ACKNOWLEDGMENTS

Being a graduate student at the Department of Computer and Information Science, Indiana University-Purdue University-Indianapolis has been a great learning experience for me. The knowledge gained will be valuable to me for the rest of my life.

I would like to take this opportunity to thank the many people who have helped make this thesis possible.

First and foremost, I would like to thank Professor Rajeev R. Raje, my advisor, for his constant encouragement and guidance through the course of my graduate studies and thesis. His immense knowledge and insights provided a strong foundation for this thesis. He constantly challenged me to achieve greater heights and realize my full potential. Dr. Raje, I thank you once again.

My special thanks to Professor Andrew Olson for being on my advisory committee and providing me guidance during critical periods of my thesis. His painstaking efforts to review my thesis and work are greatly appreciated.

I would like to thank Professor Yung-Ping Chien for being on my advisory committee and providing valuable inputs towards the thesis.

Special thanks to my colleague, Muris Ridzal, for his assistance in the testing of the URDS prototype.

I would like to thank the U.S. Department of Defense and the U.S. Office of Naval Research for supporting this research under the award number N00014-01-1-0746.

Many thanks to the faculty, staff and all my colleagues at the Department of Computer and Information Science for their cooperation and goodwill.

Finally, I would like to thank my parents, and my husband Kishan Siram for their love, encouragement and support.

ABSTRACT

Siram, Nanditha Nayani, M.S., Purdue University, May 2002. "An Architecture for the UniFrame Resource Discovery Service". Major Professor: Rajeev Raje.

The software development for any large-scale, Distributed Computing System (DCS) is a major challenge. One solution to address the design complexity of a DCS is the "UniFrame" approach. UniFrame provides a comprehensive framework unifying existing and emerging distributed component models under a common meta-model that enables the discovery, interoperability, and collaboration of components via generative software techniques. This thesis presents an architecture and implementation for the resource discovery aspect of this framework, called the UniFrame Resource Discovery Service (URDS). The proposed architecture addresses the following issues: a) the dynamic discovery of heterogeneous software components which offer and utilize services, and b) the selection of components meeting the necessary functional as well as non-functional requirements (such as desired levels of QoS Quality of Service). The thesis also compares the URDS architecture with other Resource Discovery Protocols, outlining the gaps that the URDS is trying to bridge. In the URDS the native registries/lookup services of various component models are extended to be 'active' (i.e. listen/respond to periodic multicast announcements) and also have introspection capabilities to discover not only the instances but also the specifications of the components registered with them. "Services" in UniFrame are implemented in different component models and described by their UniFrame specification outlining the computational, functional, cooperational, auxiliary attributes and QoS metrics. The URDS security model provides for the authentication of the principals involved, an access control to multicast address resources, and an encryption of data transmitted.

1. INTRODUCTION

Component-based software design has been a growing trend in the development of software solutions for distributed systems. The software realization of a distributed computing system (DCS) is typically achieved by using the notions of independently created and deployed components, with public interfaces and private implementations, loosely integrating with one another to form a coalition of distributed software components. Assembling such systems requires either automatic or semi-automatic integration of software components, taking into account the QoS (Quality of Service) constraints advertised by each component and the collection of components. The UniFrame Approach (UA) [RAJ01, RAJ02] provides a framework that allows an interoperation of heterogeneous and distributed software components and incorporates the following key concepts: a) a meta-component model (the Unified Meta Model – UMM [RAJ00]), with a associated hierarchical setup for indicating the contracts and constraints of the components and associated queries for integrating a distributed system, b) an integration of the QoS at the individual component and distributed application levels, c) the validation and assurance of the QoS, based on the concept of event grammars, and e) generative rules, along with their formal specifications, for assembling an ensemble of components out of available component choices. The UniFrame approach depends on the discovery of independently deployed software components in a networked environment. In this thesis, an architecture and implementation for the resource discovery aspect of this framework, called the UniFrame Resource Discovery Service (URDS) is described. The URDS architecture provides services for an automated discovery and the selection of components meeting the necessary QoS requirements specified by a component assembler or system integrator. URDS is designed as a

Discovery Service wherein new services are dynamically discovered while providing component assemblers with a Directory style access to services. The result of using URDS, the UniFrame Approach (UA) and its associated tools is a semi-automatic construction of a distributed system.

1.1 Problem Definition and Motivation

There has been an increase in the development of technologies for the dynamic discovery of resources such as printers, mail-boxes, memory space and disk space that are available in every network. The growth in the popularity of portable devices such as laptops, PDAs, and cell phones which require configuration each time they attach to a new network segment has also sparked the need for developing protocols which facilitate spontaneous discovery and enable such devices to connect to these resources. However, research in the area of dynamic discovery has been focused solely in the area of discovering and configuring “devices”.

There is a need to bring about a change in paradigm from dynamic discovery being purely “device” based to a “service” based approach. “Service” here refers to applications developed using different distributed computing models, with public interfaces and private implementation, that perform computation or actions on behalf of client users. Several directory-based approaches exist for discovering services. These directory-based discovery services are built around the publish-subscribe model wherein services publish their interfaces with a central directory and clients discover these services by contacting the directories. Prominent among these are Universal Description, Discovery and Integration (UDDI) registry [UDD00], CORBA Trader Services [OMG 00], Java™ Remote Method Invocation (RMI) [ORF97], Distributed Component Object Model (DCOM™) [MIC98], etc. However, almost all of these directory/registry services do not assume the presence of other models. The interoperability, which they provide, is limited mainly to the underlying hardware platform, operating system and/or

implementational languages. This defeats the underlying goal of discovery being universal.

The problem that needs to be solved is to provide for a “service” discovery model that is dynamic and encompasses services developed in diverse distributed computing models.

The motivation for creating a universal dynamic resource discovery service is as follows: The software systems in any organization constantly undergo changes and evolutions. Moreover, these organizations may be geographically (or logically) dispersed necessitating a communication between independently created and deployed components, loosely integrating with one another to form a coalition of distributed software components. In order to deal with the constant evolutions and changes in the software systems, there is a need to rapidly create software solutions for distributed environments using a component-based software development approach. The solution of decreeing a Common Off The Shelf (COTS) environment, in an organization, will require creating an ensemble of heterogeneous components, each adhering to some model. If reliable software needs to be created for a DCS by combining components, then the quality of service offered by each component needs to become a central theme of the software development approach. Assembling such systems requires either automatic or semi-automatic integration of software components.

The key to automating the process of assembling DCS is to have an infrastructure, that allows for a seamless integration of different component models and sustains cooperation among heterogeneous components. Such an infrastructure will need to provide services to dynamically discover the presence of new components in the search space which offer and utilize services, and allow for the selection of components meeting the necessary functional as well as non-functional requirements (such as desired levels of Quality of Service). The infrastructure will also need to provide translation capabilities for specific models. The UniFrame Resource Discovery Service (URDS)

architecture, proposed in this thesis, is designed to provide this infrastructure to support universal dynamic resource discovery.

1.2 Objectives: Statement of Goals

The objectives of this thesis are:

- To bring about a shift in paradigms in the field of spontaneous resource discovery from a “device” based discovery approach to a “service” based discovery approach. Traditionally the field of dynamic resource discovery has been oriented towards spontaneous discovery of “devices”. This thesis aims to use discovery techniques to detect “services” developed in diverse component models. The thesis also aims to propose a framework wherein the dynamic resource discovery service will be coupled with a container for adapters to provide integration broker capabilities.
- To propose an architecture structured as a platform independent design specification for the URDS. The architecture will address the issues of scalability, adoptability, security and fault tolerance and aim to provide an encompassing view of the end service, computation and middle support required. The architecture will provide details of the information specifications, configurations of the interacting components including detailed algorithms of the functions required to support distributed interaction between objects and an analysis of these algorithms.
- Develop a proof-of-concept prototype for the URDS and validate the principles behind URDS.
- Indicate the inter-relations between the URDS and other components of UniFrame.

1.3 Contributions of this thesis

The contributions of this thesis are:

- Provides a comprehensive survey of the existing resource discovery services detailing their characteristics. The survey outlines the purpose of existing resource discovery services and establishes the need for the development of a resource discovery service which is capable of bridging the interoperability gap that is inherent in current discovery services.
- Proposes a novel approach to discovering services dynamically based on the concept of extending the native registries of different component models to be ‘active’ and ‘introspective’. The architecture proposed also automates the process of selecting components based on their computational, cooperational, auxiliary attributes and QoS metrics.
- Proposes a framework wherein the dynamic resource discovery service can be coupled with a container for adapters to provide integration broker capabilities.
- Proposes a platform independent architectural model for the UniFrame Resource Discovery Service. The following aspects of the URDS architectural model are presented at appropriate levels of abstraction:
 - *Information Aspect* describing the scope and nature of information specifications.
 - *Computational Aspect* describing the configurations of the interacting computational objects.

- *Engineering Aspect* wherein the mechanisms and functions required to support distributed interaction between objects is described.
- *Technology Aspect* wherein a detailed description of the components and the technology used to realize the system is presented.

1.4 Organization of this thesis

This thesis is organized into 6 chapters. The introduction of the problem domain, problem statement, definition of goals and the contributions of the thesis were presented in this chapter. Chapter 2 provides a survey of the existing resource discovery services and establishes the need for a meta-level “service” based discovery service. Chapter 3 provides an overview of UA and URDS and outlines the design concepts on which the URDS architecture is based. Chapter 4 describes the URDS architecture focusing on the high-level design, and the algorithms and interactions of the components that comprise the architecture. Chapter 5 describes a prototype implementation and its validation through experimentation. Finally, this thesis concludes with a discussion of the features of URDS in comparison with other resource discovery services in Chapter 6.

2. BACKGROUND AND RELATED WORK

This chapter provides a survey of existing resource discovery protocols under the categories of directory-based and discovery-based services. Section 2.1.1 describes various directory services. Section 2.1.2 describes various discovery services. A comparison between the features of directory-based and discovery-based resource discovery services is presented in Section 2.1.3.

2.1 Resource Discovery Protocols

Resource Discovery Protocols perform the task of identifying resources on a network and making these resources accessible to users and applications. Resources may include various services such as web services, component services, or devices such as conventional computers, hand held computers (PDAs), peripheral devices such as printers, and specialized network devices such as digital cameras, and telephones. The protocols for resource discovery are presented under the following two categories:

- Lookup (Directory) Services and Static Registries.
- Discovery Services.

The primary difference between ‘discovery’ and ‘lookup’ services is that a discovery service usually supports lookup, but many ‘lookup’ services do not support discovery [MCG00]. A detailed discussion of these categories is presented in the following subsections.

2.1.1 Lookup (Directory) Services and Static Registries

Lookup as defined by McGrath in [MCG00] refers to the “*process of locating a specific object or resource either by exact name or address, or by some matching criteria. Lookup is ‘passive’, in that it is initiated by a seeker, and requires the existence of some directory or other agent to answer the request. Lookup may be done in a statically configured environment; the directory need not be writable*”. Some examples of lookup services include Universal Description, Discovery and Integration (UDDI) registry [UDD00], CORBA Naming and Trader Services [OMG00, OMG01], Light Weight Directory Access Protocol (LDAP) [WAH97], Domain Name Service (DNS) [MOC87], X.500 [COU01] and GNS [COU01]. The following subsections provide a brief discussion of the above-mentioned ‘lookup’ services.

2.1.1.1 Universal Description, Discovery and Integration (UDDI) Registry

Universal Description, Discovery and Integration (UDDI) as defined in [UDD00] is a “*specification for distributed Web-based information registries of Web services i.e., UDDI specifications define a way to publish and discover information about Web services.*” The term “Web service” is defined in [UDD00] as - “*A Web Service describes specific business functionality exposed by a company, usually through an Internet connection, for the purpose of providing a way for another company or software program to use the service*”. Since UDDI aims at providing an open specification and set of tools for discovering Web Services on the Internet it utilizes the World Wide Web Consortium (W3C) [W3C] standard service definition language - Web Services Description Language (WSDL) [CHR01]. WSDL is an XML [BRA00] grammar for describing the capabilities and technical details of Simple Object Access Protocol (SOAP) [BOX00]-based web services. UDDI data is hosted by operator nodes, which are companies that are committed to running a public node that conforms to the specifications governed by the uddi.org consortium. Three public nodes exist which include Microsoft, IBM and HP whose contents are synchronized regularly.

The components involved in the UDDI architecture are the Web Service Providers, Service Requesters and Service Brokers (UDDI Business Registries).

The fundamental operations performed by these components are:

- Service providers deploy and publish services by registering them with the Service Broker. The interaction with the Service Broker and the registration process is done using the UDDI API. The UDDI APIs are in the form of SOAP-based web services that fall into two categories, namely inquiry and publishing. To invoke these APIs SOAP message is sent with the appropriate body content.

Example: `<find_business generic='1.0' xmlns='urn:uddi-org:api'>`

`<name>XYZ industries </name>`

`</find_business>`

The SOAP response contains all businesses that match criteria and registered services for each business in the form of XML data structure.

- Service requestors find services by searching the Service broker's registry of published services. Locating services is done via a combination of UDDI and Web Services Description Language (WSDL).
- Service requestors bind to the Service provider and consume the available services. Binding to Service Providers leverages information specified in WSDL and the SOAP protocol.

2.1.1.2 CORBA Trader Services

The CORBA Trader Service [OMG00] provides “Yellow Pages” for objects, enabling them to publicize/request services. The Trader Service facilitates ‘matchmaking’ between service providers (*Exporters*) and service consumers (*Importers*). The exporters, which are CORBA objects, use the interfaces provided by the Trader Services to register their services. The information about the service registered with the Trader comprises of

a reference to the object providing the service, information about the operations supported such as their names, parameters and result types, and other properties describing the capabilities of the service. The Trader stores the type descriptions in a repository and also maintains a database of service objects. The clients or importers, which are CORBA Objects, can query the Trader for a list of services registered with it or make a request for a particular service by specifying the service type and properties desired in the service. The trader will find a match for the client based on the search criteria. Traders can be linked to form a *federation of traders*. This linkage of traders allows a trader to make the offer spaces of other traders become implicitly available to its own clients. The Trader Service does not guarantee that the registered objects are available. It also does not provide notification and security features and needs to be augmented with the CORBA event services and security services to provide these features. The Trader Service is defined as CORBA interfaces, and all advertisements, requests, and replies are CORBA objects. Since the Trader Services depends on CORBA, all participants must be cast as CORBA objects and use CORBA protocols.

2.1.1.3 X.500 and Lightweight Directory Access Protocol (LDAP)

LDAP (Lightweight Directory Access Protocol) is a software protocol for enabling anyone to locate organizations, individuals, and other resources such as files and devices in a network, whether on the public Internet or on a corporate intranet. LDAP is a "lightweight" (smaller amount of code) version of Directory Access Protocol (DAP), which is part of X.500 [ITU97], a standard for directory services in a network. The directory service is organized like a tree and is referred to as a Directory Information Tree (DIT)[WIL99]. The LDAP data format is structured as a scalable hierarchy of name spaces, with an added flexibility to form a relational grouping of *entries*. An entry in the LDAP server is analogous to a record in a relational database. LDAP is extensible, and allows storage of different kinds of information. LDAP's query model allows for search and retrieval of entries stored in the LDAP directory server. Since LDAP is organized as a hierarchy, the queries can be limited to particular parts of the hierarchy. Though the

design is scalable queries over very large domains are likely to be very inefficient. LDAP does not have any built in security model and relies on other network services for this purpose. LDAP does not specify protocols for “spontaneous” discovery and because of the complexity; it may not be well suited for either near real-time discovery, or for very large numbers of services [MCG00].

2.1.1.4 Global Name Service (GNS) and Domain Name Service (DNS)

Global Name Service [COU01] is designed to provide facilities for resource location, mail addressing and authentication. GNS manages a naming database that is composed of a tree of directories holding names and values.

Domain Name System (or Service), [MOC87], is an Internet service that translates domain names into IP addresses. The DNS protocol provides static database of name-address maps, which is hierarchically partitioned. The naming data is replicated and cached in order to achieve scalability. Recent extensions to DNS support a very limited set of service types and a few attributes that can be used to search [GUL96]. The types of queries supported by DNS include host name resolution and reverse resolution, mail host location, host information and well-known services information [COU01]. DNS is a trusted service, security is provided by controlling access to a few privileged users. Arbitrary user applications may not add or modify the DNS database.

2.1.2 Discovery Services

“Discovery” refers to the spontaneous process, in which resources or services ‘discover’ other resources on the network, and present themselves to these other resources.

Several protocols exist for service discovery, prominent among which are: Service Location Protocol (SLP) [GUT99b], JINI [SUN01a], Ninja Project: Secure Service Discovery Service (SSDS) [CZE99, NIN02], Salutation [SAL, SAL99a, SAL99b], Bluetooth [BLU], Universal Plug and Play (UPnP) [CHR99, UPNP99], and Simple Service Discovery Protocol (SSDP) [GOL99].

The following sections provide an overview of the above-mentioned discovery services.

2.1.2.1 Service Location Protocol (SLP)

SLP Version 2 [GUT99a] is an Internet Engineering Task Force (IETF) standard framework for resource discovery. SLP architecture comprises of the following components:

- *User Agents (UA)*: UAs perform service discovery on behalf of clients.
- *Service Agents (SA)*: SAs advertise the location and characteristics of services.
- *Directory Agents (DA)*: DAs act as directories which aggregate service information received from SAs in their database and respond to service requests from UAs.

DAs can be replicated or organized as hierarchical or graph of domains.

Discovery of DAs by UAs and SAs can be implemented in following configurations:

- *Active Discovery*: SAs and UAs multicast SLP requests.
- *Passive Discovery*: DAs announce their presence by periodically multicasting advertisement messages.
- *Dynamic Host Configuration Protocol (DHCP) Options for SLP* [PER99]: UAs and SAs can locate DAs using DHCP wherein DHCP servers configured with this option distribute the DA addresses to agents that require them.

SLP configuration allows the following two modes of operation [GOV00]:

- *Without DAs*: This requires no administration. UAs multicast or broadcast service requests to SAs, which are listening on well-known ports. When a match is found SAs respond to the UAs using unicast.
- *With DAs*: The protocol is more efficient, in this configuration. The UAs, SAs and DAs are configured as members of a scope and communication takes place between them only if they support the same scope. UAs and SAs communicate with DAs, which are listening on well-known ports using unicast messages.

Services are advertised using a “Service URL” [GUT99a] and a “Service Template”[GUT99c]. The Service URL comprises of the IP address of the service, the port number, and path. Service Templates specify the attributes that characterize the service and their default values. Service requests may match according to service type or by attributes. SLP supports fairly powerful syntax for attribute matching based on templates and LDAPv3 predicate [WAH97]. SLP supports authentication, but does not specify it. It does not support encryption.

2.1.2.2 JINI

JINI is Java based framework for spontaneous discovery developed by Sun Microsystems. [EDW99] JINI architecture [SUN01a] is similar to SLP. However, JINI is very tightly bound to the Java environment. Each JINI device is assumed to have a Java Virtual Machine (JVM) running on it. JINI uses Java Remote Method Invocation (RMI) [RMI] protocol for communication, which supports exchange of serialized Java objects. The main components of a JINI system and their functions are:

- *Service*: A service is a logical concept defined and identified by a Java interface. The publicly visible part of the service, which is downloaded by the clients, is referred to as the “service object” or “service proxy”. A service registers this “service object” or “service proxy” with the Lookup service.

- *Client*: The client contacts the Lookup Service requesting a service and the Lookup service returns it the “service object” or “service proxy” which is copied to the client’s JVM and any further communication with the service by the client is conducted through the proxy. The client request is basically a simple template for matching string attributes. However, the request and the matching must be implemented as Java objects, following JINI specified interfaces.
- *Lookup Service (Service Locator)*: The Lookup Service serves as a directory of available services. Lookup Service listens on a well-known port for unicast or multicast messages. When Lookup service gets requests from services to register them or from clients requesting services, it returns them a “registrar” object, which serves as a proxy to the Lookup Service and runs on the service’s or client’s JVM. Any requests, which are to be made of the Lookup service, can be made through the proxy “registrar”.

The JINI Discovery protocol is used by JINI components (services, clients, lookup services) to locate other relevant JINI components in the network. The discovery process operates in the following two modes:

- *Multicast*: The discovery processes, in this mode are categorized as *aggressive*, *lazy* and *peer lookup*. During *aggressive discovery* a JINI component transmits probes at a fixed interval for a specified period, or until it has discovered a sufficient number of Lookup services. Aggressive discovery only happens at component initiation time. After completion of aggressive discovery the component enters *lazy discovery*, where it listens for announcements sent at intervals by lookup services. During lazy discovery a lookup service both listens for announcements by other lookup services and sends its own announcements at the required intervals. *Peer Lookup* [GOV00] is mentioned in the JINI specification as a technique used by clients to discover services in the absence of a lookup service. Clients multicast request packets and they receive direct

response from the services from which the clients can select the services they are interested in and drop the rest.

- *Directed*: In this mode the components use a directed discovery process in which the components have a list of lookup services to discover with which they try to establish connection.

Other features of the JINI architecture include the concept of *Leasing*, *Remote Event Notifications* and *Transactions*. *Leasing* mandates that all advertisements and registrations are valid only for a specific period of time thus forcing all clients and services to renew their leases periodically. Leases ensure that JINI recovers from crashed entities as these are automatically purged from the lookup services when the lease expires and periodic renewal of leases by entities rebuilds the global state in case of a Lookup Server failure. *Remote Event Notifications* allows an object to transmit notifications of events that have occurred within the object to other objects, which may have registered their interest in such events. *JINI Transactions* provide for a set of wrapped operations wherein an entire set of operations succeeds or fails without scope for partial success.

Some of the drawbacks of the JINI architecture include a limited filtering mechanism as when compared to other services like LDAP, SLP, CORBA Trader Service, or other XML based approaches. JINI cannot interoperate with any other protocol or language environment. The devices must either implement a JVM, or else use a proxy. JINI security is based on the weak security provided by Java and cryptography is not mandatory.

2.1.2.3 Ninja Project: Secure Service Discovery Service (SSDS)

The SSDS [CZE99, NIN02] is part of the Ninja research project at University of California, Berkeley. The main components of the SSDS system and their function in the discovery process is as follows:

- *Service Discovery Service (SDS) Servers:* SDS Servers are organized into hierarchical domains (domain specifies their network extent). The servers periodically multicast authenticated messages containing the multicast address for sending service announcements. The SDS servers cache the service descriptions that are advertised in the domain.
- *Services:* The Services listen for SDS Server announcements and multicast the service descriptions to the multicast address using authenticated, encrypted, one-way service broadcasts.
- *Clients:* Clients discover the SDS server for their domain by listening to a well-known SDS global multicast address. A client uses Authenticated RMI [CZE99, WEL] to connect to the SDS server and submits a query in the form of an XML template.
- *Certificate Authority (CA):* The SDS uses certificates signed by the CA to authenticate bindings between principals (components in the SDS system) and their public keys.
- *Capability Manager (CM):* The SDS uses capabilities as an access control mechanism to enable services to control the set of users that are allowed to discover their existence. The CM generates and distributes capabilities to all the users.

The SSSDS shares similarities with other discovery protocols, with significant improvements in reliability, scalability, and security. SSSDS is implemented in Java and uses Java-RMI for remote calls. It uses XML for service description and location.

The protocol is designed as an exchange of XML “documents”, and service location is implemented by matching of XML tags [CZE99, HOD99]. SSSDS provides extremely strong mandatory security: all parties are authenticated, and all message traffic is encrypted. The security features supported include: assurance of authenticity of discovery service, assurance of the privacy and authenticity of service descriptions, two-way authenticated and encrypted remote method invocation, and capabilities to authenticate

all principals. The hierarchical organizations of the SDS Servers increases system scalability and also serves for failure detection and automatic restart of failed servers.

