)

operation provided by the ProcessEventSet connects ThisReceptacle to the Block event concerning

AProcess. When AProcess blocks, an event record will be stored in ThisReceptacle. In this case, the initiator of the event is the multiplexor and the sensor that detected the event is contained there. The sensor of another event concerning processes could be located in a user process which sampled a process and then generated an event containing the information just gathered. If this event is designated a *query* event, then the operation

InitiateMonitoring (SecondProcess, Query, AnotherReceptacle)

could also be performed. When the user process makes a query on SecondProcess, the information is recorded in AnotherReceptacle.

When an event is generated on a particular object (say the block event on AProcess), the event mechanism first determines whether the sensor detecting the event is enabled (see section 9.2.5). If not, then the event is considered to have not been detected (there is a philosophical issue as to whether the event has *actually* been detected anyway). If the sensor is enabled, the event has definitely been detected, and the object is checked to ensure that there is a receptacle associated with that object and that event. If so, the receptacle is checked to see if it is *enabled*. No event records are stored in a disabled receptacle. After the information is stored, a *notification* as specified in the receptacle is performed.

9.2.5. Sensors

A *sensor* is simply a mechanism for determining that an event has occurred, collecting the relevant information concerning that event, and storing that information into the appropriate receptacle. Thus, every sensor generates event records for events of a particular event type. A sensor can be enabled or disabled just as a receptacle can. However, if a sensor is disabled, no information will ever be stored in receptacles associated with that sensor. Thus, if the block event sensor is disabled, no information will be stored in ThisReceptacle regardless of whether ThisReceptacle is enabled.

By enabling or disabling a given receptacle, the monitoring data can be filtered on an object-by-object basis. A similar, though orthogonal, filtering occurs when sensors are enabled and disabled. For instance, disabling ThisReceptacle causes data concerning the blocking of AProcess (on all processors) to be filtered out. Disabling the block sensor within a particular multiplexor causes only blocks on that processor (concerning all processes) to be filtered out.

Each eventset supports the sensor-event association and the object-event type-receptacle association. Thus it may be possible for an eventset to automatically enable or disable various sensors as receptacles were added or removed from objects. From a different point of view, the eventset could reject InitiateMonitoring requests if the sensors are already disabled. The eventset might also reject *all*

InitiateMonitoring operations on the Block event if the current system does not contain a sensor for this event. An arbitrary amount of intelligence could be embedded in the eventset's InitiateMonitoring and TerminateMonitoring operations. However, the minimal functionality would be easy to implement.

9.2.6. Notification

The notification mechanism performs auxiliary actions when an event record is stored in a receptacle. These actions *notify* other entities (esp. the monitoring process(es)) that the event record has been stored or that a condition (such a queue overflow in the receptacle) occurred. This mechanism is necessitated by the separation of the sensors (and the associated storage mechanism), the receptacles where the event records are stored, and the monitoring process, which removes the event records from the receptacle for further analysis. The decoupling has several advantages, including efficiency of the monitoring portion which is synchronous with the event (e.g., the storage mechanism) and the filtering capabilities mentioned in section 9.2.5. The primary disadvantage is that the occurrence of the event can be separated from the detection of the event *by the monitor* by an arbitrarily long period of time, depending on how often the monitoring process examines each receptacle.

The notification mechanism is included to inform the monitoring process that either an event record has been stored or that a particular condition concerning the state of the receptacle has been satisfied. This mechanism should transfer minimal information, thus requiring the monitoring process to examine the receptacle for a more detailed view of the condition causing the notification.

9.2.7. Summary

A number of actions must be taken in order to collect monitoring information. First, one or more receptacles must be created, and the notification mechanism must be configured for each receptacle. Then the InitiateMonitoring operation is performed for each object-event type pair for which monitoring is desired. At this point, the receptacles start filling up with event records. It is the responsibility of the monitoring process to ensure that the event records are removed from each receptacle before the information is overwritten. The notification mechanism discussed in the next chapter is designed to aid in achieving this loose synchronization.

9.3. The Basic Implementation

There are two levels to the implementation of this mechanism. The lower level (to be specified shortly) consists of the receptacle and receptacleset data types, and the ReceptacleStore operation. The upper level consists of the eventsets and the InitiateMonitoring and TerminateMonitoring operations.

9.3.1. ReceptacleSets

The mechanism allows a receptacle to be associated with a particular event type and a particular object. This association is implemented using the *receptacleset* data type, which is simply a set of receptacles. Each object to be monitored is associated with a receptacleset. Receptaclesets can be associated with any object which has associated operations written in software, such as

- processes
- system tables
- abstract data objects
- StarOS modules
- task forces
- file control blocks

If the storage and notification mechanisms are implemented in software (as is envisioned), then the objects which cannot be associated with receptaclesets are the ones supported by firmware:

- StarOS mailboxes
- StarOS carriers
- StarOS basic objects
- StarOS dequeues
- Medusa pipes
- Medusa descriptor lists
- Medusa pages
- directories

Note that some operations on these object types are implemented in software, so that it may still be useful to associate receptaclesets with instances of them.

9.3.2. The ReceptacleStore Operation

Information is stored in a receptacle by the *ReceptacleStore* operation which takes the following parameters:

- a *receptacleset*

- a sensor identifier
- event information

The ReceptacleStore operation first ensures that the sensor is enabled, and if so, that the particular receptacle is enabled. If these conditions are satisfied, then the event information is stored in the receptacle and an optional *notification* is performed.

This mechanism is amenable to both tracing and sampling. Tracing is accomplished by embedding ReceptacleStore operations in the code for the modules of the system. Whenever this code is executed, the event would be recorded in the relevant receptacle.

Sampling is accomplished by handing over the object to be sampled to a process designed to sample the indicated object type. Periodically this process will examine the object and then execute one or more ReceptacleStore operations.

9.4. Implementation Issues

Given this framework, there are still many design issues to be resolved. The remainder of this document will outline the various options implied by these issues.

9.4.1. Internal State of a Receptacle

The internal state of a receptacle includes one or more of the following components:

- start pointer -- refers to the beginning of the circular queue (where event records are removed by the monitoring process)
- end pointer -- refers to the end of the circular queue (where event records are added)
- cycle counter -- the number of times the end pointer has been reset to the top of the queue buffer
- cumulative counter -- only necessary if event records are of variable length
- notification mailbox
- notification receptacle
- operation register
- semaphore -- for coordinating access to the receptacle
- free record limit -- used in one of the notification predicates

9.4.2. Notification

There are two aspects to the notification issue: how and when. Possible *notification predicates* are

- when an event record is stored in the receptacle;
- when the number of free records in the queue goes below the free record limit (includes buffer-full and overwrite conditions as special cases);
- when the counter reaches a specified value;
- when the cycle counter is incremented; or
- when some other condition on the internal state is satisfied.

