ABSTRACT (ONGERUBRICEERD)

A survey is presented of the 'still video' pictures that have been recorded with 3 CCD-cameras during the BEST-TWO trial in Mourmelon, France.

The composition of, and selection for two databases is described and the results of processing with the FELimage processing algorithm are given. A statistical analysis of these processing results is carried out and described. For each scenarios, one or more examples of processed images are given.

SAMENVATTING (ONGERUBRICEERD)

Een overzicht wordt gegeven van de 'still video' beelden, welke gedurende de BEST-TWO trial in Mourmelon, Frankrijk, opgenomen zijn met 3 CCD-camera's. De samenstelling van, en de selecties voor twee databases worden beschreven. Resultaten van de bewerking met het FEL-beeldbewerkings algorithme worden gegeven. Een statistische analyse van deze resultaten is uitgevoerd en beschreven. Een of meer voorbeelden van bewerking worden voor elk van de scenarios gegeven.

INTRODUCTION

On a TV-monitor not more than about 30 different grey levels can be made perceivable within one picture. Simple state of the art cameras can record more information. In large dynamic range scenery high performance cameras can be necessary to resolve small contrasts due to the recording of quite different brightness regions. Small contrasts may be caused also by atmospheric haze and fog or by dust and smoke e.g. under battle field conditions.

Image processing is always necessary to bring the recorded information within the perception domain of the monitor.

Well-known histogram modification techniques can render improved image quality perception but its effectiveness also often depends on the composition of the scene. Sometimes it can even render worse quality in local parts of the image.

At TNO-FEL, The Netherlands an image processing algorithm has been developed that, independent of its local brightness, enhances the contrasts in any part of the image [1].

With a high performance camera (12-bit), developed at the TNO-FEL, a data-base of 'still' pictures taken under various atmospheric conditions has been used for evaluation of the mentioned image processing algorithm.

It was shown that all the recorded information could be made perceivable.

Under conditions of haze and fog it resulted in a significantly extended visual range and at clear weather at least in a more clear and comfortable vision.

In chapter 2 a short description will be given of the potentials of the algorithm with 2 examples.

TNO-FEL has participated in the Best-Two trial at Mourmelon with a PC-controlled camera setup with 3 CCD-cameras, to evaluate the contrast improvement as function of various battle field conditions. Improved camera performance and dedicated image processing generally results in an extended visual range.

This measuring setup will be shortly described and discussed in chapter 3 and the pictures taken with this setup in Mourmelon will be discussed in chapter 4.

Processing results will be discussed in chapter 5, for each scenario some examples will be given in chapter 6.

It is now clear that often the contrast loss due to dust and smoke is so complete that processing often does not yield new information within the perception domain. Then the contained information is yet more clearly presented after processing.

Page

Within 10 to 20 seconds the transmission of the dust or smoke clouds is often considerably improved and new information can be made perceivably after processing.

2 POTENTIALS OF THE DEDICATED IMAGE PROCESSING

The dedicated image processing (FEL-) algorithm is based on dynamic range transformation with local, adaptive contrast enhancement [1].

The range transformation depends on the recorded luminance range in the scenery, which must be mapped on the optimum range of the monitor. This mapping usually implies a compression of range, which is accompanied by loss of contrast. A local adaptive contrast enhancement is simultaneously carried out by using local statistics. The calculations are carried out in the logarithmic domain. They result in a contrast enhancement independent of the local brightness; dark and light regions are treated in the same way. The contrast enhancement is realized by multiplying the local contrast difference by an adaptive constant, which on its turn is calculated from the local variance. The local contrast difference is calculated by a moving average filter; the size of the filter can be chosen by the operator; in far most of the cases a 3x3 size will suffice.

All the recorded information can be made perceivable without rendering artefacts and with preserving a natural appearance of the recorded scene. An example is given in fig.2.1 concerning a city view taken from the laboratory tower during a dense fog. At the top is the original 12-bit picture (before processing), at the bottom the same picture after processing. The visibility varied from 1 to about 4 km with a layer of more dense fog just beyond the horizon.

Obvious the processing results in an extended visual range and in a more comfortable image. In this example the processing result benefited to a considerable extent from the dynamic range transformation due to the limited grey level range in the original picture. This limited range is due to the luminance bias, which is caused by scattering of light at the fog particles.

Another example is given in fig.2.2, concerning now a picture taken during clear weather from the inner court of the laboratory. On top, again, the original 12-bit picture (before processing) is shown, at the bottom the same picture after processing. The full grey level range from black to white is already present in the original picture, the range transformation will not be helpfull now. Nevertheless, also in this case more information becomes perceivable after processing, especially from within the rooms. This result is mainly due to the local contrast enhancement.

Figure 2.1: City view, visibility 1 to 4 Km.
Top: before processing, bottom: after processing.

Figure 2.2: Inner court of the laboratory at clear weather. Top: before processing, bottom: after processing.

3 MEASURING SETUP

3.1 Instrumentation

For field measurements a PC-controlled setup has been developed that can control up to four 8-bit cameras and one 12-bit camera. An advanced framegrabber board of Imaging Technology Inc. (VS-100 AT) has been used as the data acquisition board.

Analog video data of the 8-bit cameras are fed directly into the framegrabber board and converted to 8-bit 512x512 digital images.

Digital data of the 12-bit camera are directly fed into the 12-bit digital input port of the framegrabber. The video-output of each CCD-pixel of the TNO-FEL camera is separately filtered according a Correlated Double Sample technique and 12-bit AD converted. The image size therefore corresponds with the number of sensor pixels (384 per line), rather than with the sensor dimensions. The prints of the camera pictures given in this report are made by a video copy processor and give the correct image size. The necessary geometrical correction to generate a correct image size has been carried out by pixel replication, such that along every image line the number of image pixels is extended from 384 to 512. Image storage was on a WORM optical storage medium.

The platform in Mourmelon contained 3 CCD-cameras:

- 1 a 12-bit daylight system
- 2 a 8-bit daylight system
- a 8-bit gated Image Intensified CCD system for day and night

Specifications of these cameras are given in table 3.1.

A photograph of the camera setup is given in fig.3.1.

On top are the 3 CCD-cameras, the white box just below contains the analog electronic circuits for controlling the 12-bit camera.

The most important circuits are:

- the drivers and receivers for the readout electronics
- drift compensation circuits
- correlated double sampling circuits
- 12-bit AD conversion

Digital data are transmitted via a junction box to the framegrabber board in the PC-Vectra computer. Analog video of the 8-bit CCD-cameras is transmitted directly to one of the analog inputs of the framegrabber board.

A photograph of the complete setup under canvas during the battlefield trial is given in fig.3.2.

Figure 3.1: PC-controlled camera setup with on top from left to right: 8-bit image intensified camera for day and night, a 12-bit and a 8-bit daylight camera.

Figure 3.2: Experimental setup under canvas at the Mourmelon site.

....

3.1.1 12-bit daylight camera

The provisions for achieving a 12-bit performance have been:

- a slow read-out of the sensor.
- b cooling the sensor down to -30 *Celsius by means of a two-stage Peltier cooler
- c correlated double sample of pixel video
- d sophisticated drift compensation

The carnera head is a modular double-walled (air-filled) chamber to prevent condensation on the chip, which with the Peltier elements is mounted in the inner compartment.

The black box with ribbons on top of the setup in fig.3.1 is the heat-sink for the Peltier cooler. The large dimensions have been chosen to prevent forced cooling.

Despite the high ambient temperatures of 40 °C or more during the Mourmelon trial, the sensor temperature of -30 °C could easily be maintained. However, due to a several extra power consuming PC-boards, a reliable operation of the controlling PC-computer could be guarantied only up to ambient temperatures of about 25 °C. During the trial therefore the computer was put

in a modified refrigerator and kept on a temperature of about 15-20 °C. Also the optical storage medium was put in the refrigerator, but more because of precautions against dust pollution.

Throughout the trial this resulted in a faultless operation of the instrumentation.

3.2 Measuring location

Description of the instrumentation areas during the Mourmelon trial can be found in several 'best-two' reports and in the best-two test plan as well [2]. A schematic layout of the test site is given in fig.3.3.