2.1.2.4 Salutation

The Salutation protocol [SAL, SAL99a, SAL99b] is an open specification that provides “spontaneous” configuration of network devices and services. The Salutation architecture defines an abstract model with three components: Client, Server, and Salutation Manager (SLM). The Salutation Manager manages all communication, and bridges across different communication media as needed. Salutation defines its protocol based on SunRPC. Salutation defines a specific (extensible) record format for describing and locating services. This format includes service type (such as ‘ [PRINT]’) and attributes (such as ‘ color’). Services advertise by registering with one or more Salutation Managers. Clients locate services by sending service requests.

2.1.2.5 Universal Plug and Play (UPnP) and Simple Service Discovery Protocol (SSDP)

UPnP [CHR99, UPNP99] is a Microsoft standard for spontaneous configuration. UPnP handles network address resolution, and coupled with the IETF proposal Simple Service Discovery Protocol [GOL99], it provides higher-level service discovery. UPnP has a similar architecture to Salutation and SLP, and was influenced by them. UPnP uses XML for device/service description and queries, which brings it into the mainstream of the evolving WWW. At the base, UPnP provides “simple discovery”, in which network addresses are discovered. Advertisement is done by a local broadcast announcement. When successful, “simple discovery” returns an IP address or URL plus a “device type”. Services are described by extended URLs, similar to (but completely incompatible with) SLP. The URL is for an XML file with an elaborate description of the device. Starting with this URL, the SSDP defines a Web based discovery protocol, which uses HTTP (with extensions).

2.1.2.6 Bluetooth Service Discovery Protocol

Bluetooth [BLU] is a new short-range wireless transmission protocol. The Bluetooth protocol stack contains the Service Discovery Protocol (SDP), which is used to locate services provided by a Bluetooth device. It is based on the Piano platform by Motorola and has been modified to suit the dynamic nature of ad hoc communications.

2.1.3 Features of Resource Discovery Protocols

The underlying problem that all the resource discovery protocols are aiming solve and the solutions to achieve the same can be broadly summarized as:

- *Service Advertisement:* Service Providers advertise their services by providing their address and other necessary information. This advertisement could be facilitated either by registration with a directory service or through multicast or broadcast communication.
- *Service Request:* Service Consumers seeking services forward their request to some centralized directory service or make known their request to the world again through the process of multicast or broadcast communication.
- *Match Making:* The process in which service producers and consumers hook up. This could again be facilitated through a directory service serving as the intermediary or a direct discovery between producers and consumers. In the case where the directory service serves as the intermediary. The discovery of the service providers could again be spontaneous or through the registration process.

Issues such as reliability and scalability are handled either through a hierarchical or federated organization. A comparison of the features of the Directory and Discovery services is provided in the table 2.1 compiled based on the characteristics summarization in [MCG00].

Feature List	Directory Services	Discovery Services
Information Storage and Retrieval	Storage of information in static databases, which can be replicated for greater scalability.	Spontaneous discovery and configuration of network services and devices. Some Discovery services like SSDS, JINI cache the service information in which case they periodically update the cache to reflect the global state of the system.
Failure Detection	Do not monitor the resources for availability or failure due to external circumstances such and node/link failure, etc. They usually do not possess any event generation mechanisms either to inform clients of resource registration or withdrawal.	Automatically configure according to service availability.
Management	Centralized control. Usually maintained by privileged administrators.	Decentralized management with limited administration.
Search Semantics	Usually provide lower flexibility with respect the search criteria that can be specified.	Allows for selection of very specific types of service.
Interoperability	No interoperability between different models or services.	Some services offer interoperability through the

		use of bridges and proxies.
--	--	-----------------------------

Table 2.1. Comparison of the Features of the Directory and Discovery services

The Directory and Discovery Services described this chapter are mostly designed for ‘closed’ systems, i.e., systems, although distributed in nature, are developed and deployed in a confined setup. Such systems do not take advantage of the heterogeneity, local autonomy and the open architecture that are characteristic of DCS. The URDS architecture on the other hand is designed for ‘open’ systems by providing for the discovery and interoperation of distributed heterogeneous software components. These systems can be extended as new needs surface.

Chapter 3 provides an overview of the UniFrame Approach and the UniFrame Resource Discovery Service.

3. OVERVIEW OF UNIFRAME APPROACH (UA) AND UNIFRAME RESOURCE DISCOVERY SERVICE (URDS)

Chapter 2 provided descriptions of various resource discovery services under the categories of directory and discovery services. This chapter provides an overview of the UniFrame Approach (UA) and how it can be used for developing DCS. The chapter also presents a brief discussion of the UniFrame Resource Discovery Service (URDS) architecture outlining the design concepts on which the architecture is based. The detailed description of the URDS architecture is presented in Chapter 4.

3.1 UniFrame Approach (UA) and UniFrame Resource Discovery Service (URDS)

The UniFrame Approach (UA) aims at facilitating an automatic or semi-automatic creation of a DCS based on an integration of heterogeneous components. The UA specifies a framework for component developers to create, test and verify from the point of view of QoS, the components they develop and deploy on the network and for component assemblers/system integrators to select and semi-automatically generate a software solution for the DCS under consideration.

As indicated in Chapter 1, the Unified Meta-Component Model (UMM) proposed in [RAJ00] is the central part of the UniFrame Approach. The following subsections describe this meta-model.

3.2 Unified Meta-Component Model (UMM)

UMM consists of three entities: a) Components, b) Services and Service Guarantees, and c) Infrastructure. URDS represents the infrastructural part of the UMM.

3.2.1 Components

Components in UniFrame are autonomous entities, whose implementations are non-uniform, i.e., each component adheres to some distributed-component model but there is no notion of a unified implementational framework. Each component has a state, an identity, a behavior, well-defined interfaces and a private implementation. In addition, each component in UMM has three aspects:

- *Computational Aspect*: The computational aspect reflects the task(s) carried out by each component. It in turn depends upon: a) the objective(s) of the task, b) the techniques used to achieve these objectives, and c) the precise specification of the functionality offered by the component. The computational aspect of a component is described by its *inherent attributes* (book-keeping aspects, e.g., author, version, etc.) and *functional attributes* (formal aspects, i.e., computation, contracts and levels of service).
- *Cooperative Aspect*: The cooperative aspect of a component indicates its interaction with other components. Informally, the cooperative aspect of a component may contain: i) *Expected collaborators* - other components that can potentially cooperate with this component, ii) *Pre-processing collaborators* - other components on which this component depends upon, and iii) *Post-processing collaborators* - other components that may depend on this component.

- *Auxiliary Aspect:* In addition to computation and cooperation, mobility, security, and fault tolerance are necessary features of a DCS. The auxiliary aspect of a component addresses these features.

3.2.2 Services and Service Guarantees

Services in UniFrame could be a computational effort or an access to underlying resources. In DCS, it is natural to have several choices for obtaining a specific service. Thus, each component, in addition to indicating its functionality, must be able to specify the quality of the service offered.

The Quality of Service (QoS) is an indication given by a software component about its confidence to carry out the required services in spite of its constantly changing execution environment and a possibility of partial failures. The QoS offered by each component is dependent upon the computation performed, algorithm used, expected computational effort and resources required, the cost of each service, and the dynamics of supply and demand. The task of guaranteeing the necessary QoS is a key issue in any quality-oriented framework. The UA to assuring the QoS of a DCS is made up of three steps: a) the creation of a catalog of QoS parameters (or metrics), b) a formal specification of these parameters, and c) a mechanism for ensuring these parameters, both at each individual component level and at the entire system level. In [RAJ02, BRA02], these three steps are described in detail.

3.2.3 Infrastructure

URDS is designed to provide the infrastructure necessary for discovering and assembling a collection of components for building a DCS.

The URDS infrastructure (illustrated in Figure 3.1) comprises of the following components: i) Internet Component Broker (ICB) which is a collection of the following services - Query Manager (QM), the Domain Security Manager (DSM), Link Manager (LM) and Adapter Manager (AM) ii) Headhunters (HHs), iii) Meta-Repositories, iv) Active-Registries, v) Services (S1..Sn), and vi) Adapter Components (AC1..ACn). Figure 3.1 also illustrates the users (C1..Cn) of the URDS system who can be the Component Assemblers, System developers or System Integrators. Section 3.5 provides a brief overview of each of these components. The numbers in the Figure 3.1 indicate the flow of activities in the URDS. These are explained, in detail, in the context of an example in section 3.5.1.

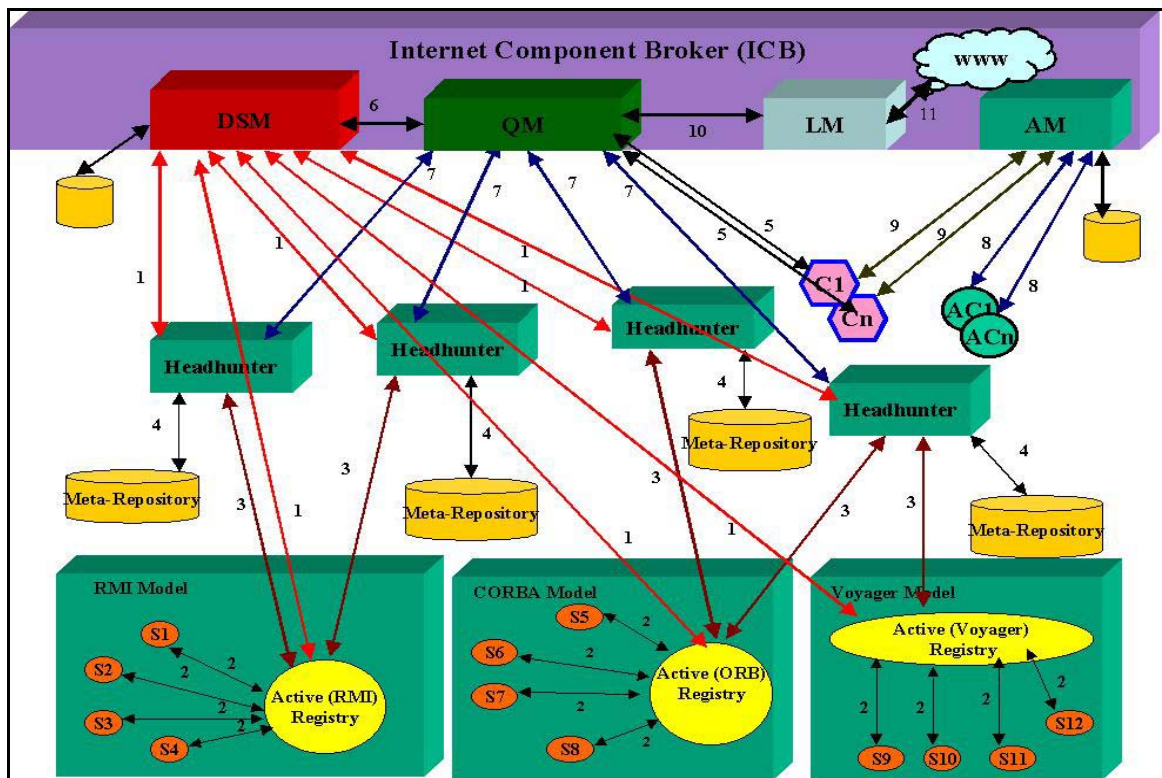

Figure 3.1. URDS Architecture

3.3 Specification of Components in UniFrame

UniFrame specifications are initially informally indicated in a natural language-like style. This natural-language style specification indicating the computational, cooperative, auxiliary attributes and QoS metrics of the component is refined into a more standard XML-based specification during the Component Development and Deployment Phase as described in Section 3.6.1. XML [BRA00] is selected as the standard for service specification since it is general enough to express the required concepts, it is rigorously specified, and it is universally accepted and deployed.

The XML-based UniFrame Service Specification, which represents the information needed to describe a service, is comprised of:

- ***ID (or Service Type Name)***: A unique identifier, comprising of the host name on which the component is running and the name with which this component binds itself to a registry will identify each service.
Example: intrepid.cs.iupui.edu/AccountServer1
- ***Component Name***: The name, with which the service component identifies itself, i.e., the class name of the implementation, which is instantiated at the time of binding. This can be different from the name with which the component binds itself to a registry.
Example: AccountServer
- ***Description***: A brief description of this service component.
Example: Provides an account management system.
- ***Function Descriptions***: A brief description of each of the functions supported by the service component.
Example: javaDeposit, javaWithdraw, javaBalance
- ***Syntactic Contracts***: A definition of the computational signature of the service interface.
Example: void javaDeposit(float ip), void javaWithdraw() throws OverDrawException, float javaBalance().

- **Purpose:** Overall function of the service component.
Exampe: Acts as an Account Server.
- **Algorithm:** The algorithms implemented by this component.
Example: Simple Addition/Subtraction
- **Complexity:** The overall order of complexity of the algorithms implemented by this component. Example: O(1)
- **Technology:** The technology used to implement this component.
Example: CORBA, Java RMI, etc.
- **QoS Metrics:** Zero or more *Quality Of Service (QoS) types*. A *QoS type name* defines the QoS value. Associated with a QoS type is the triplet of $\langle \text{QoS-type-name}, \text{measure}, \text{value} \rangle$ where *QoS-type-name* specifies the QoS metric, for example, *throughput, capacity, end-to-end delay*, etc. *Measure* indicates the quantification parameter for this type-name like *methods completed/sec, number of concurrent requests handled, time*, etc. *Value* indicates a numeric/string/boolean value for this parameter.
Example: $\langle \text{Availability}, \%, 90 \rangle$. A catalog of Quality of Service parameters and their metrics to be used in UniFrame specifications are indicated in [BRA02].

AccountServer

Informal Description: Provides an account management service. Supports functions `javaDeposit()`, `javaWithdraw()`, `javaBalance()`.

1. Computational Attributes:

1. Inherent Attributes:

a.1 id: `intrepid.cs.iupui.edu/AccountServer`

2. Functional Attributes:

b.1 Acts as an account server

b.2 Algorithm: simple addition/subtraction

b.3 Complexity: O(1)

b.4 Syntactic Contracts:

`void javaDeposit(float ip);`

`void javaWithdraw(float ip) throws overDrawException;`

`float javaBalance();`

b.5 Technology: Java-RMI

2. Cooperation Attributes:

2.1) Pre-processing Collaborators: `AccountClient`

3. Auxiliary Attributes: None

4. QoS Metrics:

Availability: 90%

End-to-End Delay: less than 10ms

Figure 3.2. Example of Informal Natural Language-based Uniframe Specification

Figure 3.2 illustrates an example of an informal natural language-like style UniFrame specification. This example is for a Java-RMI based bank account management system with services for deposit, withdraw, and check balance.

The informal natural language-like specification in Figure 3.2 is translated into an XML-based UniFrame specification illustrated in Figure 3.3.

```

<UniFrame>
  <ComponentName> AccountServer </ComponentName>
  <Description> Provides an Account Management System </Description>

  <FunctionDescription>
    <Function> javaDeposit </Function>
    <Function> javaWithdraw </Function>
    <Function> javaBalance </Function>
  </FunctionDescription>

  <ComputationalAttributes>
    <InherentAttributes>
      <ID> intrepid.cs.iupui.edu/AccountServer </ID>
    </InherentAttributes>

    <FunctionalAttributes>
      <Purpose> Acts as Account Server </Purpose>
      <Algorithm> Simple Addition/Subtraction </Algorithm>
      <Complexity> O(1) </Complexity>
      <SyntacticContract>
        <Contract> void javaDeposit(float ip) </Contract>
        <Contract>
          void javaWithdraw throws OverDrawException
        </Contract>
        <Contract> float javaBalance() </Contract>
      </SyntacticContract>
      <Technology> Java-RMI </Technology>
    </FunctionalAttributes>
  </ComputationalAttributes>

  <CooperatingAttributes>
    <PreprocessingCollaborators> AccountClient </PreprocessingCollaborators>
  </CooperatingAttributes>

  <AuxillaryAttributes>
    <Mobility> No </Mobility>
  </AuxillaryAttributes>

  <QOSMetrics>
    <Availability measure="%"> 90 </Availability>
    <End2EndDelay measure="ms" > 10 </End2EndDelay>
  </QOSMetrics>
</UniFrame>

```

Figure 3.3. Example of translated XML-based UniFrame Specification

Various aspects in the service specification can be identified through the nodes in the XML specification. Nodes can be single valued or multi-valued in which case they can hold multiple child nodes. For example; the node *ComponentName* which introduces the name of the service component is a single valued node, whereas the node *FunctionDescription* which introduces the names of the functions supported by the service component has multiple child nodes each named *Function*.

3.4 Query and Description of Target Code Architecture

The UniFrame approach allows the system developers/components assemblers/system integrators to present a query to the system in natural language-like style. This query is passed through a language query processor, which extracts the key words, constraints, and preferences from the query and applies a knowledge base of the domain maintained with it, to the query to construct an XML-based query. The XML-based query is further processed into a structured query language (SQL) statement during the process of matchmaking.

The general form of a query is a request to create a system that has certain QoS parameters. The name of the system is important in identifying the application domain and the QoS parameters help identify desired properties of the system. A sample query can be stated informally as: *Create an account management system that has availability > 50% and end-to-end delay < 50ms with preference maximum availability.* (The preference can be specified to indicate that if there are multiple solutions satisfying the requirements, then the search results returned to the developer need to be sorted in the order of greatest availability). The natural language-like query is processed into an XML-based query as depicted in Figure 3.4

```

<Query>
  <Description> Account System </Description>
  <Domain> Financial </Domain>
  <End2EndDelay constraint="<">50 </End2EndDelay>
  <Availability constraint = " ">" preference = "max"> 50 </Availability>
</Query>

```

Figure 3.4. Example of a Processed XML-based Query

During matchmaking the above XML based query is further translated into the following structured query language (SQL) statement: `SELECT * FROM componentTable A, functionTable B WHERE (A.ID = B.ID) AND ((description LIKE %account%) OR (description LIKE %system%)) AND (end2endDelay < 50) AND (availability > 50).`

The above SQL statement is specific to the implementation. The URDS architecture proposes that the UniFrame specification be stored in a database (Meta-Repository) so that the natural language-like query can be translated into a structured query language statement and executed against the tables of the database to find a match for the query. In the sample SQL statement shown the terms *componentTable*, *functionTable* refer to the database tables in which the parsed UniFrame specification is stored. The *componentTable* maintains the details associated with the component name, description, computational, cooperating, auxillary attributes, and QoS metrics. The *functionTable* holds details associated with function names and their associated syntactic contracts. The terms *description*, *end2endDelay* and *availability* correspond to the column names of the *componentTable*. The implementation specific details of terms are explained in subsection 5.2.4.1.1.3 of chapter 5.

3.5 Overview of the URDS Architecture

The URDS architecture is organized as a federated hierarchy in order to achieve scalability. Figure 3.5 illustrates this hierarchical organization. Every ICB has a one level

hierarchy of zero or more Headhunters attached to it. The ICBs in turn are linked together with unidirectional links to form a directed graph. The URDS discovery process is “administratively scoped”, i.e., it locates services within an administratively defined logical domain. ‘Domain’ in UniFrame refers to industry specific markets such as Financial Services, Health Care Services, Manufacturing Services, etc. The domains supported are determined by the organizations providing the URDS service.

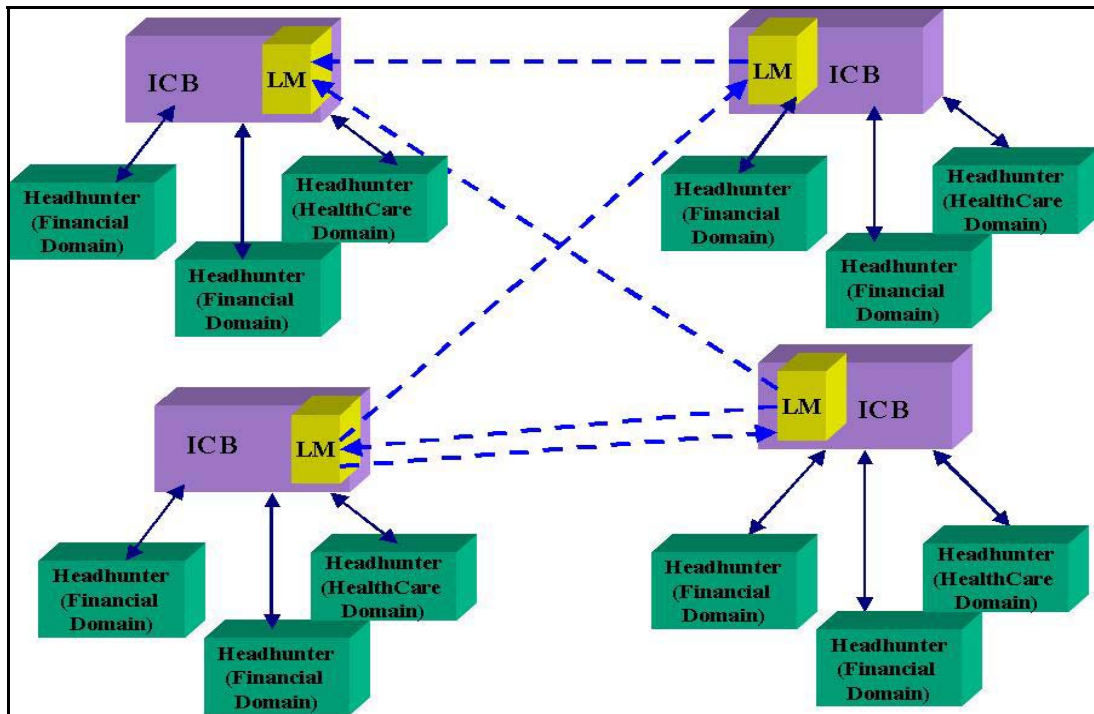

Figure 3.5. Federated Hierarchical Organization of ICBs

The URDS discovery protocol is based on periodic multicast announcements. The multicast communication is subject to various security threats, such as eavesdropping, uncontrolled group access and masquerading. URDS addresses the security threats faced in the scenario of a discovery process. The security model of URDS provides for authentication of the principals involved, an access control to multicast address resources, and an encryption of the data transmitted. The model does not at this stage provide for elaborate protocols for establishing keys, passwords, etc. These are considered as future enhancements and are mentioned in Chapter 6.

The URDS architecture is designed to handle failures through periodic announcements (in case of Headhunters), ‘heartbeat’ probes (in case of Link Managers) and information caching. A lack of communication from the recipients of the communication beyond a designated time range is deemed as a failure of that component and the state of the system is accordingly reset. The caches of the Headhunter and Link Manager are updated based on the responses received from ActiveRegistries and Link Managers in other ICBs respectively or purged based on lack of them.

Table 3.1 gives a brief description of each of the components that comprises the URDS architecture. The elaborate details are provided in the next chapter.