Possible *notification actions* are

- sending a data message to the notification mailbox indicating the current cycle count, the offset into the queue, and perhaps a timestamp;
- sending a capability message to the notification mailbox containing the receptacle which the notification concerns;
- setting or clearing enable bits in the operation register; or
- generating another event record on the *notification receptacle*.

9.4.3. Operation Register

The operation register specifies the action to be taken when a *ReceptacleStore* operation is executed. This register is a collection of switches which can be set either by a *ReceptacleSwitch* operation or by a notification. These switches enable

- the store operation itself,
- various notification actions,
- various notification predicates,
- various combinations of notification predicates and actions
- timestamps in event records,
- timestamps in notifications, and/or
- other optional operations.

9.4.4. Restrictions

Certain restrictions may be necessary in order to efficiently implement this monitoring mechanism.

Possible restrictions which came up in discussions were

- Receptacles cannot be shared by several receptaclesets
- Receptaclesets cannot be shared by several objects
- the notification receptacle must be in the same receptacleset
- the reserved capability slot in processes must contain a receptacleset capability, even if all the receptacles in that receptacleset are disabled

9.4.5. Compensation

Information may be stored in the sensor or the receptacle which would aid in calculating the effect the monitoring action had on the data in the collected event records. This information may include

- an event generation counter
- a ReceptacleStore fail counter
- an overhead estimation counter

It is difficult to design a compensation mechanism without a specific implementation in mind.

9.5. The Stage 1 Specification

The stage 1 monitoring mechanism is designed to provide the minimal functionality yet still allow a significant portion of the events to be monitored.

9.5.1. Receptacles

The mechanism consists of the receptacleset and receptacle data types and the ReceptacleStore operation. Each receptacle contains

- internal state, and
- a circular queue of event records.

Event records are fixed length records containing

- event information and
- an optional timestamp.

The internal state of a receptacle contains the following components:

- start pointer
- end pointer
- cycle counter
- notification destination
- operation register
- free record limit
- event record size

The operation register contains

- the store operation enable switch
- a notification predicate indicator
- a notification action indicator
- a switch enabling timestamps in event record

9.5.2. Notification

The notification predicates which are supported are

- an event record is stored in a receptacle
- the number of free records (as indicated by the difference between the end and start pointers) falls below the free record limit

The supported notification actions are

- setting an indicator which the monitoring process(es) can test very quickly
- clearing the store enable bit in the operation register

All the restrictions listed in section 9.4.4 are acceptable.

9.5.3. The ReceptacleStore Operation

The ReceptacleStore operation will take the following parameters:

- a `receptacleset`,
- a sensor identifier, and

- event information.

The number of words of event information is assumed to be equal to the event record size contained in the receptacle. The basic algorithm for the operation is

```

Is the receptacleset capability nil?
  Yes - exit
Index into the receptacleset to get the receptacle
Is the receptacle nil?
  Yes - exit
Is the receptacle enabled for stores?
  No - exit
Are timestamps in event records enabled?
  Yes - collect timestamp
Store event record
Is notification predicate satisfied?
  Yes - perform notification
  
```

Sensors and events are separate entities. The StoreReceptacle operation is be handed a sensor identifier, which it maps into an index into a receptacleset. The sensor is disabled by disassociating the sensor identification from an event. The eventsets are responsible for maintaining the mapping from sensors to events. This mapping is modified by the InitiateMonitoring and TerminateMonitoring operations.

9.6. The StarOS Implementation of Stage 1

The StarOS group has agreed to implement the stage 1 mechanism in its entirety. This chapter will give an overview of the correspondence between the stage 1 specification and the StarOS implementation of that specification.

9.6.1. ReceptacleSets

The following objects will have a predefined receptacleset capability slot:

- processes
- modules
- task forces

Receptacles per se will not exist; instead, the receptacles will be merged into the receptacleset. The operation registers will form an array of operation registers, and the individual queues will be combined into a single queue. This arrangement has at least three advantages:

- the proliferation of small objects (receptacles) will be avoided;

- internal fragmentation due to the presence of many small buffers will be eliminated; and
- the monitoring process will be able to manage the various queues more efficiently because they will be larger and fewer in number.

The primary disadvantages are

- receptacles cannot be shared by several receptaclesets, and
- the event type must be stored in the event record.

9.6.2. The ReceptacleStore Operation

The ReceptacleStore operation will be implemented as a procedure call in software. Hence the grain of events which can be monitored is at least an order of magnitude greater than a procedure call.

9.7. The Medusa Implementation of Stage 1

There are two possible Medusa implementations which do not involve extensive Kmap modifications. Both implementations merge receptacles into the receptacleset.

The first approach splits the receptacleset into a data structure which is stored in the object being monitored and a conventional Medusa pipe. The pipe serves as the circular buffer and the notification mechanism. The data structure consists of a capability to the pipe and the event operation registers. The monitoring process is responsible for retrieving the event records from the pipe.

The second approach involves creating a new Medusa object which is equivalent to a page object except that

- there could be several capabilities to the same object, residing in different task forces if necessary, and
- there would be less than 2K words of data, due to the presence of back pointers within the object.

Using this new object type, an implementation similar to that of StarOS could be done.

The advantages of the first approach are

- no new object types are necessary, hence no microcode modifications are involved;
- variable length event records incur no additional overhead;
- the synchronous portion of the ReceptacleStore operation is very fast; and

- the circular buffer (i.e., the pipe) can be shared.

The advantages of the second approach are

- it is more consistent with the StarOS implementation;
- it allows sharing of receptaclesets;
- recent information is retained in preference to old information if the circular buffer is full; and
- flow control (using the free record limit) is feasible.