The CCD-carnera setup was at the field instrumentation area (FIA) and is indicated in fig.3.3 by point 'B', which was about 100 m to the north of the setup of the TNO-FEL infrared group, which is indicated by point 'A' (see also de Jong [3]).

This location for the CCD-cameras has been chosen because of:

- a the shorter distances to the passing vehicles (1-1.5 Km instead of 4 to 1 Km)
- b transmission measurements in various wavelength regions from the same location
- c the presence of several contrast targets within the FOV of the cameras.

For a more detailed illustration of the FIA with its relevant facilities see, for instance de Jong [3]. A photographic survey of the site, as seen from the Field Instrumentation Area, is shown by the photographs in figs 3.4A and 3.4B. In the panorama view of figs.3.4A and 3.4B the site is pictured from the North to the South from top right to bottom left (that is according block 11, 12,...21, 22 etc. in fig.3.4A down to block 64 in fig.3.4B). The Main Instrumentation Area was located in the South, but could not be perceived from the FIA.

A photograph of a part of the site with some contrast boards (according to block 42 in fig.3.4B) is given in fig.3.5. Most of the pictures given in this report cover a large part or whole of the scene given in this photograph. The fields of view of the 8- and 12-bit cameras are mostly not the same, because the different sensor dimensions have not been fully compensated by the applied focal length of the lens.

A detail of the most often occurring scenes with the contrast boards appears in fig.3.6 with at the right a concrete bunker and at the left the contrast boards with calibrated grey levels and boards with different elevation angles, each with two different surface structures [3].

The distance between these boards and the camera setup was about 1000 m.

Figure 3.3: Schematic layout of the Mourmelon site with the F(ield) I(nstrumentation) A(rea) around the points A and B. The CCD-camera setup was located at point B.

Figure 3.4A: Northern part of a panorama view of the Mourmelon site, viewed at the Field Instrumentation Area from the North (top right) to the South (bottom left).

Figure 3.4B: Southern part of a panorama view of the Mourmelon site, viewed at the Field Instrumentation Area from the North (top right) to the South (bottom left).

Figure 3.5: Photograph of part of the site, that is pictured in most of the recorded images.

Figure 3.6: Contrast boards from left to right: white (1.0), light grey (0.8), dark grey (0.52), black (0.0), army green (0.3) and 2 boards each with glossy and rough surface, respectively at elevation angles of 90, 60, and 30 degrees; to the left a concrete bunker.

4 IMAGE DATABASE

4.1 Image distributions

Nearly 900 still video pictures have been recorded during the BEST-TWO trial with the three cameras together. A complete survey of all the recordings is given, in chronological order per day, in the bar diagram of fig.4.1., by separate bars for each of the three cameras. Special pictures, taken during periods not belonging to the regular sessions, are included. Each day two or three sessions took place, each with one scenario according the Best-Two test plan [2]. The same scenario might occur in different sessions. A short description of each session is given in Appendix A. In this description the number and the type of vehicles are given with their speed, formation and run time. Also the number of the recorded 8-bit daylight and 12-bit daylight camera images is given with the period within the sessions, during which the images have been recorded. Finally the number of processed images and the selected number of images for the US database and the number for the final TNO database is given for each session. See for a description of the sessions also [2,3,4].

A survey is given of all the recorded images for each of the separate scenario's in the bar diagrams of fig.4.2 for the 8-bit daylight camera images and in fig.4.3 for the 12-bit daylight camera images (the test week is included when applicable). In both diagrams the dark bars give the total number of recorded images and the light bars give the number of images selected for the US database for each of the given scenario's.

The selections are based on the estimated interest of the images, which is defined by a P(icture) IN(terest) code. This PIN code and the various used selection criteria will shortly be described in the next paragraph 4.2 and more extensively in the Appendix B. From fig.4.3 it is apparent that for scenarios 3B and 4A only few 12-bit pictures have been selected for the US database. This is due to the many low quality pictures, as will be explained in paragraph 4.4.3.

A complete list of the final selection for the TNO-FEL database is given in Appendix C. In this final TNO database only the complete failures have been omitted; all the images selected for the US database and all the processed images are included in the final database.

Many recording conditions, parameters and properties of the images are given in this list of recordings. A full description will be given in Appendix C and a short description in paragraph 4.3.

A survey of the 8-bit daylight and the 12-bit daylight images in this final database is given for each scenario by a bar diagram in fig.4.4.; the dark bars give the 8-bit and the light bars give the 12-bit pictures.

Figure 4.1: Survey of all pictures in chronological order per day.

8-bit daylight images

Figure 4.2: Survey of 8-bit daylight pictures per scenario; the light bars give the total number of pictures and the dark bars give the selection in the U.S. database.

12-bit images

Figure 4.3: Survey of 12-bit daylight pictures per scenario; the light bars give the total number of pictures and the dark bars give the selection in the U.S. database.

Final database 8-bit day&12-bit images

Figure 4.4: Survey of 8-bit and 12-bit daylight pictures per scenario in the final TNO database; the light bars give the 8-bit daylight pictures and the dark bars the 12-bit pictures.

4.2 Picture Interest

A picture interest code has been assigned to all the image files. This PIN code has been determined by an arrangement of two or three observers. The code is expressed with respect to the significance of the original (unprocessed) images. The most important criteria have been the effect of processing to be expected and the presence of interesting battle field effects or a unique occurrence of the picture. This significance of the picture is given by the second digit of the PIN-code or by a single digit if no second digit is given. The first digit in a 2-digit PIN code number refers to a special class of images, such as dark pictures, condensed or iced pictures or pictures with no relation with any of the regular scenario's. A picture not belonging to any special class gets assigned a single digit PIN-code number.

A full description of the picture significance-criteria and the special classes will be given in Appendix B (paragraph B.1).

A picture with an excellent photographic quality can be of no interest with respect to the mentioned criteria and will get then a value five as the relevant digit in the PIN-code number. Lower valued PIN-code numbers refer to uninteresting pictures, which have also some bad quality aspects. PIN-code numbers higher valued than five refer to pictures with some interest,

which can have, however, also bad (photographic) quality aspects. In fact, the most interesting pictures with respect to the expected image processing effect will show, in most cases, far from good photographic quality (before processing).

A survey of the assigned PIN-code number distribution for the 8-bit and 12-bit daylight pictures is given in fig.4.5. The dark bars represent the number of 8-bit and the light bars the number of 12-bit pictures for each of the PIN code numbers. The distributions are retrieved from the complete database.

The significance-value of the 8-bit images is peaking around the value 6; the 12-bit pictures are expected to be slightly more interesting as their interest is peaking around the value 7.

The mean significance-value of the pictures per scenario is given in fig.4.6. The dark bars for the 8-bit and the light bars for the 12-bit pictures. Also, here the complete database has been considered. The scenario's 2C, 3A and 3B are expected to be most interesting, which will be confirmed by the image processing results in the corresponding paragraphs.

This PIN-code has been used to select, for transmission to the US data base, a limited set of relevant data. They have been used for defining priorities with respect to the images to be processed and for composing a definite list of qualified recordings.

A full description of the selection criteria used for the various purposes is given in Appendix B, paragraph B.2.

Picture interest distribution

Figure 4.5: PIN-code number distribution for the 8-bit daylight (light bars) and the 12-bit pictures (dark bars).

Mean picture interest per scenario

Figure 4.6: Survey of the mean value of the PIN-code number per scenario for the 8-bit daylight (light bars) and the 12-bit pictures (dark bars).

The selection criteria are different for the various classes. All images with a single digit PIN-code (most of the regular images and not belonging to any special class) with a value 6 and higher have been selected for the US-database and with a value 5 and higher for the final database. For the special classes the criteria for selection have been chosen somewhat higher (see Appendix B, paragraph B.2). All the images recorded during the regular scenarios and having a PIN-code number value of 7, 8 and 9 have been processed.

Sometimes pictures with lower valued PIN-code numbers have been processed in order to complete a succeeding sequence of interesting pictures.

This might be important for studying the effect of processing as function of the time lapse after generation of peculiar obscurants. A complete survey of the processed images per scenario is given in fig.4.7; the light bars give the number of 8-bit daylight pictures per scenario and the dark bars give the number of 12-bit processed images. The processed images with PIN-code number lower than 7 have been included in fig.4.7. Nevertheless, figure 4.7 also gives a rather good representation of the distribution of the PIN-code numbers 7 to 9 for each scenario. All the processed images are included in the final listing of recordings in Appendix C and also in the final database, of which the distribution per scenario is given in fig.4.4.

