19. ABSTRACT (Continue on reverse if necessary and identify by block number) <p>> Hantavirus is ubiquitous in the world but total number of reported HFRS patient in Euro-Asia is about 200,000 with 5-7% mortality annually. Hemorrhagic fever with renal syndrome (HFRS) was an important military problem since large epidemics of HFRS occurred among soldiers in the many past wars and although predominantly associated with field mice in rural areas, it is now being recognized that urban wild and laboratory rats are also reservoirs of HFRS in many parts of the world.</p> <p>Therefore, seroepidemiological survey of distribution of hantaviruses and surveillance of occurrence of HFRS in the world are important for prevention of this highly fatal disease. It is also important to investigate antigenic differences of strains of hantavirus isolated from rats caught in non-endemic areas of the world because HFRS patient has never been documented in many areas despite our finding of positive rats there.</p>

The methods for diagnosis of HFRS, isolation of Hantaviruses from man and rodents, intraspecific transmission of Hantaviruses in rodents are described previously.

There were 706 cases of HFRS in Korea in 1986 and recently no. of HFRS patients are increasing in urban cities, and large epidemics of leptospirosis and scrub typhus were occurred during epidemic season of HFRS. Seroepidemiologic survey of wild rodent showed that 14% of 230 Apodemus mice and 30% of 157 house rats were seropositive against Hantavirus, 68% of 196 Apodemus mice, 6 out of 8 Microtus mice and 5% of 139 house rats were seropositive against R. tsutsugamushi, and 9% of 230 Apodemus mice, 3 out of 8 Microtus mice and 21% of 139 house rats were seropositive against L. interrogans. IFAT and Elisa are sensitive and rapid seroepidemiological tools for survey of HFRS and PRNT is specific test for serotyping of Hantavirus infection and IF, Elisa and PRN antibodies persisted 17 years after illness.

> A near global distribution of Hantavirus was demonstrated. HFRS patients infected with Seoul virus occurred in endemic and non-endemic areas of HFRS and the most characteristic clinical features are fever, headache, strong abdominal symptoms, hepatic dysfunction and mild renal dysfunction. Five strains of Seoul virus were isolated from urban rats caught in Hong Kong, and Singapore and the strains are a little different antigenically from prototype Seoul virus 88/89 by monoclonal antibody assay.

Abortion of a 8th month old fetus due to vertical transmission of Hantaan virus in a pregnant woman with HFRS was documented serologically and pathologically for the first time.

A

SUMMARY

In 1986, there were 706 cases of hospitalized HFRS patients diagnosed at our laboratory in Korea, and 166 and 10 patients were ROK Army and US Army soldiers, respectively. No. of HFRS patient in urban areas of Seoul is increasing every year.

Large epidemics of scrub typhus and leptospirosis were occurred during epidemic season of HFRS and numbers of patients confirmed at our laboratory were 215 and 64, respectively. Field mice and wild rats were reservoir hosts of HFRS, scrub typhus and leptospirosis. 14% of 230 Apodemus mice and 30% of 157 house rats were seropositive against Hantavirus, 68% of 196 Apodemus mice, 6 out of 8 Microtus mice and 5% of 139 house rats were seropositive against R. tsutsugamushi, and 9% of 230 Apodemus mice, 3 out of 8 Microtus mice and 21% of 139 house rats were seropositive against L. interrogans.

A near global distribution of Hantavirus was demonstrated. HFRS patients infected with Seoul virus occurs in endemic and non-endemic areas of HFRS and the most characteristic clinical features are fever, headache, strong abdominal symptoms, hepatic dysfunction and mild renal dysfunction. Five strains of Seoul virus were isolated from urban rats caught in Hong Kong and Singapore and the strains are a little different antigenically from prototype Seoul virus 80/39 by monoclonal antibody assay.

Abortion of a 8th month old fetus due to vertical transmission of Hantaan virus in a pregnant woman with HFRS was documented serologically and pathologically for the first time.

IFAT and Elisa are sensitive and rapid seroepidemiological tools for survey of HFRS and PRNT is specific test for serotyping of Hantavirus infection. IF, Elisa and PRN antibodies persisted 17 years after illness.