Internet Component Broker (ICB)	The ICB acts as an all-pervasive component broker in an interconnected environment. It encompasses the communication infrastructure necessary to identify and locate services, enforce domain security and handle mediation between heterogeneous components. The ICB is not a single component, but a collection of services comprising of the Query Manager (QM), the Domain Security Manager (DSM), Adapter Manager (AM), and the Link Manager (LM). These services are reachable at well-known addresses. It is envisioned that there will be a fixed number of ICBs deployed at well-known locations hosted by corporations or organizations supporting this initiative.
Domain Security Manager (DSM)	The DSM serves as an authorized third party that handles the secret key generation and distribution and enforces group memberships and access controls to multicast resources through authentication and use of access control lists (ACL). DSM has an associated repository (database) of valid users, passwords, multicast address resources and domains.
Query Manager (QM)	The purpose of the QM is to translate a system integrator’s natural language-like query into a structured query language statement and dispatch this query to the ‘appropriate’ Headhunters, which return the

	list of service provider components matching these search criteria expressed in the query. ‘Appropriate’ is determined by the domain of the query. Requests for service components belonging to a specific domain will be dispatched to Headhunters belonging to that domain. The QM, in conjunction with the LM, is also responsible for propagating the queries to other linked ICBs.
Link Manager (LM)	The LM serves to establish links with other ICBs for the purpose of federation and to propagate queries received from the QM to the linked ICBs. The LM is configured by an ICB administrator with the location information of LMs of other ICBs with which links are to be established.
Adapter Manager (AM)	The AM serves as a registry/lookup service for clients seeking adapter components. The adapter components register with the AM and while doing so they indicate their specialization, i.e., which component models they can bridge efficiently. Clients contact the AM to search for adapter components matching their needs.
Headhunter (HH)	The Headhunters perform the following tasks: a) Service Discovery: detect the presence of service providers (Exporters), b) register the functionality of these service providers, and c) return a list of service providers to the ICB that matches the requirements of the component assemblers/system integrators requests forwarded by the QM. The service discovery process performs the search based on multicasting.
Meta-Repository (MR)	The Meta-Repository is a data store that serves a Headhunter to hold the UniFrame specification information of exporters adhering to different models. The repository is implemented as a standard relational database.
Active Registry (AR)	The native registries/lookup services of various component models (RMI, CORBA, Voyager) are extended to be able to listen and respond to multicast messages from the Headhunters and also have introspection capabilities to discover not only the instances, but also the specifications of the components registered with them.

S1..Sn	Services implemented in different component models (RMI, CORBA, etc.) identified by the service type name and the component's informal UniFrame specification which is an XML specification outlining the computational, functional, cooperational and auxiliary attributes of the component and zero or more QoS metrics for the component.
AC1..ACn	Adapter components, which serve as bridges between components implemented in diverse models.
C1..Cn	Component Assemblers, System Integrators, System Developers searching for services matching certain functional and non-functional requirements.

Table 3.1. Description of URDS components

3.5.1 Interaction of URDS Components

Table 3.2, outlines the interactions between the URDS components in servicing a query for assembling an account management system. This example assumes the presence of a pair of Java RMI server and Java RMI client programs, and a pair of CORBA server and CORBA client programs, which are available to construct the account management system. The rows of the table are numbered corresponding to the flow of control shown in Figure 3.1. The result of this interaction will be an ensemble of components, which may be assembled into a complete system as described in Section 3.6.2.

1	<p>This indicates the interactions between the principals (Headhunters/Active Registries) and the DSM.</p> <p>The principals contact the DSM with their authentication credentials in order to obtain the secret key and the multicast address for the group communication (many to one interaction).</p> <p>Example credentials:</p> <pre><name="Headhunter1",password="xxxxx",domain="financial"></pre>
----------	---

	<p><name="registry2",password="yyyy", domain="financial"></p> <p>The DSM authenticates the principals and returns a secret key and multicast address to a valid principal (one to many interaction).</p> <p>Example response:</p> <p><secretkey = keyforFinancialDomain, multicast_address="224.2.2.2"></p>
2	<p>This indicates the interactions between Service Exporter Components and active registries.</p> <p>The service exporter components register with their respective registries (many to one interaction).</p> <p>Example: <id="intrepid.cs.iupui.edu/AccountServer"></p> <p>These registries in turn query these components for their UniFrame Specification (one to many interaction).</p> <p>Example: <introspect property = "UniFrameSpecURL"></p> <p>The components respond with the URL at which the specification is located (many to one interaction).</p> <p>Example: <url="C:\Account System\AccountServerSpec.xml"></p>
3	<p>This indicates the interactions between Headhunters and Active Registries.</p> <p>Headhunters periodically multicast their presence to multicast group addresses (one to many interaction).</p> <p>Example message: <Headhunterlocation=phoenix.cs.iupui.edu/Headhunter1></p> <p>Active Registries, which are listening for the multicast messages from the Headhunters at this group address, respond to Headhunter's multicast messages by passing their contact information to the Headhunter (many to many interaction).</p> <p>Example: <registrylocation=magellan.cs.iupui.edu/registry2></p> <p>Headhunters query the active registries, which respond to their announcements, for the UniFrame specification information of all the components registered with them (one to many interaction).</p> <p>The active registries respond by passing to the Headhunter the list of components registered with them and the detailed UniFrame specification of these components (many to many interaction).</p>

4	<p>This indicates the interactions between a Headhunter and a Meta-Repository.</p> <p>Headhunters store the component information obtained from the active registries onto the Meta-Repository (one to one interaction).</p> <p>Headhunters query the Meta-Repository to retrieve component information (one to one interaction).</p> <p>Example:</p> <p><SQL statement = “SELECT * FROM <i>componentTable A, functionTable B</i> WHERE (A.ID = B.ID) AND ((<i>description</i> LIKE %account%) OR (<i>description</i> LIKE %system%)) AND (<i>end2endDelay</i> < 50) AND (<i>availability</i> > 50)”></p> <p>Meta-Repository returns search results to Headhunter (one to one interaction).</p>
5	<p>This indicates the interactions between the QM and Component Assemblers/System Integrators.</p> <p>System Integrators contact the QM and specify the functional and non-functional search criteria. The System Integrators can optionally specify the domain for their query or allow the natural language processor of the QM to determine the domain of the query. (many to one interaction).</p> <p>Example: The natural language-like system integrator query is as follows:</p> <p><NL Query=“<i>Create an account management system that has end-to-end delay < 50 ms and availability > 50% with preference maximum availability.</i>”>.</p> <p>The QM returns the search results to the clients (one to many interaction).</p> <p>Figure 3.6 depicts an example of the search results returned to the system integrator.</p> <div data-bbox="500 1402 1312 1738" style="border: 1px solid black; padding: 10px; margin: 10px auto; width: fit-content;"> <ol style="list-style-type: none"> 1. JavaAccountServer availability = 95%, End-to-End Delay < 10 ms, Java-RMI Technology 2. JavaAccountClient availability = 90%, End-to-End Delay < 20 ms, Java Applet Technology 3. CorbaAccountServer availability = 90%, End-to-End Delay < 15ms, CORBA Technology 4. CorbaAccountClient availability = 90%, End-to-End Delay < 20 ms, CORBA Technology </div> <p style="text-align: center;">Figure 3.6. Example of Search Results.</p>

6	<p>This indicates the interaction between the QM and DSM.</p> <p>QM contacts DSM for contact information of registered Headhunters belonging to the domain of client query (one to one interaction).</p> <p>DSM responds with the list of registered Headhunters (one to one interaction).</p> <p>Example: < phoenix.cs.iupui.edu/Headhunter1, magellan.cs.iupui.edu/Headhunter2 ></p>
7	<p>This indicates the interactions between the QM and Headhunters.</p> <p>The QM propagates the System Integrator's query to all registered Headhunters, which fall in the domain of the System Integrator's search request (one to many interaction).</p> <p>The Headhunters respond to the QM query with search results matching the criteria (many to one interaction).</p>
8	<p>This indicates the interactions between adapter components and AM.</p> <p>Adapter components register with the AM, which is running at a well-known location (many to one interaction).</p>
9	<p>This shows the interactions between the clients and the AM.</p> <p>Clients contact the AM at the well-known location at which it is running with requests for specific adapter components (many to one interaction).</p> <p>The AM checks against its repository for matches and returns the results to the clients (one to many interaction).</p>
10	<p>This shows the interactions between QM and LM.</p> <p>The QM propagates the query to the LM (one to one interaction).</p> <p>LM returns search results to QM (one to one interaction).</p>

Table 3.2. Interactions between URDS components

3.6 The UniFrame Approach (UA)

Figure 3.7 depicts the UniFrame Approach for the development of software solutions for DCS. This approach as proposed in [RAJ01] has two levels:

- Component Level - in this level, different components are created by developers, tested and verified from the point of view of QoS, and then deployed on the network
- System Level -this level concentrates on assembling a collection of components, each with a specific functionality and QoS, and semi-automatically generates the software solution for the particular DCS under consideration.

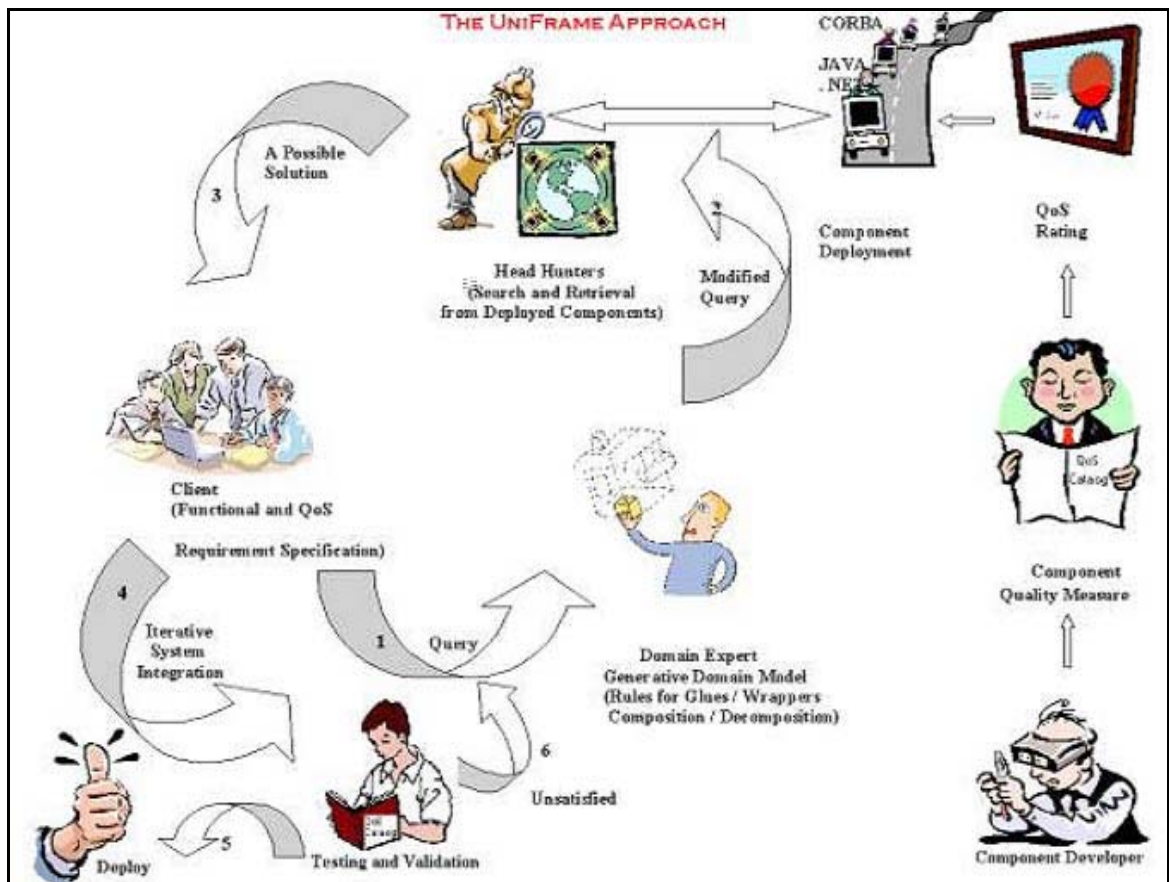

Figure 3.7. UniFrame Approach

The two levels of the UA and associated processes as described in [RAJ01] are provided below.

3.6.1 Component Development and Deployment Process

The component development and deployment process (illustrated in Figure 3.8) starts with a UniFrame specification of a component from a particular domain (see Figure 3.2). This specification is in a natural language-like format and indicates the computational, cooperative, and auxiliary aspects and QoS metrics of the component. This informal specification is then refined into a XML-based specification (see Figure 3.3). The refinement is based upon the theory of Two-Level Grammar (TLG) natural language specifications [BAR00, VAN65], and is achieved by the use of conventional natural language processing techniques (e.g., see [JUR00]) and a domain knowledge base. The refinement process also includes the generation of interfaces, which may then be integrated into an implementation using glue and wrapper code. The interface incorporates all the aspects of the component, as required by the UniFrame specification. The developer provides the necessary implementation for the computational, behavioral, and QoS methods. This process is followed by the QoS validation. If the results are

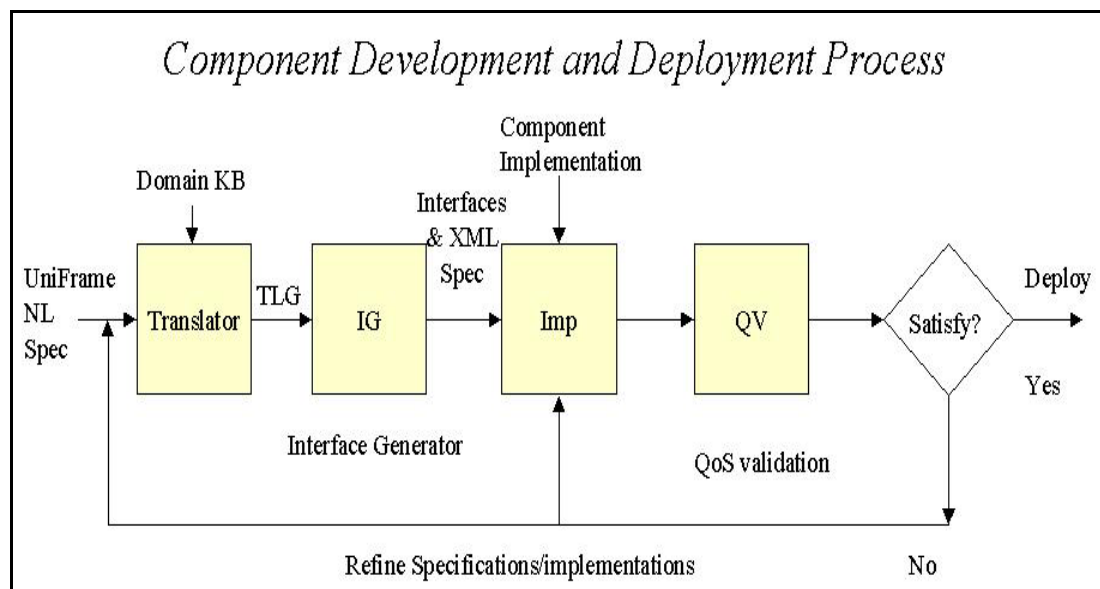

Figure 3.8. Component Development and Deployment Process

satisfactory (as required by the QoS criteria) then the component is deployed on the network and eventually, it is discovered by one or more Headhunters. If the QoS constraints are not met then either the developer refines the UniFrame specification or the implementation and the cycle repeats.

3.6.2 Automated System Generation and Evaluation based on QoS

In general, different developers will provide on the Internet a variety of possibly heterogeneous components oriented towards a specific problem domain. Once all the components necessary for implementing a specified distributed system are available, then the task is to assemble them into a solution. The proposed framework takes a pragmatic approach, based on Generative Programming [CZA00], to component-based programming. It is assumed that the generation environment will be built around a generative domain specific model (GDM) supporting component-based assembly. The distinctive features of the proposed approach are as follows:

The developer of the desired distributed system presents to this process a system query, in a structured form of natural language that describes the required characteristics of the distributed system. The natural language processor (NLP) processes the query. It does this aided by the domain knowledge (such as key concepts from the domain) and a knowledge-base containing the UniFrame description of the components for that domain. From this query a set of search parameters is generated which guides Headhunter agents for a component search in the distributed environment.

The framework, with the help of the infrastructure described in Section 3.5, collects a set of potential components for that domain, each of which meets the QoS requirement specified by the developer. From these, the developer, or a program acting as a proxy of the developer, selects some components. After the components are fetched, the system is assembled according to the generation rules embedded in the generative domain

model. These components along with the appropriate adapters (if needed) form a software implementation of the distributed system.

Next this implementation is tested using event traces and the set of test cases to verify that it meets the desired QoS criteria. If it does not, it is discarded. After that, another implementation is chosen from the component collection. This process is repeated until an optimal (with respect to the QoS) implementation is found, or until the collection is exhausted. In the latter case, the process may request additional components or it may attempt to refine the query by adding more information about the desired solution from the problem domain. Once a satisfactory implementation is found, it is ready for deployment.

The process for automated system generation and evaluation is illustrated in Figure 3.9.

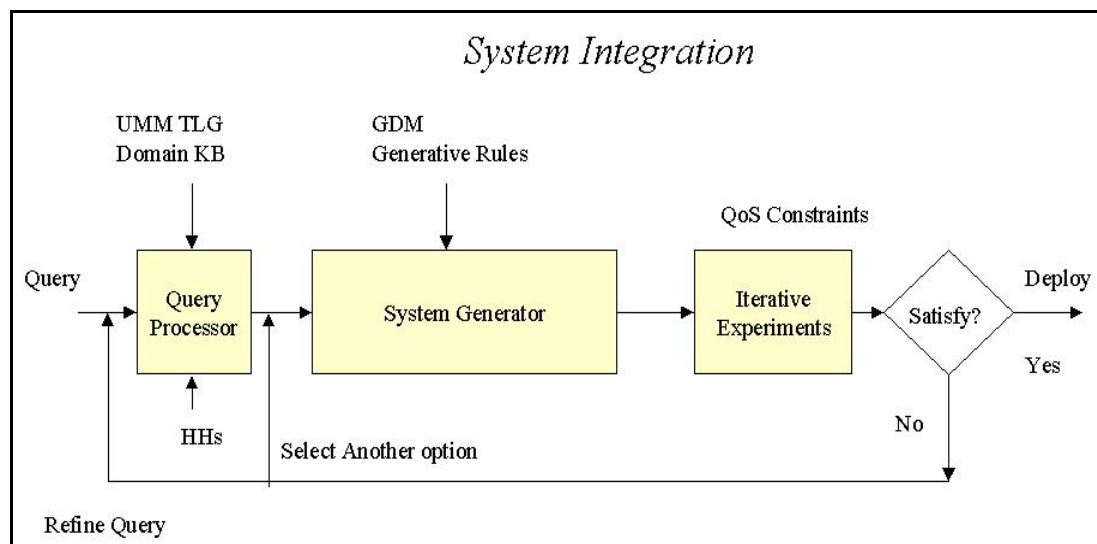

Figure 3.9. Automated System Generation and Evaluation

This chapter provided an overview of the UniFrame Approach to developing a software solution for a DCS. The next chapter elaborates on the URDS architecture by providing a detailed high-level description of the URDS components.

4. URDS ARCHITECTURE

Chapter 3 provided an overview to the UniFrame Approach and the URDS architecture. The present chapter describes the URDS architecture in detail, focusing on the high-level design, the algorithms, and the interactions of the components that comprise the URDS architecture. The descriptions in this chapter are at a conceptual level and are not tied to the software that may implement the architecture. The implementation specific details will be covered in Chapter 5.

Figure 4.1 below illustrates the components of the URDS architecture outlined in Chapter 3.

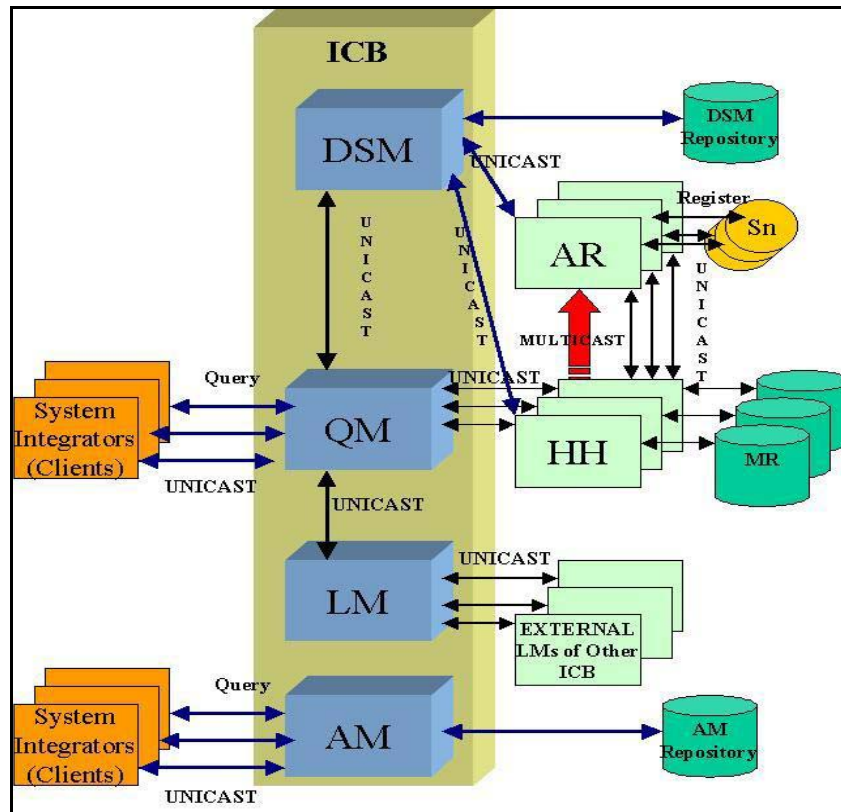

Figure 4.1. Components of the URDS Architecture

The overview of the URDS architecture presented in Chapter 3 highlighted the functions of its components namely: i) Internet Component Broker (ICB) which is a collection of the following services - Query Manager (QM), the Domain Security Manager (DSM), Link Manager (LM) and Adapter Manager (AM) ii) Headhunters (HHs), iii) Meta-Repositories (MR), and iv) Active-Registries (AR). The URDS architecture is designed to discover heterogeneous services (S1..Sn). The clients/users of the URDS system are the Component Assemblers, System Developers or System Integrators.

The following subsections provide the high-level design details and algorithms for each of the components in the URDS architecture.

4.1 Internet Component Broker

The ICB acts as an all-pervasive component broker in the interconnected environment providing a platform for the discovery and seamless integration of disparate components. The ICB is not a single component but is a collection of services comprising of the Query Manager (QM), the Domain Security Manager (DSM), Adapter Manager (AM), and the Link Manager (LM). It is envisioned that there will be a fixed number of ICBs deployed at well-known locations hosted by corporations or organizations supporting the UniFrame initiative. The functionality of the ICB is similar to that of an Object Request Broker. However, the ICB has certain key features that are unique. It provides component mappings and component model adapters. The ICB, in conjunction with Headhunters, provides the infrastructure necessary for scalable, reliable, and secure discovery and registry services using the interconnected infrastructure.

The chief functionalities provided by the ICB are:

- Authenticate the principals (Headhunters and Active Registries) in the system and enforce access control over the multicast address resources for a domain with the help of the Domain Security Manager (DSM).
- Attempt at matchmaking between service producers and consumers with the help of the Headhunters and Query Manager. ICBs may cooperate with each other in order to increase the search space for matchmaking. The cooperation techniques of ICBs are facilitated through the Link Manager (LM).
- Act as a mediator between two components adhering to different component models. The mediation capabilities of the ICB are facilitated through the Adapter Manager (AM).

4.1.1 Algorithm for ICB Initialization

In the algorithm the ICB initializes all the services i.e., the DSM, QM, LM and AM by calling their initialization routines.

ICB_INITIALIZATION

 CALL *DSM_INITIALIZATION* (see Algorithm 4.2.4.1)

 CALL *QM_INITIALIZATION* (see Algorithm 4.3.3.1)

 CALL *LM_INITIALIZATION* (see Algorithm 4.4.1.1)

 CALL *AM_INITIALIZATION* (see Algorithm 4.5.1.1)

END_ICB_INITIALIZATION

The following subsections provide a description of the services that comprise the ICB and their contribution to providing the functionality of the ICB.

