Abstract

There is a recognized need for automated path planning for unmanned air vehicles (UAVs) and guided munitions. Evolutionary programming approaches provide an alternative to classical functional optimization methods with the capability of incorporating a variety of optimization goals, while tolerating vehicle constraints. In this work, we introduce an evolutionary flight path planning algorithm capable of mapping paths for free-flying vehicles functioning under several aerodynamic constraints. An air-to-ground targeting scenario was selected to demonstrate the algorithm. The task of the path planner was to generate inputs flying a munition to a point where it could fire a projectile to eliminate a ground target. Vehicle flight constraints, path destination, and final orientation were optimized through fitness evaluation and iterative improvement of generations of candidate flight paths. Evolutionary operators comprised of one crossover operation and six mutation operators. Several cases for air-to-ground vehicle targeting have been successfully executed by the evolutionary flight path planning algorithm under challenging initial conditions. A feasible path is typically found rapidly (<100 generations), with further optimization (~3000 generations) insuring a strike very near target center. These results clearly demonstrate that evolutionary optimization using can achieve flight objectives for air vehicles without violating limits of the aircraft.

I. Introduction

Autonomous free-flying entities such as unmanned aircraft, cruise missiles and other precision guided air vehicles are increasingly dependent on automatic control. As these devices become more sophisticated in their capabilities, corresponding task directives and potential applications also grow in complexity, thus demanding fast, efficient and independent

path planning systems applicable to entire families of such agents. One highly relevant scenario is the need for automated path planning within critical vehicle constraints for unmanned air vehicles (UAVs) and guided munitions for target-seeking and/or goal orientation operations. Necessary features of such a system include: rapid autorouting capability, incorporation of vehicular and environmental constraints into path generation, and the ability to efficiently perform path planning functions within strict time constraints¹.

Current path planning technologies do not fully achieve future demands for guided air vehicles^{1,2}. Specific deficiencies include:

- Many autorouters only address higher-level path planning behavior; vehicular dynamics and constraints are not fully considered,
- Many existing path planning methods are of little use in path planning in situations involving vehicle constraints, resulting in bottle-necks with many local minima³,
- The need for autorouting for 6 degree of freedom (dof) platforms under strict vehicle constraints has not been fully addressed⁴,
- Conventional path planners typically use a fixed path representation; such methods cannot self-adjust to problem complexity⁵,
- Accounting for time-varying or non-holonomic constraints in dynamic environments often hampers planner performance,
- Optimization criterion often are complex and subjective; many traditional planners optimize only with respect to the shortest path⁵ without full consideration of critical constraints.

Global planning approaches^{6,7} are in general complete in that if a path exists, it will be found, yet the computational expense grows with vehicle complexity. Although local methods such as potential field procedures^{8,9} are more efficient, they can become trapped in local

*corresponding author: rxv@po.cwru.edu

minima. In general, functional optimization methods have tendencies to become trapped within local minima, and may be difficult to implement on free-flying platforms since complexity grows exponentially with vehicle degrees of freedom¹⁰. Furthermore, enumerative techniques are susceptible to inefficiencies when dealing with complex vehicles due to size of search space.

A class of heuristic searching methods based upon simulated evolution known broadly as *Genetic Algorithms* (GA) has become very popular lately for discrete optimization problems characterized by many local minima in nondifferentiable, discontinuous or constrained problem spaces. These evolutionary techniques are population-oriented: successive populations of feasible solutions are generated in a stochastic manner following laws similar to that of natural selection. This contrasts standard programming techniques that normally follow a single trajectory repeatedly until a satisfactory solution is reached. In the evolutionary approach, multiple stochastic solution trajectories proceed simultaneously, allowing various interactions mimicking genetic exchange, thus progressing towards one or more regions of the search space. These approaches are justified by the fact that a population-oriented algorithm automatically stores a time-sampled replica of the profile of the function being optimized, providing important clues to its global structure. Additionally, evolutionary approaches can also easily be implemented on a massively parallel machine to achieve super-linear speed up with the number of processors.

Many previous path planners cannot accommodate a variety of optimization criteria or allow changes in these standards without changing the characteristics of the planner or the search map. Evolutionary approaches, on the other hand, can handle a variety of optimization goals and are very tolerant to the form of the evaluation function. Functions to be optimized need not be differentiable or continuous. Evolutionary path planning approaches are also flexible to changes in environment and are robust to uncertainties.