A chronological listing of the recordings in the final database is given in Appendix C with relevant comments and is shortly described in the next paragraph 4.3.

processed images

Figure 4.7: Survey of processed pictures per scenario for the 8-bit and 12-bit daylight cameras; the light bars give the 8-bit daylight pictures and the dark bars the 12-bit pictures.

4.3 Listing of recorded pictures

During most sessions, pictures have been taken with the 8- and 12-bit daylight cameras and a limited number with the Image Intensified CCD- camera. With the daylight cameras pictures have been taken in 3 wavelength regions, defined by the used filter:

- from 400 to 1100 nanometer (without filter); in column 8 of the list of recordings (Appendix C), the corresponding image files are coded with '0'.
- b from 400 to 650 nanometer (photopic region); in column 8 of the list of recordings, the corresponding image files are coded with 'v'.
- c from 675 to 1100 nanometer (near infrared region); in column 8 of the list of recordings the corresponding image files are coded with 'n'.

With the LLL camera in most cases recordings have been made in the wavelength region of 300 to 875 nanometer (= without filter).

Only one picture (with one of the cameras) in about 10 to 20 seconds could be recorded, which turned out to be a serious drawback for comparison 8 and 12-bit performance or wavelength dependence in situations of fast changing transmission characteristics of smoke and dust. Within 10 to 20 seconds after sand bag explosions, the transmission was often already considerably changed. The transmission of dust clouds due to moving vehicles depends among others on the speed of the vehicles, the atmospheric and terrain conditions, the mutual distance of the vehicles, the wind velocity and wind direction with respect to the cameras. Also, in these situations the transmission changed considerably within 10 to 20 seconds.

A selection has been made by 3 observers with respect to the interest of the original (unprocessed) images; most of the very low quality pictures and evident irrelevant pictures have been deleted from the list; some pictures with bad quality regions however are maintained because of their unique occurrence or interesting properties.

A chronological listing of the recordings, selected for the final database, is given in the Appendix C.

For each of the recorded pictures several relevant conditions and parameters of the cameras, the trial, the weather, also some image properties and various codes, are given.

For the cameras:

applied focal length of the lens,
applied diaphragm in lens stop units,
exposure time or gating time (II-CCD camera),
applied wavelength and/or neutral density filter.

For the trial:

Date and local time.

type of scenario,

remarks on special battle field effects and/or the presence of special objects in the scene (eventually after processing).

For the weather conditions:

visibility from SITE.2US,
transmission from LOWTRAN.US,
luminance level at FIA location,
air temperature at FIA location,
effective temperature from MIA1.GE,
relative humidity at FIA location,

wind direction and velocity from MIA1.GE.

effective humidity from MIA1.GE,

For the images:

The filename, in which the date, the number of the session, the type of camera is incorporated.

The PIN-code with the expected interest, sometimes a special class indication.

The Image Quality code with in its first digit an indication of the photographic quality before processing, in the second digit a code for the effect of applied image processing (see paragraph 4.4.4).

For the selections:

the selected images for the US-database are indicated by a letter 'd', the selection of the final database, according the stringent selection criteria given in Appendix A, by a letter 'r' and the processed images by a letter 'p'. In the final database all the image files coded either with a 'r' and/or a 'p' are included. All the image files with a 'd' also are coded with an 'r' and therefore are included in the final database.

A survey of all the recorded image files has been given already in the bar diagram of fig.4.1; the numbers refer to the chronological sessions, two or three each day (in the best two schedules for the session numbers the corresponding type of scenario can be read then). For a description of the scenarios is referred to Appendix A and to the Best Two test plan [2]. For a detailed description of the position of moving vehicles in scenarios one and two see Valeton cs. [4].

4.4 Image Quality

It must be realized that only 'still' pictures have been recorded and the photographs therefore also represent only one frame of video information.

4.4.1 Dust and Smoke

Most of the pictures have been taken in the direction of the contrast targets during passing of the vehicles; therefore, the most frequently occurring obscurant in the pictures will be dust.

Immediately after sand bag explosions scenes behind dust clouds are not visible, nor can be made perceivable by image processing. Within 10 to 20 seconds after the explosion the transmission was often already considerably better; scenes behind clouds then become visible and more information can be made perceivable by processing.

The transmission of smoke, caused by fires, generally is better than that of sand clouds. These pictures often benefited more from image processing.

The transmission of dust clouds due to moving vehicles depends on many parameters, e.g. the number of vehicles, its speed and its mutual distance, the wind speed and its direction, atmospheric and terrain conditions as well. Also, under these various conditions the transmission changed often considerably within 10 to 20 seconds. Pictures with dust raised by a column of moving vehicles benefited most from the image processing.

4.4.2 Comparison of cameras

Within a period of 10 to 20 seconds only one camera-image could be recorded; at daylight the 8-bit and 12-bit cameras have been used alternately most of the time. Therefore, a reliable comparison of 8- and 12-bit performance is not possible due to the fast changing transmission characteristics of smoke and dust within the occurring time delay.

Other drawbacks for a reliable comparison of 8-bit and 12-bit daylight camera performance are their slightly different FOV's and the better spatial resolution of the 8-bit camera.

The perception of a monitor displayed original picture, taken with this camera, is often better than the picture taken (at about the same time) with the 12-bit camera. The spatial resolution of the 8-bit camera is better than that of the 12-bit camera. The monitor display shows, of any image, only the 8 most significant bits.

Both aspects benefit the perception of the 8-bit pictures before processing. Nevertheless after processing the 12-bit pictures look sharper, which is due to the low contrasts that can be recorded by the 12-bit camera.

Apart from the large intrascene dynamic range of the 12-bit camera, also long exposure times can be applied, which allows to take pictures at low light levels.

4.4.3 Low quality pictures

a 12-bit daylight CCD-camera.

Sometimes, at the beginning of some morning sessions, water condense was on the sensor; it has been shown afterwards that this condensation was due to the applied high cooling rate; with a moderate rate condensation can be prevented. Most of these pictures have been erased from the list of qualified pictures.

b 8-bit image intensified CCD-camera.

All pictures taken at night are severely blurred and often fully bloomed by the presence of light sources in the field. Especially, the 1 Hz flashlight in use as aircraft beacon during the night trials, caused a catastrophic blooming effect, also when the source was not within the field of view of the camera.

Pictures taken by day with the LLL camera show a poor quality with respect to the pictures taken with the daylight cameras. All these pictures have been taken with an automatic gain control of the image intensifier and of the CCD-sensor. It has been shown afterwards that an appreciably better quality can be achieved by using a minimum Image Intensifier gain, if a sufficient large entrance aperture and/or gating time can be applied. Most of these bloomed pictures have been omitted from the list of qualified images.

4.4.4 The Image Quality code

To all the processed pictures a two digit image quality (IQ) code has been assigned. The first digit gives an indication of the 'photographic' quality before processing and the second digit gives the class of image improvement due to the applied dedicated image processing. The digit for the

'photographic' image quality before processing runs from '0' for a completely unsuccessful image up to a '9' for a high quality picture, free from any blurring.

The digit for the effect of image processing runs from '0' for no effect at all, up to '3' for making a perceivable and remarkable improvement, presenting more information due to the processing.

The IQ-code number has been determined by an arrangement of two or three (untrained) observers.

An extensive description of both digits in this IQ-code number is given in Appendix B, paragraph B.3.

An indication of the 'photographic' quality after processing can be found by summing the two digits in the IQ-code. It is just an indication, because some aspects are difficult to compare and therefore the same 'photographic' quality before and after processing will never be observed. The sharpness, eg in the processed pictures due to processing, never occurs in the unprocessed pictures, as will be shown in the examples to be given in chapter 6.

Statistical results of the effect of image processing will be given in the next chapter, but will not be valid as a result for a random selection of images. Mainly the images with a picture interest code number of 7, 8 and 9 have been processed. Therefore, the corresponding 'photographic' quality before processing of this selection is not valid for a sample taken at random. The connection between the picture interest (2nd digit in the PIN-code) and the image quality before processing (1st digit in IQ-code) of the processed images is given by the 3-D graphs in the figs 4.8 and 4.9 for respectively the 8-bit and the 12-bit images. In these graphs the image quality is given along the horizontal axis, the picture interest on the slant axis and the corresponding number of pictures in the vertical direction.