4.2 Domain Security Manager (DSM)

The URDS discovery protocol is based on periodic multicast announcements. Multicasting [ERI94] is a scalable solution for the group communication. However, there are various security issues that have to be addressed in a multicast communication, which do not arise in an unicast communication [BAL95]. Security threats that need to be addressed are:

- *Eavesdropping*: Since multicast addresses are not private, any interested host can gain access to the multicast data by just becoming a member of that group. These kinds of security attacks, where adversaries try to gain access to the data without really disrupting the secure multicast protocol, are called passive attacks [STA95]. Potential adversaries may also use the data collected by means of eavesdropping for cryptanalysis purposes or replay the data at a later time.
- *Uncontrolled Group Access*: Since access to the group is not controlled in multicast communication, any host can send data to a multicast group which can cause congestion and also possibilities of a *Denial Of Service* attack against the group.
- *Masquerading*: An adversary may also pose as another host that is a member of the group. This enables the adversary to send data, receive data and or acquire access to the secret-keys by posing as a legitimate member of the group. Masquerading is a form of active attack.

[DON99] has identified the following components; a) *Group Membership Control*, b) *Secure Communication*, and c) *Key Distribution* as being critical to effectively combating the security threats faced in multicast communication. The following subsections provide a brief overview of these security mechanisms and explain how they are incorporated in the URDS architecture with the help of the DSM.

4.2.1 Group Membership Control (GMC)

The GMC allows only authorized hosts to join a multicast group, guarding against otherwise unilateral subscriptions by arbitrary hosts. Group membership control can be exercised in two ways:

- *Access Control Lists*: Access Control Lists allow a sender or an authorized third party to maintain an inclusion or an exclusion list of hosts on the Internet corresponding to a multicast group. Each time a host requests to join the multicast group, the sender or the third party checks with the access control list to determine whether the host is authorized to join the group. [ACC97] defines an ACL as a “data structure that guards access to resources”. An ACL data structure is comprised of multiple entries, each of which contains a set of permissions associated with a particular principal. A principal represents an entity such as an individual user or a group. Each entry can be specified as being either positive (i.e., permissions are granted to the associated principal) or negative (i.e., permissions are denied). An ACL is independent of the authentication scheme used to verify the validity of the principal, the encryption scheme used to transmit the data across the network and the resource that it guards. The ACL is consulted after the authentication phase. After the principal is verified to be an authenticated user in the system, the principal may access resources. For each such resource, the principal may or may not be granted an access depending on the permissions that are granted to the principal in the ACL that guards the resource. The ACL can be consulted to find the list of permissions a particular principal has or to find out whether or not a principal is granted a particular permission [ACC97]. The details of how the ACL is created is presented in the algorithm for creating ACL entries in subsection 4.2.4.2.
- *Use of Capability Certificates* [DON99]: Capability Certificates are issued by a designated third party to receivers. Capability Certificates authenticate the receivers and authorize them to participate in a multicast group. The receivers

present the capability certificates to the sender or an authorized third party to gain access to the group.

The Group Membership Control in the URDS is enforced through the use of userid/password authentication and Access Control Lists. The resources being guarded are the multicast addresses allocated to a particular *domain*. The Domain Security Manager (DSM) serves as an authorized third party, which maintains an inclusion list of Principals (Headhunters or registries) corresponding to a domain. DSM has an associated repository (database) of valid principals, passwords, multicast address resources and domains. Every Headhunter or Active Registry is associated with a domain. The Active Registries associated with a domain have components registered with them, which belong to that domain. The Headhunter in turn detects Registries, which belong to the same domain as itself, and hence, the service components detected by the Headhunter will belong to a particular domain. The Principal (authenticated user), is allowed access only to the multicast address mapped to the domain with which it is associated. A Principal that wishes to participate in the discovery process contacts the DSM with its credentials (id, password, domain). The DSM authenticates the principal and checks its authorizations against the domain ACL. The DSM returns a secret-key and a multicast address mapped to the corresponding domain to a valid principal. The DSM_Repository is created and populated by an administrator. The mappings between multicast addresses and domains, and users and domains are established by the organization providing the DSM service.

4.2.2 Secure Communication

A Secure communication can be ensured by the transmission of encrypted data. There are several cryptographic mechanisms such as secret-key [STA95] and public-key [STA95] mechanisms.

In the URDS, the security of transmitted data is ensured through the process of Secret-Key Encryption. A secret-key is a symmetric key wherein the sender and receiver use the same key for purposes of encryption and decryption. The DSM is responsible for generating a unique secret-key for each domain.

4.2.3 Key Distribution

A Key distribution scheme should ensure that the security key is not compromised and the communication does not yield to active security attacks such as masquerading. Many schemes exist for securing key distribution such as Centralized Flat Key Management Scheme [BLU97, CAR98, GON94, HAR97], Hierarchical Key Management Scheme [BAL96, CAR98, MIT97, WAL97], and Distributed Flat Key Management Scheme [CAR98].

The URDS follows a Centralized Flat Key Management scheme wherein the DSM serves as the central authority, which generates and distributes the secret-key to authenticated principals. An overview of the DSM Security Enforcement Protocol is provided below:

- DSM acts as an authorized third party centralized controller for the secret-key distribution and the multicast address allocation to Headhunters and Registries.
- Secret-Key and Address allocation is domain specific.
- Headhunter/Registries communicate to DSM their authentication credentials (id, password, domain).
- DSM verifies authentication credentials and checks permissions against the ACL to verify the user access to that domain.
- DSM returns to the authorized users a multicast address picked at random from the list of addresses allocated to that domain and a secret-key generated for that domain.

- In case the principal is a Headhunter the DSM registers the contact information of the Headhunter with itself. The QM uses this information for the query propagation.

4.2.4 Algorithms for DSM Functions

Data structures used:

Hash table ¹ <i>userDomainTable</i>	Mapping between principal names and their corresponding domains. The principal name serves as the key for this mapping.
Hash table <i>domainTable</i>	Mapping between multicast addresses and corresponding domain names. The multicast address serves as the key for this mapping.
Hash table <i>HHAddressAllocTable</i>	Mapping between multicast addresses allocated to Headhunters and their corresponding domains. The multicast address serves as the key.
Hash table <i>registeredHHTable</i>	Mapping between registered Headhunter locations and their domain. The registered Headhunters are the authorized principals who have received a multicast address and secret-key from the DSM.
Hash table <i>keyTable</i>	Mapping between domains and corresponding Secret-Keys. The domain names serve as the key.
ACL ² <i>domainACL</i>	ACL of usernames and their associated permissions (i.e. domains).

Table 4.1. Data Structure for DSM functions

¹ The algorithms in this section and succeeding sections use the hash table ADT to represent key-value pair mappings. These hash tables are maintained as memory resident tables.

² The ACL is maintained in memory after creation.

4.2.4.1 Algorithm for DSM Initialization

The DSM configuration process comprises of setting up the DSM_Repository with the information about the domains, associated multicast addresses, authorized users and their passwords. The information is stored in the DSM_Repository as a collection of tables (refer sub section 5.3.4.1.1.3 in Chapter 5 for implementation specific details on these tables). The DSM configuration is performed by an administrator. The DSM upon initialization creates an ACL of usernames and their associated permissions and generates secret-keys for each of the domains. It then activates the authentication service, which can respond to remote calls by the Headhunters and active registries. New entries to the DSM_Repository are added on an as-needed basis and the in-memory ACL is updated accordingly.

DSM_INITIALIZATION

CREATE DSM_REPOSITORY

CALL DSM_CREATE_ACL_ENTRIES

CALL DSM_GENERATE_SECRET_KEYS

ACTIVATE DSM_AUTHENTICATION_SERVICE

END_DSM_INITIALIZATION

4.2.4.2 Algorithm for Creating Entries in the ACL

This algorithm outlines the process for creating principals and permissions using usernames and domain names. It also describes the process for creating ACL entries using these principal-permission pairs and adding these entries to the ACL.

```

DSM_CREATE_ACL_ENTRIES
  LOAD userDomainTable from DSM_Repository
  userNameList = GET enumeration of user names from userdomainTable
  WHILE userNameList HAS MORE ELEMENTS
    username = GET NEXT ELEMENT from userNameList
    domainName = GET value in userdomainTable for username key.
    Create a new PRINCIPAL with the username
    Create a new ACLENTY with the new PRINCIPAL
    Create a new PERMISSION with the domainName
    Add PERMISSION to ACLENTY
    Add ACLENTY to domainACL
  ENDWHILE
END_DSM_CREATE_ACL_ENTRIES

```

4.2.4.3 Algorithm for Generating Secret-Keys

This algorithm outlines the process for generating secret-keys using any standard secret-key-generating algorithm such as DES, Triple DES, Blowfish, etc. A secret-key is generated for each domain and stored in a hash table ADT of domain names and secret-key pairs.

```

DSM_GENERATE_SECRET_KEYS
  domains = GET enumeration of domain names from domainTable
  //Create a key generator component capable of generating secret-keys that
  // corresponds to a given key generating algorithm.
  keyGenerator =
  CREATE a new KEYGENERATOR with keyGeneratingAlgorithm
  //Generate a secret-key for each domain.

```

```

WHILE domains HAS MORE ELEMENTS
    domainName = GET NEXT ELEMENT from domains
    secretKey = GENERATEKEY with keyGenerator
    PUT < domainName, secretKey > in keyTable
ENDWHILE
END_DSM_GENERATE_SECRET_KEYS

```

4.2.4.4 Algorithm for Authentication, and Secret-Key and Multicast Address Distribution

This algorithm outlines the process for authenticating a principal by verifying their authentication credentials against the DSM_Repository. The authorization of user permissions is done by checking against the ACL. A multicast address is picked at random from the list of multicast addresses allocated to that domain. An authenticated packet comprising of the multicast address and secret-key for the domain is returned to the user.

```

DSM_AUTHENTICATION_SERVICE
IN: userType, userName, password, contactLocation, domain
OUT: authenticatedPacket containing multicastAddress and secretKey
WHILE TRUE
    IF contacted by user
        isUserAuthenticated =
            VALIDATE userType, userName, password against
                DSM_Repository.
        IF isUserAuthenticated EQUALS TRUE
            CREATE a new PRINCIPAL for the username
            CREATE a new PERMISSION for the domain
            isUserAuthorized = CHECK PRINCIPAL's PERMISSION
                in domainACL

```

IF *isUserAuthorized* EQUALS TRUE

/* If a multicast address for a domain is requested by a Registry and there are addresses allocated to Headhunters for this domain then get the list of *domainAddresses* from *HHAddressAllocTable* corresponding to *domainName* and select an address at random from this list. */

IF (*userType* EQUALS "Registry") AND
(*HHAddressAllocTable* CONTAINS VALUE
domainName)

mcastaddressList =

GET the list of *domainAddresses* from
HHAddressAllocTable corresponding to
domainName.

domainAddress =

SELECT RANDOM address from
mcastaddressList

ELSE

/* If a HeadHunter/Registry requests multicast address for a domain pick an address at random from the *domainTable*— i.e. from the list of addresses allocated to this domain. */

mcastaddressList =

GET list of *domainAddresses* from
domainTable corresponding to
domainName.

domainAddress =

SELECT RANDOM address from
mcastaddressList

```

IF (userType EQUALS "Headhunter")
/* Maintain a list of Headhunter contact
locations */
PUT<contactLocation, domainName> in
registeredHHTable
/* Maintain a list of addresses-domain
mappings allocated to Headhunters. */
PUT <domainAddress, domainName> in
HHAddressAllocTable
ENDIF
ENDIF
secretKey =
GET secretkey from keyTable corresponding to
domainName
CREATE authenticatedPacket and Send
Response to user
ENDIF //authorized user
ENDIF //authenticated user
ENDIF //contacted by user
ENDWHILE
END_DSM_AUTHENTICATION_SERVICE

```

4.2.4.5 Algorithm for Withdrawing Headhunters from DSM

This algorithm outlines the process for withdrawing a Headhunter from the DSM.

DSM_WITHDRAW

IN: *HeadhunterLocation*

REMOVE key-value pair corresponding to *HeadhunterLocation* from

RegisteredHHTable
END_DSM_WITHDRAW

4.3 Query Manager (QM)

The QM is responsible for finding services matching the client's query requests. The QM uses a parser [LEE02] to translate a service consumer's natural language-like query into an XML-based query. The QM parses the XML based query to generate a structured query language statement and dispatches this query to the 'appropriate' Headhunters (determined by the domain of the query). Requests for service components belonging to a specific domain will be dispatched to Headhunters belonging to that domain and the Headhunters return the list of matching service providers to the QM. The QM obtains the list of registered Headhunters from the DSM. The QM in conjunction with the LM is also responsible for propagating the queries to other linked ICBs.

The QM is configured by an administrator with a *Query Propagation Policy*. The QM propagates a query to the LM based on the *Query Propagation Policy* specified. The *Query Propagation Policy* can be specified as:

- *If No Local*: Propagate a query to the LM only if there are no local search results that satisfy the query
- *Always*: Always propagate a query to the LM

4.3.1 Result Selection Process

The total search space for a service selection may be very large; including services from all Headhunters associated with a particular Internet Component Broker (ICB) and all linked ICBs. The QM uses policies (explained in subsection 4.3.1.1) to

identify a set S_1 of services to return. The QoS type and constraint (explained in subsection 4.3.1.2) are applied to S_1 to produce the set S_2 that satisfies the service type and constraint. Then this can be ordered using the preferences specified in the query (explained in subsection 4.3.1.3), before returning the services to the service requesters.

4.3.1.1 Policies

Policies provide information to affect QM behavior at run time. Policies are represented as name-value pairs. Policies can be grouped into two categories: a) policies that scope the extent of a search, and b) policies that determine the functionality applied to an operation. The examples for *search scoping policies* are i) upper bound of offers to be searched, ii) upper bound of offers to be returned, and iii) upper bound of matched offers to be ordered, etc. Examples for *functionality scoping policies* are minimum number of QoS types desired to be matched.

4.3.1.2 Constraints

Service Requesters use QoS types and constraints to select the set of service offers in which they have an interest. Constraints are described by the 3-tuple $\langle QoS\text{-type-name}, Operators, Literals \rangle$ where *QoS-type-name* specifies the QoS metric on which the constraint is being applied, *Operators* are comparison, boolean connective, substring, arithmetic operators, etc., and *Literals* are the numeric/string/boolean values corresponding to the QoS types. Example: $\langle \text{availability}, >, 50 \rangle$

4.3.1.3 Preferences

Preferences are applied to the set of services matched by application of the QoS type, constraint expression, and various policies. The application of the preferences can determine the order used to return matched services to the service requesters. Preferences

are associated with the 2-tuple $\langle \textit{Sort Order}, \textit{QoS-type-name} \rangle$. The sort order can be specified as *max* (matched offers are returned in descending order of QoS-type values), *min* (matched offers are returned in ascending order of QoS-type values), and *first* (matched offers are returned in the order they are discovered).

4.3.2 Query Handling Process

The QM Query Request Handling Protocol consists of the following steps:

- Parse a component assembler's/system integrator's natural language-like query and extract the keywords and phrases pertaining to various attributes of the components UniFrame specification.
- Extract the consumer-specified constraints, preferences and policies to be applied to the various attributes.
- Compose the extracted information into an XML-based query.
- Translate the XML-based query to a structured query language statement.
- Dispatch this structured query to all the Headhunters associated with the domain on which the search is being performed and also forward the query based on the *Query Propagation Policy* to the Link Manager, which will propagate the query to other ICBs.
- The Headhunters will query associated Meta-Repositories and return a list (possibly non-empty) of components matching the search criteria to the QM, which is returned to the system integrator making the query.
- QM will wait for a specified time period for results to be returned from the Headhunters/other ICBs before timing out. A default timeout period for a session is configured into the QM by an administrator. A session constitutes each new query operation serviced.
- The system integrator has the option to specify search-scoping policies to affect the time spent on the search process.

4.3.3 Algorithms for QM Functions

Data structures used:

Entity ³ <i>queryEntity</i>	An entity, which holds all the attributes corresponding to the client's query request with accessors for accessing the attributes. The attributes of the <i>queryEntity</i> include the computational, cooperational, and auxiliary attributes, QoS Metrics, QM Policies, Constraints, and Preferences.
Hash table <i>resultTable</i>	Mapping between Component IDs and components holding the detailed UniFrame Specification.

Table 4.2. Data Structure for QM functions

³ An Entity data structure is a conceptual representation for an object and holds all the attributes that describe the object with accessors for accessing these attributes.

4.3.3.1 Algorithm for QM Initialization

The QM initialization activates the client request handler. This process receives requests from clients and responds with results. It also activates the query propagation service, which can be called by QM or LM.

QM_INITIALIZATION

 ACTIVATE *QM_CLIENT_REQUEST_HANDLER*

 ACTIVATE *QM_PROPAGATE_QUERY*

END_QM_INITIALIZATION

4.3.3.2 Algorithm for Handling Query Requests from Clients

This algorithm outlines the process for servicing requests from Clients. Clients contact the QM with a natural language-like query. This is processed into an XML query, which is parsed to construct an entity that embodies all the attributes of the query. The *queryEntity* is propagated to Headhunters, which are associated with the domain of the query and also to the LM based on the results obtained from the Headhunters and the *QueryPropagationPolicy* set on the QM. The final results returned from the Headhunters and LMs are ordered as per the client's preferences and returned to the client. Each client request is handled as a separate session. The session timeout period is configured in the QM.

QM_CLIENT_REQUEST_HANDLER

IN: *naturalLanguageQuery*

OUT: *resultTable*

//Get handle to DSM and LM by contacting them at the well-known locations.

dsm = LOOKUP *dsmLocation*

lm = LOOKUP *lmLocation*

WHILE TRUE

 IF contacted by client with *naturalLanguageQuery* Request

 /* The natural language query is parsed and keywords, constraints, preferences, and policies extracted and domain knowledge base is applied to the extracted information and written to a XML File */

 Parse *naturalLanguageQuery* and generate XML File.

 /* The XML query is parsed and the values populated into an entity which contains the logic to construct the structured query language statement. */

xmlQueryDocument =

 Parse XML file and load XML document into memory.

 /* The *QM_PROCESS_XML_QUERY* function populates

```

the queryEntity instantiated here. */
CREATE a new queryEntity
CALL QM_PROCESS_XML_QUERY with xmlQueryDocument
//Propagate the query to all Headhunters in the domain of query
resultTable =
CALL QM_PROPAGATE_QUERY with queryEntity
/* Check if the search scoping policies have been met
example if upper bound of offers to be returned
has been met and if so return results to client. */
searchScopePolicy = GET search scoping policy from queryEntity
IF (searchScopePolicy is specified) AND
    (searchScopePolicy is satisfied)
    resultTable = CALL QM_ORDER_RESULTS
    with queryEntity, resultTable
    Send response to client with resultTable
ENDIF
/* If further propagation of query is required
Check the Query Propagation Policy on the QM.
If QueryPropagationPolicy = "IfNoLocal" and
there are no results matching the search criteria
then propagate query.
If the QueryPropagationPolicy = "Always"
then propagate query irrespective of whether there are local
search results. */
IF ((resultTable NOT NULL)) OR
((QueryPropagationPolicy EQUALS "Always"))
    results = CALL LM_PROPAGATE_QUERY on lm
    with queryEntity
    ADD results to resultTable
ENDIF

```

```

        //Order the results as per client preferences
        resultTable =
        CALL QM_ORDER_RESULTS with queryEntity, resultTable
        Send response to client with resultTable
    ENDIF
ENDWHILE
END_QM_CLIENT_REQUEST_HANDLER

```

4.3.3.3 Algorithm for Processing XML Query

This algorithm uses recursion to parse through the nodes of the XML tree, extract the node values and store these values in the *queryEntity*. The algorithm starts parsing at the root node element. It extracts the node name and checks if the node name matches any attribute in *queryEntity* and populates it with the value in this node. It then finds all the children of that node and repeats the process through recursion.

```

QM_PROCESS_XML_QUERY
    IN: nodeElement
    nodeName = GET NODE NAME from nodeElement
    FOR each attribute in queryEntity
        IF nodeName EQUALS attribute
            nodeValue = GET NODE VALUE from nodeElement
            SET attribute value in queryEntity to nodeValue
        ENDIF
    ENDFOR
    // Get the list of children for this Node.
    NODELIST childrenList = GET CHILDNODES for nodeElement
    IF childrenList NOT NULL
        // For every child node in the list

```

```

FOR i = 0 to LENGTH of childrenList
    childNode = childrenList[i]
    /* Recurse through the function PROCESS_XML_QUERY
    passing it the childNode as reference.*/
    CALL QM_PROCESS_XML_QUERY with childNode
ENDFOR
ENDIF
END_QM_PROCESS_XML_QUERY

```

4.3.3.4 Algorithm for Propagating Query to Headhunters

This algorithm outlines the process for propagating a query request to the Headhunters. The domain of a client's query and the search scoping policies are retrieved from the *queryEntity*. The DSM is contacted to obtain a list of registered Headhunter locations matching this *domain*. The query is then propagated to each Headhunter and the search scoping policies are checked after each propagation to verify whether the policies have been satisfied. If the policies are satisfied then further propagation is terminated and the results are ordered as per client preferences and returned.

QM_PROPAGATE_QUERY

IN: *queryEntity*

OUT: *resultTable*

WHILE TRUE

IF contacted by this QM or LM

//The *queryEntity* stores the details of the query such as the domain
// and other attributes of the query.

domain = GET *domainName* of query from *queryEntity*

/* Get location list of registered Headhunters for the domain of the
query. */

```

hhLocationList = GET Headhunter locations list from dsm with
                    domain
//Propagate the query to each registered Headhunter in the domain.
FOR i=0 to LENGTH of hhLocationList
    //Get the location of the Headhunter
    hhlocation = hhLocationList[i]
    //Get a handle to the Headhunter
    Headhunter = LOOKUP hhlocation
    //Propagate query to each Headhunter.
    results = CALL HH_EXECUTE_QUERY
                on Headhunter with queryEntity
    ADD results to resultTable
ENDFOR
RETURN resultTable
ENDIF
ENDWHILE
END_QM_PROPAGATE_QUERY

```

4.3.3.5 Algorithm for Ordering Search Results

This algorithm outlines the process for retrieving client preferences (sort order ascending or descending) and the QoS type on which the ordering is to be performed. The results are then ordered accordingly and returned.

QM_ORDER_RESULTS

IN: *queryEntity*, *resultTable*

OUT: *resultTable*

orderPreference = GET ordering preference from *queryEntity*

qosTypeToOrder = GET the *QoS-Type-Name* to order by from *queryEntity*

```

IF orderPreference NOT NULL // If an order preference was specified
    resultTable = SORT elements of resultTable on qosTypeToOrder
    RETURN resultTable
ELSE
    RETURN resultTable to client
ENDIF
END_QM_ORDER_RESULTS

```

4.3.3.6 Algorithm for Generating Structured Query Language (SQL) Statement

This algorithm forms a part of the operations performed by *queryEntity*. This algorithm outlines the process for generating a SQL statement based on the attributes extracted from the client's query. These attributes are captured in the *queryEntity*. The attribute names, values and constraints stored in the query entity are built into a SQL statement.

```

QE_GENERATE_SQL_QUERY
IN: queryEntity
OUT: sqlQuery
attributeList = GET all attributes in queryEntity
FOR i=0 to LENGTH of attributeList
    attribute = attributeList[i]
    IF attribute is selected as search parameter
        attributeValue = GET value of this attribute from queryEntity
        attributeConstraint = GET constraint value from queryEntity
        CONCATENATE to BUILD SQL query the
        attribute, attributeConstraint, and attributeValue
    ENDIF

```

```
ENDFOR
RETURN sqlQuery
END_QE_GENERATE_SQL_QUERY
```

4.4 Link Manager (LM)

ICBs are linked to form a *Federation of Brokers* (refer Figure 3.5 in Chapter 3) in order to allow for an effective utilization of the *distributed offer space*. ICBs may propagate the search query issued by the system integrator to other ICBs to which they are linked. This linkage of ICBs makes the offer spaces of the linked ICBs implicitly available to the ICB's own clients.