Evolutionary approaches provide an alternative form of path generation capable of incorporating a variety of optimization goals, while tolerating vehicle constraints. These benefits have led to the development of several evolutionary path

planners (a brief summary and reference list is presented in⁵). In this work, our past research^{5,11,12} in multi-dimensional path planning is expanded to create an *evolutionary flight-path planning algorithm* capable of mapping paths for free-flying vehicles functioning under a host of aerodynamic constraints. The generation of flight trajectories for air-to-ground targeting for autonomous munitions is selected as a benchmark situation to demonstrate the utility of the path planning genetic algorithm.

The organization of this paper is as follows: in **Section II** the dynamics of a candidate autonomous air vehicle are modeled, **Section III** gives a description of the representation used for encoding paths, **Section IV** enumerates work performed within evolutionary evaluation function to incorporate aerodynamic constraints and flight objectives, **Section V** delineates the genetic operators of the path planning algorithm, **Section VI** summarizes the operation of the path planner for air-to-ground target seeking, **Section VII** presents results of the algorithm when implemented on a candidate aircraft, and **Section VIII** briefly discusses conclusions, ongoing, and future work.

II. Air Vehicle Model Development

The general equations of motion of a 6 degree of freedom (dof) rigid airframe may be described through Newton's Laws in terms of the nomenclature enumerated in **Table 1**:

$$\tilde{F} = m \left(\frac{d\tilde{s}}{dt} + \tilde{\omega} \times \tilde{s} \right) \quad (1 \text{ a, b})$$

$$\tilde{M} = \frac{\partial(I \cdot \tilde{\omega})}{\partial t} + \tilde{\omega} \times (I \cdot \tilde{\omega})$$

Aerodynamic forces acting on an air vehicle, are often expressed in the form¹³:

$$\begin{aligned} \tilde{F}_A &= [C_f(\tilde{z})][Q_f] \\ \tilde{M}_A &= [C_m(\tilde{z})][Q_m] \end{aligned} \quad (2 \text{ a, b})$$

Where both [C] matrices are dimensionless coefficients which are functions primarily of aircraft state $\tilde{z} = (V, \alpha, \beta, p, q, r)$, and each [Q] is a product of flight dynamic pressure, and aircraft reference area or characteristic length, respectively. The system inputs, $u(t)$, include aerodynamic forces developed by actuator deflections and propulsive forces, and environmental effects, whose impact on the air vehicle may be reflected in state space form as:

Variable	Parameter Description
\tilde{F}	Total force vector acting on airframe
\tilde{M}	Total moment vector acting on airframe
\tilde{s}	Position vector of mass center of airframe
$\tilde{\omega}$	Angular velocity of airframe (body-fixed)
m	Air vehicle mass
I	Inertia matrix of air vehicle
$\delta p, \delta q, \delta r$	Elevator, aileron, and rudder deflections
V	Absolute vehicle airspeed (global)
u	Forward velocity (body centered)
v	Side velocity (body centered)
w	Downward velocity (body centered)
α	Angle of attack= $\tan^{-1}(w/u)$
β	Sideslip angle= $\tan^{-1}(v/u)$
p	Angular roll rate
q	Angular pitch rate
r	Angular yaw rate
ψ	Euler Angle 3
θ	Euler Angle 2
ϕ	Euler Angle 1
x_e	X position (global)
y_e	Y position (global)
H	Altitude (global)

Table 1 – Nomenclature (global refers to ground coordinate system, body-fixed refers to inertial frame attached to aircraft)

$$\tilde{\dot{z}} = A\tilde{z} + B\tilde{u} \quad (3)$$

The essential mode of operation for air vehicle autopilot systems is to move control surfaces (δp , δq , δr) in response to desired roll rate (p), pitch rate (q), and yaw rate (r) commands. Typical operation allows equations (1), (2) and (3), when operating under specific constraints, to be linearized in the form of (3).

Similar to the autopilot the evolutionary algorithm also plans functions based upon a linear airframe response. The actual control inputs to the system (i.e. control surface deflections) are generated and modified by the path planner through the evolutionary path generation process to achieve desired targeting objectives. Additionally, since the genetic algorithm also changes the time of each control input, the minimum time step is constrained by the frequency response characteristics of the actuators themselves. These inputs are integrated over time to produce the time history of the state variables, including aircraft roll, pitch and yaw rates. During real-time operation, these rates directly form inputs to the autopilot, which then directs the aircraft to follow the trajectory developed by the genetic algorithm.