10. Description File Specifications

Richard Snodgrass

10.1. Introduction

During the initial development of the low level event collection mechanism for the Cm* monitoring system, it became apparent that there were several procedural difficulties in the placement of sensors in the StarOS and Medusa operating systems. One difficulty was the that the Sensor macro (which stores the event records) was becoming quite cumbersome. One design required twelve parameters for a typical sensor involving three domains! Since the sensors were to be placed in critical portions of the operating system, there was little room for error in the specification of these parameters. A second problem was the assignment of event numbers; an incorrect event number in a Sensor macro would result in the absence of event records of that type--a situation that might be difficult to detect by the user interacting with SIMON. Two sensors with the same event number would cause havoc within SIMON. A third problem is maintaining consistency between SIMON's view of the world and the world as it actually is. This is especially true during the early development of the monitor, when the collection of sensors inside the operating system, and the various attributes of those sensors, is changing frequently.

Finally, all these problems are exacerbated by the sheer number of sensors: I can easily envision several hundred sensors in both StarOS and Medusa when the monitoring system has been fully developed. The task of ensuring that all of these sensors, which are distributed among many source files, are correct and consistent, both within each other and with SIMON, is unmanageable if it remains a manual one.

The solution, described in this document, is to create a database, called the *sensor description file (SDF)*, which contains information on the sensors defined in a given taskforce. As work progressed on designing the sensor description file, it became apparent that the syntax (as well as the programs processing that syntax) were general enough so that databases could be designed to contain information other than that related to the sensors. In fact, the *description files* will be used to communicate *all* static information to SIMON from other programming environment tools.

This document details the syntax and semantics of the various description files. Each chapter describes a particular use and format for the description file; a table can be found at the end of the chapter summarizing the file format. Both user-level and implementation-level information is included, usually in separate sections. This chapter provides an overview of the syntax followed by all the description files, and describes the processing of these files.

10.1.1. Syntax and Definitions

A description file consists of a set of *objects* partitioned into *classes*. Each object is associated with a set of class-dependent *attributes*. There can be one or more *values* for each attribute, and some attributes can have objects as values. To describe a particular format, one must specify the object types, the attributes for each type, and the allowable values for each attribute.

The syntax follows the above description quite closely:

```

<description file>      ::= <objects>

<objects>                ::= <object> | <object> <objects>
<object>                 ::= ( <class> <attribute list> )

<attribute list>         ::= <attribute> | <attribute> <attribute list>
<attribute>              ::= ( <attribute name> <attribute values> )

<attribute values>       ::= <attribute value> | <attribute value> <attribute values>
<attribute value>        ::= <object> | <object name> | <atom> | <integer> | <string> | <list>

<class>                  ::= <atom>
<objectname>             ::= <atom>
<attributename>          ::= <atom>

```

<integer> can be positive or negative; <atom> are converted to uppercase.

As an example, the following description file has one object with two attributes:

```

(oneclass (name abc)
          (objectattribute 3)
)

```

10.1.2. The Description File Preprocessor

The *description file preprocessor* (DFPRE) reads in a description, performs syntax and semantic checking, and outputs one or more files containing information derived from the input file. The syntax is specified in another description file called a *description format file* (FDF) (see chapter 10.3 for details). The semantics is contained in a function inside DFPRE which must be provided for each format. This function performs various checks on the information in the file and derives new information to be placed in one of the output files.

Once a description file has been processed, the information can then be output in a number of ways, depending on the requirements of the format. All formats can be output as a *Simon description*. This file

is a PDP-11 assembly language file which is assembled and placed in a taskforce to be loaded onto Cm*. Once the information is in the taskforce in this special format, it can be easily and efficiently sent over to SIMON by the resident monitor (see section 10.3.7).

Other object files may be produced by DFPRE. These files are dependent on the individual formats and will be described in the relevant chapter.

10.2. Sensor Description File (SDF)

There are actually two sensor description file formats, one for StarOS and one for Medusa. However, the formats are similar, so they will be discussed together. All unqualified statements apply to both Medusa and StarOS. The **Name** attribute is required for all objects. The **Documentation** (or **Doc**) attribute allows comments to be given. Note that parentheses must be matched in all attributes, including **Documentation** and **Doc**.

10.2.1. TaskForce

An SDF describes the sensors defined in a given taskforce. Since StarOS is itself a taskforce, an SDF describes all the sensors within the operating system. Medusa requires several SDF's, one for each utility.

There are only a few user-supplied attributes for TaskForces. The **SimonFileName** specifies the name of the file where DFPRE will place the Simon description (see section 10.3.7). The **Version** attribute is for documentation purposes.

10.2.2. ObjectType

This class describes the objects which can be monitored by sensors defined in this SDF. Objects monitored in StarOS must reserve one word and one capability slot for monitoring information; their locations are defined by **WordOffset** and **RSOffset**. Medusa objects must reserve 17 words starting at the field named by **ExternSensOffset**.

10.2.3. SensorProcess

The **Inline** attribute specifies whether inline code for sensors is to be used at all. This attribute, if false, overrides the **SpaceTimeRatio** attribute in events. The **RequireFileName** specifies where the sensor macro definitions are to be placed. The other attributes apply on for StarOS SDFs. The **FunctionName** and **ModuleName** attributes will be used in conjunction with the naming description file (see chapter NDF); until that interface is working the **FunctionNumber** will be used. If the process contains any

internal events (see below), then the **ROffset** and **WordOffset** attributes must be specified, analogously to **ObjectTypes**. The **ClockPage** attribute specifies the address, if any, the clock may be found.

10.2.4. Event

The **Location** attribute identifies the sensorprocess containing the sensor for this event. The **Object** attribute specifies the objecttype this event refers to. The **Timestamp** attribute specifies whether timestamps are to be included in the event record. Note that **SIMON** uses the timestamp to identify the sensor and the object referred to in the event record. The **WaitTime** attribute specifies the number of microseconds to wait for space to be made available in the receptacle for an event record. A **WaitTime** of 0 indicates no waiting; a **WaitTime** of -1 indicates infinite waiting.

The **SpaceTimeRatio** attribute indicates the relative tradeoff desired between space and time efficiency in the sensor. A high spacetime ratio (near 100) specifies a sensor which optimizes space as much as possible; analogously, a low spacetime ratio (near 0) optimizes the time efficiency. The **InLine** attribute is equivalent to a low spacetime ratio if true and a high spacetime ratio otherwise.

Several attributes relate to event enabling. If the **AssumeEnabled** attribute is true, then the event is always enabled. This attribute is useful for message- and invocation-sampled events (see below). If the **CheckOneTime** attribute is true, then the onetime bit will be queried after the event record is stored to determine whether to turn off the enable bit. If the **checkonetime** attribute is false or not specified, then the **AssumeOneTime** attribute must be specified. If true, then the enable bit will always be turned off after the event record is stored; otherwise, the enable bit will not be touched.