The LM performs the functions of the ICB associated with establishing links and propagating the queries. *Links* represent paths for propagation of queries from a source ICB to a target ICB. Each link is unidirectional and corresponds to an edge in a directed graph, in which the vertices are LMs.

The Link Manager supports the following operations:

- *Query*: The query operation is responsible for propagating the query from the source LM to the list of Target LMs maintained with the Source LM.
- *Failure Detection*: This involves keeping track of LMs, which may no longer be active due to network failure, node failure, etc. Periodically ($TP_{unicast}$ ms – time period between successive failure detection cycles) the source LM contacts the list of target LMs with which it is configured, to re-establish links and to create a fresh target LM list. If the target LMs respond to the source LM, it means the Target LM is 'alive' to service requests. This target LM location is added to the

list of target LMs to whom requests will be propagated in that cycle. If the target LMs do not respond then that target LM may have failed. During subsequent cycles if a previously failed target LM is now alive to service requests, then it is added to the list of LMs to receive queries for that cycle.

4.4.1 Algorithms for LM Functions

Data structures used:

List <i>aliveTargetLMList</i>	List of Target LM locations, which are alive and can service query requests.
List <i>targetLMList</i>	List of locations of LM's with which this LM registers. This can be specified with the configuration information at LM initialization.

Table 4.3. Data Structure for LM functions

4.4.1.1 Algorithm for LM Initialization

The LM upon initialization establishes links with the list of target LMs passed to it as configuration information. It starts failure detection processes, which stay alive as an active processes and runs periodically in the background. It also activates the query propagation and link checking processes, which can be called from remote LMs.

LM_INITIALIZATION

IN: *targetLMList*

CALL *LM_ESTABLISH_LINKS*

START *LM_FAILURE_DETECTION*

```

ACTIVATE LM_PROPAGATE_QUERY
ACTIVATE LM_CHECK_LINK
END_LM_INITIALIZATION

```

4.4.1.2 Algorithm for Establishing Links with Target LMs

This algorithm outlines the process followed by the LM for establishing links with Target LMs. The LM steps through the list of target LM locations it is configured with and contacts each of these target LMs. If the target LM responds, then this target LM location is added to the *aliveTargetLMList*, which maintains a list of all alive target LMs to whom the queries will be propagated. If the LM does not respond due to link or node failure then the failed target LM address is not stored.

```

LM_ESTABLISH_LINKS
  CREATE aliveTargetLMList
  //Contact the LMs specified in configuration.
  FOR i=0 to LENGTH targetLMList
    targetLMLocation = targetLMList[i]
    targetLM = LOOKUP targetLMLocation
    isAlive = CALL LM_CHECK_LINK on targetLM
    //If target LM is alive then add this target LM location
    //to the list.
    IF isAlive
      //Maintain a list of LMs with whom registration was
      // successful
      ADD targetLMLocation to aliveTargetLMList
    ENDIF
  ENDFOR
END_LM_ESTABLISH_LINKS

```

4.4.1.3 Algorithm for Checking whether Links can be Established

The LM contacts target LMs to check if they are functioning. When contacted by a source LM the target LM returns a “true” response indicating it is alive to service requests.

```

LM_CHECK_LINK
  OUT: isAlive
  WHILE TRUE
    IF contacted by LM
      RETURN TRUE
    ENDIF
  ENDIF
END_LM_CHECK_LINK

```

4.4.1.4 Algorithm for Propagating a Query by the LM

This algorithm outlines the process for receiving a query from the QM in the same ICB and propagating it to LMs in other ICBs or receiving a query from LMs in other ICBs and propagating query to the QM in the same ICB. The determination of where the query is coming from is made based on the value of the *requestID* attribute in *queryEntity*. The *requestID* is a *String* value, which is set to the value “*LinkManager*” if the query is received from an external LM or holds a default value of “*QueryManager*” when the *queryEntity* is instantiated by the QM for propagation. When the LM receives a query it inspects the value of the *requestID* attribute. If the *requestID* is set to “*QueryManager*” it means the query has originated from a QM in the same ICB and

needs to be propagated to other LMs. If the *requestID* set to “LinkManager”, it means the query is coming from another LM and needs to be propagated to the QM in the same ICB as the LM.

LM_PROPAGATE_QUERY

IN: *queryEntity*

OUT: *resultTable*

WHILE TRUE

 IF contacted by QM in same ICB or LM in different ICB

requestID = GET *requestID* from *queryEntity*

 //If the propagation request has come from LM in the different ICB

 IF (*requestID* EQUALS “LinkManager”)

 //Propagate the request to QM located in same ICB as LM.

resultTable = CALL *QM_PROPAGATE_QUERY* on *qm*
 with *queryEntity*

 RETURN *resultTable*

 //If the propagation request has come from QM in the same

 //ICB as LM. The *requestID* would be set to “QueryManager”.

 ELSE

 //This query will now be propagated to target LMs

 //hence the *requestID* parameter has to reflect this

 //that it is coming from a LM.

 SET *requestID* = “LinkManager” in *queryEntity*

 CREATE *resultTable*

 //Get list of all alive LMs to whom the query can be

 //propagated.

 FOR i = 0 to LENGTH of *aliveTargetLMList*

targetLMLocation = *aliveTargetLMList*[i]

targetLM = LOOKUP *targetLMLocation*

results =

```

        CALL LM_PROPAGATE_QUERY on targetLM
        with queryEntity
        ADD results to resultTable
    ENDFOR
    RETURN resultTable
ENDIF
ENDIF
ENDWHILE
END_LM_PROPAGATE_QUERY

```

4.4.1.4 Algorithm for Failure Detection of Target LMs

The LMs periodically check whether all the target LMs maintained in the target LM list are still alive by establishing contact with the target LMs.

```

LM_FAILURE_DETECTION
    WHILE TRUE
        CALL LM_ESTABLISH_LINKS
        // Periodically ( $TP_{unicast}$  millisecs) refresh links so that
        // a list of 'alive' Target LMs is maintained. The optimal
        //  $TP_{unicast}$  time is determined based on experimentation.
        SLEEP  $TP_{unicast}$ 
    ENDWHILE
END_LM_FAILURE_DETECTION

```

4.5 Adapter Manager (AM)

The AM serves as a registry/lookup service for clients seeking adapter components. The adapter components register with the AM and while doing so they indicate their specialization (i.e., which heterogeneous component models they can bridge efficiently). System Integrators contact the AM to search for adapter components matching their needs. The AM utilizes adapter technology, each adapter component providing translation capabilities for specific component architectures. Thus, a computational aspect of the adapter component indicates the models for which it provides interoperability. The adapter components achieve interoperability using the principles of wrap and glue technology [LUQ01]. A reliable, and cost-effective development of wrap and glue is realized by the automatic generation of glue and wrappers based on component specifications. Wrapper software provides a common message-passing interface for components that frees developers from the error prone tasks of implementing interface and data conversion for individual components. The glue software schedules time-constrained actions and carries out the actual communication between components.

4.5.1 Algorithms for AM Functions

Data structures used:

Entity <i>adapterQueryEntity</i>	An entity, which holds all the attributes corresponding to the client's query request with access modifiers for accessing the attributes.
List <i>adapterResults</i>	List of adapter components matching the query requirements.

Table 4.4. Data Structure for AM functions

4.5.1.1 Algorithm for AM Initialization

The AM on initialization creates the AM_REPOSITORY where the adapter component service information is stored. It activates the client request handler, which services client's query requests for adapter components and the adapter registration handler process, which receives calls from remote services to register them with the AM.

AM_INITIALIZATION

 CREATE *AM_REPOSITORY*

 ACTIVATE *AM_CLIENT_REQUEST_HANDLER*

 ACTIVATE *AM_SERVICE_REGISTRATION_HANDLER*

END_AM_INITIALIZATION

4.5.1.2 Algorithm for Handling Client Requests for Adapters

The AM receives natural language-like query requests for adapter components from clients. The process of parsing the query and generating a structured query language statement is similar to that used in the QM (Algorithm *QM_PROCESS_XML_QUERY* and *QE_GENERATE_SQL_QUERY*). The AM executes the resultant SQL query against the AM Repository and obtains the list of adapter components matching the search criteria.

AM_CLIENT_REQUEST_HANDLER

 IN: *naturalLanguageAdapterQuery*

 OUT: *adapterResults*

 WHILE TRUE

 IF contacted by client with REQUEST for adapter components

 // Refer algorithms *QM_PROCESS_XML_QUERY* and

```

// QE_GENERATE_SQL_QUERY
sqlQuery = PROCESS naturalLanguageAdapterQuery
adapterResults = EXECUTE QUERY sqlQuery on
                AM_REPOSITORY
return adapterResults to Client
ENDIF
ENDWHILE
END_AM_CLIENT_REQUEST_HANDLER

```

4.5.1.3 Algorithm for Registering Adapter Components

The AM receives the XML based specification of the adapter components and parses these specifications to extract the data and stores this information in the AM_REPOSITORY.

```

AM_ADAPTER_REGISTRATION_HANDLER
IN: adapterComponentSpecification
WHILE TRUE
    IF contacted by adapter component with REQUEST for registration
        STORE adapterComponentSpecification in AM_REPOSITORY
    ENDIF
ENDWHILE
END_AM_ADAPTER_REGISTRATION_HANDLER

```

4.6 Headhunters

Another critical component of URDS is a Headhunter. The Headhunters perform the following tasks: a) Service Discovery: detect the presence of service providers (Exporters), b) register the functionality of these service providers, and c) return a list of service providers to the ICB that matches the requirements of the consumer (Importers) requests forwarded by the QM.

The service discovery process performs the search based on multicasting. Once deployed in the UniFrame environment, the Headhunters periodically (TP_{mcast} ms - time period between successive multicast cycles) multicast their presence (location address of the Headhunter) to a multicast group. The multicast group address is obtained from the DSM. The active registries (extended native registries), which also obtain a multicast group address from the DSM, listen for multicast messages from Headhunters on these multicast groups. When Active Registries receive a multicast message from a Headhunter with its location they respond to the message by unicasting their location information to the Headhunter. The Headhunters maintain a cache of the pairs $\langle \text{registry address}, T_r \text{ (time-stamp of receipt)} \rangle$. The Headhunter uses the registry location information received to query the Registries for the component information of service providers they contain in order to register the service information details with itself. During the registration, the Headhunter stores into the meta-repository all the details of the service providers, including the UniFrame specifications. It uses this information during a matching-making process where it tries to find services that satisfy the computational, cooperational, auxillary attributes and QoS metrics specified in the search query. A component may be registered with multiple Headhunters. The functionality of Headhunters makes it necessary for them to communicate with Active Registries belonging to any model, implying that the cooperative aspect of Headhunters be universal.

The two main issues that need to be handled by the Headhunter apart from the stated functions are:

- *Failure Detection:* Failure detection (FD) involves keeping track of service exporter components which may no longer be active in the system for various reasons including voluntary withdrawal from their respective registries, network failure, node failure, etc. The failure detection in the Headhunter is done at the level of detecting failure of the active registries, which hold the service exporter components. The Headhunter keeps track of the time at which it obtains registry location information from various active registries. At regular time intervals (TP_{purge} ms – time period between successive purge cycles) the Headhunter notes the ‘freshness’ of the information it holds and purges the registry information, which it deems to be ‘stale’. ‘Fresh’ or ‘Stale’ are determined based on the time elapsed between the receipt of the registry address through unicast communication (T_r) and the current time (T_c). If the elapsed time is greater than 2 purge cycles (i.e. $(T_c - T_r) > 2TP_{\text{purge}}$) then it signifies that the registry is not responding and may be dead or ‘stale’, else the registry information is deemed to be ‘fresh’. This is essentially based on the principle that if a registry is still active in the system it will respond to the Headhunter with its location information and thus have a later timestamp. A registry which for whatever reason is unable to contact the Headhunter with its information will hold a ‘stale’ timestamp and it will be assumed that all service exporter components held by this registry are no longer available for rendering service.
- *Multicast Security:* This involves securing the multicast data transmission mechanism from security threats such as eavesdropping, and masquerading. The Headhunter uses Secret-Key Encryption to ensure security of transmitted data. The secret-key used is a symmetric key wherein the sender and receiver use the same key for purposes of encryption and decryption.

4.6.1 Algorithms for HH Functions

Data structures used:

Hash table <i>registryTable</i>	Mapping between Active Registry location addresses and the timestamp of when this location address information was received by the Headhunter.
Hash table <i>componentTable</i>	Mapping between Component IDs and components holding the detailed UniFrame Specification.

Table 4.5. Data Structure for HH functions.

4.6.1.1 Algorithm for HH Initialization

The Headhunter is configured at startup by the deployer with the DSM location information, domain name, username, and password. The Headhunter upon initialization contacts the DSM with its authentication credentials in order to obtain a multicast address and secret-key for its domain. The Headhunter then creates the meta-repository, joins the multicast group and starts the processes for sending multicast communication and failure detection, which execute periodically. It also activates the process to receive unicast communication, which receives calls from remote registries.

HH_INITIALIZATION

IN: *DSMLocation*

// Obtain handle to DSM which runs at well-known location

dsm = LOOKUP *DSMLocation*

/* Obtain an authenticated packet by contacting the DSM. Pass the authentication information (userType, userName, password, contactLocation, domain) to the DSM and wait for response */

```

authenticatedPacket =
CALL DSM_AUTHENTICATION_SERVICE on dsm with
userType, userName, password, contactLocation, domain
//Extract multicast address and secret-key from authenticatedPacket.
multicastAddress = GET multicastAddress from authenticatedPacket
secretKey = GET secretKey from authenticatedPacket
CREATE META_REPOSITORY
// Once multicast address is obtained join the multicast group.
JOIN multicast group with multicastAddress
START HH_SEND_MULTICAST_COMMUNICATION
START HH_FAILURE_DETECTION
ACTIVATE HH_RECEIVE_UNICAST_COMMUNICATION
END_HH_INITIALIZATION

```

4.6.1.2 Algorithm for Headhunter Multicast Announcements

This algorithm outlines the process for periodic encrypted multicast announcements by the Headhunter.

```

HH_SEND_MULTICAST_COMMUNICATION
  WHILE TRUE
    /* Keep multicasting the encrypted contact information of this Headhunter
    at regular intervals to the multicast group address, which has
    subscriptions from listeners, which are the active registries. */
    encryptedHeadhunterLocation = ENCRYPTsecretKey{HeadhunterLocation}
    MULTICAST encryptedHeadhunterLocation
    // Put the multicasting thread to sleep for  $TP_{mcast}$  millisecs before the next
    // multicast.
    SLEEP  $TP_{mcast}$ 

```

```

    ENDWHILE
END_HH_SEND_MULTICAST_COMMUNICATION

```

4.6.1.3 Algorithm for Receiving Unicast Communication from Active Registries

In this algorithm, the Headhunter receives the registry location from active registries. It then computes the timestamp of receipt and stores the registry location and timestamp in a hash table. It then uses the registry location information it has received to contact the registry and retrieve component information available with the registry to store in the meta-repository.

```

HH_RECEIVE_UNICAST_COMMUNICATION
    IN: registryLocation
    WHILE TRUE
        IF contacted by registry with registryLocation
            /* Compute the timestamp when information was obtained
            The timestamp is computed as the number of millisecs elapsed
            since January 1st, 1970 GMT. */
             $T_r =$  COMPUTE CURRENT_TIMESTAMP
            /* Add the registry location information and timestamp to the
            registry table.*/
            PUT <registryLocation,  $T_r$ >in registryTable
            CALL HH_POPULATE_META_REPOSITORY with
            registryLocation
        ENDIF
    ENDWHILE
END_HH_RECEIVE_UNICAST_COMMUNICATION

```

4.6.1.4 Algorithm for Populating Meta Repository

This algorithm demonstrates how the Headhunter gets a handle to the active registries using their registry location and contacts the registries to retrieve the component information, which it stores onto the meta-repository.

HH_POPULATE_META_REPOSITORY

```

    IN: registryLocation
    // Get handle to active registry using its registryLocation
    activeRegistry = LOOKUP registryLocation
    // Obtain the component data stored in this registry.
    componentTable = CALL AR_GET_COMPONENT_DATA on activeRegistry
    // Store the component information from the componentTable into the Meta-
    // Repository
    WHILE componentTable HAS MORE ELEMENTS.
        componentInfo = GET NEXT ELEMENT from componentTable
        STORE componentInfo to META_REPOSITORY
    ENDWHILE
END_HH_POPULATE_META_REPOSITORY

```

4.6.1.5 Algorithm to Retrieve Search Results from the Meta-Repository

This algorithm outlines the process in which the Headhunter generates the SQL query from the *queryEntity* and executes this query against the meta-repository to retrieve the list of components matching the search criteria.

HH_EXECUTE_QUERY

IN: *queryEntity*

OUT: *resultTable*

sqlQuery = CALL *QE_GENERATE_SQL_QUERY* on *queryEntity*

resultTable = EXECUTE QUERY *sqlQuery* on *META_REPOSITORY*

RETURN *resultTable*

END_HH_EXECUTE_QUERY

4.6.1.6 Algorithm to Detect Failure of Active Registries

This failure detection algorithm of the Headhunter involves keeping track of active registries which may no longer be alive. The Headhunter records the timestamp of responses received from these registries and periodically checks the freshness of the registry timestamps purging a reference to all the ‘stale’ registries and also deleting all the component information obtained from them.

HH_FAILURE_DETECTION

WHILE TRUE

/* The Headhunter maintains time stamped entries of responses received from the active registries. Periodically (TP_{purge} millisecs) a check is performed to verify the ‘currentness’ of members */

SLEEP TP_{purge}

T_c = COMPUTE CURRENT_TIMESTAMP

registryList = GET enumeration of locations from *registryTable*

WHILE *registryList* HAS MORE ELEMENTS.

registryLocation = GET NEXT ELEMENT from *registryList*

T_r = GET timestamp in *registryTable* for *registryLocation*

IF $(T_c - T_r) > 2TP_{\text{purge}}$

```

        DELETE components in repository obtained from this
        registryLocation
        REMOVE <registryLocation, Tr> from registryTable
    ENDIF
ENDWHILE
ENDWHILE
END_HH_FAILURE_DETECTION

```

4.6.1.7 Algorithm for Headhunter Shutdown

The Headhunter before shutdown withdraws from the DSM, leaves the multicast group and terminates all the active processes.

```

HH_SHUTDOWN
    // Withdraw Headhunter registration from DSM
    CALL DSM_WITHDRAW on dsm with hhLocation
    // Leave multicast group.
    LEAVE multicast group at multicastAddress
    // Stop all active threads of control..
    STOP HH_SEND_MULTICAST_COMMUNICATION
    STOP HH_FAILURE_DETECTION
HH_SHUTDOWN

```

4.7 Meta-Repository (MR)

The Meta-Repository is a data store that holds service information of components adhering to different models. The Meta-repository stores the *Meta* level service

information comprising of: a) Service type name, b) Details of its informal specification, and c) Zero or more QoS values for that service for each of the components. The implementation of a Meta-Repository is database-oriented and all the component information is stored onto a database. Using a database implementation provides an opportunity to perform searches for components matching the search criteria by using the inbuilt searching techniques. The Meta-Repository is a *passive component*, i.e., a Headhunter brings information and stores it in the meta-repository.

4.8 Active Registry (AR)

The native registries (e.g., RMI Registry or CORBA registry) are extended to have the following features:

- *Activeness*: The registries are modified to be able to listen to multicast messages from the Headhunter and respond with their registry location information.
- *Introspection Capabilities*: The registries are extended to not only keep a list of component URLs of those components registered with them but also their detailed UniFrame specifications. This is achieved by querying the components (using principles of introspection) to obtain the URL of their XML based specifications. The registries parse the specification and maintain the details in a memory resident table, which is returned to the Headhunter upon request.

4.8.1 Algorithms for AR Functions

Data structures used:

Hash table <i>componentTable</i>	Mapping between Component ID and component specification details.
Entity <i>componentEntity</i>	An entity, which can be persisted to a repository and holds all the attributes corresponding to the UniFrame specification with access modifiers for accessing the attributes.

Table 4.6. Data Structure for AR functions.

4.8.1.1 Algorithm for AR Initialization

The algorithm for AR initialization involves contacting the DSM for an authenticated packet of the multicast address and the secret-key. Using the multicast address the AR joins the multicast group and starts listening for multicast communication from the Headhunters on this multicast group.

AR_INITIALIZATION

IN: *DSMLocation*

// Obtain handle to DSM which runs at well-known location

dsm = LOOKUP *DSMLocation*

/* Obtain an authenticated packet by contacting the DSM. Pass the authentication information (userType, userName, password, contactLocation, domain) to the DSM and wait for response */

authenticatedPacket =

CALL *DSM_AUTHENTICATION_SERVICE* of *dsm* with
userType, userName, password, contactLocation, domain

```

//Extract multicast address and secret-key from authenticatedPacket.
multicastAddress = GET multicastAddress from authenticatedPacket
secretKey = GET secretKey from authenticatedPacket
// Once multicast address is obtained join the multicast group.
JOIN multicast group with multicastAddress
START AR_RECEIVE_MULTICAST_COMMUNICATION
ACTIVATE AR_GET_COMPONENT_DATA
END_AR_INITIALIZATION

```

4.8.1.2 Algorithm for AR Receiving Multicast Communication

This algorithm outlines the process in which an AR receives multicast communication from the Headhunters. On receiving the Headhunter multicast messages with its location information the AR decrypts the message using the secret-key and unicasts it's encrypted contact location to the Headhunter.

```

AR_RECEIVE_MULTICAST_COMMUNICATION
  IN: encryptedHeadhunterLocation
  WHILE TRUE
    IF contacted by Headhunter with encryptedHeadhunterLocation
      /* Receive encrypted Headhunter location information multicast to
      registry by Headhunters. Decrypt the location information using
      secret-key. */
      HeadhunterLocation =
        DECRYPTsecretKey {encryptedHeadhunterLocation}
      //Get a handle to the headunter running at the location
      Headhunter = LOOKUP HeadhunterLocation
      CALL HH_RECEIVE_UNICAST_COMMUNICATION on
      Headhunter with registryLocation

```

```

        ENDIF
    ENDWHILE
END_AR_RECEIVE_MULTICAST_COMMUNICATION

```

4.8.1.3 Algorithm for Obtaining UniFrame Specifications of Registered Components

This algorithm outlines the process for obtaining the UniFrame specifications of the components registered with an AR. The AR gets a URL list of all the components registered with it. It then steps through this list and gets a handle to each of these components. Using the component reference, the AR examines the component's properties to check for a property returning the URL of its UniFrame specification. The AR then reads the XML-based UniFrame specification from the URL and parses this specification to obtain all the component details, which it stores in an entity object *componentEntity*. The AR builds a hash table of such entities corresponding to each of the components registered with it and returns this hash table to the Headhunter.

```
AR_GET_COMPONENT_DATA
```

```
    OUT: componentTable
```

```
    WHILE TRUE
```

```
        IF contacted by HH to retrieve component data
```

```
            CREATE a new componentTable
```

```
            //Obtain a list of object URL's of all objects registered with this
```

```
            // registry.
```

```
            registeredServicesURLList = GET LIST of service components
                                     registered with this Active Registry
```

```
            // For each object in this URL list
```

```
            FOR i=0 to LENGTH of registeredServicesURLList
```

```
                registeredServiceURL = registeredServicesURLList[i]
```

```
                // Lookup and obtain the reference to the services from the
```

```

// registry using the registered service URL.
serviceObject = LOOKUP registeredServiceURL
// Obtain the location (URL) of the UniFrame Specification
// for this service by introspecting its property name called
// "uniFrameSpecification".
uniFrameSpecURL =
CALL      AR_INTROSPECT_PROPERTY      with
serviceObject, "uniFrameSpecification"
// Parse the UniFrame Specification and construct a
// componentEntity which can be persisted.
CREATE a componentEntity
document = PARSE uri and load XML document
CALL AR_PARSE_UNIFRAME_SPEC with document
//Add the component to the componentTable
PUT < registeredServiceURL, componentEntity>
in componentTable
ENDFOR
RETURN componentTable
ENDIF
ENDWHILE
END_AR_GET_COMPONENT_DATA

```

4.8.1.4 Algorithm for Parsing the UniFrame Specification

This algorithm uses recursion to parse through the nodes of the XML tree, extract the node values and store these values in the *componentEntity*. The algorithm starts parsing at the root node element. It extracts the node name and checks if the node name matches any attribute in *componentEntity* and populates it with the value in this node. It then finds all the children of that node and repeats the process through recursion.

```

AR_PARSE_UNIFRAME_SPEC
  IN: nodeElement
  nodeName = GET NODE NAME from nodeElement
  FOR each attribute in componentEntity
    IF nodeName EQUALS attribute
      nodeValue = GET NODE VALUE from nodeElement
      SET attribute value in componentEntity to nodeValue
    ENDIF
  ENDFOR
  // Get the list of children for this Node.
  NODELIST childrenList = GET CHILDNODES for nodeElement
  IF childrenList NOT NULL
    // For every child node in the list
    FOR i = 0 to LENGTH of childrenList
      childNode = childrenList[i]
      // Recurse through the function READ_NODE passing it the
      // childNode as reference.
      CALL AR_PARSE_UNIFRAME_SPEC with childNode
    ENDFOR
  ENDIF
END_AR_PARSE_UNIFRAME_SPEC

```

4.8.1.5 Algorithm for Introspection of the Registered Components

This algorithm outlines the process for examining a service object to find a specific property and retrieve its value. The algorithm gets a list of all the properties from the service object and tries to find a match for the specific property of interest. Once the

property is found, a handle to the Read accessor method (getter) of this property is obtained and invoked.