For the 8-bit pictures the maximum number occurs for an image quality coded with 6 for the considered PIN-code numbers 7 to 9. For a PIN-code = 7 no pictures with an image quality code 9 occur, for a PIN-code = 8 no pictures with an image quality code 8 and 9 occur and for a PIN-code = 9 no pictures with an image quality code 7, 8 or 9 occur.

For the 12-bit pictures the maximum number occurs for an image quality coded with 6 for the considered PIN-code numbers 7 and 8 and image quality 5 for the PIN-code = 9. For a PIN-code equal to 7 and 8 no pictures with an image quality code 9 occur and for a PIN-code equal to 9 no pictures with an image quality code 7,8 or 9 occur. In general, the more interesting a picture is, the lower the image quality.

Picture Interest versus Image Quait.

Figure 4.8: Number of processed 8-bit daylight pictures for each of the assigned Image Quality codes with the connected Picture Interest codes.

Picture Interest versus Image Qualit.

Figure 4.9: Number of processed 12-bit pictures for each of the assigned Image Quality codes with the connected Picture Interest codes.

5 PROCESSING RESULTS

5.1 Processing parameters

The processing is based on dynamic range transformation and an adaptive local contrast enhancement [1]. The range transformation is a global processing technique, using global statistics (histogram distribution of recorded grey level values) and the adaptive contrast enhancement is a local processing technique, using only local statistics. The contrast enhancement then is independent of the luminance range and can be carried out in the same way in any part of the image.

DYNAMIC RANGE TRANSFORMATION.

The main parameters for the global processing are the used input range and the output range:

Xi = Xmax-Xmin = the input range,

Xmax = maximum greylevel value in the original picture, used for the range transformation.

Xmin = minimum grey level value of the original picture, used for the range transformation.

The absolute maximum value that can occur is 4095 for a 12-bit picture and 255 for a 8-bit picture.

Often a lower value than the maximum occurring value, and a higher value than the minimum occurring value in the original picture is used for the input range. For an autonomous image processing a percentage of the total number of pixels can be chosen at either side in the histogram distribution. These values are kept then outside the input range for the processing. For all the pictures considered in this report, the input range is chosen by the operator for each picture separately. For this purpose, by means of the histogram distribution, a selectable range of high and of low pixel values can get assigned a typical colour in the black and white presentation of the picture on the monitor. High and low pixel values occurring only in irrelevant parts of the scene (eg white spots in the sky or black spots in the foreground) can be excluded then from the input range. Examples will be given in paragraph 5.5.5.

Yo = Ymax-Ymin = the output range,

Ymax = maximum grey level value, that is used in the range transformation for the output range.

Ymin = minimum grey level value, that is used in the range transformation for the output range.

The maximum output range runs from 0 to 255, to generate a normalized monitor input.

In most cases the output range, chosen for the range transformation, runs from 10 to 240. The small range beyond the black level and below the white level also allows a local contrast enhancement in these extreme luminance regions.

The dynamic range matching is carried out in the logarithmic domain according the following function:

$$y = k x^{\gamma}$$

x = the input grey level and y = the output grey level value. In the logarithmic domain then is:

$$dy/y = \gamma dx/x$$
 or $C_v = \gamma C_x$

with C_x is the input and C_y is the output contrast.

So the output contrast is multiplied by γ , and the variation of the contrast due to this range transformation is independent of the local brightness; thus contrasts in bright and dark regions are treated in the same way. Depending on the value of γ used, we have dynamic range expansion (γ -1, always for 8-bit-pictures) or compression (γ -1, often in case of 12-bit images). A loss of contrast by dynamic range compression will be compensated by the measure of local contrast enhancement. In the used algorithm both the range transformation and the contrast enhancement are performed as a combined operation in the logarithmic domain. For the mathematics, see de Vries [1].

The parameters k and γ are not optional to the operator, but automatically derived from the given input and output range.

LOCAL CONTRAST ENHANCEMENT

The main parameters for the local contrast enhancement are the contrast multiplier and the control parameters for suppression possible artefacts:

Gc = contrast multiplier

The local difference in the logarithmic domain z is equal to the contrast in the input domain x (for small values of the contrast). So, by deriving from the z-signal the local difference signal, we can operate on the contrast of the input image x, simply by multiplying this local difference signal by Gc. The contrast enhancement then is independent of the local brightness.

The local difference is determined by using a moving average filter for a window size of 3x3 pixels.

$$L_d(z) = z - L_m(z)$$

with L_d = local difference and L_m = local mean

The size of the window can be chosen by the operator, but for most cases the 3x3 size is the best choice. The 3x3 filter size is used for all the processed pictures, dealt with in this report.

Vn(%) = percentage determining the threshold for the adaptivity

Vn = processor constant determining the adaptivity parameter.

Vn is the threshold value in the histogram distribution of the local variance. The contrast multiplier for pixels with a local variance beyond this value will gradually decrease to unity. The adaptivity parameter is a function of the relevant local variance and the threshold Vn.

Vn(%) is the percentage of the total number of pixels with its values for the local variance beyond the threshold. This percentage is optional to the operator and then determines the threshold, but the threshold itself also is an option.

For the mathematics, see de Vries [1].

LISTING OF PROCESSING PARAMETERS.

For all the processed pictures, the used parameters Xmax, Xmin, Ymax, Ymin, Vn, Vn(%) and Gc are given in the 'Listing of processed images and processing parameters' of Appendix D.

The filenames of the images before processing, given in this listing, are the same as given in Appendix C. The filenames for the corresponding processed images have the same filename, except for the extension, which is formed by a P and a following number. The type of processed image always is a 8-bit image; the original type can no longer be inferred from the extension.

The listing finally contains some comments and whether a copy on paper, made with a videoprinter, is available. The availability is indicated by the date of the print.

5.2 Processing statistics

5.2.1 Selection

All the images with a picture interest code value of 7, 8 or 9 have been processed. Some images with a PIN-code lower than 7 have been processed in order to complete a succeeding sequence of interesting images, as is already described in paragraph 4.2 on the Picture INterest code. A survey of all the processed pictures already has been given in fig.4.7. The processed pictures are coded with a 'p' in the listing of recordings in Appendix C.

5.2.2 Parameter statistics

Most of the images have been well exposed and, therefore, their maximum grey level value Xmax in most cases will be 255 for the 8-bit and 4095 for the 12-bit images. The maximum grey level range in the input image then will be determined by the minimum grey level value Xmin. The mean value of the used Xmin in processing the pictures is given for each of the scenarios separately in fig. 5.1. The light bars represent the 8-bit pictures and the dark bars the 12-bit pictures. There is an obvious increase in background luminance from scenario 1 to scenario 3. The background luminance arises from light scattering at dust and / or smoke particles. The increase is a result of an increasing number of dust particles in the atmosphere due to an increasing number of vehicles and / or increasing speed of these vehicles.

The increase of minimum grey level in the 12-bit pictures for the various scenarios 4 is not really significant because of the small number of processed pictures (see fig.4.7). The decrease of the mean value of Xmin in scenario 3B for the 12-bit images is due to a large number of 12-bit pictures in the corresponding session, taken with condense on the sensor. This resulted in considerably darker pictures.

A survey of the used grey level ranges Xi with corresponding Xmin in the input images is given in the scatter diagrams of fig. 5.2 and fig.5.3 for respectively the processed 8-bit daylight images and the processed 12-bit images.

The higher the value of the minimum grey level Xmin, the smaller relevant range for the range mapping will result. For the pictures exposed up to and with the saturation level of the sensor, the maximum input range for the 8-bit images is:

Xi = 255-Xmin.

and for the 12-bit images is:

Xi = 4095-Xmin

which represents the straight lines along the diagonals in the figs. 5.2 and 5.3.

The Xi ranges below these lines can arise because of underexposed pictures (e.g. 12-bit pictures at low light levels during early night sessions). It may also be a result of excluding regions with high luminance levels.