The **MinorType** attribute specifies the event type. There are five types of events: object-traced, sensor-traced*, receptacle-sampled*, message-sampled, and invocation-sampled. The event types designated by (*) are **Internal** (a generated attribute, see below), indicating that the receptacleset contained in the sensorprocess, rather than in the object, is to be used.

A traced event record is written *when the event occurs*. The traced events are enabled by setting the appropriate bits in the appropriate receptacleset. An object-traced event uses the receptacleset associated with the *object* to determine the various aspects of the event record: whether it is to be stored at all, where it is to be stored, etc. A sensor-traced event uses the receptacleset associated with the *sensor* for this information. When a sensor-traced event occurs (an example is the reading of a file), the process sensing the event (in this case, a filesystem process) will first check the store enable bit in its internal receptacleset. If this bit is set, then the process will store the event record. As far as the

implementor of the process is concerned, the only change in the source code will be a single Sensor macro call. When an object-traced event occurs (the reading of a file might be both a sensor and an object-traced event), the same sequence is executed, except that the object's (in this case, the file control block object) receptacle`set` is used.

A sampled event record is written at the request of SIMON. Sampled events require more cooperation from the implementor of the process sensing the event. Sensors for receptacle-sampled events still refer to the enable bits located in the sensor process's internal receptacle`set`. However, these bits are not checked when an operation is performed; instead, the process must periodically query these bits. If the bit for an receptacle-sampled event is set, then the sensor process must generate the event records *at that time*. In the usual case, the onetime bit will also be set, resulting in the clearing of the enable bit after the event records are generated. An example of a receptacle-sampled event is an event in the process which generates an event record specifying the number of free words in a data structure within the process. To determine this value, SIMON tells the resident monitor to enable this particular event; the event record is generated the next time the enable bit is queried by the process (hopefully soon after the bit is set), and the enable bit is cleared so that no more event records will be generated.

The last two types of events, message and invocation-sampled events, requires even more cooperation. Whenever SIMON desires an event record concerning a particular object (and/or process or module), a `SAMPLE` command will be sent to the resident monitor, which will either send a message containing the object to the indicated process, which must then generate the requested event record(s), or perform a function invocation on the indicated module, which must also generate the requested event record(s). In either case, it is the implementor's responsibility to see that the message or invocation is received and the event records are produced.

Although the `minortype`, `onetime`, and `assumeonetime` attributes are specified independently, most of the time the values will follow these patterns:

(minortype object-trace)	(checkonetime t)	
(minortype sensor-trace)	(checkonetime t)	
(minortype receptacle-sample)	(checkonetime nil)	(assumeonetime t)
(minortype message-sample)	(checkonetime nil)	(assumeonetime nil)
(minortype invocation-sample)	(checkonetime nil)	(assumeonetime nil)

The `DeclareObject` attribute causes the sensor to declare the object to the resident monitor so that

the resident monitor can later associate a receptacleset with this object. This attribute will probably be set for create (sensor-traced) or receptacle-sampled events, and are relevant only for StarOS sensors. The **Domains** attribute lists the domains included in this event.

10.2.5. Domain

Since domains have attributes of their own, they are treated as separate objects. Domains are ordered within events. The **Type** attribute specifies the format of the domain within the event record.

10.2.6. Generated Attributes

DFPRE generates attributes to be used by SIMON and to be used in producing require files. The **Index** attribute for domains indicates the relative ordering of the domains within the event, with the first domain having an index of 1. The **EnableBitStatus** attribute is derived from the **AssumeEnabled**, **AssumeOneTime**, and **CheckOneTime** attributes. The **Internal** attribute is derived from the **MinorType** attribute. The **EnableIndex** attribute specifies the bit position in the receptacleset associated with this event, and is also used as the event number.

Several attributes are generated for both object types and sensor processes, describing aggregates over the events defined for those objects. The number of enable bits in the external receptacleset for an object type (and the internal receptacleset for a sensor process) is recorded in the **NumEnableBits** attribute. The **Events** attribute contains all the events associated with the object type or sensor process.

If one of the events associated with a sensorprocess is internal, then the **InternalEvent** attribute is true. The data and time the SDF was processed by DFPRE is recorded in the **Minute**, **Hour**, **Day**, **Month**, and **Year** attributes; the name of the SDF appears in the **SDFFileName** attribute.

10.2.7. Require Files

DFPRE produces several files from an SDF: (1) a Simon description to be loaded with the taskforce and sent to SIMON by the resident monitor; (2) a require file containing definitions for each sensorprocess (in the case of a StarOS SDF) or the taskforce (for a Medusa SDF); and (3) a require file for each object type. The goal is to imbed much of the detail of the event collection mechanism in these require files, so that few modifications are necessary to the source code of the processes containing the sensors.

10.2.7.1. Sensor Process Require Files

The sensor process require file has the following components (*Name* is replaced by the name of the sensor process):

- MakeInternalRS macro (if internal events are defined for this process--expands to a call to the MakeReceptacleSet macro);
- require statements for the receptacleSet definitions and for each object type referenced by the process;
- Namesensor macro (for each event located in this sensor process--expands to a call to the Sensor macro);
- NumberOfEvents definition;
- MaxRecordSize definition.

10.2.7.2. Object Type Require Files

The require file for each object type contains the following components (*Name* is replaced by the name of the object type):

- MakeNameRS macro (expands to a call to the MakeReceptacleSet macro);
- NumberOfNameEvents definition.

10.2.8. Summary

<u>Class</u> ⁸	<u>Attribute</u>	<u>Value</u> ⁹	<u>Notes</u> ¹⁰	<u>Description</u>
Class	Doc	Anything		
Class	Documentation			
Class	Name	Atom	O,R	
Domain	Index	Integer	G,O	
Domain	MaxSize	Integer ¹¹	?	

⁸If *Class*, then attribute applies to all classes.

⁹Either a defined type (anything, atom, boolean, or integer), a class name, or a special type, whose values are listed in a footnote.

¹⁰G = generated by DFPRE, M = only for Medusa, O = output to Simon Description, R = Required, S = only for StarOS, T = if in a Medusa SDF, then specified in the Taskforce, but generated for the sensorprocess, X = will eventually be removed, ? = not documented.

¹¹Only if the Type is string.

