FOREWORD

The work documented in this technical report was performed at the Naval Surface Weapons Center (NSWC) by the Mathematical Statistics Staff (K106), Space and Surface Systems Division, Strategic Systems Department. The date of completion was October 1983.

This report was reviewed by Carlton W. Duke, Jr., Head, Space and Surface Systems Division.

Approved by:

CHAPTER 1

INTRODUCTION

A common parameter for describing the accuracy of a weapon is the circular probable error, generally referred to as CEP. CEP is simply the bivariate analog of the univariate probable error and measures the radius of a mean-centered circle which includes 50% of the bivariate probability. In the case of circular normal errors where the error variances are the same in both directions, CEP can be expressed as a function of the common miss distance standard deviation. Also, CEP estimators based on observed miss distances are easily formulated and can be used to construct confidence intervals for CEP. In the case of elliptical normal errors, CEP cannot be expressed explicitly as a function of the miss distance standard deviations. Here, one must obtain CEP by numerical methods or by referring to tabular values. This has led to the development of a number of approximations by which CEP can be expressed as a function of the miss distance standard deviations. While CEP estimators based on observed miss distances are easily formulated from these approximations, their probability distributions are too complicated to be useful for CEP confidence intervals. In this report, these probability distributions are approximated with distributions which are more practical for the formulation and application of CEP confidence intervals. Approximate CEP confidence intervals are then formulated and their accuracy determined through Monte Carlo sampling.

The first part of this report is tutorial in the development of CEP and discusses the commonly used approximations for the elliptical case. The development of approximate confidence intervals begins with Chapter 4.

CHAPTER 2

REVIEW OF CIRCULAR CASE

In general, it will be assumed that the errors in the X and Y directions are independent with mean zero and variances σ_x^2 and σ_y^2 , respectively. Under the circular normal assumption, $\sigma_x^2 = \sigma_y^2 = \sigma^2$ and the bivariate distribution of errors is given by

$$f_c(x,y) = \frac{1}{2\pi\sigma^2} e^{-(x^2 + y^2)/2\sigma^2}, \quad -\infty < x, y < \infty \quad (2.1)$$

where the subscript c denotes circular. The distribution of the radial miss distance is derived by first obtaining the distribution of the polar variables (R, θ) where

$$X = R \cos \theta$$

$$Y = R \sin \theta.$$

This is found to be

$$g_c(r,\theta) = \frac{r}{2\pi\sigma^2} e^{-r^2/2\sigma^2}, \quad 0 < r < \infty, \quad 0 < \theta < 2\pi. \quad (2.2)$$

The distribution of $R = (X^2 + Y^2)^{1/2}$ is now obtained from (2.2) by using the marginal rule; i.e.,

$$g_c(r) = \int_0^{2\pi} g_c(r,\theta) d\theta = \frac{r}{\sigma^2} e^{-r^2/2\sigma^2}, \quad r > 0. \quad (2.3)$$

This is the well-known Rayleigh distribution (see Lindgren (1968)) with cumulative distribution function

$$P(R < r) = G_c(r) = 1 - e^{-r^2/2\sigma^2}. \quad (2.4)$$

By definition, $G_c(\text{CEP}) = .5$ and the solution of (2.4) yield the frequently used expression

$$\text{CEP} = [-2 \ln(.50)]^{1/2} \sigma = 1.1774 \sigma. \quad (2.5)$$

Consider now that σ (and hence, CEP) is unknown and is estimated from n observed miss distances. These miss distances will be designated as (x_i, y_i) , $i = 1, \dots, n$ in the X and Y directions, respectively. Moranda (1959) has shown that the maximum likelihood estimator for σ is

$$\hat{\sigma} = \left\{ \sum_{i=1}^n (x_i^2 + y_i^2) / 2n \right\}^{\frac{1}{2}}, \quad (2.6)$$

and the corresponding estimator for CEP is simply $\hat{CEP} = 1.1774 \hat{\sigma}$. This estimator is biased for CEP, i.e., the expectation of CEP is not equal to CEP. However, the bias is small and the unbiasing factor is cumbersome. Therefore, it will be retained in its slightly biased form.

To place confidence limits on CEP, it will be necessary to examine the probability distribution of $\hat{CEP}$. It is well-known under normal theory (see Mood and Graybill (1963)) that if $\{W_i\}$, $i = 1, \dots, n$ is a random sample from a normal population with mean μ and variance σ^2 , then $\sum (W_i - \mu)^2 / \sigma^2$ has a chi-square distribution with n degrees of freedom. One can consider $\{x_i\}$, $i = 1, \dots, n$ and $\{y_i\}$, $i = 1, \dots, n$ to be a random sample of size $2n$ from a normal population with mean zero and variance σ^2 . Therefore,

$$\sum_{i=1}^n \frac{(x_i^2 + y_i^2)}{\sigma^2} = \frac{2n\hat{\sigma}^2}{\sigma^2} = \frac{2n\hat{CEP}^2}{CEP^2} \sim \chi_{2n}^2 \quad (2.7)$$

where " $\sim$ " designates "is distributed as" and χ_{2n}^2 designates a chi-square probability distribution with $2n$ degrees of freedom. The 100 $(1 - \alpha)\%$ confidence limits are now easily constructed using the probability statement

$$\text{Prob} \left\{ \chi_{2n, \alpha/2}^2 < \frac{2n\hat{CEP}^2}{CEP^2} < \chi_{2n, 1-\alpha/2}^2 \right\} = 1 - \alpha \quad (2.8)$$