The most important parameter for the local contrast enhancement is the contrast multiplier Gc. The range mapping results itself also in a contrast expansion (8-bit) or compression (in most cases for 12-bit), which is expected to be inverse proportional to the quotient of the used input range Xi and output range Yo. The total contrast enhancement will be subjected to a maximum due to a limited signal to noise ratio. The maximum contrast multiplier Gc in the local contrast enhancement then will be dependent on the used input range. This dependence is also expected to be inverse proportional to the mentioned quotient.

Figure 5.1: Mean value of used lowest grey level Xmin in the processing of 8-bit daylight (light bars) and 12-bit pictures (dark bars) for each scenario.

Figure 5.2: The used input grey level ranges with corresponding minimum grey level for processing the 8-bit daylight images.

Figure 5.3: The used input grey level ranges with corresponding minimum grey level for processing the 12-bit images.

A survey of the used values for the contrast multiplier Gc is given in the scatter diagrams of fig.5.4 and fig.5.5 for respectively the processed 8-bit daylight and the processed 12-bit pictures. The values of Gc are given with the corresponding values of the used input ranges Xi. For the 12-bit images a slight correlation between Gc and Xi is perceivable, but is not really significant. For the 8-bit images any correlation is absent. The slight increase of the contrast multiplier Gc with increasing input range for the 12-bit pictures might be due to the increasing range compression.

A survey of the mean value of the used contrast multiplier Gc is given for each scenario separately in the bar diagram of fig. 5.6 for both the processed 8-bit daylight (light bars) and the processed 12-bit pictures (dark bars). There is an obvious dependence on the type of scenario. The mean values of the contrast multiplier are higher for the 12-bit pictures than for the 8-bit pictures, which is valid for all the scenarios (the number of processed images of scenario 4, is too small for relevant conclusions; see fig.4.7).

Figure 5.4: The used values for the contrast multiplier Gc with corresponding input grey level ranges in processing the 8-bit daylight images.

Figure 5.5: The used values for the contrast multiplier Gc with corresponding input grey level ranges in processing the 12 bit images.

Figure 5.6: The mean value of the used contrast multiplier Gc for each scenario; the light bars represent the rocessed 8-bit daylight pictures and the dark bars the processed 12-bit pictures.

5.2.3 Effect of processing

The effect of processing has been classified according the following 4 categories:

- 0 = no relevant effect of processing.
- 1 = processing results in a more clear and sharp picture, but no more obvious and relevant information becomes perceivable.
- 2 = some new information becomes perceivable together with a clear and sharp presentation.
- 3 = remarkable new information has become perceivable by processing.

These categories are given by the second digit in the IQ-code number, which is more extensively described in Appendix B.

The distribution of the 'effect of processing' result, according this classification, is given in figure 5.7 as a percentage of the total number of processed pictures (per camera). The light bars give the effect for the 8-bit daylight images and the dark bars for the 12-bit images. For both the image types the maximum occurs for class 1 of the 'effect of processing', but for the 12-bit images the 'distribution curve' is clearly shifted to a higher value compared to the distribution for the 8-bit images.

The mean value of the 'effect of processing' class number is given in figure 5.8 for each of the scenarios separately; the light bars give the mean effect for the 8-bit daylight images and the dark bars for the 12-bit images. For all the scenarios the mean effect of processing for the 12-bit images is higher than for the 8-bit images. For the 12-bit images the mean effect is highest in scenario 3A and for the 8-bit images in scenario 3B.

In both scenarios the main obscurant is dust, raised by a column of driving vehicles; in scenario 3B smoke is added by fires near the path of the vehicles. In general, it may be expected that the effect of image processing is most spectacular for the scenario 3B conditions, also (and may be especially) for the 12-bit pictures. The lower effect compared to scenario 3A for the 12-bit pictures in our case is due to a large number of low quality pictures, and this not because of the obscurant, but due to a condensed sensor (see also paragraph 4.4.3). Image processing then enhances the condensed spots.

More than 60% of the total database has been processed; nevertheless the processing results might not be fully significant for the complete database. The most interesting pictures have been processed, which often correspond with a less good image quality before processing (see also the figures 4.8. and 4.9). The mean value of the image quality before processing (1st digit in IQ-code number) is given in figure 5.9 for each of the scenarios separately; the light bars represent the 8-bit daylight and the dark bars the 12-bit pictures. Now the 12-bit pictures have a lower quality

compared to the 8-bit pictures for nearly all the scenarios. On the monitor (and in the pictures) only the 8 most significant bits of 12-bit pictures can be displayed. The better spatial resolution of the 8-bit camera then becomes a significant property for the image quality (before processing); see also paragraph 4.4.2.

The results for scenario 4 are not very significant because of the small number of processed images (see figure 4.7).

The smaller the contrasts (after the range transformation), the larger the applied (optimum) contrast multiplier Gc and the larger the effect of processing possibly might be.

A correlation then might exist between the effect of processing and the applied contrast multiplier. A distribution of the applied (optimum) contrast multipliers is given in the figures 5.10 and 5.11 for respectively the 8-bit daylight and the 12-bit pictures. The contribution of each of the 4 classes of 'effect of processing' is given separately as a percentage of the total number of processed images. The separate percentages of the 4 classes are stacked at each value of the contrast multiplier Gc. The most applied value for the contrast multiplier Gc is 5 for the 8-bit and 8 for the 12-bit images.

A distribution of the applied (optimum) contrast multipliers for each of the 4 classes of 'effect of processing' separately, is given in the curves of the figures 5.12 and 5.13 for respectively the 8-bit daylight and the 12-bit pictures. Also here for each of the values of Gc the percentage of the total number of processed images is given for each of the 'effect of processing' classes. For the 8-bit images the maximum number for class 1 (picture sharpening) occurs at a value 5 and for class 2 at a value 8 of the contrast multiplier. For the 12-bit images the maximum number for class 1 (picture sharpening) occurs at a value around 7 and for class 2 at a value 10 of the contrast multiplier. Class 3 'effect of processing' hardly occurs for 8-bit images; for the 12-bit images the maximum number of class 3 occurs at a value 10 of Gc (same as class 2).

Figure 5.7: Effect of processing 8-bit daylight (light bars) and 12-bit images (dark bars); result in percentage of the total number of 8 / 12-bit processed images for each of the 4 IQ-codes for 'effect of processing'.

Figure 5.8: Effect of processing 8-bit daylight (light bars) and 12-bit images (dark bars) for each scenario; the processing result is given as the mean value of the 4 IQ-codes for 'effect of processing'.

Figure 5.9: The mean value of the IQ-codes for 'image quality before processing' for each scenario; the light bars for the processed 8-bit daylight and the dark bars for the processed 12-bit images.

Figure 5.10: Effect of processing 8-bit daylight images for each of the used values of the contrast multiplier Gc; a percentage of the total number of 8-bit processed images is given for each of the 4 IQ-codes for 'effect of processing' and stacked at each of the multipliers.

Figure 5.11: Effect of processing 12-bit images for each of the used values of the contrast multiplier Gc; a percentage of the total number of 12-bit processed images is given for each of the 4 IQ-codes for 'effect of processing' and stacked at each of the multipliers.

Figure 5.12: Effect of processing 8-bit daylight images for each of the used values of the contrast multiplier Gc; a percentage of the total number of 8-bit processed images is given for each of the 4 IQ-codes for 'effect of processing' separately.

Figure 5.13: Effect of processing 12-bit images for each of the used values of the contrast multiplier Gc; a percentage of the total number of 12-bit processed images is given for each of the 4 IQ-codes for 'effect of processing' separately.

6 EXAMPLES OF PROCESSING RESULTS

6.1 Scenario 1

Detection and recognition of a single static vehicle, without further battle field effects.

In most pictures taken during these sessions the information is already quite clearly presented, because of the good weather conditions at Mourmelon and the absence of battle field effects. Image processing results mainly in a sharper picture and thus in a more obvious presentation, but hardly ever new information becomes perceivable. A good example of picture sharpening and a comfortable presentation is given by the 8-bit picture in figure 6.1.

Some relevant conditions and parameters for this picture are:

Figure 6.1: file: M0208A29.IM8 / 8-bit without photopic filter,

date: 2-8-1990 / local time: 10:12:04,

session: 2.1 / scenario: 1R, site block: 23/24, fig.3.4A, PIN-code= 7 / IQ-code=81,

processing input range: 16-164 / contrast multiplier Gc=5.