Domain	Type	DomainType ¹²	O,R
Event	AssumeEnabled	Boolean	
Event	AssumeOneTime	Boolean	
Event	CheckOnetime	Boolean	
Event	DeclareObject	Boolean	S
Event	Domains	Domain	
Event	EnableBitStatus	Atom ¹³	G
Event	EnableIndex	Integer	G,O
Event	IndexCap	Integer	G
Event	Inline	Boolean	
Event	Internal	Boolean	G,O
Event	Location	SensorProcess	R
Event	MinorType	MType ¹⁴	O,R
Event	Object	ObjectType	O
Event	SpaceTimeRatio	Integer	
Event	StartCap	Integer	G
Event	TimeStamp	Boolean	S
Event	WaitTime	Integer	
ObjectType	Events	Event	G
ObjectType	ExternSensOffset	Atom	M,X
ObjectType	MaxEventSize	Integer	G,?
ObjectType	MinEventSize	Integer	?
ObjectType	NumEnableBits	Integer	G
ObjectType	RequireFileName	Atom	S
ObjectType	RSSlot	Anything ¹⁵	S,R,X
ObjectType	WordOffset	Anything	S,R,X
SensorProcess	ClockPage	Anything	S
SensorProcess	Events	Event	G
SensorProcess	FunctionName	Atom	O,S
SensorProcess	FunctionNumber	Integer	O,S
SensorProcess	Inline	Boolean	T
SensorProcess	InternalEvent	Boolean	G
SensorProcess	MaxEventSize	Integer	G,?
SensorProcess	MinEventSize	Integer	T,?
SensorProcess	ModuleName	Atom	O,S
SensorProcess	NumEnableBits	Integer	G
SensorProcess	Objects	ObjectType	G
SensorProcess	RequireFileName	Atom	T

¹²One of DoubleInteger, Integer, or String.

¹³One of CheckOneTime, ClearStoreEnable, DontTouchStoreEnable, AssumeEnabled.

¹⁴One of ObjectTraced, SensorTraced, ReceptacleSampled, MessageSampled, or InvocationSampled.

¹⁵Usually an integer or an atom.

SensorProcess	RSSlot	Anything	R,S,X
TaskForce	Day	Integer	G,O
TaskForce	Hour	Integer	G,O
TaskForce	Inline	Boolean	M
TaskForce	SimonFileName	Atom	
TaskForce	MinEventSize	Integer	M,?
TaskForce	Minute	Integer	G,O
TaskForce	Month	Integer	G,O
TaskForce	PipeName	Atom	M
TaskForce	RequireFileName	Atom	M
TaskForce	SDFFileName	Atom	G,O
TaskForce	SystemName	Atom	G,O,S,?
TaskForce	Version	Integer	O
TaskForce	Year	Integer	G,O

10.3. Format Description File (FDF)

Each description file format is associated with a set of classes, a set of attributes for each class, and a set of values for each attribute. For instance, the event class can be used in a sensor description file, the **TimeStamp** attribute is defined for events, and the values **True** and **False** are acceptable for the **Timestamp** attribute. Rather than imbedding this format-specific information in DFPRE, it is placed in a file called a *format description file* (FDF). Using a FDF has several advantages: the various classes, attributes, and values for a format can be modified easily by the format designer, the structure of DFPRE is less complex, one version of DFPRE works for several formats, and the same routines in DFPRE which process the input description file (the SDF, etc.) can be used to initially process the format description file, since the FDF is in the same syntax as the other description files.

The classes in the FDF specify the tasks to be performed when reading in the input file (the **FieldTypes**, **Input**, and **Default** classes), the processing of the input file (the **General** class), and the generation of the Simon description (the **Output** class). Each of these classes will be described here. This chapter also contains a description of the internal structure of DFPRE. Perhaps the best way to understand this material is to study several existing FDF's to see how the various classes are used.

10.3.1. FieldTypes

The allowed values for an attribute are divided into (potentially overlapping) *fieldtypes*. The predefined fieldtypes are

boolean	True, T, False, F
anything	A general list except nil

Lisp Predicate The most common values are *fixp* (integers) and *atom* (names).

The field types class allows the format designer to define new fieldtypes for a particular format. The attributes of the field types class are the names of the fieldtypes, and the values are the values that belonging to that fieldtype. For instance, the specification

```
(fieldtypes (atype 1 2 3 a b c)
            (anothertype one two three a)
)
```

includes two field types (atype and anothertype); the former allows six possible values and the latter, only four. These field types can later be used as values of attributes of the Input class.

10.3.2. Input

This class specifies the typechecking to be done on the file being read in. Each object in this class describes the valid attributes for a class in the input file and the values of these attributes indicate the fieldtype of the value of the attribute when given in the input file. For instance, the specification

```
(input      (specifies oneclass)
            (objectattribute fixp)
            (asecondattribute atom)
)
```

describes a class called oneclass, which has two attributes. The first attribute, objectattribute, can have integer values. The other attribute, called asecondattribute, can have names as values.

10.3.3. Default

The default class defines values to be assumed if none are specified by the user. The syntax is similar to the input class:

```
(default    (specifies event)
            (timestamp f)
)
```

Note: This class is not implemented.

10.3.4. General

This class controls the processing of input files. The successive steps are:

- read in the appropriate FDF, with type-checking disabled;
- read in the input file, performing type checking as specified in the input class;

- add defaults if necessary as specified in the default class;
- perform any format-specific processing (by calling the **ProcNodeFunction**);
- ask for commands and generate output files (by calling the **CommandFunction**).

The two functions must be defined in DFPRE (see the source code for DFPRE for examples of **ProcNodeFunction** and **CommandFunction**). The **FileDefault** attribute applies to the input file; the **RequireFileDefault** applies to any require file generated by DFPRE.

10.3.5. Output

In the usual case, only a subset of the attributes are sent to SIMON via the Simon description. The output class specifies which attributes are to be placed in the Simon description, and the format of the values for the attributes.

10.3.6. Internal Representation

As the input file is read in, an internal representation of the objects defined in the file is constructed. This representation is based on *frames*, which are attached as properties to atoms. Frames are composed of *slots*, which are further composed of *facets*, which have *values* (note the intentional correspondence with objects, classes, attributes, and values). An atom is generated for each object defined in the input file.