AR_INTROSPECT_PROPERTY

IN: *serviceObject*, *propertyName*

OUT: *property*

//Introspect and retrieve all information pertaining to this service object.

serviceObjectInfo = INTROSPECT *serviceObject* to retrieve object information

//Get a description list of all properties of this object.

propertyDescriptorList =

GET PROPERTY DESCRIPTORS from *serviceObjectInfo*

//Iterate through the description list to find the desired property.

FOR i=0 to LENGTH of *propertyDescriptorList*

propertyDescriptor = *propertyDescriptorList*[i]

propertyDescriptorName = GET NAME of *propertyDescriptor*

 //If the property descriptor name matches the desired property name

 IF *propertyDescriptorName* EQUALS *propertyName*

 //Get the accessor method that returns the property value.

method = GET READ METHOD of *propertyDescriptor*

 //Invoke the method to retrieve the value.

property = INVOKE *method* of *serviceObject*

 //Return this property to the requester.

 RETURN *property*

 ENDIF

ENDFOR

END_AR_INTROSPECT_PROPERTY

4.9 Services

Service Exporter Components are implemented in different models, e.g., Java RMI, CORBA, EJB, etc. The components are identified by their *Service Offers* comprising of service type name, b) informal UniFrame specification, and c) zero or more QoS values for that service. A component registers its interfaces with an Active Registry. The component interface contains a method, which returns the URL of its informal specification. The informal specification is stored as an XML file adhering to certain syntactic contracts to facilitate parsing. These service exporter components will be tailored for specific domains such as Financial Services, Health Care Services, Manufacturing Services, etc., and will adhere to the relevant standards, business architectures, and research and technologies for these industry specific markets.

This chapter presented the high-level design for the components in the URDS architecture. The next chapter presents a prototype implementation for the URDS architecture.

5. IMPLEMENTATION OF THE URDS ARCHITECTURE

Chapter 4 provided a conceptual perspective of the URDS architecture. The architecture presented did not adhere to any specific implementation methodology. The URDS architecture can be realized using several different software/hardware technologies. This chapter describes a prototype implementation for the URDS architecture using Java and Java based technologies.

The chapter is organized as follows: Section 5.1 presents technological artifacts and architectural models, which were used in the prototype implementation. Section 5.2 presents the prototype implementation followed by experimental results from the prototype in Section 5.3. Section 5.4 outlines implementation strategies that can be used to enhance the prototype implementation.

5.1 Technology

This section describes various architectural artifacts and technologies that have been leveraged in the implementation the URDS architecture.

5.1.1 Web Servers and Application Servers

A *Web Server* consists of computer hardware and software programs that serve up static content like HTML pages, images and documents to remote browsers accessing the web server. Web Servers are assigned IP addresses using which remote applications can

access it using the HTTP protocol. Web Servers are also called HTTP servers. Examples for Web Servers include the IBM Http Server [IBMa], iPlanet Web Server Enterprise Edition [IPL], and Apache Http Server [APA].

Application Servers are software components that collaborate with Web Servers to return customized results (dynamic content) to a client's request. Examples of Application servers include IBM WebSphere Application Server [IBMb], WebLogic [BEA], and IIS [MIC]. Figure 5.1 illustrates the relationship between Browsers/Clients, Web Servers and Application Server. The browser clients communicate with the web servers using HTTP protocol. The web servers in turn communicate with the application servers to retrieve dynamic content, which is returned to the clients. The application servers communicate with back-end database systems/directory servers using standard communication protocols.

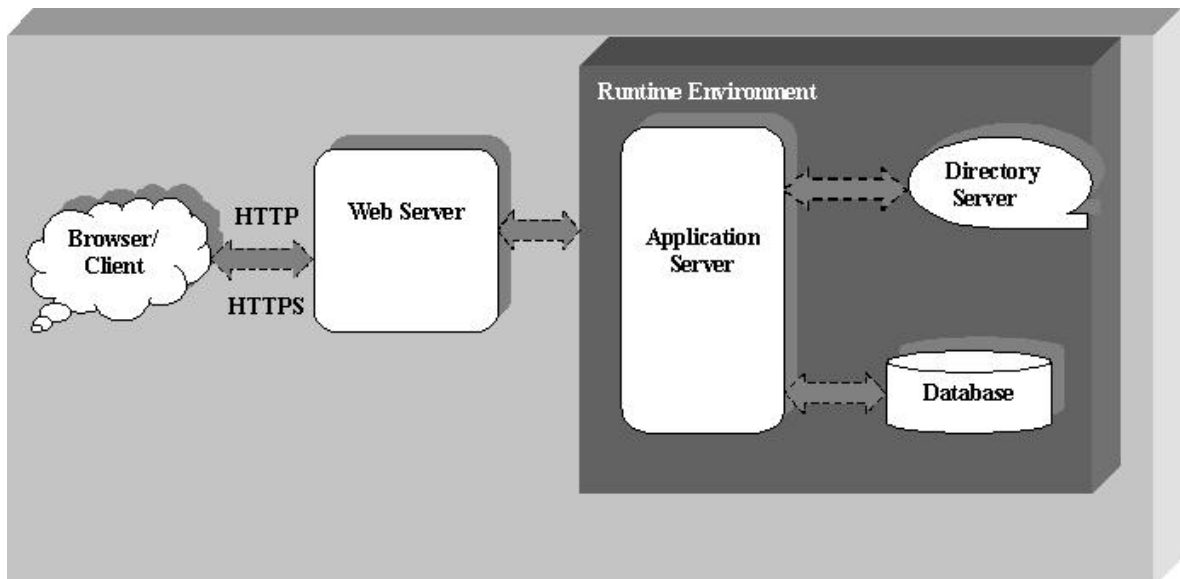

Figure 5.1. Interaction between Clients, Web Servers and Application Servers.

5.1.2 Java™ 2 Platform Enterprise Edition (J2EE™)

The prototype implementation is based on the architectural model laid out by [SUN01b] in J2EE™. J2EE™ defines a standard that applies to all aspects of

architecting, developing, and deploying multi-tier, server-based applications. Figure 5.2 [SUN01b] shows the components of the J2EE Model.

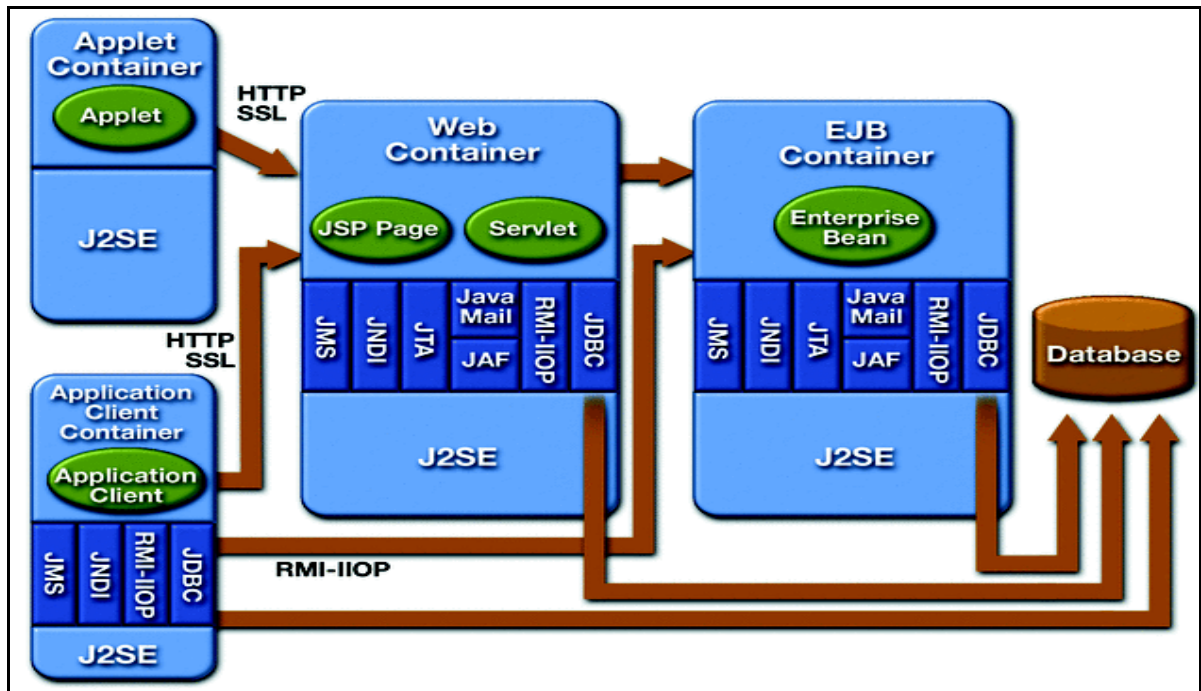

Figure 5.2. Components and Containers of J2EE Model.

(Figure 5.2 is courtesy SUN Microsystems, [SUNa])

The J2EE™ platform specifies technologies to support multi-tier enterprise applications. These technologies fall into three categories [SUN01b]: Component, Service, and Communication. The following sub-sections outline the technologies (see Figure 5.2) in each of these categories that have been used in the implementation. (The Java based technologies described in these sections are proprietary technologies of SUN Microsystems [SUN01b]).

5.1.2.1 Component Technologies

Components are application-level software units. All J2EE components depend on the runtime support of a system-level entity called a “*Container*”. Containers provide

components with services such as life cycle management, security, deployment, and threading.

The J2EE Component technologies have been used in the prototype to create the front-end client components and back-end service components. The prototype supports two types of clients: *Application Clients* which are structured as *Application Client Components* (described in section 5.1.2.1.1) and *Web Clients*, which interact with the *Web Components* (described in section 5.1.2.1.2). The prototype also uses the *JavaBean Components* (described in section 5.1.2.1.3) in the client and server tiers of the implementation.

The different types of J2EE components used in the prototype are described below:

5.1.2.1.1 Application Client Components

Application clients are client components that execute in their own Java virtual machine. *Application clients* are hosted in a *Application Client Container*.

5.1.2.1.2 Web Components

A *Web Component* is a software entity that provides a response to a request. The J2EE platform specifies two types of Web components: Servlets and JavaServer Pages™ (JSP) pages. A *Web Container* hosts web components.

- *Java Servlet Technology 2.3*: Servlets extend the capabilities of web servers that host applications accessed by way of a request-response programming model. Java Servlet technology has provisions for defining HTTP-specific servlet classes. Although servlets can respond to any type of request, they are commonly used to extend the applications hosted by Web servers.
- *JavaServer Pages Technology 1.2*: The JavaServer Pages (JSP) technology provides an extensible way to generate dynamic content for a Web client. A JSP

page is a text-based document that describes how to process a request to create a response. It contains two types of text: static template data, which can be expressed in any text-based format such as HTML, WML, and XML, and JSP elements (snippets of servlet code), which determine how the page constructs dynamic content.

5.1.2.1.3 JavaBean and Enterprise JavaBean Components

A *JavaBean* Component is a body of code with fields and methods to implement modules of business logic. The server and client tiers can include components based on the JavaBeans component architecture. *Enterprise JavaBeans* are server-side components that encapsulate the business logic of an application and support enterprise level processing by making the JavaBeans scalable, transactional, and multi-user secure. An EJB container hosts Enterprise beans.

5.1.2.2 Service Technologies

The J2EE platform service technologies allow applications to access a variety of services. The prominent service technologies supported are *JDBCTM API 2.0* which provides access to databases, *Java Transaction API (JTA) 1.0* for transaction processing, *Java Naming and Directory Interface (JNDI) 1.2* which provides access to naming and directory services, and *J2EE Connector Architecture 1.0* which supports access to enterprise information systems.

The service technologies used in the prototype are described below:

- *JDBCTM API 2.0*: The JDBCTM API provides methods to invoke SQL commands from Java programming language methods. The JDBC API has two parts: an application-level interface used by the application components to access a database, and a service provider interface to attach a JDBC driver to the J2EE platform.

- *Java API for XML Processing 1.1*: XML is a language for representing text-based data so the data can be read and handled by any program or tool. Programs and tools can generate XML documents that other programs and tools can read and handle. Java API for XML Processing (JAXP) supports processing of XML documents using DOM, SAX, and XSLT parsers. JAXP enables applications to parse and transform XML documents independent of a particular XML processing implementation.

5.1.2.3 Communication Technologies

Communication technologies provide mechanisms for communication between clients and servers and between collaborating objects hosted by different servers. Some of the communications technologies supported by the J2EE Platform include - Transport Control Protocol over Internet Protocol (TCP/IP), Hypertext Transfer Protocol HTTP 1.0, Secure Socket Layer SSL 3.0, Java Remote Method Protocol (JRMP), Java IDL, Remote Method Invocation over Internet Inter ORB Protocol (RMI-IIOP), Java Message Service 1.0 (JMS), JavaMail and Java Activation Framework.

The prototype uses the *HTTP 1.0 Protocol* for communication between the browser-based clients and server side components. The inter-component communication on the server side is achieved through Java Remote Method Invocation.

The protocols used in the prototype are described below.

- *HTTP 1.0 Protocol*: The Hypertext Transfer Protocol (HTTP) is an application-level, generic stateless protocol for distributed, collaborative, hypermedia information systems.
- *Java Remote Method Protocol (JRMP)*: Remote Method Invocation (RMI) is a set of APIs in the Java programming language that enables developers to build distributed applications. RMI uses Java language interfaces to define remote objects and a

combination of Java serialization technology and the Java Remote Method Protocol (JRMP) for performing remote method invocations.

5.2 Prototype Implementation

This section describes an implementation of a prototype for the URDS architecture described in Chapter 4. Figure 5.3 illustrates this implementation. The architecture is implemented as a multi-tier, distributed application model, which means

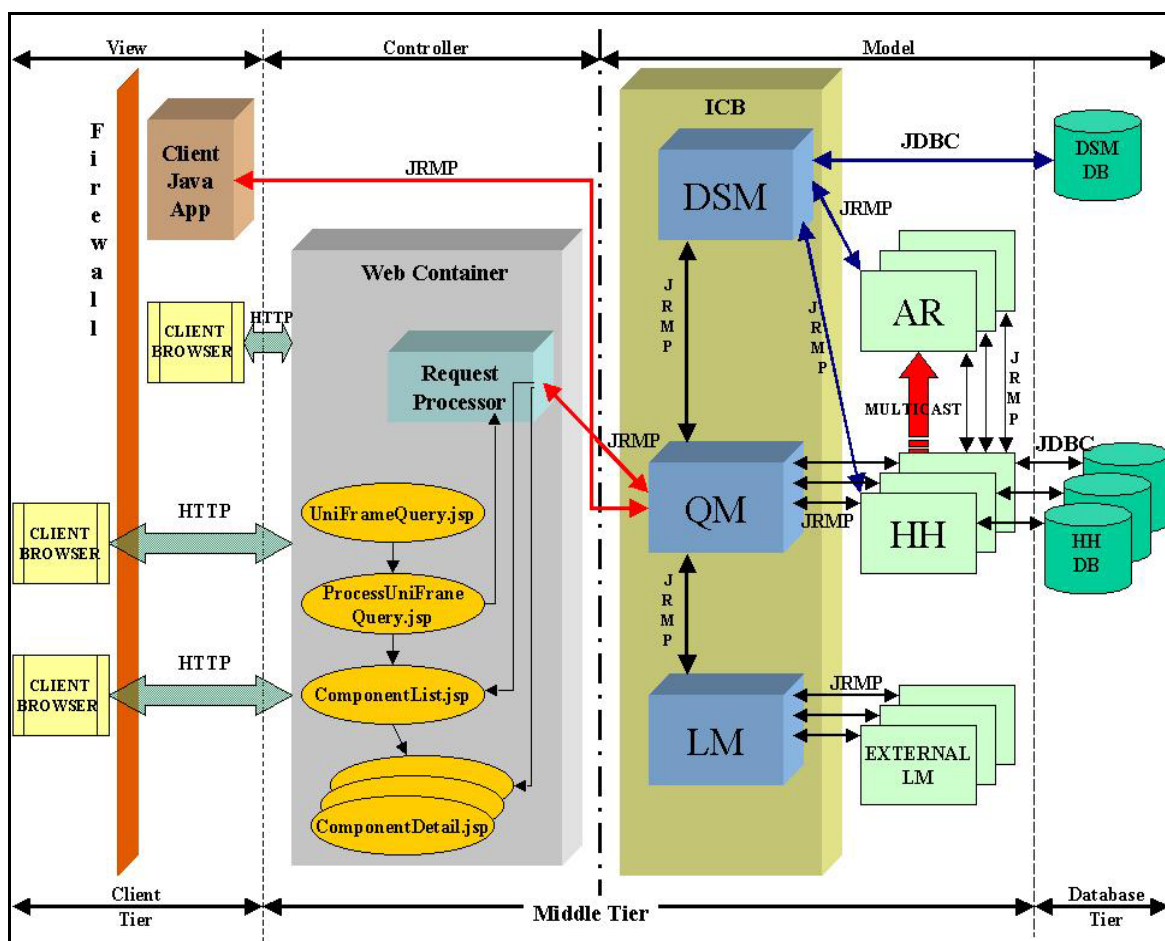

Figure 5.3. URDS Implementation

that the various parts of the prototype implementation can run on different machines. This is in conformance with the J2EE architecture, which defines a *client tier*, a *middle tier* (consisting of one or more sub tiers), and a backend tier providing services of enterprise information systems. In the prototype, the client tier supports a variety of client types, both application clients as well as web-based clients. The middle tier supports client services through Web containers in the *Web tier*. The middle tier also supports the component services (DSM, QM, LM, HH, AR which form the core of the URDS architecture) as Java-RMI based services. The *Database tier* supports access to the repositories by means of standard APIs.

5.2.1 Platform and Environment

In the prototype, the algorithms outlined for the various components are implemented using the Java™ 2 Platform, Standard Edition (J2SE) [SUNb] version 1.4 software environment. The core architectural components (DSM, QM, LM, HH, and AR) are implemented as Java-RMI based services. The repositories (DSM_Repository and Meta_Repositories) are database-oriented implementations based on Oracle v 8.0. The web-based components (JSPs), which service client interactions, are housed in the Tomcat 4.0 Servlet/JSP Container.

5.2.2 Communication Infrastructure

The unicast communication between the core architectural components is based on JRMP. The multicast communication between HHs and ARs is achieved through Multicast Sockets based on UDP/IP. The connections to the databases are established using JDBC APIs. Interactions between the clients (users) and the web components are based on HTTP protocol.

5.2.3 Security Infrastructure

The security infrastructure in the URDS utilizes the security and cryptography APIs that form a part of the Java™ Cryptography Architecture (JCA) [SUN02] and Java™ Cryptography Extension (JCE) frameworks [SUN00]. The specifications outlined in the JCA encompass the parts of the Java 2 SDK Security API related to cryptography. The JCE provides a framework and implementations for encryption, key generation and key agreement, and Message Authentication Code (MAC) algorithms. The JCA and JCE frameworks are based on the concepts of “engine classes” and a “provider” architecture. An *engine class* defines a cryptographic service in an abstract fashion (without a concrete implementation). The actual implementations (from one or more providers) are those for specific algorithms. A “provider” refers to a package or set of packages that implement one or more cryptographic services, such as digital signature algorithms, message digest algorithms, and key generation algorithms. The JCE Provider used in the prototype is the “SunJCE”[SUN00] which comes as a pre-installed and registered standard JCE Provider with the Java 2 SDK, v 1.4 release.

5.2.4 Programming Model

In the implementation of the prototype, the URDS functionality is partitioned into modules, and these modules are decomposed into specific objects to represent the behavior and data of the application. The prototype adapts the Model-View-Controller (MVC) architecture. The MVC architecture [GAM95, YOU95] can be described as: *“The **Model** represents the application data and the rules that govern access and modification of this data. The **View** renders the contents of a model. It accesses data from the model and defines how that data should be presented. The **Controller** defines application behavior; it translates user gestures into actions to be performed by the model”*.

5.2.4.1 Implementation Details

In order to structure an application along the lines of the MVC architecture it is necessary to divide the application into objects and assign these objects to tiers. This process is referred to as object decomposition. Typically an application can be divided into three logical categories of objects: *“These are objects that deal with presentation aspects of the application, objects that deal with the application rules and data, and objects that accept and interpret user requests and control the application objects to fulfill these request”* [SUNa].

Following sections outline the object decomposition in the prototype along the lines of the MVC architecture and explain the functionality served by each of these objects in the prototype.

5.2.4.1.1 The Model

This section explains the subdivision of components in the “Model” segment of the architecture. The components in this segment have been categorized as: *Entity Objects, Helper Objects, Persistent Data,* and the *Component Services* depending on their functionality.

5.2.4.1.1.1 Entity Objects

Entity objects serve to represent the individual rows in a database as objects or to encapsulate an application specific concept in terms of an object. The entity objects in the prototype support accessor methods to set and retrieve the values of the attributes they hold. These objects can be passed by value as serializable Java objects. The prototype contains the following entity objects *ComponentBean, FunctionBean, QueryBean, AuthenticatedPacket* whose class diagrams are illustrated in Figure 5.4.