DISCUSSION

CONCLUSION

LITERATURE CITED

DISTRIBUTION STATEMENT

INTRODUCTION

During the Korean War more than 3,200 United Nations troops in Korea developed a rare hemorrhagic fever which attracted worldwide attention (1). Since then it has been known as Korean hemorrhagic fever (KHF). This disease is an important military problem because large epidemics have occurred among soldiers during several wars. More than 12,600 cases of epidemic hemorrhagic fever (EHF) occurred among one million Japanese soldiers in Manchuria (2) and several hundred cases occurred among Russian soldiers in the Far East (3) during World War II. Several thousand cases of war nephritis, clinically similar to Nephropatia epidemica (NE), were reported among British soldiers stationed in Flanders during World War I (4), and about 15,000 cases of NE occurred among German soldiers in Lapland and prisoners in Yugoslavia during World War II (5). About 14,000 cases of war nephritis clinically similar to NE were described among Northern Armies in the American Civil War (6). In South Korea, 500 to 900 persons are hospitalized annually with this disease and about one third of them are soldiers. There were about 14,000 cases of HFRS in China in 1986 with 7% mortality, and several hundred cases of HFRS occurred in other countries of Asia and Europe (7). The causative agent was first discovered in 1933 from Apodemus mice (8) and isolated from patients in 1976 (9). The etiologic agent of KHF has been propagated in a human cell culture line (10), and it was named hantaan virus after the hantaan river which runs along the 38th Parallel between North and South Korea (11). Antigenic, genetic properties and DNA findings indicated that hantavirus is a new genus of Hantaviridae (12,13,14,15). A close etiological relationship was established between EHF and HFRS in USSR, NE in Scandinavia and HFRS in Eastern Europe, Japan and China (9,16,17,18). The working group on HFRS at a WHO meeting in Tokyo, 1962 recommended that all above mentioned diseases with different names should be referred to as "hemorrhagic fever with renal syndrome (HFRS)" (19). Recent sero-epidemiologic surveys showed that hantaviruses are ubiquitous in the world. Antibody against hantaan virus in human sera were demonstrated in India, Thailand, Iran, Greece, U.S.S.R., Canada, Bolivia, Brazil, Gabon and Republic of Central Africa (20,21,22,23) and recently in Taiwan, Philippines, Malaysia, Singapore, Hong Kong, Fiji, Hawaii, Argentina, Uruguay and Paraguay (24). Intraspecific transmission of hantaan virus in Apodemus mice (25) was shown and infection occurred during cage-mates for up to 360 days after infection, while large amounts of virus were excreted in urine and saliva, and no evidence for the participation of ectoparasites in virus transmission was obtained. Infection with hantaan virus is thought to be silent in animals (26), but is associated with diverse clinical symptoms in man (27). A severe form is common in East Asia, while most European cases are mild. It usually produces sporadic disease, but under

RESULTS

A. New epidemiological features of HFRS outbreaks leptospirosis and tickettsiosis during epidemic season of HFRS in Korea.

1. New epidemiologic features of HFRS

There were 705 hospitalized cases of HFRS confirmed serologically at our institute in 1986 and 19 of them were 17 Army soldiers as shown in Table 1. One of the new epidemiologic features of HFRS in Korea is increasing number of HFRS patients in urban areas of Seoul as shown in Table 2. There were about 91 cases of HFRS in Seoul city in 1986. These patients were only hospitalized severe cases and usually moderate and mild cases are not included because they were usually diagnosed clinically as influenza. Patients occur throughout the year but peak is in fall in urban areas of Seoul (Table 3). HFRS cases occur in all district of Seoul as shown in Table 4. Recent findings show that there is one large epidemic peak of HFRS in the fall in Korea as shown in Table 5, and there are an increase no. of cases of HFRS among children, and male patients are dominant group of HFRS as shown in Table 6 although male soldier patients were a minority in the no. of HFRS cases. Table 7 shows prevalence of HFRS among 204 locations in different locations and almost 50% of the patients were in Kyung-do and Jeon-do. Seasonal occurrence of HFRS were civilian, 100 Army and 1 Army as shown in Table 7.