In this expression, $\chi_{\nu, \alpha}^2$ designates the 100 α percentage point for a chi-square with ν degrees of freedom. Tabular values for integral ν can be found in the back of most statistics texts. A more complete table is found in Hald (1952). Manipulating the inequality in (2.8) leads to the following 100 $(1 - \alpha)\%$ confidence limits for CEP:

$$\left[\frac{\hat{CEP}}{(\chi_{2n, 1-\alpha/2}^2 / 2n)^{\frac{1}{2}}}, \frac{\hat{CEP}}{(\chi_{2n, \alpha/2}^2 / 2n)^{\frac{1}{2}}} \right] \quad (2.9)$$

The interpretation here is that one is 100 $(1 - \alpha)\%$ confident that the interval in (2.9) contains the population CEP. This formula is valid only for the case where the errors are known to be circular, i.e., the case where $\sigma_x^2 = \sigma_y^2 = \sigma^2$.

Before leaving this review of the circular case, it will be instructive to work through an example. Suppose confidence limits on CEP are desired from the ten round sample shown in Table 2-1. We first need to compute $\hat{\sigma}$ in (2.6). One notes that the sum under the radical in (2.6) can be expressed as

$$\left(\frac{\sum x_i^2}{n} + \frac{\sum y_i^2}{n} \right) / 2.$$

The two components are independent estimates of the common variance σ^2 . If they differ significantly, it would cast doubt on the circular normal assumption.

These components will be referred to as s_x^2 and s_y^2 so that $\hat{\sigma}$ in (2.6) becomes

$$\hat{\sigma} = \left[(s_x^2 + s_y^2) / 2 \right]^{1/2}.$$

For this example, one finds

$$s_x^2 = \sum x_i^2 / n = 9565.3$$

$$s_y^2 = \sum y_i^2 / n = 9688.5$$

$$\hat{\sigma} = [(9565.3 + 9688.5) / 2]^{1/2} = 98.12$$

$$\hat{\text{CEP}} = 1.1774 \hat{\sigma} = 115.53.$$

To form confidence limits, the computations in (2.9) are required. Let us consider 95% limits so $\alpha = .05$ and the tabular values required are

$$\chi_{20, .025}^2 = 9.59$$

$$\chi_{20, .975}^2 = 34.20.$$

These would both be divided by $2n = 20$ to form the terms under the radical in (2.9). One could also use a table of chi-square percentage points divided by the degrees of freedom here to avoid the latter step. Such a table is in Hald (1952) and provides

$$\chi^2_{20, .025} / 20 = .4796$$

$$\chi^2_{20, .975} / 20 = 1.7085$$

The 95% confidence limits on CEP can now be completed and are found to be

$$\left(\frac{115.53}{(1.7085)^{\frac{1}{2}}}, \frac{115.53}{(.4796)^{\frac{1}{2}}} \right) = (88.39, 166.82)$$

The units are feet, the same as the miss distance units in Table 2-1. The interpretation is that one is 95% confident that the true (or population) CEP lies in the interval (88.39, 166.82). The result is valid only if the probability distribution of miss distances follows a circular normal distribution. Application of (2.9) when the probability distribution is elliptical can lead to serious errors. A discussion of the elliptical case begins with Chapter 3.

CHAPTER 3

CEP DERIVATION AND APPROXIMATIONS FOR ELLIPTICAL ERRORS

In the elliptical case, the error variances are unequal and the bivariate distribution of errors is given by

$$f_E(x,y) = \frac{1}{2\pi\sigma_x\sigma_y} e^{-\frac{1}{2}[(x/\sigma_x)^2 + (y/\sigma_y)^2]}, \quad -\infty < x,y < \infty$$

where the subscript E denotes elliptical. The distribution of the radial error R for this case was derived by Chew and Boyce (1961). They proceeded, as in the circular case, by first obtaining the distribution of the polar variables (R,θ). This was found to be

$$g_E(r,\theta) = \frac{r}{2\pi\sigma_x\sigma_y} e^{-ar^2} e^{(-br^2\cos 2\theta)}, \quad \begin{matrix} 0 < r < \infty \\ 0 < \theta < 2\pi \end{matrix} \quad (3.1)$$

where

$$a = \frac{\sigma_y^2 + \sigma_x^2}{(2\sigma_x\sigma_y)^2}, \quad b = \frac{\sigma_y^2 - \sigma_x^2}{(2\sigma_x\sigma_y)^2}.$$

Using the marginal rule, the distribution of R was obtained by integrating $g_E(r,\theta)$ in (3.1) with respect to θ between 0 and 2π . This integration cannot be expressed in tractable form, so they expressed their result in terms of a modified Bessel function as

$$g_E(r) = \frac{r}{\sigma_x\sigma_y} e^{-ar^2} I_0(br^2), \quad 0 < r < \infty. \quad (3.2)$$