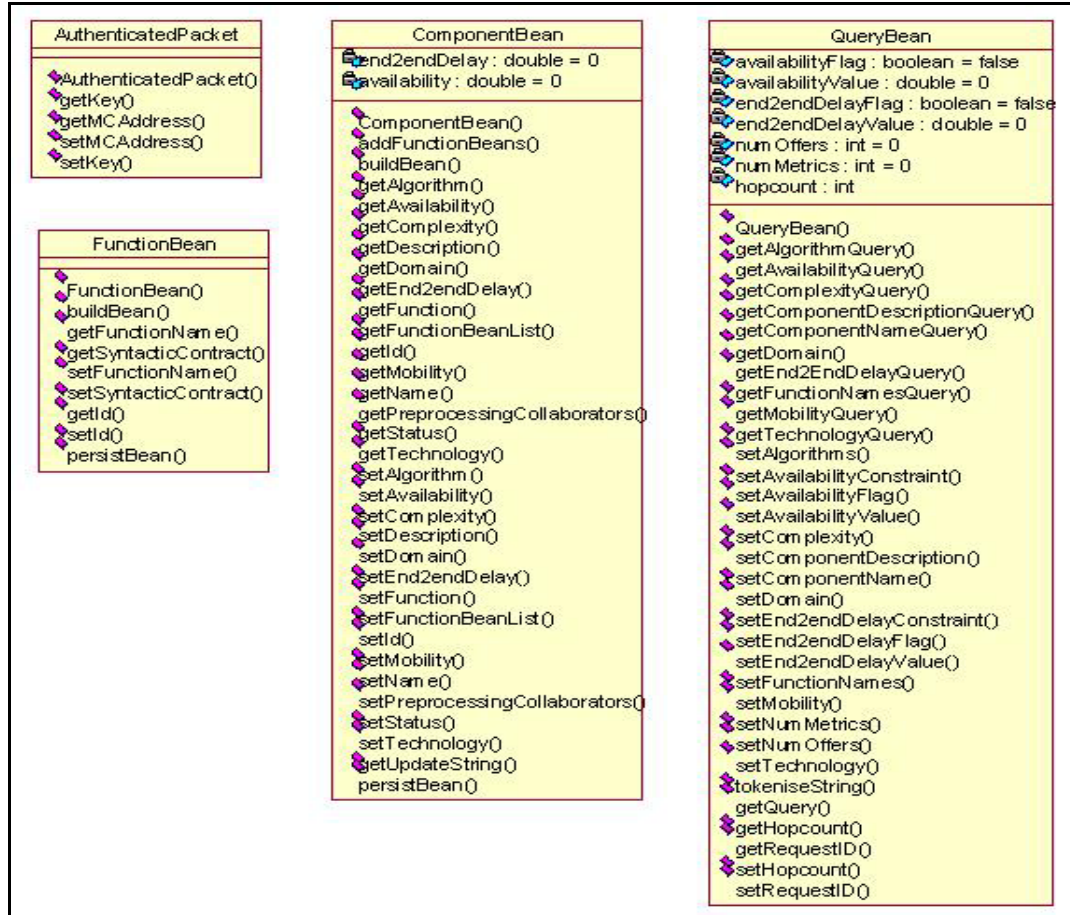

Figure 5.4. Class Diagrams for the URDS Entity Objects

Following is an explanation of these entity objects.

ComponentBean: The attributes of the *ComponentBean* class mirror the fields of the table *Component* (see Section 5.2.4.1.1.3). The *ComponentBean* internally holds a list of *FunctionBean* objects. The *ComponentBean* has functionality built in to persist it to a database.

FunctionBean: The attributes of the *FunctionBean* mirror the fields of the table *Function* (see Section 5.2.4.1.1.3). The *FunctionBean* has functionality built in to persist it to a database.

QueryBean: The *QueryBean* encapsulates the attributes of a Query received from the client. The bean also has the logic associated with generating a SQL query based on the attributes it holds.

AuthenticatedPacket: The *AuthenticatedPacket* encapsulates the multicast address and secret-key returned to the principals (Headhunters/ActiveRegistries) by the Domain Security Manager.

5.2.4.1.1.2 Helper Objects

The prototype uses Helper objects for purposes such as data access or for performing specific utility functions. The following classes serve as Helper classes and have been sub-classified under the categories of Data Access Objects and Dependent Objects.

5.2.4.1.1.2.1 Data Access Objects

The data access objects used in the prototype encapsulate access to databases.

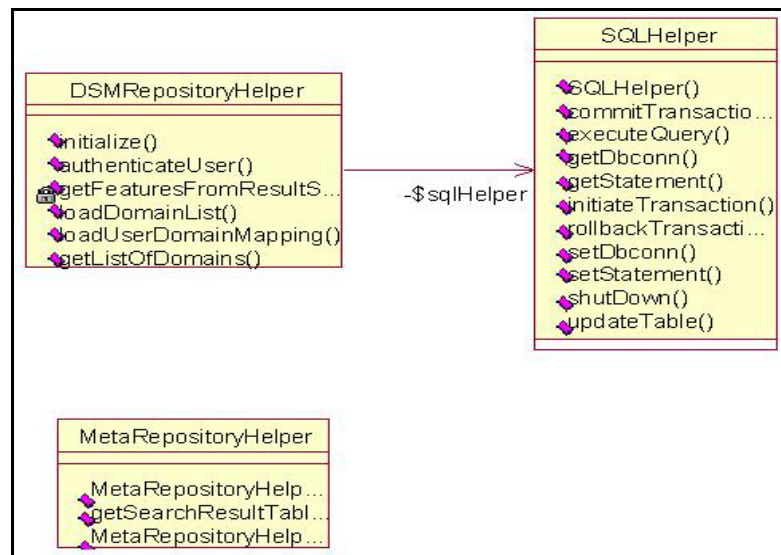

Figure 5.5. Class Diagrams for the Data Access Objects

Figure 5.5 illustrates the class diagrams of the data access objects. A description of the data access objects used in the prototype is provided here:

DSMRepositoryHelper: This class performs functions associated with accessing the *DSM_Repository* to retrieve user-domain mappings and for user authentication.

MetaRepositoryHelper: This class performs functions associated with accessing the *Meta_Repository* to retrieve search results.

SQLEngine: This class acts as a wrapper, which encapsulates the essential, JDBC API methods and performs functions associated with establishing database connections and executing the queries. It is used by the *DSMRepositoryHelper* and *MetaRepositoryHelper* classes.

5.2.4.1.1.2.2 Dependent Objects

The prototype uses dependent objects for performing utility functions. These dependent objects are immutable and the objects that create and use them manage their life cycle.

Figure 5.6 illustrates the class diagrams of the dependent objects. A description of the dependent objects is provided below:

CreateKey: This utility class is used to generate secret-keys. The keys are generated using a SUN provided engine class *javax.crypto.KeyGenerator*, which provides the functionality of a (symmetric) key generator. An instance of the *javax.crypto.KeyGenerator* class is obtained by specifying the Provider and the algorithm for key generation. The Provider used is the “*SunJCE*” an instance of which can be obtained by instantiating the *com.sun.crypto.provider.SunJCE* class. The algorithm specified is “DES” (Data Encryption Standard) [DES77].

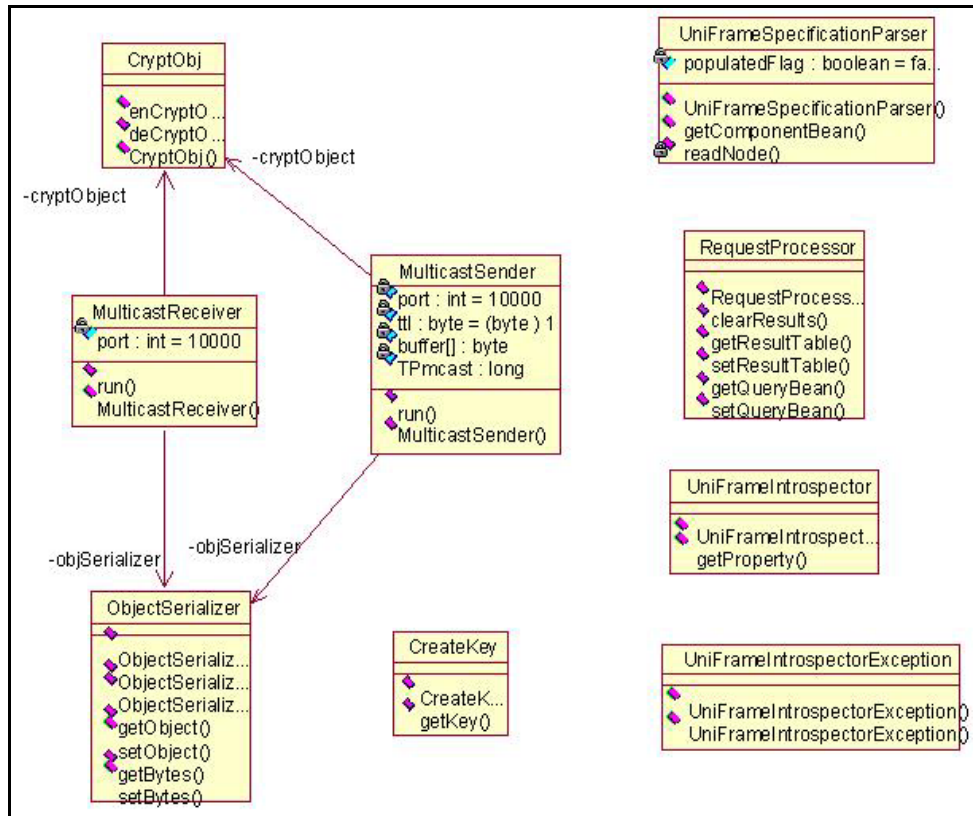

Figure 5.6. Class Diagrams for the Dependent Objects

CryptObj: This class provides the utility functions for encrypting and decrypting data. The class utilizes a SUN provided engine class *javax.crypto.Cipher*, which is capable of carrying out encryption and decryption according to an encryption scheme (algorithm). An instance of the Cipher class can be obtained by specifying a *transformation* of the form "*algorithm/mode/padding*". The transformation used in the prototype is "*DES/ECB/PKCS5Padding*" where algorithm = "DES", mode = "ECB" (Electronic Codebook Mode) [ECB80] and padding = "PKCS5Padding" (The Public Key Cryptography Standards #5)[RSA93]. Modes and padding schemes are present in the Cipher class because that class implements what is known as a block cipher; that is, it expects to operate on data one block (e.g., 8 bytes) at a time. Padding schemes are required in order to ensure that the length of the data is an integral number of blocks. Modes are provided to further alter the encrypted data in an attempt to make it harder to

break the encryption. The *CryptObj* class encrypts an object with a cryptographic algorithm to create an instance of *javax.crypto.SealedObject*.

ObjectSerializer: This utility class converts an object to byte array and reconstructs an object from byte array. To be used in secure multicast for serializing Sealed Objects.

UniFrameIntrospector: This utility class uses reflection to analyze the properties of an object and retrieve the value corresponding to a specific attribute.

UniFrameSpecificationParser: This class is used to parse a UniFrame XML specification file and construct an instance of the *ComponentBean*.

MulticastSender: This class operates as a *Thread* which executes periodically. This *Thread* has a connection to a *MulticastSocket* to which it keeps multicasting *DatagramPackets* at regular intervals of time. This thread utilizes the *CryptObject* and *ObjectSerializer* Helper objects to multicast encrypted serialized messages.

MulticastReceiver: This class operates on a *Thread*, which constantly listens for multicast messages on a *MulticastSocket* and receives the incoming *DatagramPackets*. This thread utilizes the *CryptObject* and *ObjectSerializer* Helper objects to decrypt and reconstruct the multicast messages received.

5.2.4.1.1.3 Persistent Data

The prototype maintains persistent data in database tables. These databases are associated with the service components (i.e. DSM and HH). The databases used in the prototype are the *DSM_Repository* and the *Meta_Repository*.

DSM_Repository

Figure 5.7 illustrates the schema for the *DSM_Repository*.

Table 5.1: USERS	
Column Name	Column Type
USERID	NUMBER
USERTYPE	VARCHAR
USERNAME	VARCHAR
PASSWORD	VARCHAR

Table 5.2: PERMISSIONS	
Column Name	Column Type
PERMISSIONID	NUMBER
PERMISSIONNAME	VARCHAR

Table 5.3: USER_PERMISSION_XREF		
Column Name	Column Type	
USERID	NUMBER	Foreign Key References USERS(USERID)
PERMISSIONID	NUMBER	Foreign Key References PERMISSIONS (PERMISSIONID)

Table 5.4: DOMAINLIST		
Column Name	Column Type	
DOMAINID	NUMBER	Foreign Key References PERMISSIONS (PERMISSIONID)
DOMAINADDRESS	VARCHAR	

Figure 5.7. *DSM_Repository*

The *DSM_Repository* comprises of four tables *Users*, *Permissions*, *User_Permission_Xref*, and *DomainList*.

The *Users* table serves to hold the Headhunter/ActiveRegistry information. The columns of this table are *userid* (numeric identifier), *usertype* (whether Headhunter or Registry), *username*, and *password*. The primary-key in this table is the *userid*. Example of a record of this table is as follows: <1,'Headhunter', 'Headhunter1', 'xxxx'>.

The *Permissions* table serves to hold a list of allowed permissions (or domains). The columns in this table are *permissionid* (numeric id for permission) and *permissionname* (domain name like Finance, Manufacturing, etc.). The *permissionid* serves as the primary-key for this table. Example of a record of this table is as follows: <1, 'Manufacturing'>.

The *User_Permission_Xref* table serves to map the permission to be assigned to a user. The table contains two numeric columns *userid* which references the *userid* in *Users* and *permissionid* which references *permissionid* in *Permissions*. The combination of the $\langle userid, permissionid \rangle$ serve as the primary key. Example of a record of this table is as follows: $\langle 1, 2 \rangle$.

The *DomainList* table serves to hold the list of multicast addresses and the domains that they map to. The table contains two columns *domainid*, which references *permissionid* of *Permissions* and *domainaddress*, which serves to hold the multicast address. The combination of the $\langle domainid, domainaddress \rangle$ serve as the primary key. Example of a record of this table is as follows: $\langle 1, '224.2.2.2' \rangle$.

Meta_Repository

Figure 5.8 illustrates the schema for the *Meta_Repository*.

Table 5.5: COMPONENT	
Column Name	Column Type
ID	VARCHAR
NAME	VARCHAR
DESCRIPTION	VARCHAR
FUNCTION	VARCHAR
ALGORITHM	VARCHAR
COMPLEXITY	VARCHAR
DOMAIN	VARCHAR
TECHNOLOGY	VARCHAR
COLLABORATORS	VARCHAR
END2ENDDELAY	VARCHAR
AVAILABILITY	VARCHAR
MOBILITY	VARCHAR

Table 5.6: FUNCTION		
Column Name	Column Type	
ID	VARCHAR	Foreign Key References COMPONENT(ID)
FUNCTION_NAME	VARCHAR	
SYNTACTIC_CONTRACT	VARCHAR	

Figure 5.8. Meta_Repository

The *Meta_Repository* comprises of two tables *Component*, *Function*.

The *Component* table serves to hold the UniFrame Specification information of the components. The columns of this table are *id* (alpha numeric compinent id), and other variables which describe a component like *name*, *description*, *function*, *algorithm*, *complexity*, *domain*, *technology*, *collaborators*, *end2endDelay*, *availability*, *mobility*. The primary-key in this table is the *id*. Example of a record of this table is as follows: <'intrepid.cs.iupui.edu','AccountServer','Provides An Account Management System','Acts As An Account Server','Simple Addition And Subtraction','O(1)','Financial','Java-RMI','AccountClient',10,100,'No'>

The *Function* table serves to hold a list of all functions and the syntactic contracts . The columns in this table are *id* which references *id* of the *Component* table, *function_name* and *syntactic_contract*. The combination of <*id*, *function_name*, *syntactic_contract*> serves as the primary-key for this table. Example of a record of this table is as follows: <'intrepid.cs.iupui.edu','javaDeposit','void javaDeposit(float ip)'>

5.2.4.1.1.4 Service Components

A service component here refers to a software unit that provides a service. The service provided could be a computational effort or an access to underlying resources. A service component consists of one or more artifacts (software, hardware, libraries) that are integrated together to provide the service. Service Components are described by a remote interface and an implementation for this interface. Each Service Component is a stand-alone functional unit, which accepts inputs through its published interfaces, and returns results. Clients or other components can remotely access a service component using standard communication protocols. For a component to be remotely accessible, it should be deployed in a runtime environment (e.g. Application Server) with ports open to receive incoming requests and return results.

Figure 5.9 describes an example of a stand-alone remote accessible service component, which uses the HTTP protocol to accept and return results.

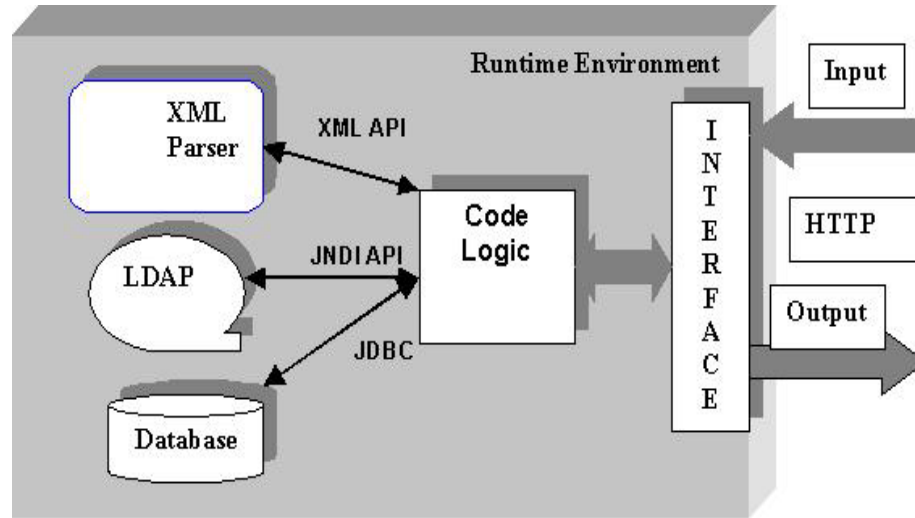

Figure 5.9. Example of a Stand-Alone Remote Accessible Service Component.

The service components implemented in the prototype are the DSM, QM, HH, and AR. These service components utilize the Entity Objects and Helper Objects to achieve their functionalities and store and retrieve information from their respective repositories.

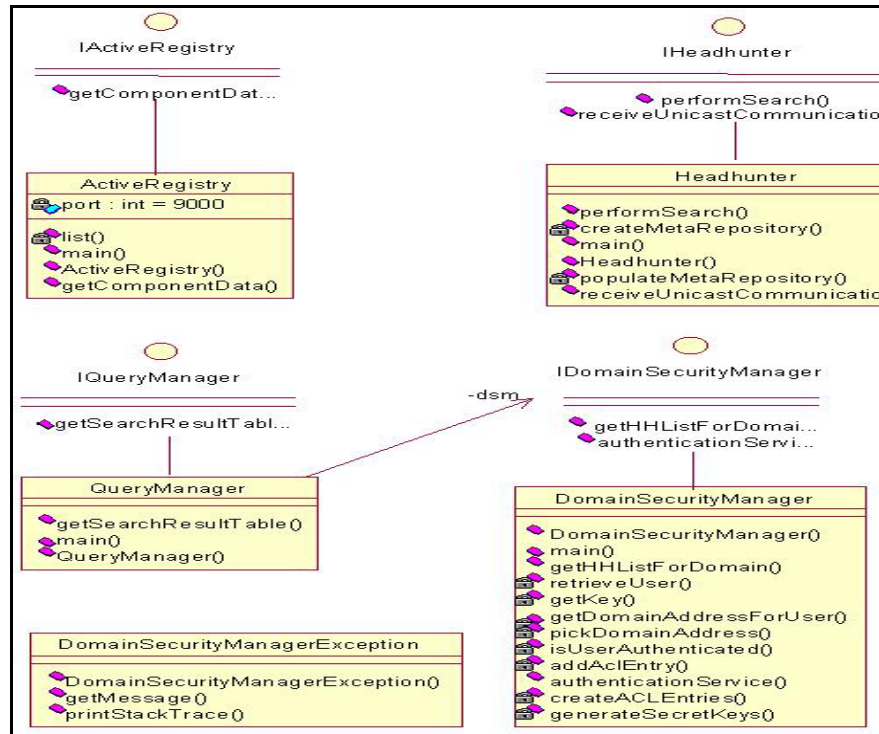

Figure 5.10. Class Diagrams for the Service Components

Figure 5.10 illustrates the class diagrams of the Service Components. The following subsections describe these service components.

5.2.4.1.1.4.1 Domain Security Manager Service

IDomainSecurityManager: This is the interface for the DomainSecurityManager service. This interface publishes two methods:

- *getHHListForDomain*: This method is invoked by the QueryManager. The purpose of this method is to return a list of registered Headhunters for a particular domain to the QueryManager.
- *authenticationService*: This method is invoked by the Headhunter and ActiveRegistry components to authenticate themselves with the DSM.

DomainSecurityManager: This class implements *IDomainSecurityManager* interface. The implementation is based on the algorithms outlined for the DSM in Chapter 4. The

DSM performs the functions of generating secret-keys for the domains using the *CreateKey* helper class. It authenticates the principals against the *DSM_Repository* with the help of the *DSMRepositoryHelper* and distributes the secret-keys and multicast addresses to Headhunters and Active Registries. The communication between the parties is based on RMI-JRMP.

5.2.4.1.1.4.2 Query Manager Service

IQueryManager: This is the interface for the *QueryManager* service. This interface publishes the following method:

- *getSearchResultTable*: This method is invoked by the *RequestProcessor* to obtain a list of services matching the search criteria specified by a component assembler.

QueryManager: This class implements the *IQueryManager* interface. The *QueryManager* class propagates the search query as a *QueryBean* object to the list of *Headhunter* components obtained from *DomainSecurityManager* and returns search results to the *RequestProcessor*. The interaction between these components is based on RMI-JRMP.

5.2.4.1.1.4.3 Headhunter Service

IHeadhunter: This is the interface for the Headhunter service. This interface publishes the following methods:

- *performSearch*: This method is invoked by the *QueryManager* to propagate a search query.
- *receiveUnicastCommunication*: This method is invoked by the *ActiveRegistry* to inform the Headhunter of its location.

Headhunter: This class implements the *IHeadhunter* interface. The implementation is based on the algorithms outlined in the previous Chapter for the Headhunter functions. The Headhunter class interacts with the *QueryManager* and *DomainSecurityManager*

using RMI-JRMP. The Headhunter uses the *MulticastSender* to multicast encrypted messages to *ActiveRegistry* services. The Headhunter also communicates with the *ActiveRegistry* services through unicast RMI-JRMP for the purpose of obtaining the component information as a *Hashtable* of *ComponentBean* objects. The HeadHunter saves this component information to the *Meta_Repository* and uses the *MetaRepositoryHelper* for the purpose of performing searches against the repository. The SQL query for the searches is obtained from the *QueryBean* which is propagated to the *Headhunter* by the *QueryManager*.

5.2.4.1.1.4 Active Registry Service

IActiveRegistry: This is the interface for the *ActiveRegistry* service. This interface publishes the following method:

- *getComponentData*: This method is invoked by the *Headhunter* to retrieve component information from the *ActiveRegistry*.

ActiveRegistry: This class implements the *IActiveRegistry* interface. The implementation is based on the algorithms outlined in the previous Chapter for the *ActiveRegistry* functions. The *ActiveRegistry* class receives multicast messages from the *Headhunter* by using the *MulticastReceiver* class. Interaction with the *Headhunter* for passing its contact information and component information are done through RMI-JRMP. It also communicates with the *DomainSecurityManager* for authentication purposes using RMI-JRMP. The *ActiveRegistry* uses the *UniFrameIntrospector* for the purpose of obtaining the *UniFrame* specifications of the components registered with it. It also uses the *UniFrameSpecificationParser* for parsing the specifications and building instances of *ComponentBean* objects, which it returns to the *Headhunter*.

5.2.4.1.2 The View

The view determines the presentation of the user interface of the prototype. The components that work together to implement the view are the JSP pages and the

JavaBeans components. The JSP pages are used for dynamic generation of HTML responses. JavaBeans components represent the contract between JSP pages and the model. JSP pages rely on these beans to read model data to be rendered to HTML. The following are the JSP pages, which present a View to the user: *UniFrameQuery.jsp* (see Figure 5.11 and Figure 5.12), *ComponentList.jsp* (see Figure 5.13), *ComponentDetail.jsp* (see Figure 5.14). The controller functionality associated with these views is explained in Section 5.2.4.1.3.