As a case study for evolutionary flight path generation, an air-to-ground targeting scenario was chosen. In this scenario, a small airborne autonomous munition fires a kinetic energy projectile straight downward from its center of gravity to strike a ground target. The firing action of the munition is depicted in **Figure 1**, with global and body fixed reference frames delineated, along with the projectile trajectory. The task of the path planner was to generate a set of inputs which would fly the munition to a point where the projectile trajectory would strike as near as possible to the target center. For realistic depiction of targeting scenarios, the aircraft was forced into "glide mode" (forward thrust could not be generated), to provide a state analogous to endgame situations where engines may not respond quickly enough to reach a target at close range.

Figure 1

To develop realistic flight model path planning tests, the Flight Dynamics and Control Analysis (FDC) 1.2 toolbox for the MatLab/Simulink environment was used¹⁴. The FDC toolbox includes a complete non-linear model of a DHC-2 Beaver; a light, single engine, high wing aircraft. This model was modified to improve responsiveness, and more closely resemble the flight characteristics of autonomous airborne munitions.

The linearized model comprised of equations (1), (2), and (3) was implemented within the genetic algorithm to evaluate system flight performance during evolutionary optimization. The path planner modified control surface inputs (limited by the validity of the linearized model), and time step between control surface inputs (limited by actuator responsiveness) to produce an effective flight path to the target. In flight, roll, pitch, and yaw rates resulting from the

control inputs can be fed directly to an autopilot to guide the air vehicle along the path.

III. Multiresolution Flight Trajectory Representation

A fundamental aspect of any heuristic optimization is the specific structure of encoded information enabling iterative progression towards an ideal solution. For air vehicle flight trajectory generation, a *multiresolution binary tree* representation is introduced such that complex paths of higher dimensionality may be portrayed in a form allowing efficient evolutionary reproduction and mutation to produce entire generations of candidate flight trajectories.

Multiresolution methods have been used in signal and image processing to provide efficient data representation adapted to the complexity of the signal content, as well as in our own past work^{5,11,12} for path planning of autonomous robots with less stringent motion constraints. Furthermore, tree-like representations have seen extensive use in genetic programming¹⁵, particularly in situations where mutation is relied on to play a significant role in evolution^{16,17,18}. The algorithm implemented for automatic routing of autonomous air vehicles in this work utilizes a related approach to path representation. In addition to accurate path encryption, the use of iterative multiresolution path representation can greatly reduce expected search lengths for trajectory generation. If a successful path is found early in the search hierarchy (at a low level of resolution), further expansion of that portion of the path search is not necessary; the structure of the binary tree is thus internally optimized based upon problem complexity. This advantage is mapped into the search space and the string length is adjusted accordingly, enhancing precision and computational efficiency.

Within the binary tree, air vehicle flight paths are represented by hierarchically ordered nodes, each containing a specific set of control surface deflections, $\Delta i_n = (\delta p_n, \delta q_n, \delta r_n)$, accompanied by a time shift, Δt_n , to form a complete array of parameters, Δu_n , at each node. Δt_n represents the delay from the last input Δi_{n-1} , to the current input Δi_n . The tracking of all such nodes maps the total set of control inputs and time intervals piloting the air vehicle over the flight trajectory. These nodes are organized in a tree-like structure, as shown in the left section of Figure 2

2. The complete path from start to finish is reflected by this binary tree, with the n^{th} node corresponding to the input Δu_n , which is comprised of the control surface deflection Δi_n ,

occurring at the time $t = \sum_{j=0}^{j=n} \Delta t_j$.

The *in-order* traversal of this binary tree provides a sequence of knot points representing all control inputs over the flight trajectory from start to finish, as described by each P_i in the right section of Figure 2, shown with start (S) and end (G) points. Intermediate nodes in the figure are generated randomly, and may subsequently be perturbed, inserted, or removed to modify and optimize the path. The sequence of nodes defined by the bottom of Figure 2 is: (S = start, G = goal): S → P₄ → P₃ → P₅ → P₂ → P₆ → P₁ → P₈ → P₉ → P₇ → G.