In this expression, the subscript E denotes elliptical and I_0 is a modified Bessel function of the first kind and zero order, i.e.,

$$I_0(x) = \frac{1}{\pi} \int_0^\pi e^{-x\cos\theta} d\theta.$$

The cumulative distribution function for R is denoted by

$$P(R < r) = G_E(r) = \int_0^r g_E(t) dt. \quad (3.3)$$

However, $G_E(r)$ cannot be expressed in tractable form because $g_E(t)$ cannot be so expressed. This means that the radius of the 50% circle for the elliptical case cannot be expressed by a simple formula as it was in the circular case. One has to solve $G_E(CEP) = .5$ by numerical methods or by referring to tables prepared by Harter (1960), DiDonato and Jarnagin (1962), and others. To avoid using these tables or numerical procedures for CEP evaluation, a number of approximations have been developed over the years. Five of the most common are shown below; they are designated as CEP₁ through CEP₅:

$$CEP_1 = 1.1774 \left(\frac{\sigma_x^2 + \sigma_y^2}{2} \right)^{\frac{1}{2}}$$

$$CEP_2 = 1.1774 \left(\frac{\sigma_x + \sigma_y}{2} \right)$$

$$CEP_3 = \left(2 \chi_{0,.50}^2 / u \right)^{\frac{1}{2}} \left(\frac{\sigma_x^2 + \sigma_y^2}{2} \right)^{\frac{1}{2}}$$

$$u = \frac{\left(\frac{\sigma_x^2 + \sigma_y^2}{2} \right)^2}{\sigma_x^4 + \sigma_y^4}$$

$$CEP_4 = .565 \sigma_{\max} + .612 \sigma_{\min}, \sigma_{\min}/\sigma_{\max} \geq .25$$

$$= .667 \sigma_{\max} + .206 \sigma_{\min}, \sigma_{\min}/\sigma_{\max} < .25$$

$$CEP_5 = \left[2^{\frac{1}{3}} \left(1 - \frac{2}{9u} \right) \right]^{\frac{3}{2}} \left(\frac{\sigma_x^2 + \sigma_y^2}{2} \right)^{\frac{1}{2}}.$$

CEP₁ and CEP₂ were taken from Groves (1961); CEP₃ was formulated using the chi-square approximation for calculating hit probabilities provided by Grubbs (1964). It was also derived independent of the Grubbs approximation by Thomas and Taub (1978). CEP₄ is a piece-wise linear combination of standard deviations which is commonly used in the missile community; CEP₅ was formulated by Terzian (1974) using the Wilson-Hilferty approximation for calculating hit probabilities provided by Grubbs (1964). Plots of each approximation versus the true CEP as a function of $\sigma_{\min}/\sigma_{\max}$ are shown in Figures 3-1 through 3-5. These give a fairly good indication of how well each performs. It is seen that CEP₁ deteriorates rapidly as we depart from the circular case (for which CEP₁ degenerates to 1.1774σ), CEP₂ is reasonably good if the ratio $\sigma_{\min}/\sigma_{\max}$ is not less than about .2; CEP₃ appears good for all ratios, and CEP₄ and CEP₅ appear good to a lesser extent for all ratios.

FIGURE 3-1. CEP_1 APPROXIMATION VERSUS TRUE CEP

FIGURE 3-2. CEP_2 APPROXIMATION VERSUS TRUE CEP

FIGURE 3-3. CEP_3 APPROXIMATION VERSUS TRUE CEPFIGURE 3-4. CEP_4 APPROXIMATION VERSUS TRUE CEP

FIGURE 3-5. CEP₅ APPROXIMATION VERSUS TRUE CEP

To recap the elliptical case thus far, for known values of σ_x and σ_y , one can compute the exact CEP by solving $G_E(\text{CEP}) = .50$ or compute an approximate CEP by using an approximation such as CEP₁ to CEP₅. Consider now that σ_x and σ_y (and hence CEP) are unknown and are to be estimated from n observed miss distances. These miss distances will be designated as before, as (x_i, y_i) , $i = 1, \dots, n$ in the X and Y directions, respectively. The maximum likelihood estimators for σ_x and σ_y pose no problem. They are given by

$$s_x = \hat{\sigma}_x = \left\{ \sum_{i=1}^n x_i^2 / n \right\}^{1/2}, \quad s_y = \hat{\sigma}_y = \left\{ \sum_{i=1}^n y_i^2 / n \right\}^{1/2} \quad (3.4)$$

as shown in Lindgren (1968). These estimators are slightly biased and as before, they will not be corrected due to the cumbersome nature of the correction factor. They can now be substituted for the unknown σ 's in (3.3) to obtain a numerical estimate of CEP by solving $G_E(\text{CEP}) = .50$ or they can be substituted into CEP₁ to CEP₅ to obtain estimates of the approximate CEP. These latter estimators will be referred to as CEP₁ to CEP₅ and have the appeal of being explicitly expressible. Hence, estimates of CEP for the elliptical case can be rather easily obtained.

The problem of obtaining confidence limits for CEP in this case is more complex. The complexity is based on the fact that to find confidence limits for a parameter, one needs information regarding the probability distribution of the estimator for the parameter. As previously noted, CEP can be obtained by solving $G_E(\hat{\text{CEP}}) = .50$. Symbolically, we can write

$$\hat{\text{CEP}} = G_E^{-1}(.50) \quad (3.5)$$

but to obtain it requires recursive numerical integration or the use of previously noted tables. Hence, the formulation of confidence limits based on this estimator holds little promise for a practical solution. Therefore, we shall consider the formulation of confidence limits based on the estimators of the approximate CEP. The distributions of these estimators are extremely complicated since they involve radicals and linear combinations of sample variances and standard deviations. Hence, these distributions were approximated and confidence limits formulated on the basis of the approximate distributions. This development is provided in Chapter 4.