Figure 6.1: 8-bit picture with vehicle in halt position / scenario 1R. Top before processing, bottom after processing.

6.2 Scenario 2

Detection and recognition of a single moving vehicle with battlefield effects.

In scenario 2A only vehicle raised dust is present and most dominant behind the vehicle. Most of the other parts of the scene will only be slightly blurred by dust, because of the low speed of the vehicle. This overall slightly blurring can be 'removed' by image processing in most cases. An example is given in fig.6.2 by a 12-bit picture taken without spectral filters.

Figure 6.2: File: M3107P41.IM1 / 12-bit without photopic filter,

date: 31-7-1990 / local time: 16:03:25, session: 31.3 / scenario: 2ALF,

site block: 22, fig.3.4A, PIN-code=7/IQ-code=61,

processing input range: 1500-4095 / contrast multiplier Gc=8.

Apart from the dust cloud behind the tank the information throughout the scene is clearly presented after the processing.

Another example of a 12-bit picture is given in figure 6.3, taken 1.5 minute after the picture in fig.6.2, but from another part of the site. The 'dusty' conditions are about the same, yet some new information becomes perceivable after processing.

Figure 6.3: File: M3107P45.IM1 / 12-bit without photopic filter,

date: 31-7-1990 / local time: 16:05:05, session: 31.3 / scenario: 2ALF,

site block: 42, fig.3.4B, PIN-code= 7 / IQ-code=61/62.

processing input range: 1300-4095 / contrast multiplier Gc=7.

In scenario 2B also smoke generated by fire can be present beside the vehicle raised dust. The representation of the smoke clouds is darker than that of the dust clouds, especially after processing. Most of the blurring due to the smoke can be removed by processing. The contours and the origin of the smoke cloud become clearly discernible after processing. An example is given in fig. 6.4 by a 12-bit picture taken with a photopic filter (dust is hardly present in this example).

Figure 6.4: File: M0108P07.IM1 / 12-bit with photopic filter,

date: 1-8-1990 / local time: 14:25:02, session: 1.3 / scenario: 2BLF, site block: 34, fig.3.4A, PIN-code= 8 / IQ-code=62,

processing input range: 600-2100 / contrast multiplier Gc=7.

In scenario 2C also dust clouds due to sand bag explosions are present.

Examples are given in fig.6.5 by an 8-bit picture taken immediately after the explosion of two sand bags between the camera and the contrast boards; in fig.6.6 by a 12-bit picture, taken 24 seconds later and in fig.6.7 by an 8-bit picture taken another 12 seconds later. All three pictures are taken with a photopic filter.

Figure 6.5: File: M3107A17.IM8 / 8-bit with photopic filter,

date: 31-7-1990 / local time: 10:22:40, session: 31.2 / scenario: 2CLS, site block: 42, fig.3.4B, PIN-code= 6 / IQ-code=40,

processing input range: 20-240 / contrast multiplier Gc=10.

Figure 6.6: File: M3107A18.IM1 / 12-bit with photopic filter,

date: 31-7-1990 / local time: 10:23:04, session: 31.2 / scenario: 2CLS, site block: 42, fig.3.4B, PIN-code= 8 / IQ-code=51,

processing input range: 1800-3630 / contrast multiplier Gc=10.

Figure 6.7: File: M3107A19.IM8 / 8-bit with photopic filter,

date: 31-7-1990 / local time: 10:23:16,

session: 31.2 / scenario: 2CLS, site block: 42, fig.3.4B, PIN-code= 8 / IQ-code=62,

processing input range: 80-215 / contrast multiplier Gc=12.

In fig.6.5 no information from scenes behind the dust cloud becomes perceivable after processing, while (after 36 seconds) in fig.6.7 many details become perceivable and after processing also a better contouring of the dust cloud can be observed. Processing the 12-bit picture in fig.6.6 (24 seconds after explosion) also gives a better contouring of the dust cloud and the blurring due to the extension of the original cloud is removed. Relevant new information does not yet become available after processing. This sequence of pictures illustrates the rate of transmission change after a sand bag explosion.

Figure 6.2: 12-bit image with vehicle raised dust / scenario 2ALF. Top before processing, bottom after processing.

Figure 6.3: 12-bit picture with dust raised by moving vehicles / scenario 2ALF. Top before processing, bottom after processing.

Figure 6.4: 12 bit picture with vehicle raised dust and smoke / scenario 2BLF. Top before processing, bottom after processing.

Figure 6.5: 8-bit picture with sand bag explosion / scenario 2CLS. Top before processing, bottom after processing.

Figure 6.6: 12-bit picture after sand bag explosion; taken 24 seconds later than picture in fig.6.5 / scenario 2CLS.

Top before processing, bottom after processing.

Figure 6.7: 8-bit picture as in fig.6.5, 36 seconds after sand bag explosion and 12 sec. after picture in fig.6.6 / scenario 2CLS.

Top before processing, bottom after processing.

6.3 Scenario 3

Detection/recognition of vehicles driving in column, with and without battle field effects.

In scenario 3A only vehicle raised dust is present. Large parts of the scene are often blurred by a moderate thick layer of dust because of the relative high speed (20 km/hr) and the small distance between the vehicles. This resulted in a larger offset or higher minimum grey level than in most of the other scenarios (see e.g. fig.5.1). Often most of the blurring can be removed by image processing and many details become perceivable then. The transmission of the dust clouds is dependent on a large number of conditions in a column of driving vehicles and this transmission can change fast. During a large part of session 7.3 the (often complete) obscurance of the scene was such, that the difference in performance of the 8-bit and the 12-bit camera became quite significant. The 8-bit pictures remained completely obscured even after processing, while the 12-bit pictures showed a lot of information, especially after processing. Examples are given in figure 6.8 for the 8-bit images and in figures 6.9 and 6.10 for the 12-bit images. The 12-bit picture in fig.6.9 is taken only nine seconds after the 8-bit picture in fig.6.8. In figure 6.9 the perception before processing is somewhat better than for the 8-bit image in figure 6.8, but for the 12-bit image in figure 6.10 the perception before processing is about the same as for this 8-bit picture. However the effect of processing is quite different.

Figure 6.8: File: M0708P44.IM8 / 8-bit with photopic filter date: 7-8-1990 / local time: 14:36:52, session: 7.3 / scenario: 3A, site block: 42, fig.3.4B, PIN-code= 6 / IQ-code=40,

processing input range: 40-165 / contrast multiplier Gc=12.

Figure 6.9: File: M0708P45.IM1 / 12-bit with photopic filter, date: 7-8-1990 / local time: 14:37:01,

session: 7.3 / scenario: 3A, site block: 42, fig.3.4B, PIN-code= 8 / IQ-code=53,

processing input range: 1700-3900 / contrast multiplier Gc=10.

Figure 6.10: File: M0708P20.IM1 / 12-bit with photopic filter,

date: 7-8-1990 / local time: 14:37:01,

session: 7.3 / scenario: 3A, site block: 42, fig.3.4B, PIN-code= 9 / IQ-code=52,

processing input range: 750-4095 / contrast multiplier Gc=17.

In the 12-bit picture of figure 6.10 a considerable range of the lower valued grey levels only occurs in the foreground of the scene and a smaller input range can be applied for the image processing, without loss of information in the relevant regions. In figure 6.11 another processing result for the same 12-bit picture of figure 6.10 is given; the used input range now is 2800 to 4095 instead of 750 to 4095. The available information in the relevant region now is more obvious and clearly presented. The optimum contrast multiplier Gc now is smaller than in figure 6.10, and apparently is caused by the extended range transformation, which now contributes to a part of the contrast enhancement

Figure 6.11: File: M0708P20.IM1 / processed 12-bit with photopic filter,

date: 7-8-1990 / local time: 14:37:01,

session: 7.3 / scenario: 3A, site block: 42, fig.3.4B, PIN-code= 9 / IQ-code=53,

processing input range: 2800-4095 / contrast multiplier Gc=10.