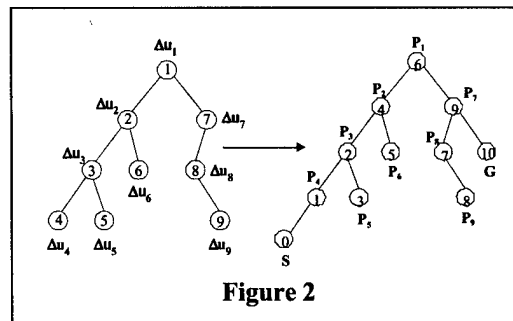

Figure 2

The trajectories represented through multiresolution binary trees do not correspond directly to actual aircraft flight paths; rather they *decode into a set of piloting commands, which may be passed directly to an autopilot for the air vehicle to maneuver itself along the flight trajectory*. Large arrays of candidate flight trajectories may be created rapidly using multiresolution path representation by generating and ordering random sets of control surface inputs (Δi), along with random time intervals (Δt) between inputs. Provided each Δi falls within acceptable control surface deflections, and each Δt is greater than or equal to the system actuator delay, the flight path will be achievable within vehicle actuator constraints. Vehicle flight dynamics and constraints, as well as path destination and final orientation, may be optimized through proper fitness evaluation and iterative improvement of collections of multiresolution flight paths.

IV. Evolutionary Fitness Evaluation

The evolutionary scoring of candidate flight trajectories demands several adjustments in the manner in which genetic algorithms are typically implemented. The primary hindrance lies in the fact that evolutionary optimization is classically a *static* process; dynamic constraints incurred by time dependent variables are not typically considered during evolutionary optimization. Indeed, the incorporation of time dependent dynamics such as those encountered in flight path planning requires the inclusion of entirely new sets of criteria for optimization. Classic methodologies, such as shortest path optimization or energy minimization, are inadequate because it is difficult to incorporate constraints such as those presented by the flight envelope. Interdependent variables whose parameters are fluctuating rapidly with time must all be optimized simultaneously. This execution subsequently requires mathematical integration over several candidate solutions within the evolutionary process. Novel methods of optimizing within the constraints of flight critical parameters, while still maintaining aircraft stability and attaining flight goals, are consequently vital to achieving evolutionary flight trajectory generation. Fitness evaluation functions therefore must be capable of accounting for a host of such factors simultaneously when scoring paths for evolutionary operation to improve future generations of solutions.

In order to functionally evaluate the fitness of multiresolution flight trajectories, actuator commands represented by the binary tree must first be decoded into a mapping of the actual flight motion of the aircraft itself. The decoded motion map may then be used to assess flight envelope violations, aerodynamic forces and constraints, and success in attaining flight objectives. Decoding requires a flight model of the air vehicle (Section II), an n node multiresolution path of flight inputs ($\Delta u_i, i=1, \dots, n$) (Section III), the aircraft's initial state (z_0), and passive actuator position (Δi_0).

The decoding process begins through the generation of a map of the aircraft's motion from its initial state, to the time (Δt_1) of the first actuator input (Δi_1) by: 1) solving and integrating equation (3) from $t=0 \rightarrow \Delta t_1$ with input $u=\Delta i_0$ to obtain all aircraft states (z) over the interval, 2) solving equations (2 a & b) using the derived states (z) to determine all applied forces (F) and

moments (M) from $t=0 \rightarrow \Delta t_1$, and 3) solving and integrating equation (1 a & b) to obtain a global map of all aircraft translational positions (s) and angular orientations (ω) from $t=0 \rightarrow \Delta t_1$. The end result of this decoding is the set of all states, global positions, and angular orientations of the aircraft following the flight trajectory from starting position to the first node on the multiresolution path. This process is repeated from node 1 to node 2 for $t=\Delta t_1 \rightarrow \Delta t_1 + \Delta t_2$, with the actuator input $u=\Delta i_1$, and continues until the

$$\text{interval } t = \sum_{j=1}^{j=n-1} \Delta t_j \rightarrow \sum_{j=1}^{j=n} \Delta t_j \text{ with input } u=\Delta i_{n-1}$$

is reached covering node ($n-1$) to node n . In the final decoding step, the actuator delay, Δt_{\min} is added to the time at node n to provide integration limits from node n to end node G for the final input Δi_n , hence providing a map of aircraft translational positions, angular orientations, and flight states over the entire multiresolution flight path.