CHAPTER 4

APPROXIMATE DISTRIBUTIONS OF CEP ESTIMATORS

The five estimators for CEP fall into two classes. One class involves the square root of linear combinations of sample variances and the other involves linear combinations of sample standard deviations. $\hat{CEP}_1$, $\hat{CEP}_3$, and $\hat{CEP}_5$ fall into the first class and can be written in the form

$$\hat{CEP}_i = K_i \left(\frac{s_x^2 + s_y^2}{2} \right)^{\frac{1}{2}}, \quad i = 1, 3, 5 \quad (4.1)$$

where

$$K_1 = 1.1774$$

$$K_3 = \left(2 \chi_{0,.50}^2 / v \right)^{\frac{1}{2}}$$

$$K_5 = \left[2^{1/3} (1 - 2/9v) \right]^{3/2}.$$

$\hat{CEP}_2$ and $\hat{CEP}_4$ fall into the second class and can be written in the form

$$\hat{CEP}_i = a_1 s_{\max} + a_2 s_{\min}, \quad i = 2, 4 \quad (4.2)$$

where for $i = 2$, $a_1 = a_2 = 1.1774/2$

and for $i = 4$, $a_1 = .565$ and $a_2 = .612$ when $s_{\min}/s_{\max} \geq .25$

$a_1 = .667$ and $a_2 = .206$ when $s_{\min}/s_{\max} < .25$.

The distribution of the square of each estimator can be approximated by a chi-square distribution with appropriate degrees of freedom. The following is the rationale for these approximations. The squares of $\hat{CEP}_1$, $\hat{CEP}_3$, and $\hat{CEP}_5$ are linear combinations of sample variances. Satterthwaite (1946) has shown that one can approximate the distribution of such linear combinations with a chi-square distribution with degrees of freedom chosen so the approximate distribution has a variance equal to that of the exact distribution. Here, one is approximating the distribution of a linear combination of sample variances with a chi-square. A natural extension is to approximate the distribution of a linear combination of sample standard deviations with a chi-distribution (see Appendix C). Hence, the distributions of $\hat{CEP}_2$ and $\hat{CEP}_4$ were approximated by a chi-distribution with degrees of freedom chosen so the approximate distribution has a variance equal

to that of the exact distribution. Since the square of a chi-variable has a chi-square distribution, the squares of $\hat{CEP}_2$ and $\hat{CEP}_4$ also have approximate chi-square distributions. The major task is to find the appropriate degrees of freedom for each class of estimator.

First, one sees that $\hat{CEP}_1$ has the same form as the maximum likelihood estimator for CEP in the circular case. In that case, the degrees of freedom associated with CEP were $2n$. These same degrees of freedom will be retained here for $\hat{CEP}_1$. This will eventually show how poorly $\hat{CEP}_1$ performs as an estimator for CEP when the error distribution is elliptical vice circular.

Next, consider $\hat{CEP}_3$ and $\hat{CEP}_5$ of the first class. Each has form

$$CEP_i = K_i \left(\frac{s_x^2 + s_y^2}{2} \right)^{\frac{1}{2}}.$$

To obtain ν' , the degrees of freedom for our chi-square, we need to equate the variance of $\hat{CEP}_i^2 / CEP_i^2$ with $2\nu'$ (the variance of a chi-square with ν' degrees of freedom) and solve for ν' . Now

$$\frac{\hat{CEP}_i^2}{CEP_i^2} = \frac{\nu' K_i^2 (s_x^2 + s_y^2)}{2 CEP_i^2}$$

and the variance of this expression is

$$\frac{(\nu')^2 K_i^4}{4 CEP_i^4} \left(\frac{2\sigma_x^4}{n} + \frac{2\sigma_y^4}{n} \right).$$

Upon substituting $K_i \left(\frac{\sigma_x^2 + \sigma_y^2}{2} \right)^{\frac{1}{2}}$ for CEP_i , this becomes

$$\frac{(\nu')^2 (\sigma_x^4 + \sigma_y^4)}{n(\sigma_x^2 + \sigma_y^2)^2}.$$

Equating this expression to $2\nu'$ and solving for ν' yields

$$\nu' = \frac{n(\sigma_x^2 + \sigma_y^2)^2}{(\sigma_x^4 + \sigma_y^4)} = n \nu \quad (4.3)$$

where ν was previously defined to be

$$u = \frac{(\sigma_x^2 + \sigma_y^2)^2}{\sigma_x^4 + \sigma_y^4} . \quad (4.4)$$

Consider next, $\hat{CEP}_2$ and $\hat{CEP}_4$ of the second class. Each of these estimators has the form

$$\hat{CEP}_i = a_1 s_{\max} + a_2 s_{\min} \quad i = 2, 4 .$$

To obtain u^* , the degrees of freedom for the chi-square in this class, we equate

$$\text{the variance of } \frac{(\hat{CEP}_i)^{\frac{1}{2}}}{\hat{CEP}_i} \text{ with } u^* = 2 \left[\frac{\Gamma\left(\frac{u^* + 1}{2}\right)}{\Gamma\left(\frac{u^*}{2}\right)} \right]^2 \quad (\text{the variance of a chi-random}$$

variable with u^* degrees of freedom) and solve for u^* . Now,

$$\frac{(\hat{CEP}_i)^{\frac{1}{2}}}{\hat{CEP}_i} = \frac{(\hat{CEP}_i)^{\frac{1}{2}} (a_1 s_{\max} + a_2 s_{\min})}{(a_1 \sigma_{\max}^2 + a_2 \sigma_{\min}^2)}$$

and the variance of this expression is

$$\frac{u^* (a_1^2 V(s_{\max}) + a_2^2 V(s_{\min}))}{(a_1 \sigma_{\max}^2 + a_2 \sigma_{\min}^2)^2} . \quad (4.5)$$