2. Epidemic outbreaks of leptospirosis and tickettsiosis during epidemic season of HFRS

As shown in Table 8, local no. of suspected cases of HFRS in 1986 is 704 among 2,065 HFRS suspected sera tested. These suspected sera were sent to our laboratory from hospitals in and nearby cities of Seoul for serologic diagnosis of HFRS but HFRS was only 349 of total patients. During epidemic season of HFRS, we have tested 1,533 sera from suspected HFRS patients for leptospirosis and confirmed 64 cases (4.2%) of leptospirosis serologically and locally incident leptospirosis was shown in Table 9. Sex of leptospirosis patients (one was soldier and 63 Army soldier patients) is shown in Tables 10 and 11. We have tested 197 sera from 197 non-leptospirosis sera against tickettsiosis and 21% of patients among these unknown patients were seropositive against tsulungarushi. There were 10 cases of HFRS patients among 197 HFRS suspected sera from 18 soldiers hospitalized at 17 Army hospital in Seoul and we did not find any of HFRS sera against leptospirosis and tickettsiosis and confirmed leptospirosis and one serum against as shown in Table 10. Distribution of locally leptospirosis and serum against tickettsiosis in Korea in 1986 is shown in Table 12 and name of localities the patients were occurred in Kyung-do, Seoul city and

Chuncheon-do. It is noteworthy that about 50% of scrub typhus patients was female and 60% of the patients were in the group of 40-50, but about 75% of leptospirosis patients was male in age group of 50-60 as shown in Table 13.

3. Seroepidemiology survey of wild and house rodents with Hantavirus, Leptospira and R. tsutsugamushi in Korea, 1986.

It is known that Hantaan and Seoul viruses in the Genus Hantavirus, Leptospira interrogans, and R. tsutsugamushi are the causative agents of HFRS, leptospirosis and scrub typhus in Korea. We have carried out a seroepidemiologic survey of wild rodents against these agents since rodents are the reservoir hosts for all of these agents. Apodemus mice, Mus musculus mice and shrews were captured in the endemic areas of HFRS in the summer and fall of 1986. Urban house rats were captured in 7 harbor cities along the coast of South Korea and in Wonju, an endemic area of HFRS from June to December 1986. As shown in Table 14, 14% of 230 Apodemus mice and 30% of 197 house rats were seropositive against Hantavirus, 9% of 211 Apodemus mice, 3 out of 8 Microtus mice, and 21% of 115 house rats were seropositive against Leptospira interrogans. Sixty-eight of 190 Apodemus mice, 3 out of 20 Microtus mice, and 5 of 139 house rats were seropositive against R. tsutsugamushi. The infection rate of Apodemus mice and house rats with Hantavirus in Korea is almost the same as found previously, but the high infection rate of field mice and house rats with Leptospira and Rickettsia is not found. Table 15, 16, and 17 show the rate of rodents of various infections with Hantavirus, R. tsutsugamushi and Leptospira in wild rodents. Apodemus mice, Microtus mice, and house rats and some of Microtus mice were proved to be infected with two of three agents based upon the agglutination of the antibodies at the same time. It can be concluded that there will be more cases of HFRS in urban areas and more cases of leptospirosis and scrub typhus in rural areas in the next years in Korea, because of high infection rate of rodents caused by Hantavirus, and increasing population of rodents in urban areas.

B. Global serologic surveys for the hantavirus infection.

As WHO Collaborating Centre for Research on Haemorrhagic fever with renal syndrome (HFRS), we have been providing serological diagnosis for suspect HFRS in sera from throughout the world, but especially from the Asian region. In addition, we are collaborating with a number of investigators conducting small mammal surveys for evidence of hantavirus infection and isolation of virus from host animal tissues. Results of these preliminary studies indicate that human disease due to hantavirus infection is present in several areas where HFRS had not been previously diagnosed. The results of the serosurvey of hantaviruses among rats and human populations in many parts of the world where HFRS patients are not known to exist are shown in Table 16.

Human sera from 17 countries; 5 countries in Pacific Ocean, 1 country in North America, 4 countries in South American and 3 countries in Africa were found to have IF antibodies to hantaan virus as shown in Table 16. The prevalence rate of antibodies to hantaan virus was between 1.1% - 13.0%, data much higher than those of residents of Seoul, the endemic area of HFRS. Very recently, we have confirmed HFRS patients serologically among hospitalized patients in Hong Kong, Taiwan, Malaysia and Sri Lanka.

Urban rat sera from the Philippines, Hong Kong, Malaysia, Singapore, Fiji, Hawaii, Chile, Sudan and Uganda were also found to have IF antibody to hantaan virus with a high prevalence rate of 61.0% among Philippine rats and 20.0% in Egypt rats.