Examples with large regions obscured by vehicle raised dust and fast changing transmission characteristics are given in fig.6.12 by a 12-bit picture; in fig.6.13 by a similar 8-bit picture, taken 13 seconds later and in fig.6.14 by a 12-bit picture, taken another 14 seconds later. All three pictures are taken without a photopic filter. In fig.5.14 the transmission of the dust cloud is clearly decreased now compared with the previous pictures, but still sufficient to make perceivable some more information from the scene behind the dust by means of the image processing. The contours of a vehicle for instance can be observed now. It might be clear that the 8-bit versus 12-bit performance cannot be evaluated with such sequences of pictures, because the transmission changes significantly within 10 to 20 seconds, which is often the time delay necessary for taking and saving successive pictures (see also paragraph 4.4).

Figure 6.12: File: M0808A48.IM1 / 12-bit without photopic filter,

date: 8-8-1990 / local time: 10:51:11,

session: 8.2 / scenario: 3A, site block: 42, fig.3.4B, PIN-code= 8 / IQ-code=62,

processing input range: 2500-4095 / contrast multiplier Gc=9.

Figure 6.13: File: M0808A49.IM8 / 8-bit without photopic filter,

session: 8.2 / scenario: 3A, site block: 42, fig.3.4B, PIN-code= 9 / IQ-code=62,

processing input range: 115-215 / contrast multiplier Gc=10.

Figure 6.14: File: M0808A50.IM1 / 12-bit without photopic filter,

date: 8-8-1990 / local time: 10:51:38,

session: 8.2 / scenario: 3A, site block: 42, fig.3.4B,

PIN-code= 8 / IQ-code=43/52,

processing input range: 2700-4095 / contrast multiplier Gc=8.

In scenario 3B also smoke generated by fire can be present, beside the (fast moving) vehicle raised dust. An example is given in fig.6.15 by an 8-bit picture taken with a photopic filter.

The remarks on scene blurring and processing results, given with the examples under the scenarios 3A (fast moving vehicles) and 2B (smoke), are also especially valid for this example. By processing the contours of the smoke as well of the dust cloud from a passing vehicle can be made visible in a different way; smoke always with darker grey levels than dust clouds. Also the origin of the fire can clearly be observed now and many details along the forest border. In general the transmission of smoke is better than that of dust clouds.

Another example of an 8-bit picture taken without a photopic filter, with mainly smoke as the obscurant, is given in figure 6.16. Because of the darkened picture in the relevant regions, a very small input range could be applied in the processing, which results in a remarkable improvement. Also, here the origin of the fire becomes perceivable. In general, scenario 3B and scenario 3A benefited most from the image processing. Especially, when smoke is the main obscurant, image processing often results in a spectacular improvement in vision.

Figure 6.15: File: M0608P19.IM8 / 8-bit with photopic filter,

Figure 6.16: 8-bit picture with mainly smoke as obscurant / scenario 3B. Top before processing, bottom after processing.

6.4 Scenario 4

Detection/recognition of vehicles in attack formation.

In scenario 4A only vehicle raised dust is present and in scenario 4B also dust clouds from sand bag explosions can be perceived. In scenarios 4C through 4E the battle field effects were generated near the observers at the MIA (Main Instrumentation Area) and could not be recorded by the cameras at the FIA (about 2.5 km from the MIA). Because of the relative low speed of the vehicles, the scene blurring is comparable with that in the scenarios 2 and 1. Most of the information is already perceivable before processing. Processing often results in clearer and sharper pictures, thus a comfortable presentation. Examples of such sharpened images are given with the 8-bit images in figure 6.17 for scenario 4A and in figure 6.18 for scenario 4B. Especially in figure 6.18, the perception of the jeep is considerably improved.

Figure 6.17 file: M3007P18.IM8 / 8-bit with photopic filter,

date: 30-7-1990 / local time: 15:02:54,

session: 30.3 / scenario: 4A, site block: 42, fig.3.4B, PIN-code=7/IQ-code=71,

processing input range: 15-180 / contrast multiplier Gc=5.

Figure 6.18 file: M0608A08.IM8 / 8-bit with photopic filter,

date: 6-8-1990 / local time: 12:47:34,

session: 6.2 / scenario: 4B, site block: 42, fig.3.4B, PIN-code= 46 / IQ-code=81,

processing input range: 25-240 / contrast multiplier Gc=10.

Figure 6.18: 8-bit picture with vehicles in attack formation / scenario 4B. Top before processing, bottom after processing.

6.5 Low Light Level imaging

A two stage Image Intensified CCD-camera has been used during some night trials, to record still video pictures at very low light levels. The specification of this camera has been given in table 3.1.

Nearly all the pictures, taken at night with this II CCD-camera, are severely blurred by the 1 Hz flashlight that was used as aircraft beacon during the night trials. An example of such a picture is given in fig.6.19.

Figure 6.19: File: M0208N08.IM9 / image intensified without photopic filter,

date: 2-8-1990 / local time: 05:13:16,

session: 2.1 / scenario: 1L, site block: 227, fig.3.4A, PIN-code= 8/ IQ-code=40,

processing input range: 5-250 / contrast multiplier Gc=1.

Processing renders only some better contours of the black board in the upper right of the picture. The full range of grey levels is already present in the original picture, so any relevant range transformation is not possible. Also an effective local contrast enhancement cannot be carried out (see Gc = 1) because of the very low contrast dynamics (mainly black and white spots), which is present in the original picture.

Also by daylight, pictures could be taken with the II CCD-camera due to the fast gating utility in the first stage of the image intensifier tube (MCP part). The contrast resolution in the Image Intensified daylight pictures showed to be significant lower than in the 8-bit daylight CCD-camera pictures and equal or less than that of the monitor. In general, processing then results only in a more comfortable presentation of information that can already be perceived in the unprocessed picture. Unfortunately the image intensifier gain could not be fixed at a wanted low level during the trial. It has been shown afterwards that an as low as possible gain with a corresponding longer gating time can result in considerably better pictures.

An example of an automatic gain controlled image intensified daylight picture, recorded in Mourmelon, is given in fig.6.20.

Figure 6.20: File: M0808A23.IM9 / image intensified with photopic filter,

date: 8-8-1990 / local time: 10:02:27,

session: 8.2. / scenario: 3A, site block: 42/43, fig.3.4B, PIN-code= 8/ IQ-code=50,

processing input range: 50-255 / contrast multiplier Gc=1.

Cooling the sensor of the 12-bit camera limits the thermal generated noise to the specified level and results in a background limited imaging system. This allows long exposure times under low light level conditions. The photo in fig.6.21 represents a picture taken early in the morning with an exposure time of four seconds and yet with the illumination just up to a small fraction of the sensors saturation level (see input range).

The processing shows nonetheless that relevant information has been recorded and can be made perceivable by processing.

Figure 6.21: F.le: M0208N13.IM1 / 12-bit without photopic filter,

date: 2-8-1990 / local time: 05:19:54,

session: 2.1 / scenario: 1L, site block: 22, fig.3.4A, PIN-code= 8 / IQ-code=41/32,

processing input range: 40-450 / contrast multiplier Gc=2.

Page 78

Some of the images in table 6.1 have been assigned two values for its IQ-code. The first mentioned value corresponds with the value (for the corresponding image) given in the list of recordings (Appendix C) and in the list of processed images (Appendix D). These values have been determined on basis of the monitor displayed pictures. An eventual second value of the IQ-code has been chosen on basis of the (original) video-prints as they are used in this report. The codes are not always unambiguous; the effect of processing, for instance, might be appreciated between 1 and 2 or between 2 and 3. The final choice then can depend on the way of displaying the picture.

7 CONCLUSIONS AND RECOMMENDATIONS

- Processing results in a relevant improvement of the monitor perception of still video pictures for about 90% of the processed 12-bit pictures and for about 70% of the processed 8-bit daylight pictures.
- b Pictures blurred by smoke due to fires and/or blurred by dust, raised by fast-moving vehicles (scenario 3B and scenario 3A) benefited most from the dedicated image processing. Simple analysis shows that in general the transmission through smoke has been somewhat better than through dust, at Mourmelon. The transmission of dust clouds can change considerably within 10 to 20 seconds.
- c The contrast loss through dust clouds in pictures, taken immediately after sand bag explosions, is so large that neither before nor after image processing any information about the scene behind the dust cloud was observed and therefore no information had been recorded. However, within about 30 seconds after the explosion the transmission is already considerably improved, a significant effect of processing is observed as well.
- d The difference in performance of the 8-bit daylight and of the 12-bit camera can clearly be shown by, and only after, image processing. An improved camera performance is relevant therefore in combination with image processing.
- Pictures, taken with automatic gain control of Image Intensified CCD-cameras, are severely bloomed by flash light sources. Sometimes a solution might be found by optimizing the gating and gain controls. In daylight pictures the intensifier gain must be kept as low as possible.