If we denote the function $H(x)$ as

$$H(x) = \sqrt{\frac{2}{x}} \frac{\Gamma\left(\frac{x+1}{2}\right)}{\Gamma\left(\frac{x}{2}\right)} , \quad (4.6)$$

then the variance of a sample standard deviation based on n observations, i.e., the variance of s_x or s_y shown in (3.4) can be expressed as

$$V(s_x) = V(s_y) = \sigma^2 [1 - H^2(n)] .$$

Using this notation in (4.5) and equating the latter to the variance of a chi-random variable yields

$$\frac{(a_1^2 \sigma_x^2 + a_2^2 \sigma_y^2)(1 - H^2(n))}{(a_1 \sigma_x^2 + a_2 \sigma_y^2)^2} = 1 - H^2(u^*)$$

or

$$H(u^*) = \left[1 - \{1 - H^2(n)\} \frac{(a_1^2 \sigma_x^2 + a_2^2 \sigma_y^2)}{(a_1 \sigma_x^2 + a_2 \sigma_y^2)^2} \right]^{\frac{1}{2}} . \quad (4.7)$$

The value of u^* cannot be computed explicitly but is easily obtained using the following procedure.

Evaluate the right-hand side of (4.7) using estimates of σ_x and σ_y obtained from n sample data points and values of a_1 and a_2 determined by (4.2). Call this value w . Refer to Appendix B which contains tabled values of x and $H(x)$. Enter the table and find the value of x for which $H(x) = w$. This value of x is u^* . An example which incorporates this procedure begins in Chapter 5.

Clearly, u' and u^* may take on fractional (non-integral) values. However, this poses no problem. Although the question of fractional degrees of freedom is rarely addressed in standard statistics texts, an extensive table of chi-square percentage points with fractional degrees of freedom has been generated by DiDonato and Hageman (1977). Also, one can obtain such percentage points using the MDCHI subroutine available in IMSL (1982).

For each of the five CEP estimators, it has been shown that the distribution of

$$\frac{u_i \hat{CEP}_i^2}{CEP_i^2} \quad i = 1, 2, \dots, 5 \quad (4.8)$$

can be approximated by a chi-square distribution with u_i degrees of freedom where u_i is either $2n$, u' , or u^* defined previously. Since the form of a confidence interval for a chi-square random variable is well-known, construction of confidence intervals for CEP, using (4.8), is straightforward.

CHAPTER 5

APPROXIMATE CEP CONFIDENCE INTERVALS

An approximate 100 (1 - α)% confidence interval for the true (population) CEP can be constructed using the probability statement

$$\text{Prob} \left\{ \chi_{\nu_i}^2, \alpha/2 < \frac{\nu_i \hat{\text{CEP}}_i^2}{\text{CEP}_i^2} < \chi_{\nu_i}^2, 1-\alpha/2 \right\} = 1 - \alpha . \quad (5.1)$$

The subscript i is used to indicate the approximation on which the estimate $\hat{\text{CEP}}_i$ and the degrees of freedom, ν_i , are based. Rewriting (5.1) in terms of CEP_i yields

$$\left(\frac{\hat{\text{CEP}}_i}{(\chi_{\nu_i}^2, 1-\alpha/2/\nu_i)^{1/2}} < \text{CEP}_i < \frac{\hat{\text{CEP}}_i}{(\chi_{\nu_i}^2, \alpha/2/\nu_i)^{1/2}} \right) . \quad (5.2)$$

However, CEP_i represents an approximation to the true CEP for any i . Therefore, (5.2) may be considered an approximate confidence interval for CEP and expressed as

$$\left(\frac{\hat{\text{CEP}}_i}{(\chi_{\nu_i}^2, 1-\alpha/2/\nu_i)^{1/2}} < \text{CEP} < \frac{\hat{\text{CEP}}_i}{(\chi_{\nu_i}^2, \alpha/2/\nu_i)^{1/2}} \right) . \quad (5.3)$$

In the following example, approximate confidence intervals will be computed for CEP using two CEP estimators, $\hat{\text{CEP}}_3$ and $\hat{\text{CEP}}_4$. Using (3.4), estimates of σ_x and σ_y can be computed for the 12 sample miss distances given in Table 5-1.

TABLE 5-1. 12 HYPOTHETICAL MISS DISTANCES (FEET)

<u>x</u>	<u>y</u>
-163	-363

TABLE 5-1. (Cont.)

<u>x</u>	<u>y</u>
197	-147
-266	61
135	626
107	187
-112	-11

For these data, one finds

$$s_x^2 = \sum_{i=1}^n x_i^2/n = 17,505.00$$

$$s_y^2 = \sum_{i=1}^n y_i^2/n = 72,191.75$$

As previously defined,

$$\hat{CEP}_3 = \left(2\chi_{U,.50/U}^2 \right)^{\frac{1}{2}} \left(\frac{s_x^2 + s_y^2}{2} \right)^{\frac{1}{2}}$$

Since U assumes values between 1 and 2 inclusively, a table of the $(2\chi_{U,.50/U}^2)^{\frac{1}{2}}$ factor is readily constructed using chi-square percentage points taken from DiDonato and Hageman (1977). Table 5-2 is a short table that has been prepared to facilitate computation.