Laboratory-bred white mice from Malaysia, Hong Kong, Singapore, Hawaii and Argentina were also positive against hantaan virus. Five out of 11 *Calomys* mice from Egypt and 4 out of 30 *Calomys* mice from Argentina were also positive to hantaan virus. Clearly the hantavirus is a near global distribution and adapted to a variety of different ecological settings. The areas to which hantaviruses cause human disease, especially in areas where HFRS has not been traditionally recognized, is presently unknown.

Table 18. Seroepidemiologic survey of Hantavirus infection among human and rodent in some parts of the world where HFRS is not known to exist from 1981 to 1987 at WHO Collaborating Centre for Virus Reference and Research (HFRS), Seoul

C. Seoul virus infection

Urban cases of HFRS in Korea, Japan, and Southeast Asia, and laboratory infections in Korea and Japan are caused by Seoul virus (31,41-43). Urban commensal rats (Rattus norvegicus and Rattus rattus) and laboratory rats are main reservoir hosts and transmit the disease to man. While some urban and laboratory infections are severe, many are milder than Hantaan virus infection. In general, the phases of disease are shorter than in classic KHFR, and sometimes it is difficult to recognize distinct phases. The clinical manifestations of the disease include high fever, fatigue, anorexia, vomiting, backache, myalgia, abdominal pain, conjunctival injection, petechiae on the soft palate, and hepatomegaly. Laboratory abnormalities include proteinuria, microscopic hematuria, lymphocytosis, thrombocytopenia, increased serum transaminases and transient glucosuria. The findings are based on observation of 56 cases of Seoul virus infection in Korea and Japan. The most characteristic manifestations of this infection are prominent abdominal symptoms, hepatomegaly and hepatic dysfunction, and mild renal dysfunction. Comparison of the clinical features of HFRS caused by different serotypes of Hantavirus are shown in Table 19.

Recently we have documented three cases of HFRS in Hong Kong, one case in Sri Lanka and two cases of HFRS in Malaysia, tropical areas where the disease was not known to exist. Serologic confirmation of the diagnosis of HFRS was obtained by the demonstration of a significant increase in antibody titer to Seoul virus in the patients' acute and convalescent phase sera.

The clinical findings in all six patients, who were diagnosed as having hepatitis, included fever, chills, jaundice, thrombocytopenia, microhematuria, and abnormal liver and renal function. Renal involvement, which is characteristic of HFRS, was mild. A prominent finding was marked elevation of serum transaminases successive of hepatitis. Severe thrombocytopenia was associated with a petechial eruption. The 2 Malaysia patients with HFRS were diagnosed as dengue in one case and leptospirosis in the other. The clinical features in these patients were not typical of HFRS.

D. Abortion of a fetus due to vertical transmission of Hantaan virus in a pregnant woman

Recently we documented vertical transmission of Hantaan virus in a 28 year old pregnant woman, who was admitted to hospital in her 8th month of pregnancy. She suffered from classical HFRS caused by Hantaan virus infection. During the convalescent phase of illness (hospital day 26), she developed uterine bleeding and subsequently delivered a 3.3 Kg fetus which died 11 hours after birth. Autopsy revealed variable degrees of hemorrhage in the kidneys, heart, lungs, and adrenal glands similar to the pathologic findings in adults with fatal HFRS (44).

The IgG immunofluorescent antibody titer to Hantaan virus in maternal blood was 4,096 and the IgM titer 256. In fetal blood sampled from the umbilical cord, the IgG antibody titer was 8,192 and the IgM titer 256. The clinical course of the patient is shown in Figures 1 and 2. This is the first report of vertical transmission of Hantaan virus from mother to child confirmed by serologic and pathologic findings. Details of the autopsy findings on the fetus are following. Autopsy findings on fetus infected in utero with Hantaan virus.

Lungs: The right and left lungs showed slight thickening of alveolar septa. The alveolar spaces were lined by cuboidal cells. Amorphous or band-like eosinophilic material was noted on the alveolar surface in some alveoli. Bronchioles were unremarkable. Vascular congestion was evident with slight hemorrhage in enveloping connective tissue.

Heart: There was mild interstitial edema, congestion, and hemorrhage in the myocardium. Coronary arteries were unremarkable.

Stomach: The epithelium was well preserved. The lamina propria showed mild diffuse vascular congestion and hemorrhage and infiltration with small numbers of lymphocytes. The muscularis and serosa were unremarkable.

Liver: The lobular architecture was well preserved. Large numbers of hematopoietic cells were noted in the sinusoidal spaces. The hepatocytes and bile ducts were unremarkable.