10.3.7. Simon Description Format

The Simon description file consists of a list of triples, each containing two integers and either a third integer or a character string. The first integer indicates the attribute, the second, the object, and the third element is the value of this attribute for this object. Since attributes are represented by integers, there must be some way to associate an attribute with an integer. This is done using four "meta" attributes: **DefineNodeAttribute** (value 1), for attributes having objects as values; **DefineLitAttribute**(2), for attributes having either integers or strings as values; **DefineAAttribute** (3), for attributes having other attributes as values, and **DefineNode** (4), to define classes. The example given earlier:

```
(oneclass (name abc)
  (objectattribute 3)
)
```

would be described by these triples:

(4 {DefineNode}, 5, "OneClass")	oneclass = 5
(5 {oneclass}, 1, "abc")	object # 1
(2 {DefineLitAttribute}, 6, "objectattribute")	objectattribute = 6
(6 {objectattribute}, 1, 3)	

In this way, SIMON needs only to know the values for the four meta-attributes; the names of the classes and attributes are sent along with the rest of the description.

10.3.8. Summary

<u>Class</u>	<u>Attribute</u> ¹⁶	<u>Value</u>	<u>Notes</u> ¹⁷	<u>Description</u>
Default	<i>Attribute</i>	<i>Default Value</i>		
Default	Required	Attribute	?	
Default	Specifies	Class		
FieldTypes	<i>Type</i>	<i>Allowed Values</i>		
General	CommandFunction	Function Name		
General	FileDefault	Filespec ¹⁸		
General	ProcNodeFunction	Function Name		
General	RequireFileDefault	Filespec		
Input	<i>Attribute</i>	<i>Type</i>		
Input	Specifies	Class		
Output	<i>Attribute</i>	<i>OutputType</i> ¹⁹		
Output	Specifies	Class		

As the input file is read in, the following attributes are generated within DFPRE:

<u>Node Name</u> ²⁰	<u>Slot</u> ²¹	<u>Facet</u>	<u>Value</u> ²²	<u>Notes</u> ²³	<u>Description</u>
All Nodes	Node	Class	Class		
All Nodes	Node	ID	Integer	O	
All Nodes	Node	IsNode	True		
All Nodes	Node	Name	Atom	O	

¹⁶ If in *italics*, then substitute a defined attribute or type.

¹⁷ ? = not documented.

¹⁸ A filespec refers to a (partial or full) name for a file, and may be a list or a string. If a list, it may be in one of two formats: ((dev dir) name ext) or (name ext dev dir). The usual value for this attribute is "'.dfs'".

¹⁹ One of Attribute, Boolean, Class, Integer, or String

²⁰ The frame name is identical to the name of the node.

²¹ If a class, then substitute a defined class.

²² A Node is a generated atom associated with a frame of the same name.

²³ O = Output to Simon.

Name	Class	Node	Node
ThisFile	Attributes	<i>Attribute</i>	Integer
ThisFile	Class	<i>Attribute</i>	Value
ThisFile	General	Class	Node
ThisFile	General	NodeList	Node
ThisFile	General	NumAttributes	Integer
ThisFile	General	ObjFileName	Atom
ThisFile	General	SDFFileName	Atom

On the SIMON side, the structure is somewhat different, emphasizing access of an attribute quickly given a Descr node²⁴:

<u>Node Name</u> ²⁵	<u>Slot</u>	<u>Facet</u>	<u>Value</u>	<u>Notes</u> ²⁶	<u>Description</u>
<i>Descr</i>	AttributeList	<i>AttributeType</i> ²⁷	Attribute		
<i>Descr</i>	Attributes	<i>AttributeID</i>	Attribute		
<i>Descr</i>	Class	<i>Name</i>	NodeID		
<i>Descr</i>	Class	Class	NameNode		
<i>Descr</i>	Class	NodeID	Class		
<i>Descr</i>	General	Complete	Timestamp		
<i>Descr</i>	General	DescrType	DescrType		
<i>Descr</i>	General	NumAttributes	Integer		
<i>Descr</i>	General	ObjectName	ObjectName		name of description object
<i>Descr</i>	General	TaskForce	TFNode		
<i>Descr</i>	Name	NodeID	Atom		
<i>Descr</i>	NodeList	NodeID	Node		
General	Accountant	BufferSize	Integer		
General	Accountant	TraceToggle	Integer		
General	<i>DescrType</i>	<i>ObjectName</i>	DescrNode		name of task force
General	Derived	<i>RelationName</i>	NodeName	C	update node name
General	DescNodes	<i>ObjectName</i>	DescrNode		name of description object
General	Domains	<i>RelationName</i>	DomainName	C	
General	EventClass	MaxValue	Integer		
General	EventClass	<i>ObjectName</i>	Integer		name of a task force
General	NumOfClass	Class	Integer		
General	OS	RMName	ObjectName		name of resident monitor
General	OS	TFName	ObjectName		name of task force

²⁴ If in *italics*, substitute a value of the indicated type. A *NodeID* is a small integer, as is an *AttributeID*. Nodes and Attributes are assigned ID's starting at 1 in each *Descr*. An *ObjectName* is a (large) integer. A *DescrType* is one of Hardware, Naming, or Sensor.

²⁵ If in *italics*, then substitute a generated name. The frame name is identical to the node name.

²⁶ C = Only in monitor core, * = Not implemented.

²⁷ One of attributes, listattributes, nodeattributes, nodes.

General	TaskForces	TFNodes	TFNode		
General	TupleVariables	TVName	RelationName	C	
General	ObjectName	UserName	ObjectName		Second Obj is a component of first Obj
General	Primitive	RelationName	NodeName		update node name
Mod	General	Name	Atom		
Mod	General	ObjectName	ObjectName		
Mod	Process	FunctionNumber	ObjectName		
Name Node	Class	Attribute	Value		
Name Node	Class	Name	Atom		
Name Node	Class	UniqueID	Integer		uses General - NumOfClass
Name Node	Node	Class	Class		
Name Node	Node	Descr	DescrNode		
Name Node	Node	ID	NodeID		
Query	General	TupleVariables	TVName	C	
Query	General	Relations	RelationName	C	
TF	Components	Name	ObjectName		
TF	Components	ModulesNode	ModuleNode	*

TF	General	Name	Atom		
TF	General	ObjectName	ObjectName		
TF	General	Processes	ObjectName	C	

11. The Cm* / Simon Protocol Specification

P.T. Highnam and Richard Snodgrass

11.1. Introduction

This document details in a fairly system independent way the relationship between the resident monitors on Cm* and the master monitoring process SIMON on a VAX. The resident monitors are STARMON under the StarOS operating system, and MEDIC under the Medusa operating system, communicating with SIMON under the Unix operating system via the EtherNet.