TABLE 5-2. MULTIPLYING FACTORS OF $\left(\frac{s_x^2 + s_y^2}{2} \right)^{\frac{1}{2}}$ FOR CEP_3 APPROXIMATION

<u>U</u>	<u>$(2 \chi_{U,.50/U}^2)^{\frac{1}{2}}$</u>

1.7	1.1365
1.8	1.1516
1.9	1.1652
2.0	1.1774

$$U = \frac{(\sigma_x^2 + \sigma_y^2)^2}{\sigma_x^4 + \sigma_y^4}$$

The 12 sample miss distances in Table 5-1 are used to obtain estimates of $\hat{v}$ and $\hat{v}'$ given by $\hat{v}$ and $\hat{v}'$ below:

$$\hat{v} = \frac{(s_x^2 + s_y^2)^2}{s_x^4 + s_y^4} = 1.46 \quad \hat{v}' = n\hat{v} = 17.52$$

Interpolation in Table 5-2 gives $(2 \chi_{\hat{v}, .50}^2 / \hat{v})^{1/2} = 1.0919$ so that

$$\hat{CEP}_3 = (1.0919) (211.77) = 231.23$$

To form confidence limits, the computations in (5.3) are needed. If 95% limits are considered, the chi-square tabular values for $\alpha = .05$ are obtained via interpolation in DiDonato and Hageman (1977) and are

$$\chi_{\hat{v}, .025}^2 = 7.91$$

$$\chi_{\hat{v}, .975}^2 = 30.89$$

The approximate 95% confidence interval for CEP based on approximation 3 is, therefore

$$\left(\frac{231.23}{(30.89/17.52)^{1/2}} < CEP < \frac{231.23}{(7.91/17.52)^{1/2}} \right)$$

or

$$(174.14 < CEP < 344.13)$$

The interpretation here is that one is approximately 95% confident that the true CEP lies in the computed interval.

Let us next consider the approximate 95% confidence interval obtained by using $\hat{CEP}_4$. Before using estimator 4, one must compute the ratio $c = s_{\min}/s_{\max}$ to determine which half of the piece-wise approximation should be used. In this case, $c = .49$ so that

$$\hat{CEP}_4 = .565 s_{\max} + .612 s_{\min} = 232.78.$$

This is reasonably close to the 231.23 obtained for $\hat{CEP}_3$.

To determine $\hat{v}^*$, an estimate of v^* , evaluate

$$H(\hat{v}^*) = \left[1 - (1 - H^2(n)) \frac{(.565^2 s_{\max}^2 + .612^2 s_{\min}^2)}{(.565 s_{\max} + .612 s_{\min})^2} \right]^{1/2}$$

$H^2(n)$ may be determined using tabled values of the gamma function provided in the National Bureau of Standards Applied Mathematics Series document by Salzer (1951). An abbreviated version is given in Appendix A. $H(n)$ may also be read directly from the table provided in Appendix B.

Now

$$H^2(n) = (2/12) \left(\frac{\Gamma(6.5)}{\Gamma(6)} \right)^2 = .9592$$

and

$$\hat{H}(u^*) = .9888 .$$

Entering Appendix B with .9888 and interpolating between .9887 and .9890 yields $\hat{u}^* = 22.17$. From DiDonato and Hageman (1977), obtain

$$\chi_{\hat{u}^*, .025}^2 = 11.10$$

$$\chi_{\hat{u}^*, .975}^2 = 37.00$$

via interpolation. An approximate 95% confidence interval for CEP using the fourth estimator is, therefore, given by

$$\left(\frac{232.78}{(37.00/22.17)^{\frac{1}{2}}} < \text{CEP} < \frac{232.78}{(11.10/22.17)^{\frac{1}{2}}} \right)$$

or

$$(180.19 < \text{CEP} < 328.98).$$

One notes that these two intervals are different. Had the other three estimators been used to construct confidence intervals, they too would have been different. We now have the problem of deciding which estimator to use for constructing confidence intervals. This will be discussed in the next chapter.

Before leaving this chapter, something needs to be said regarding the assumption of zero means. Throughout the development in the report, it has been assumed that the errors have zero mean in both directions. An error has been assumed to be a miss distance from a target, and zero mean implies there is no bias, i.e., the target coincides with the distribution mean. There are applications where the errors are not miss distances, per se, but deviations from the mean impact point. This occurs when there is bias in either or both directions or when there is no target, i.e., the firings are conducted to estimate dispersion without regard to a target. In either case, the impact distribution is no longer centered on the target but on an unknown point (μ_x, μ_y) , and CEP is the radius of the 50% circle which is centered on this point vice the target. To apply the methodology in this report to these cases, the squares of s_x and s_y in (3.4) must be modified to read

$$s_x^2 = \hat{\sigma}_x^2 = \frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n - 1} = \frac{\sum_{i=1}^n x_i^2 - (\sum_{i=1}^n x_i)^2/n}{n - 1} \quad (5.4)$$

$$s_y^2 = \hat{\sigma}_y^2 = \frac{\sum_{i=1}^n (y_i - \bar{y})^2}{n - 1} = \frac{\sum_{i=1}^n y_i^2 - (\sum_{i=1}^n y_i)^2/n}{n - 1}$$