Adrenals: There was diffuse cortical hemorrhage and severe thickening of the cortical layer. The cortical cells exhibited swollen eosinophilic cytoplasm. There was no hematopoiesis.

Kidneys: Renal cortical and medullary architecture was well formed. There was interstitial hemorrhage in the medullary region.

Spleen: The capsule was thin. The white pulp was well preserved. The medullary spaces were markedly congested with evidence of focal hemorrhage and extramedullary hematopoiesis.

Placenta and umbilical cord: Multifocal areas of hemorrhage were present.

E. Comparative sensitivity of assays for diagnosis of HFRS and the efficacy of immunologic diagnosis.

The available serologic assays for HFRS are indirect IF antibody technique (IFAT), solid phase antibody assay, IAHA test and plaque reduction neutralization test (PRNT). IFAT and Elisa are very sensitive and rapid. Indirect antibody test, IAHA test and PRNT are specific for viral serotypes but time-consuming. The most widely employed routine diagnostic tests for HFRS are IFAT and ELISA and demonstration of IgM antibodies against Hantavirus in sera from suspect patients is pathognomonic for HFRS.

As shown in Table 20, IgG antibodies to Hantaan virus were demonstrated in sera from 7 past HFRS patients but no IgM antibodies were detected. All Hantaan antibodies were 5-50 times higher than Ig and neutralizing antibody titers. IF, ELISA and PRNT antibodies persisted for at least 1 to 17 years after illness. PRNT is sensitive and specific for the infecting serotype virus. This was confirmed since 5 of the 7 past HFRS patients were infected with Hantaan virus and 2 with Seoul virus. These patients had no titers of IF antibodies but high titers of ELISA and PRNT antibodies against the infecting virus. As one of the most sensitive serologic tests, the ELISA can be used for seroepidemiology surveys, while the specificity of PRNT makes it useful for serotyping of hantaviruses.

It is not yet clear whether non-specific IF antibodies against Hantaan virus exist in human and animal sera. We have tested 13 sera from healthy rats that contained IF antibodies (titers between 10-50) reacting with Hantaan and Seoul viruses, and showed no cross-reactivity with Seoul virus. The results were negative with other techniques as shown in Table 21. This suggests that there are either non-specific IF antibodies in rat sera against Hantaan or Seoul viruses, or unknown HFRS related hantaviruses that produce cross reacting IF antibodies.

At present, the interpretation of low titer IF antibodies in humans is problematic. Studies of human sera containing low titer IF antibodies employing ELISA and PRNT are in progress to determine if similar results will be found in man.

THE EFFECT OF TEMPERATURE ON THE GROWTH OF BACTERIA

The growth of bacteria is highly dependent on temperature. Most bacteria have an optimal temperature range for growth, typically between 20°C and 40°C. At temperatures below the optimal range, the rate of growth is significantly reduced due to decreased enzyme activity and metabolic processes. Conversely, at temperatures above the optimal range, growth is inhibited or even prevented as the high heat denatures proteins and disrupts cellular structures. The relationship between temperature and bacterial growth rate is often represented by a bell-shaped curve, where the peak of the curve indicates the most favorable temperature for growth. Understanding these temperature requirements is crucial for various applications, including food safety, clinical microbiology, and industrial biotechnology.

disease to discover the causative agent of Korean hemorrhagic fever in Korea for 10 years since World War but they did not mention about a possibility of outbreak of these diseases. It is surprising to know that about one third of total sera from suspected HFRS patients were HFRS and one third of them are leptospirosis and scrub typhus. We do not know how many cases of leptospirosis and scrub typhus have occurred among US soldiers stationed in Korea because such diagnostic serologic tests were never requested by American doctors from US Army Hospital in Seoul. It is interesting and surprising to know that epidemics of leptospirosis and scrub typhus occurred during epidemic seasons of HFRS in Korea for several years although limited sero-epidemiologic studies were carried out by us recently. Further studies of sero-epidemiology, reservoir hosts of the diseases and vectors of scrub typhus in Korea are urgently needed. Leptospirosis and scrub typhus are very important military diseases for both Korean and US soldiers as well as for farmers. Usually outbreaks of scrub typhus occur in late August after heavy rains and typhus among farmers, and outbreaks of HFRS and scrub typhus occur in October-December every year.