Based upon the generated flight map, the aircraft path planner performs evolutionary fitness evaluation in three stages for the inclusion of all vital optimization criteria: **Stage 1** evaluates flight paths purely in relation to maintaining flight stability and avoiding flight envelope violations, **Stage 2** assesses path fitness in terms of non-critical flight parameters; *i.e.* constraints whose violation will not cause loss of aircraft control, yet whose limits ideally should not be exceeded, while **Stage 3** analyzes the path with respect to flight objectives by combining three factors: 1) proximity of path to desired goal, 2) orientation of aircraft, and 3) time of flight. The total evolutionary fitness for a given path is the weighted sum of scores from each stage, each of which is scaled according to its importance to flight goals.

In its implementation for ground vehicle targeting, a flight envelope consisting of limits on all flight parameters ($V, \alpha, \beta, p, q, r, \psi, \theta, \phi, x_e, y_e, H$) was developed based upon the aircraft's dynamics; flying within these limits maintains flight control and stability. **Stage 1** of fitness evaluation analyzed the decoded flight map for violations of these limits providing fitness score S_1 :

$$S_1 = \left[\sum_{i=1}^{i=k} V_i \right] * \rho_1 \quad (4)$$

where the summation represents the total number of states whose limits were exceeded, k is the amount of states, and ρ_1 is a scaling constant for normalization. For these experiments, the only relevant parameter in **Stage 2** fitness were altitude limits given by:

$$S_2 = [V] * \rho_2 \quad (5)$$

where the quantity in brackets reflects flight path altitude violations, and ρ_2 provides normalization. The air vehicle ideally should not infringe these altitude limits (e.g. too low exposes the plane to ground fire, too high causes uncertainty in targeting), but in the event that no alternative options exist, these limits may be exceeded.

Three factors comprised the **Stage 3** fitness:

$$S_3 = D(p) * \rho_{31} + O(p) * \rho_{32} + T(p) * \rho_{33} \quad (6)$$

$D(p)$ measures the distance (Euclidean norm) from the targeting point of the vehicle to the center of the target.

$$D(p) = \|\tilde{f} - \tilde{c}\| \quad (7)$$

where c is a vector containing the target center coordinates, and f is a vector of the current target of the aircraft given by:

$$\tilde{f} = \begin{bmatrix} x_{e_f} + H_f * (\tan \hat{\theta}_f \cos \hat{\psi}_f + \tan \hat{\phi}_f \sin \hat{\psi}_f) \\ y_{e_f} + H_f * (\tan \hat{\phi}_f \cos \hat{\psi}_f + \tan \hat{\theta}_f \sin \hat{\psi}_f) \end{bmatrix} \quad (8)$$

The subscript f indicates states at the final point of flight and the \wedge symbol represents the Euler angles transformed into angular orientations on the body fixed frame.

Since a hit from directly above the target is preferable to one at an angle, $O(p)$ is included in **Stage 3** as:

$$O(p) = \left[\tan^{-1} \left(\frac{\|\tilde{d}\|}{H} \right) \right]^{-1} \quad (9)$$

where d is the vector difference between the target center and the point directly under the aircraft projected onto the plane of the target. $O(p)$ thus approaches 0 as the angle or the target trajectory approaches 90° . The final fitness measure in **Stage 3** $T(p)$ is simply the normalized time of flight. Note that ρ_{31} , ρ_{32} , and ρ_{33} are scaling constants.

Therefore, for a path (p) represented by an ordered set of nodes from beginning to end, the total evolutionary fitness score, $F(p)$ is defined as the sum of each of the stages, or:

$$F(p) = S_1 + S_2 + S_3 \quad (10)$$

V. Evolutionary Operators

The use of multiresolution representation with variable length encoding for air vehicle trajectories introduces many unique opportunities for evolutionary operation with respect to the binary tree structures. Given that each node Δu , represents a set of control inputs occurring at a specified time with respect only to the preceding node, intermediate nodes may be freely interchanged with those from binary trees of other candidate trajectories, allowing infinite crossover possibilities between individuals within a generation. Furthermore, this same representation enables a host of mutation possibilities; the insertion and removal of nodes, as well as random or directed perturbation of existing nodes, may be applied without any loss of generality in path representation. Evolutionary operators utilized by the flight path planner expanded upon our past work⁵ to generate one crossover operator, five random mutation operators, and one "intelligent" mutation operator suitable for aircraft targeting trajectory optimization. Operators implemented to manipulate genetic material encoded within the intermediate nodes of trajectory representation consisted of:

- **Swap-Subtree Crossover:** combines two paths to reproduce two new ones by selecting a node at random from each parent, and exchanging subtrees branching from that node in their offspring. **Figure 3** delineates crossover operation, (one parent in white; its mate in black), where the "X" marked nodes are selected. The binary trees may possess different numbers of nodes, and the subtrees swapped may have different topologies and could map different portions of corresponding parent trees. The practical impact of this operation will be to exchange sets of inputs

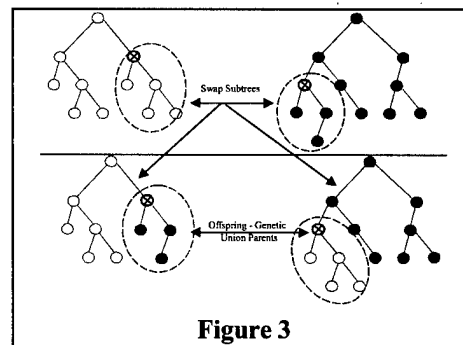

Figure 3

between candidate paths.

- **Perturb 1 Mutator:** randomly selects a node (n) in the binary tree and perturbs its contents (Δu_n) a small amount. This operator allows for fine tuning of acceptable, but not ideal, paths by making small changes in control surface deflection and input time for path modification.
- **Perturb 2 Mutator:** randomly selects a node (n) in the binary tree and perturbs its contents (Δu_n) a large amount. This mutation makes significant alterations in flight trajectory, ideally to change an infeasible path into a feasible one, or to move an inaccurate path much closer to its target.
- **Swap-Node Mutator:** exchanges the contents (Δu) of two randomly picked nodes in the binary tree, shown in Figure 4.
- **Insert-Node Mutator:** creates a new intermediate path input (Δu), by inserting a node into the binary tree, shown in Figure 5.

- **Flip Mutator:** changes the sign of Δi within a randomly picked node
- **Fix Mutator** ("intelligent" mutation): operates in a similar manner to the Perturb 2 Mutator, except that its operation is not random. Within the selected binary tree, inputs Δu are changed specifically in relation to states violating flight constraints. For example, a binary tree mapping a flight path with too great a pitch angle θ , will be fixed by manipulating deflections within Δi such that θ is reduced for that section of the flight. The operation of this mutation is designed to fix input/output relationships of completely infeasible paths by altering the input and time of input, forcing the path into feasible regions.

VI. Evolutionary Target Seeking Implementation Process

Figure 6 outlines the implementation process for the evolutionary generation of ground targeting trajectories for air vehicles. Since certain evolutionary operators (Section V) are best suited to correcting infeasible paths, while

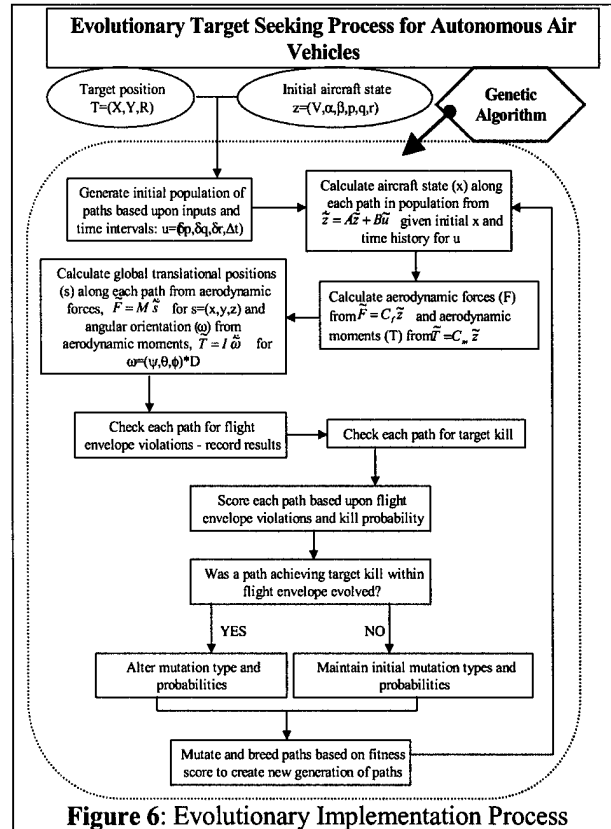

Figure 6: Evolutionary Implementation Process

others optimize feasible paths for greater accuracy, selection probabilities of each are adjusted once a target strike is achieved.