In (5.4), $\bar{x}$ and $\bar{y}$ are the averages of the impact point locations in the x and y directions, respectively. In addition, the degrees of freedom associated with each estimator must be reduced by replacing n with n - 1 in each as follows:

<u>ESTIMATOR</u>	<u>MODIFIED d.f. FOR NON-ZERO MEANS</u>
CEP ₁	2 (n - 1)
CEP ₃ } CEP ₅ }	(n - 1)u
CEP ₂ } CEP ₄ }	$H(u^*) = \left[1 - \left\{ 1 - H^2 (n - 1) \right\} \frac{(a_1^2 \sigma_x^2 + a_2^2 \sigma_y^2)}{(a_1 \sigma_x + a_2 \sigma_y)^2} \right]^{\frac{1}{2}}$

This reduction in degrees of freedom means a slight reduction in precision. In effect, it requires n + 1 deviations from the mean to provide the same precision as n miss distances.

CHAPTER 6

MONTE CARLO VERIFICATION

To ascertain if the formulated approximations produced confidence intervals with confidence close to $1 - \alpha$, a Monte Carlo simulation was written for the CDC 6700. This would also provide a means of comparing the estimators with respect to their confidence level and their expected confidence interval length. One replicate of the simulation entailed generating a sample of n miss distances from a bivariate normal distribution with zero mean and variances σ_x^2 and σ_y^2 . These n values were then used to compute a CEP confidence interval using the five estimators $\hat{CEP}_1$ to $\hat{CEP}_5$. The length of each interval was computed, and for each interval, it was determined whether the interval contained the true (population) CEP. This process was replicated $N = 10,000$ times. The proportion of replicates in which the confidence interval contained the true CEP provided an estimate of the confidence associated with each estimator, and the average interval length for each provided an estimate of the expected length.

The values of the parameters used in the simulation are:

n = number of miss distances = sample size = 5, 10, 20

N = number of replicates = 10,000

$1 - \alpha$ = nominal confidence level = .95

$c = \sigma_{\min} / \sigma_{\max} = 1.0, .75, .50, .35, .20, .05.$

It was necessary to run a large number of replicates to ensure results with reasonable precision. The 10,000 replicates used provided estimates of confidence with an error of less than .01 with probability .95. Because of the large N , the sample sizes were restricted to small values to keep the computer time within bounds. A nominal value of $\alpha = .05$ ($\implies$ a nominal confidence level of .95) was used in the construction of all confidence intervals within the simulation. It follows that if the confidence intervals were exact (vice approximate), the Monte Carlo confidence estimates should be within .01 of .95 or $.95 \pm .01$ with probability .95. Hence, any confidence estimate which departs seriously from $.95 \pm .01$ will reflect poorly on the estimator which produced it. One additional comment is required before discussing the results. The simulated confidence levels depend only on the ratio of the sigmas so that it was not necessary to vary both standard deviations. The larger was designated σ_y and set equal to unity while the smaller was designated σ_x and set equal to the ratio c . While the average confidence interval lengths are dependent on both sigmas, they were

only constructed for $\sigma_x = c$, $\sigma_y = 1$. This is all that is required for comparison purposes. If such lengths are needed for values of σ_x and σ_y other than c and 1 , they can be obtained by multiplying the tabled entry for appropriate c by $\sigma_y = \sigma_{\max}$.

The results of the simulations are set out in Tables 6-1 and 6-2. Let us first discuss the simulated confidence levels shown in Table 6-1. One first notes that all five estimators provide confidence within (or nearly within) the sampling variations ($\pm .01$) of $.95$ when $c = 1$. This is the circular case and all the estimators except $\hat{CEP}_5$ degenerate properly to the maximum likelihood estimator for CEP. Hence, the result that all do well for $c = 1$ is not unexpected. Next, one notes that as c departs from unity (that is, as the impact distribution departs from circularity), the confidence associated with $\hat{CEP}_1$ departs seriously from $.95$. For example, with $n = 10$ and $c = .20$ (5 to 1 ratio of the sigmas) the confidence associated with $\hat{CEP}_1$ is only $.689$. This means that if one were to use circular theory to construct a 95% confidence interval for CEP when the distribution was elliptical with a 5 to 1 ratio of the sigmas, his interval would have confidence of less than $.7$! This rules out $\hat{CEP}_1$ unless one is nearly certain that the impact distribution is circular normal. This result is also not unexpected, but it does quantify how poorly the circular estimator performs in the elliptical case.