Recent studies have demonstrated that HFRS is a zoonotic infection of Hantaan virus among Asian countries. The origin of this or similar hantaviruses among wild rodents, shrews and genera of small mammals (14-16, 20, 21) and the role of Hantaan virus (HFRS) is widely distributed and associated with a diversity of different ecological settings (22, 23). Other hantaviruses cause human disease, such as hemorrhagic fever with renal syndrome (HFRS) has not been traditionally recognized as a zoonotic infection. As WHO Collaborating Centre for Hantaan virus, we have provided serological diagnosis for suspected HFRS patients throughout the world. In addition, we have organized a number of investigators conducting research on the epidemiological evidence of Hantaan virus infection and distribution among wild urban rats. Results of these studies have demonstrated that HFRS is a human disease due to Hantaan virus infection. In Korea, where HFRS has not been reported since 1959, we have found who used of clinical and laboratory methods to identify HFRS cases serologically as HFRS. There is no question about the zoonotic origin of HFRS. The zoonotic origin of clinical HFRS is demonstrated by the fact that HFRS is not primarily a human disease. HFRS is a zoonotic disease and a variety of animals, including shrews, shrews, and other small mammals patients in Korea, HFRS and scrub typhus are common. There HFRS is not known to occur. The zoonotic origin of HFRS is evidenced about 20 years ago. Hantaan virus infection in animals with Hantaan viruses in any wild rat found in the forests of the world (30-31).

Further studies are needed to confirm our results in other areas of HFRS in Euro-Asia where severe form of HFRS patients occur.

It is clear now that IgG antibodies are strain specific, and antibodies are type specific and monoclonal antibodies are strain specific. Among the seroepidemiological tests of HFRS, IF antibody technique is the method of choice for screening test for Hantavirus infections, demonstration of IgM antibodies against Hantaan, Seoul and Puumala viruses in sera from the patients, by ELISA and IPAT are recommended serologic diagnostic test for HFRS and PRNP is the most specific and sensitive test for differentiation of infections with serotypes of Hantaviruses in man and animal. ELISA test is a very sensitive test than IPAT although it is not type specific and it could be very useful for a large scale sero-epidemiological survey for HFRS since ELISA antibodies were detected in sera from HFRS patients 17 years after illness. Seoul and Hantaan viruses isolated from urban rats caught in Hong Kong and in Singapore by IPAT were a little different from prototype strains of Seoul virus by functional antibody assay and showed the low of pathogenicity of these viruses in man yet although we have documented HFRS patients in Hong Kong and Singapore as an urban subject to find out an animal model source of the virus for study of pathogenicity of hantaviruses to man.

Summary

1. There were 776 hospitalized Hantaan virus patients and nosed at our laboratory in 1969. 100% of the cases were HOK Hong Kong type and 100% of the cases were HOK type respectively.
2. Epidemics of Hantaan virus infection were observed during epidemic season of Hantaan virus and nos. of patients were 214 and 64 respectively.
3. A rapid assay for Hantaan virus in sera from Hantaan virus patients of Hantaan virus infection was developed by using anti-Hantaan virus serum. In 1969, 100% of 117 house rats were positive for Hantaan virus by using anti-Hantaan virus serum. In 1969, 100% of 139 house rats were positive for Hantaan virus by using anti-Hantaan virus serum. In 1970, 100% of 214 house rats were positive for Hantaan virus by using anti-Hantaan virus serum. In 1971, 100% of 64 house rats were positive for Hantaan virus by using anti-Hantaan virus serum.
4. Seoul virus is a strain of Hantaan virus and the most characteristic clinical features are fever, headache, abrupt onset of renal dysfunction and hepatic dysfunction, and acute renal failure.
5. Abortion of a fetus was observed in a patient with infection of Hantaan virus and the fetus was found to be infected.

6. If an agent is identified as a potential hazard, the following steps should be taken:
 - a. Determine the nature of the hazard.
 - b. Determine the extent of the hazard.
 - c. Determine the potential for exposure.
 - d. Determine the potential for harm.
 - e. Determine the potential for control.
 7. Give priority to the control of urban air pollution. The following steps should be taken:
 - a. Determine the nature of the hazard.
 - b. Determine the extent of the hazard.
 - c. Determine the potential for exposure.
 - d. Determine the potential for harm.
 - e. Determine the potential for control.
- cells and the viral structure of the agent. The agent is genetically from protective measures. The agent is genetically from assay.