We describe the EtherNet communication protocol, the packet formats, the command and data record formats, and the initialisation and naming scheme. The details of the sensors, the internal design of SIMON, and the system-dependent aspects of STARMON and MEDIC are described in separate documents and in section 11.7.1.

11.2. EtherNet protocol

The conversation is conducted using PUPs (PARC universal packets) and a protocol similar to that of EFTP (EtherNet file transfer protocol) simulating a transmission from SIMON to the resident monitor. The PUP types sent to the resident monitor will be EFTPData with the complete communication terminated by an EFTPEnd packet from SIMON. The resident monitor will always be sending EFTPack packets containing monitoring data as an acknowledgement for each EFTPData packet. Nothing will be sent by the resident monitor until requested -- this applies to every transmission. Thus, SIMON always serves as the master, and the resident monitor as the slave in the protocol. One should note that the PUP types are totally arbitrary and were chosen so that the implementors could look up the values independently.

Each EFTPData packet will contain a sequence number, which starts at 0 and is incremented by one with each successful packet transmission. The EFTPack packet will contain the sequence number of the EFTPData packet it is acknowledging. The resident monitor will resend the last EFTPack packet if it gets a packet with an invalid sequence number. Similarly, SIMON will retransmit an EFTPData packet if an invalid EFTPack packet is received or if a proper acknowledgement is not received in a reasonable amount of time. This, SIMON and the resident monitor should be out of synch by no more than one packet.

Each packet will be used to carry multiple commands from SIMON or multiple data records from the resident monitor (see chapter 11.4). Note that the data part of a packet may range between 0 and 266 (decimal) words in size (each word is two bytes, or 16 bits). The Pup encapsulation uses another 11

words.

There is no notion of time in the resident monitor; any time-outs will be generated solely by SIMON. When the resident monitor receives an EFTPEnd packet, it should return to its initial state (see chapter 11.6).

11.3. Object Identification

A single 21-bit entity (called the *object-id*) will identify every object known to the resident monitor. The format of this word is defined solely by the internal considerations of the monitor. If the object associated with the *object-id* is deleted, the resident monitor is required to send a NEW NAME data record (see section 11.4.3) containing a timestamp which indicates that this *object-id*, if used again in an event record which is stamped with a time after that in the corresponding NEW NAME data record, will refer to a different object (see section 11.7.1 for details on how this data record is handled).

More comments on the interpretation of the *object-id* by the resident monitor, in particular the means chosen to deal with object creation and deletion, can be found in the STARMON and MEDIC documents.

11.4. Packet Formats

11.4.1. Parameter Sizes

The following lists the sizes for the various parameter types used in this chapter:

<u>Type</u>	<u>Size in bytes</u>	<u>Size in bits</u>
Command	1	8
Flag	.	1
<i>object-id</i>	3	21
entry-id	1	8
event-number	1	7
Data Record type	1	8
Data Record length	1	8
Timestamp	4	32
Entry value	4	32

11.4.2. Command Format (Simon to Cm*)

← Command → Flag(s) → Long Parameter → Short Parameter →
 byte byte 4 bytes 2 bytes

Each command packet will contain several commands. The last command in the sequence will be an

END command. The commands are shown below; with each is (a) a numeric code (intended to be used to identify the corresponding command in the implementation), and (b) parameters. If there is a single END command then it is in response to a LAST RECORD record from the resident monitor with a parameter value greater than zero (indicating that there are further data records waiting to be sent). The list below summarizes the commands. The parameters are in the order of *Long Parameter, Short Parameter, Flag(s)*.

- ADJUST OBJECT[1] *object-id bit-position bit-value*
 Alter the specified enable-bit of the specified object. The *bit-position* specifies the word offset (top 12 bits) and the bit within the word (bottom 4 bits). No response required.
- CHECKPOINT[2] -- *object-type*
 This is a checkup on a particular object-type. This will tell SIMON that there no events on objects of this type occurring before, but unaccounted for at, a particular time after this command was received. The CHECK data record specifies this time as a timestamp. In the first version the *object-type* will be ignored, and all pipes will be check-pointed. If a CHECKPOINT command arrives before an earlier one has been completely processed, it will be ignored.
- READ ENTRY[3] -- *entry-id*
 There are some things wired into the resident monitor, for example, how many pipes are in use, where to find the current time, etc. This command requests the dispatch of the aforesaid value, as a *Report* data record [2 words]. This command and WRITE ENTRY have some common entries. Appendix I contains a cumulative list and description.
- WRITE ENTRY[4] *value entry-id*
 The complement of READ ENTRY. Appendix I contains a tentative list and description. No response required.
- SAMPLE[5] *object-id event-number*
 This is a request for a particular event on a specified object to be sampled and sent back to SIMON as an EVENT RECORD. The semantics for this command is system-dependent.
- END[6] This indicates the last (physically) command in this packet.

11.4.3. Data Format (Cm* to Simon)

Normally the resident monitor picks up every event it receives and puts it into an EFTPack packet for transmission when it receives an EFTPData packet from SIMON -- such items are called EVENT RECORDS. Response to specific enquiries, immediate (READ ENTRY) or instigated (CHECKPOINT) is made using the REPORT and CHECK data records, respectively. The termination of a data packet is indicated by a LAST RECORD record.

Should a particularly unpleasant situation be discovered by the resident monitor there is provision for notification of the error to SIMON using an ERROR data record. This will occupy three words, the second word being an *error number*, and the third being extra information (if necessary). Of course this only makes sense if SIMON is responding!

← Type → Length(words) → Parameters →
 byte byte 1 or more words each

The length specifies the number of words of parameters. The following summarises the types and gives an index number for each which is intended for use within the implementation.