In general, the others do reasonably well unless c is small. One notes this especially for $\hat{CEP}_2$ when $c = .05$; the confidence falls from $.930$ for $n = 5$ to $.912$ for $n = 20$. It would continue to decrease as n increases due to the error in CEP approximation for small c (see Figure 3-2). The distribution of $\hat{CEP}_2$ becomes more concentrated about the approximate CEP as n increases. If the approximation is in serious error (which it is for small c), then the distribution is concentrated about the wrong value. The simulation was run for $n = 100$ at $c = .05$ with a resulting confidence estimate of only $.714$. We see the same behavior at larger c values but to a lesser extent. For example, at $c = .35$, the confidence estimate is $.942$ for $n = 20$ but dips to $.922$ for $n = 100$. The upshot here is that $\hat{CEP}_2$ would be a problem for small c or even moderate c if the sample is large enough. With regard to $\hat{CEP}_3$, one sees that small values of c pose no problem. In fact, the confidence for $\hat{CEP}_3$ is asymptotic to $.95$ at $c = 0$. Also, for values of c around $.5$, the confidence estimates are slightly higher than $.95$. It tends to peak out at about $.97$. Selected runs for $n = 100$ show that this result changes very little with n . There is a slight price to pay for this extra confidence, and this will be addressed when Table 6-2 is discussed. $\hat{CEP}_4$ provides confidence close to $.95$ for all values of c except those where $\hat{CEP}_4$ departs from CEP (see Figure 3-4). At those values, there is a reduction in confidence which increases with n but not as severely as for $\hat{CEP}_2$. The performance of $\hat{CEP}_5$ is not poor with respect to confidence. However,

there is little rationale for its use in constructing confidence intervals. The Wilson-Hilferty approximation avoids the use of chi-square percentage points for fractional degrees of freedom in forming $\hat{CEP}_4$. However, they are needed in the computation of the interval, so little effort is saved.

Let us now discuss the average confidence interval lengths in Table 6-2. As previously noted, these lengths depend on both σ_x and σ_y but were computed only for values of the ratio of σ_x to σ_y for comparison purposes. However, we need not compare all five since some were eliminated as viable candidates in our discussions of Table 6-1. $\hat{CEP}_1$ was eliminated because its confidence eroded seriously as c departed from unity. $\hat{CEP}_2$ had a less serious but similar problem, and $\hat{CEP}_5$ was eliminated because it offered no improvement over $\hat{CEP}_3$ and only a slight reduction in computation. This leaves only $\hat{CEP}_3$ and $\hat{CEP}_4$ to discuss here. One notes that the average lengths are uniformly less for $\hat{CEP}_4$ than for $\hat{CEP}_3$. At mid values of c , this is due in part to the inflated confidence inherent in the approximation of the distribution of $\hat{CEP}_3$, i.e., the higher the confidence, the longer the confidence length. However, not all of the difference in length can be attributed to higher confidence. A study by Taub and Thomas (1982) shows that the variance of $\hat{CEP}_4$ is less than the variance of $\hat{CEP}_3$, and this is the primary reason for the difference in length. Even so, $\hat{CEP}_4$ suffers from the bias caused by the error in approximation shown in Figure 3-4. This has an effect on the confidence level associated with $\hat{CEP}_4$ for some values of c , but it would not be appreciable for small n .

In summary, we can state that the logical choice lies between $\hat{CEP}_3$ and $\hat{CEP}_4$. The third holds for all values of c , regardless of n , and is easy to implement. The fourth offers somewhat shorter confidence lengths but it is cumbersome to implement and would provide a reduced confidence level for some values of n and c .

It would be highly desirable to have a CEP estimator with a variance as small or smaller than $\hat{CEP}_4$ which would have negligible bias for all $0 < c \leq 1$, and which would avoid the cumbersomeness of a piece-wise linear function. The authors have several ideas along this line and hope to explore their merits in the near future.

APPENDIX C
THE CHI DISTRIBUTION

A discussion of the chi-square probability distribution can be found in most probability and statistics textbooks. It is a special case of the more general gamma distribution and its density function is given by

$$f_X(x) = \frac{1}{\Gamma\left(\frac{n}{2}\right) 2^{n/2}} x^{n/2 - 1} e^{-x/2}, \quad 0 < x < \infty.$$

Rarely, however, is the CHI distribution discussed in detail. Because this distribution is critical to the development of the approximate distributions for CEP₂ and CEP₄, the following is a brief introduction to the CHI distribution.

If X is defined as a chi-square random variable, then $Y = \sqrt{X}$ is distributed as a CHI random variable whose density function is written as

$$f_Y(y) = \frac{2}{\Gamma\left(\frac{n}{2}\right) 2^{\frac{n}{2} - 1}} x^{n - 1} e^{-\frac{x^2}{2}}, \quad 0 < x < \infty.$$

The mean of Y is given by

$$E(Y) = \frac{\Gamma\left(\frac{n+1}{2}\right) 2^{\frac{1}{2}}}{\Gamma\left(\frac{n}{2}\right)}$$

and the variance of Y is given by

$$V(Y) = n - 2 \left[\frac{\Gamma\left(\frac{n+1}{2}\right)^2}{\Gamma\left(\frac{n}{2}\right)} \right].$$

In general, the r^{th} moment of Y is given by

$$E(Y^r) = \frac{\Gamma\left(\frac{n+r}{2}\right) 2^{r/2}}{\Gamma\left(\frac{n}{2}\right)}.$$

If s is the sample standard deviation with u degrees of freedom, then the previous results can be used to establish that

$$E(s) = \sqrt{\frac{2}{u}} \frac{\Gamma\left(\frac{u+1}{2}\right)}{\Gamma\left(\frac{u}{2}\right)}$$

and

$$V(s) = \sigma^2 - \frac{2\sigma^2}{u} \left\{ \frac{\Gamma\left(\frac{u+1}{2}\right)}{\Gamma\left(\frac{u}{2}\right)} \right\}^2 .$$

These results are needed to determine the degrees of freedom associated with $\hat{CEP}_2$ and $\hat{CEP}_4$. Additional information on the CHI distribution may be found in Krutchkoff (1970).