No relevant effect in processing the image intensified pictures is observed.

f With high performance cameras, relevant 'still' pictures can be made at low light levels (with a better quality than with LLL cameras down to a limited light level).

B.1 THE PIN CODE

The PIN code (Picture Interest) is a one or two digit number, that is assigned to any of the image files. This number can be found in column 18 of the listing of recordings given in Annex C.

The first digit (if present) refers to a special class of images and the second to the interest of the picture. The interest of the picture may be determined by the effect of processing, to be expected, but may also refer to interesting aspects of the site, the trials or interesting battle field effects. Low quality pictures with few information may e.g. have a high interest number when they can be used for demonstration purposes of special effects or phenomena to be described.

A nice picture with a lot of information can be of low interest (PIN code = 5 e.g.), especially when the information already is presented in a clear and comfortable way and several specimen of this kind of pictures already are present in the data base. On the other hand, such a picture may have a high Image Quality (IQ) number (see paragraph B.3).

All the PIN code numbers have been determined by mutual arrangement of 2 or 3 independent observers.

The first digit of the PIN code refers to one of the following classes:

- 1 = image disturbed by camera movements
- 2 = condense on sensor surface
- 3 = dark picture (for determining noise level e.g.)
- 4 = over-exposed image
- 5 = ice on sensor surface
- 6, 7 and 8 are pictures, taken at the Mourmelon site, but not during the official battle field sessions. Pictures may nevertheless contain 'battle field' like aspects. These pictures are differentiated according:
 - 6 = pictures of this special category and simultaneously belonging to one of the categories 1, 2 and/or 5
 - 7 = pictures of this special category and simultaneously belonging to one of the categories 3 and/or 4
 - 8 = pictures of this special category, but not belonging to one of the categories 1 up to and including 5
- 9 = private pictures and/or pictures without any connection with the Mourmelon trials.

Most of the regular pictures do not belong to one of these categories and then have only a one digit PIN code number, which refers to the interest of the picture.

The list of image files, to be given in Annex C will contain no pictures out of categories 1, 6 and 9. All the categories are mentioned here in order to explain the differences between this list and the first (draft) list, distributed at the 'Soesterberg' meeting in October 1990 [5].

The second (or single) digit of the PIN code refers to the interest of the picture in the following way:

- 0 = completely unsuccessful pictures; will not be included in the final list of recordings.
- 1 = n.a.
- 2 = n.a.
- 3 = unsharp images; will not be included in the final list of recordings.
- 4 = bad quality and uninteresting pictures; will not be included in the final list of recordings.
- 5 = uninteresting pictures, because of missing any battle field effects and/or no effect of image processing is expected and/or many similar pictures are present in the data base.
 Nevertheless these pictures might have good image quality.
- 6 = moderate interesting, because of its frequent occurrence. Some effect of processing is expected.
- 7 = reasonably interesting pictures with respect to battle field effects or processing effects.
- 8 = large effect of processing expected and/or special battle field effect present.
- 9 = unique picture, because of its occurrence and/or processing effect.

B.2 SELECTIONS

The selections for the US-database and for the Final database have been made only by using the described picture interest (second digit in the PIN-code number or the single digit PIN-code number). In assigning the PIN-code, a wanted selection might have been taken into account.

B.2.1 Selection for the US-database

The selected images for (and transmitted to) the US-database are indicated by a letter 'd' in column 20 of the listing of recordings in Appendix C. These image files are available from the US-database.

The selection rules have been:

- a of class 0 (single digit PIN-code) images with PIN-code 6,7,8 and 9
- b of class 1 no images
- c of class 2 images with FIN-code 8 and 9
- d of class 3 images with PIN-code 7,8 and 9
- e of class 4 images with PIN-code 7,8 and 9
- f of class 5 images with PIN-code 8 and 9
- g of class 6 no images
- h of class 7 images with PIN-code 8 and 9
- i of class 8 images with PIN-code 7,8 and 9
- j of class 9 no images
- k of Image Intensified CCD images (extension *.IM9) the images with PIN-code 8 and 9

B.2.2 Selection for the final database

The selections for the final database (at FEL-TNO), according the here below given rules, are indicated with the letter 'r' in column 20 of the listing of recordings in appendix C. All the image files in the US-database also are included in the final database; the selection is somewhat extended; for the final database, the lowest PIN-code numbers are 1 lower than for the US-database.

For RSG15 nation members, the image files in the final database, coded with a 'r' and which are not available from the US-database, can be made available by a request to the author of this

report. In the final database, as described in appendix C, also all the processed images are included; some of these have low image quality and are not coded with a 'r'.

The selection rules for 'r' coded images in the final database have been:

- a of class 0 (single digit PIN-code) images with PIN-code 5,6,7,8 and 9
- b of class 1 no images
- c of class 2 images with PIN-code 7,8 and 9
- d of class 3 images with PIN-code 6,7,8 and 9
- e of class 4 images with PIN-code 6,7,8 and 9
- f of class 5 images with PIN-code 7,8 and 9
- g of class 6 no images
- h of class 7 images with PIN-code 7,8 and 9
- of class 8 images with PIN-code 6,7,8 and 9
- j of class 9 no images
- k of Image Intensified CCD images (extension * IM9) images with PIN-code 7,8 and 9

B.3 THE IQ CODE

The IQ code (Image Quality) is a two digit number describing the 'photographic' quality of the picture. This number can be found in column 19 of the listing of recordings given in Annex C. The first digit describes the image quality before processing. The second digit gives the effect of the dedicated image processing.

The first digit of the IQ code refers to the quality of the original picture before processing in the following way:

- 0 = completely unsuccessful image
- 1 = unsharp and/or blurred by camera movements
- 2 = condense or ice on the surface of the sensor
- 3 = dark picture or picture without any information, except some grass in the foreground.
- 4 = picture without any relevant information visible. The presence of only trees, grass (all kind of vegetation) and the sky with clouds is accepted to be of no relevance, even when these objects are clearly presented before processing.
- 5 = bad picture with some relevant information.
- 6 = relevant information clearly presented in local parts of the image; large parts may be blurred however by battle field effects.
- 7 = picture with reasonable photographic quality; yet small parts may be blurred by dust and/or smoke.
- 8 = nice picture; small battle field effects may be present, but will not disturb other relevant information.
- 9 = fully clear pictures; it is not expected, that image processing will result in image quality improvement.

The second digit in the IQ code number indicates the effect of the dedicated image processing in the following way:

- 0 = there is no effect of image processing; no new information has become visible, nor the already visible information is more clearly presented.
- 1 = no new information has become visible, but the image processing has resulted in a clear and sharp picture with a more clear and comfortable presentation of the visible information.

- 2 = some new information has become visible and a more clear presentation of all the information has resulted.
- 3 = remarkable (much) new information has become available and is clearly presented.

The IQ code number has been determined by a single observer or by mutual arrangement of two observers. The IQ code numbers of a limited selection have been determined by mutual arrangement of three observers. This limited selection can be used as a test case for a single observer. The image file names of this selection are given below with the corresponding code numbers.

| file name before processing | extension file name after processing | IQ code |
|--------------------------------|---|---------|
| 12-bit images : | | |

Page C.20 Appendix C: Listing of recordings in final database

LEGEND OF LISTING

filename extension *.IMn: original (unprocessed) images

see appendix A and C

extension *.Pxx: processed image of coresponding original

image with same name before extension.

scen scenario

pr date video print available (with print date)

Gc contrast multiplier

Vn(%) percentage determining the threshold for the adaptivity
Vn processor constant determining the adaptivity parameter.
Xmin lowest used grey level value of input range in processing
Xmax highest used grey level value of input range in processing
Ymin lowest used grey level value of output range in processing

Ymax highest used grey level value of output range in processing

IQ image quality code (see 4.4.4)

comments on trial aspects or processing aspects.