VII. Implementation Results

Utilizing the fixed wing aircraft model (Section II), evolutionary fitness scoring routines, and operators, the multiresolution aircraft path planning algorithm was implemented for optimal trajectory generation for ground target seeking. The movements of three control surfaces (elevator, aileron, and rudder) were optimized to develop a trajectory for the vehicle to reach a position such that its firing trajectory would strike a circular land based target of 2.5m radius. Actuator delay was set at $\Delta t_{\min}=0.25$ sec, with input allowable at $t=0$, and an initial $V=45$ m/s. Elementary targeting scenarios were run for very simple targeting tasks in a LINUX C++ programming environment. Following these simple cases, the air vehicle was assigned a set of challenging initial conditions including: β and θ directed away from its target, and α very near its allowable limit (an aircraft passive state). Sample results for initial populations varying from 50 to 70 individuals, a mutation probability

of 0.65, and a crossover probability of 0.35 are shown in Figures 7 to 10.

Figure 7 shows frontal, lateral, and aerial views of critical munition positions along the path evolved to strike a target 30m directly in front (X dimension) and 100 m below (Z dimension) the air vehicle's initial position. Dashed lines in the lateral and top views show the projectile trajectory. For this situation, the path planner created a trajectory piloting the vehicle to an orientation allowing accurate target strike (0.027m from target center) in 0.59 sec of flight time. The angular orientations of the

aircraft through flight (in radians) versus time are plotted in the lower right corner, while a logarithmic (base 10) plot of the best candidate in each generation versus the generation count is shown in the lower left (the flat line indicates the minimum fitness score necessary to strike the target).

Figures 8, 9, and 10 show successful targeting paths for varying goal positions lateral to the aircraft (Y dimension). The target is not shown in the aerial views in Figures 9 and 10 for better visualization of the aircraft, although the viewable portion of the projectile trajectory is

IC: Initial $\alpha, \beta, \theta, 2.5$ m rad. target 30m x, 0m y
Evolutionary Evaluation: 500 Generations, Target acquired @ ~100
Output: 0.59 sec flight, target pt. 0.027m off center

Figure 7

IC: Initial $\alpha, \beta, \theta, 2.5$ m rad. target 30m x, 5m y

Figure 10

still shown. Specific information for each run including: target position, generations necessary for target acquisition, total number of generations, time of flight, initial conditions and final strike point is enumerated at the top of each figure. In each of these runs, the target position forced the angular orientations allowing accurate target strike; most notably in **Figure 10** where roll and pitch angles are combined to achieve a firing trajectory 0.01m off a target center 10m lateral to plane starting position.

VIII. Conclusions

The results presented in **Section VII** demonstrate that evolutionary flight path optimization using multiresolution representation can achieve flight objectives without violating limits of the aircraft. Several cases for air-to-ground vehicle targeting have been successfully executed under challenging initial conditions. In most situations, a feasible path is found rapidly (<100 generations), although further optimization is necessary to insure a strike very near target center. Future work plans include planning for target motion through optimization of intercept point, while current efforts involve the training of

neural networks to reproduce generated flight trajectories for instantaneous reaction.

EGLIN AIR FORCE BASE, FLORIDA

11 July 2000

MEMORANDUM FOR AFRL/CA-N

FROM: AFRL/MNGN

SUBJECT: Request for Review and Clearance

1. Request review and approval of the attached presentation. Pertinent information is as follows:

Title: "Evolutionary Path Planning for Autonomous Air Vehicles using Multiresolution Path Representation"

Author(s): Vaidyanathan, Ravi; Prince, Troy S. (Orbital Research, Inc.); Hocaoglu, Cem (State Univ of New York at Stony Brook); Quinn, Roger D. (Case Western Reserve University).

Submission: AIAA Missile Sciences Conference; Monterrey, CA; Nov 2000.

Sponsor: AIAA

Distribution and Classification of Proceedings: Unclassified, DTIC. Paper will be marked for Distribution Statement A, Unlimited Distribution.

Submission Date: 11 Jul 2000

No Foreign Nationals will be in attendance.

2. The material contained in the attached presentation is technically accurate, unclassified, and suitable for public release.

3. Even though key words that appear on the Militarily Critical Technologies List (MCTL) are included in the presentation, the particular aspect of technology which this presentation addresses is not included as part of the MCTL and will not result in the transfer of any militarily critical technology.

4. Please contact Mr. Johnny Evers, AFRL/MNGN, 882-2220, ext. 3330, if you have any questions.

SANDRA M. LEFSTAD
Chief, Advanced Guidance Division