- EVENT RECORD[1] *object-id* (of sensor) *event-number* *object-id* (of object) *optional fields*
 This record type is sent in response to a SAMPLE command and whenever an event is sent to the resident monitor by a sensor. The top byte is 0 and the *object-id* of the sensor is in the next 3 bytes. The next byte holds the *event-number* and the next three bytes, the *object-id* of the object. The optional fields follow, word-aligned.
- REPORT[2] *entry-id value*[2 words]
 In response to a READ ENTRY.
- CHECK[3] *timestamp*[2 words]
 In response to a CHECKPOINT. The timestamp is the monitor-saw-it-when time. This data record is generated after all of the event records relating to this *object-type* have been removed from internal buffers and sent to SIMON. In future versions, an *object-id* parameter may be added.
- LAST RECORD[4] *word-count*[1 word]
 The physically last record within a data packet. The count tells how many words of data there were waiting to be sent when this packet was sent.
- ERROR[5] *error-number*[1 word] *additional information* [2 words]
 Panic time. The resident monitor has discovered something amiss (see Appendix II for a list of possible errors).
- NEW NAME[6] *object-id timestamp*[2 words]
 The object corresponding to this *object-id* has been deleted by the operating system at *this* time. Any reference to this *object-id* in the future (i.e., with a later *timestamp*) will involve a different object. Note that SIMON might never have heard about this *object-id* before.

11.5. Simon Description Page Format

A Simon Description Page contains information which is specially formatted to allow easy transmission over the EtherNet to SIMON. There are currently two types of Simon Description Pages, both associated with *task forces*: *SensorDescription* and *NamingDescription*. The location of the page is of course system-

dependent. These pages are produced by a preprocessor from sensor description file (SDF), or a naming description file (NDF), respectively. For information on the contents of this page, see the *Sensor Description File Specification*.

A Simon Description Page is formatted as a contiguous list of words (a read-only page in Medusa and a data-only basic object in StarOS) containing one or more triples. The first two elements of each triple are integers; the third is either an integer (if the first element is positive) or a string (if the first element is negative). A first element of zero indicates that there are no more triples. A string is encoded as a zero-terminated sequence of bytes. All elements are word-aligned.

The RequestSensorDescription sensor (an internal sampled event) will send the triples from the SensorDescription page of the object designated by the *object-id* over as SimonDescriptionInteger and SimonDescriptionString event records. These events are both internal traced events.

11.6. Initial Connection

When the resident monitor first comes up on Cm* (presumably when the operating system is booted), it will open the correct socket (see below) and wait for a packet to be delivered to this socket. All monitoring activity should be turned off while the resident monitor is in this initial state. The initiation of communication will be carried out by SIMON sending a EFTPData packet to the following socket on Cm*²⁸

Host Net: # 52 (CMU local network)
Host Number: # 222 (CML2) for Medusa, # 223 (CML5) for StarOS
Socket Number: # 135,0 (low,high)

The sequence number carried by this initial packet will be (0,0). The initial packet from SIMON will also carry the net, host and socket on which SIMON is living. These will be picked up the Cm* process and used thereafter. Note that this allows SIMON to live anywhere. The data contained in this first packet has not been specified. The resident monitor will respond, as always, with an EFTPack packet. The data in this packet has also not been specified, except that it must include the *object-id* of the resident monitor.

When SIMON first makes contact with the resident monitor, it knows of three events: RequestSensorDescription, SimonDescriptionInteger, and SimonDescriptionString. The second packet sent to the resident monitor will contain exactly four commands:

²⁸In the first implementation, the socket number will be fixed. Later versions may use a rendezvous protocol to determine the correct socket.

```

AdjustObject    <enable SensorDescriptionInteger>

AdjustObject    <enable SensorDescriptionString>

AdjustObject    <enable RequestSensorDescription>

End

```

The third command instructs the resident monitor to send over the Sensor Description associated with the resident monitor; the RequestSensorDescription is an internal sampled event. Once SIMON receives all of these event records, it will be able to communicate fully with the resident monitor.

11.7. Interaction with Simon

11.7.1. Simon Names

The names (*object-ids*) stored in event records received by SIMON are unique except for reuse after deletion on Cm*. However, each *Simon name* must uniquely specify a Cm* object. An *epoch* (essentially a 8-bit counter) will be used to convert an *object-id* into a *Simon name*. Associated with each *object-id* will be a list of timestamp-epoch pairs. Initially, the list will contain one pair, with a timestamp of 0 and an epoch of 0. Whenever a NEW NAME data record is received, a new pair will be added to the appropriate list (determined by the *object-id* of the data record), with an epoch one greater than the last epoch and a timestamp equal to that in the data record. As event records flow over from Cm*, each 24-bit *object-id* will be converted to a 32-bit *Simon name* by concatenating the epoch which was valid when the event record was stored (usually the last epoch in the list). If no timestamp was associated with this event record, then the current epoch is used. Conversely, when a *Simon name* is to be sent to the resident monitor on Cm*, the epoch is first stripped off of the name. If the epoch is not the current epoch, then the command containing the *Simon name* must be discarded. Otherwise, the *object-id* portion of the *Simon name* is sent.

11.7.2. Event Numbers

The event number stored in an EVENT RECORD does not uniquely specify a primitive relation, since event numbers are allocated per task force and event per objecttype or sensorprocess by the SDF preprocessor (see chapter 11.5). The correspondence depends on whether the event is an internal or an external one. If the event is internal, then the actual event is determined by the *object-id* of the activity (process) containing the sensor which stored the event record. This field identifies the *sensorprocess* described by one of the SensorDescriptions sent over by the resident monitor. The events associated with this

sensorprocess are searched for one with the sensorindex attribute equal to the event number.

If the event is an external one, the *object-id* is used to identify the *objecttype* (also found in a SensorDescription); the events associated with this objecttype are searched for one with the objectindex attribute equal to the event number.

Appendix V

Readable and Writable Entries

<u>Entry [Value]</u>	<u>Description</u>
# # # [?]	Maximum number of messages to be processed by a MEDIC Packet Filler before it goes back to sleep. [Read/Write]
# # # [?]	Number of commands to be performed by the MEDIC Command Server before it goes back to sleep. [Read/Write]

Appendix VI

Errors found by the Resident Monitor

<u>Error [Value]</u>	<u>Parameter</u> <u>Description</u>
### [?]	??? In danger of losing information because buffers are getting full.
### [?]	<i>Bad Sequence Number</i> Out of sequence packet arrived. (Useful for looking at the EtherNet performance and for debugging.)
### [?]	<i>Bad Type</i> Packet with a bad type arrived. (Useful for looking at the EtherNet performance and for debugging).
### [?]	<i>Sequence Number</i> No END in the command packet.
### [?]	<i>object-id</i> Invalid <i>object-id</i> sent in a command packet.
### [?]	<i>object-id</i> ReceptacleSet overflow; lost information concerning this object.
### [?]	<i>object-type</i> ReceptacleSet overflow; lost information concerning this object type.