The screenshot shows a Netscape browser window displaying the UniFrameQuery.jsp view. The form is organized into several sections:

- Search By Component Details:**
 - Domain: Finance (dropdown)
 - Component Name: AccountServer (text input)
 - Component: Account Management System (text input)
 - Description: (text input)
 - Function Names: deposit withdraw balance (text input)
- Search By Functional Attributes:**
 - Desired Algorithms: addition subtraction (text input)
 - Desired Complexity: O(1) (text input)
 - Technology: Java-RMI (dropdown)
- Search By Auxillary Atributes:**
 - Mobility: No (dropdown)
- Search By QOS Metrics:**
 - Select: (checkbox)
 - QOS Parameter: End To (text input)
 - Constraints: (checkbox) 50 (text input)
 - Preferences: None (dropdown)

The browser's status bar at the bottom shows "Document: Done".

Figure 5.11 UniFrameQuery.jsp View

Figure 5.11 and 5.12 illustrate the UniFrameQuery.jsp view which allows the component assembler or system integrator to specify various search criteria.

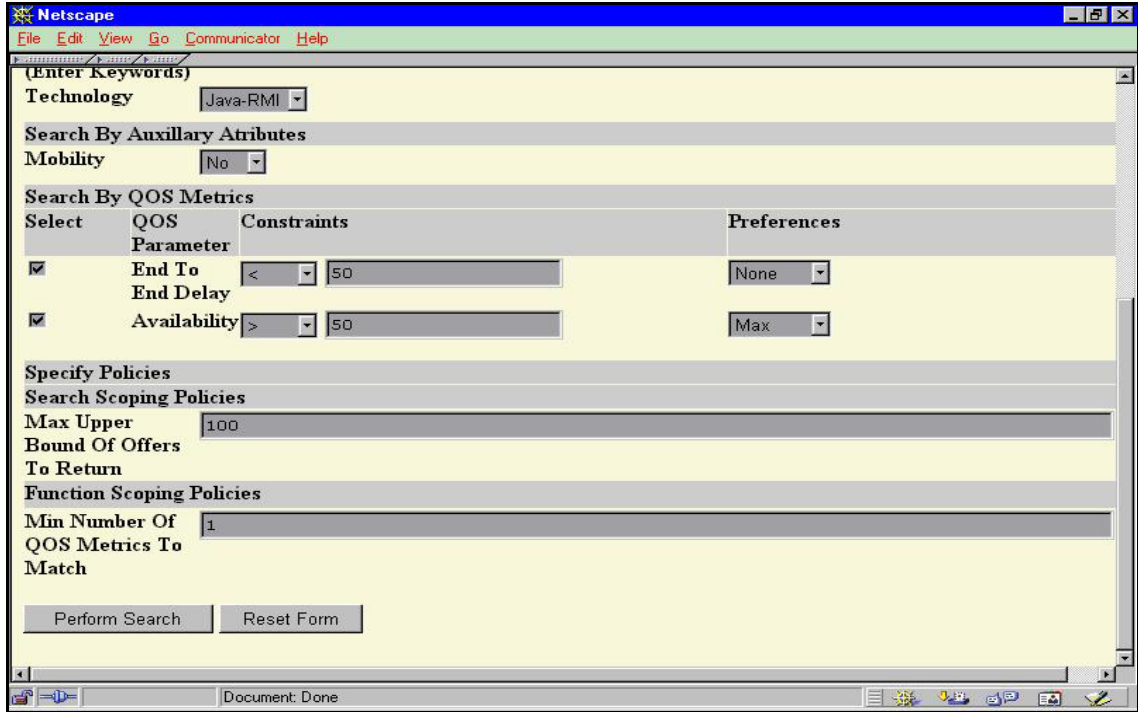

Figure 5.12 UniFrameQuery.jsp View Continued.

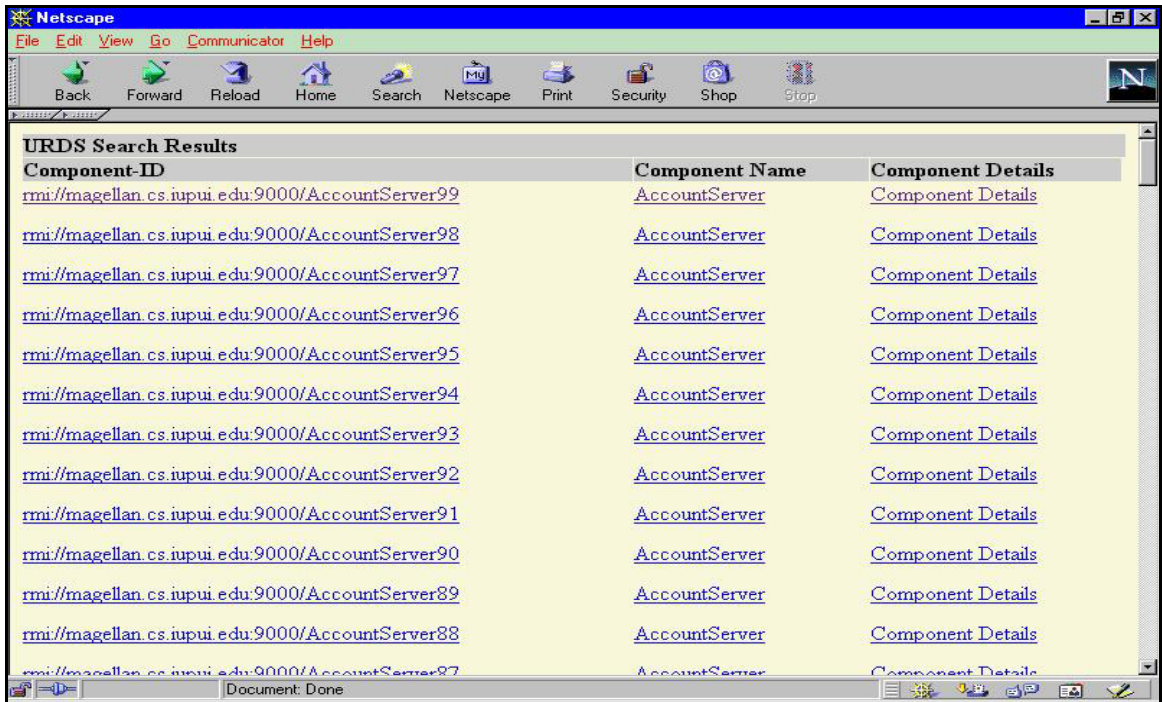

Figure 5.13 ComponentList.jsp View

Figure 5.13 above illustrates the view ComponentList.jsp. In this view the list of components matching the search criteria is displayed to the component assembler. The user can click on the Component Details hyperlink to view the details of a particular component which takes them to the next view ComponentDetails.jsp illustrated in Figure 5.14. The ComponentDetails.jsp view provides all the information specified by the component developer in the UniFrame specification of the component.

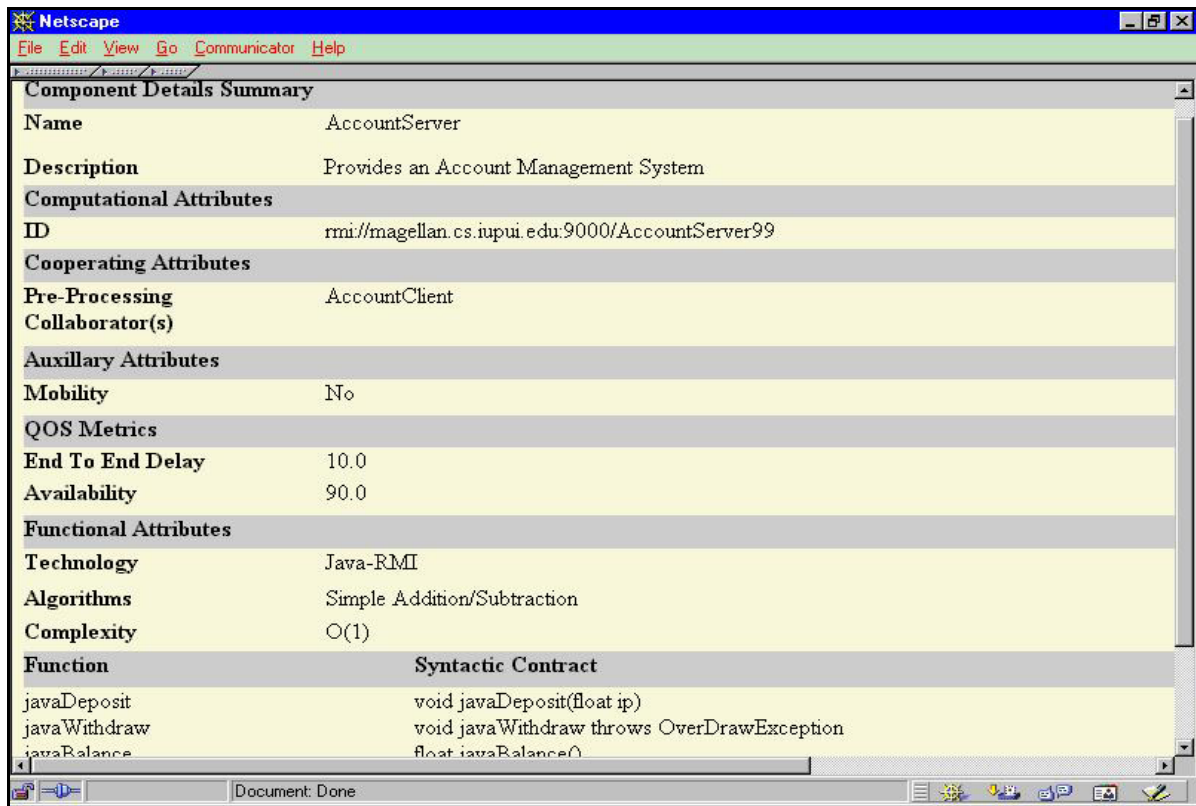

Figure 5.14 ComponentDetail.jsp View

5.2.4.1.3 Controller

The prototype must reflect the state of a user's interaction with the discovery service and the current values of persistent data in the user interface. Following the MVC architecture, this functionality is implemented within the controller. The controller is responsible for coordinating the model and view. The following controller components provide this functionality in the prototype:

UniFrameQuery.jsp: Receives and processes HTTP requests. The servlet generated from *UniFrameQuery.jsp* receives all HTTP requests.

ProcessUniFrameQuery.jsp: Processes the information from the *HttpServletRequest* to create an instance of *QueryBean* and passes it to the *RequestProcessor*, which coordinates all handling of the request.

RequestProcessor: *RequestProcessor* provides the glue in the Web tier for holding the application components together. It contains logic that needs to be executed for each request. *RequestProcessor* collaborates with the *QueryManager* and gets a *Hashtable* of search results from the *QueryManager*, which it forwards to the View *ComponentList.jsp*.

ComponentList.jsp: Provides a *master view* of the lists of components matching the search criteria.

ComponentDetail.jsp: Provides a *detail view* that describes the details of a particular component. Users click on an item in the master view to zoom in on details, including a description, and other details of the *UniFrame* specifications.

5.2.4.1.3.1 Managing the State of a Session

Every client session needs to track the information associated with the client requests (client query) and the associated responses (results matching the search criteria). In the JSPs an HTTP session object maintains the *JavaBeans* that are specific to a client. The following state information is maintained.

Query Information: The information associated with the client query is captured in the *QueryBean* and passed on to the *QueryManager* via the *RequestProcessor*.

The Query Results: The *RequestProcessor* class maintains a list of results matching the search criteria. The result list is stored as a *Hashtable* of *ComponentBean* objects within

the *RequestProcessor* class. These results are displayed in the *ComponentList.jsp* view to the users.

5.3 Experimental Results

Some experimental tests were conducted to validate the performance of the prototype. The Service Components in the experimental setup comprised of one ICB (having a QueryManager and a DomainSecurityManager), one Headhunter and one ActiveRegistry (extended RMI registry). A single client (Application Client Component) was used in the experiment. The experimental tests were conducted with queries having different types of search constraints.

The measurements presented are averaged over 100 trials and were conducted on Sun Solaris machines running Sun Solaris Unix v5.8. Sun's JDK 1.4 was used to run the components of the URDS system.

The following performance metrics were gathered:

Average Authentication Time (T_{auth}): This is computed as the time taken by the DomainSecurityManager to authenticate a principal. It is computed from the time a Headhunter/ActiveRegistry sends the DSM its authentication credentials to the time it receives a response from the DSM.

Average Query Service Time (T_{query}): This is the average time taken to service a query. It is computed from the time a query is presented by a client to the URDS system to the time a response is received.

Average Registry Discovery Time ($T_{discovery}$): This is the average time taken by a Headhunter to discover an ActiveRegistry. It is computed from the time the Headhunter multicasts its location to the time it receives a response from the Registry. This time

includes the time taken by the ActiveRegistry to decrypt the encrypted multicast communication received from the Headhunter.

Average Component Information Retrieval Time ($T_{info-retrieval}$): This is the average time taken by the Headhunter to retrieve component information from an ActiveRegistry. It is computed from the time the Headhunter requests an ActiveRegistry for component information to the time it receives a response from the ActiveRegistry. This time includes the time taken by an ActiveRegistry to obtain the UniFrame Specification URLs from the list of components registered with it and to parse the XML specifications to extract the component information.

The Average Authentication Time was computed to be = 690.5 milliseecs.

The Average Query Service Time, Average Registry Discovery Time, and Average Component Information Retrieval Time were calculated for the following two cases:

Varying the Time period between successive multicast cycles of the Headhunter (T_{mcast}) keeping the Number of Components ($N_{components}$) registered with the Active Registry constant.

Varying the Number of Components ($N_{components}$) registered with the Active Registry keeping the Time period between successive multicast cycles of the Headhunter (T_{mcast}) constant.

Figure 5.15 shows the variation of T_{query} , $T_{discovery}$, $T_{info-retrieval}$ with $N_{component}$ when T_{mcast} was kept constant at 5000 ms. It can be observed from the graph that the average time taken the Headhunter to discover registries and the average time taken to service a query increase marginally with an increasing number of registered components. However, the time taken by the Headhunter to retrieve component information from the registries increases substantially with increasing number of registered components.

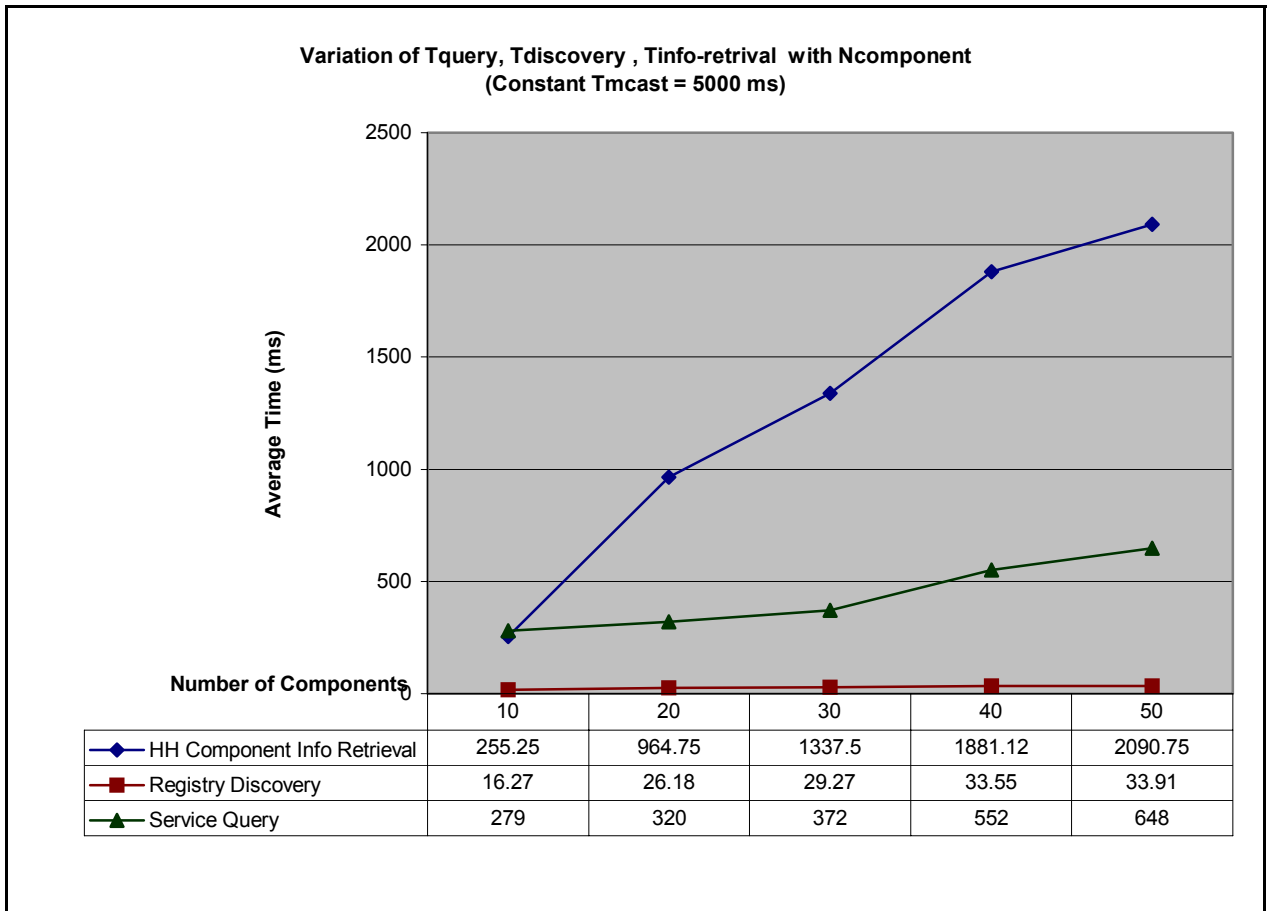

Figure 5.15 Variation of T_{query} , $T_{discovery}$, $T_{info-retrieval}$ with $N_{component}$

Figure 5.16 shows the variation of T_{query} , $T_{discovery}$, $T_{info-retrieval}$ with T_{mcast} when $N_{component}$ was kept constant at 10. It can be observed from the graph that the average time taken the Headhunter to discover registries remains almost constant with increase in time period between successive multicasts. The average time taken to service a query and the time taken by the Headhunter to retrieve component information from the registries also do not show much variation until the time period between multicast cycles is increased to 5000 ms, when they show an increase in the time taken.

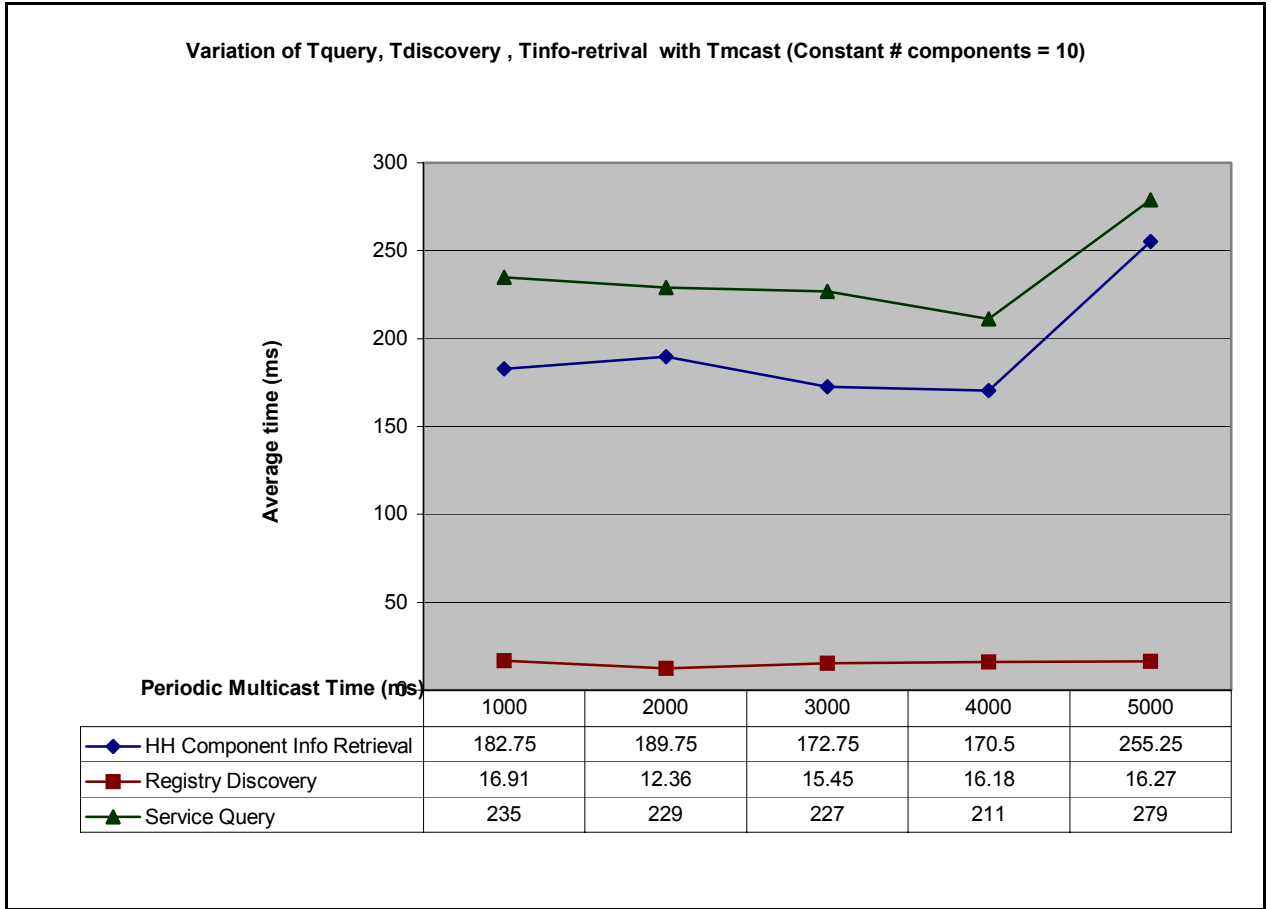

Figure 5.16. Variation of T_{query} , $T_{discovery}$, $T_{info-retrieval}$ with T_{mcast}

5.4 Implementation Strategies for Enhancing the Prototype

This section discusses implementation strategies, to enhance the prototype at an application level and make the implementation more scalable, fault tolerant, maintainable, interoperable and secure. The strategies outline alternative deployment environments or communication protocols that can be used to implement the service components. The following are the performance areas in the implementation where these strategies are applicable:

Improving Scalability and Fault Tolerance of the Implementation

The prototype application supports various services like DSM, QM, HH, etc., It is desirable that these services be able to handle a large number of requests for services without their efficiency being adversely affected. Services that are scalable and easy to maintain usually have better QoS ratings. It would also be desired that these services be “available” for service most of the time and are not “unavailable” due to reasons such as hardware/software failure or “downtime” due to maintenance upgrades of the software/hardware units they are deployed in.

A suggested implementation for realizing these requirements is to deploy the Service Components in a runtime environment such as an Application Server, which supports the concept of Workload Management. An example of such an application server that implements Workload Management capabilities is IBM’s WebSphere Application Server 4.0 [IBM02].

Workload Management (WLM) is the process of spreading multiple requests for a service over resources that can accomplish the task. WLM balances request processing by allowing incoming work requests to be distributed across application servers, containing identical versions of the service called ‘Clones’, according to a configured WLM selection policy. The software/hardware, which dispatches requests to the different servers in the pool, is called an “IPSprayer”. Workload management is most effective when used in systems that contain servers on multiple machines. It can also be used in systems that contain multiple servers on a single, high-capacity machine. This enables the system to make the most effective use of the available computing resources.

If a server in the pool is down due to reasons such as hardware/software failure or maintenance upgrades then the requests for the services can be directed to another server in the pool containing the service clone. WLM improves the performance, scalability and reliability of an application by providing for load balancing and failover capabilities.

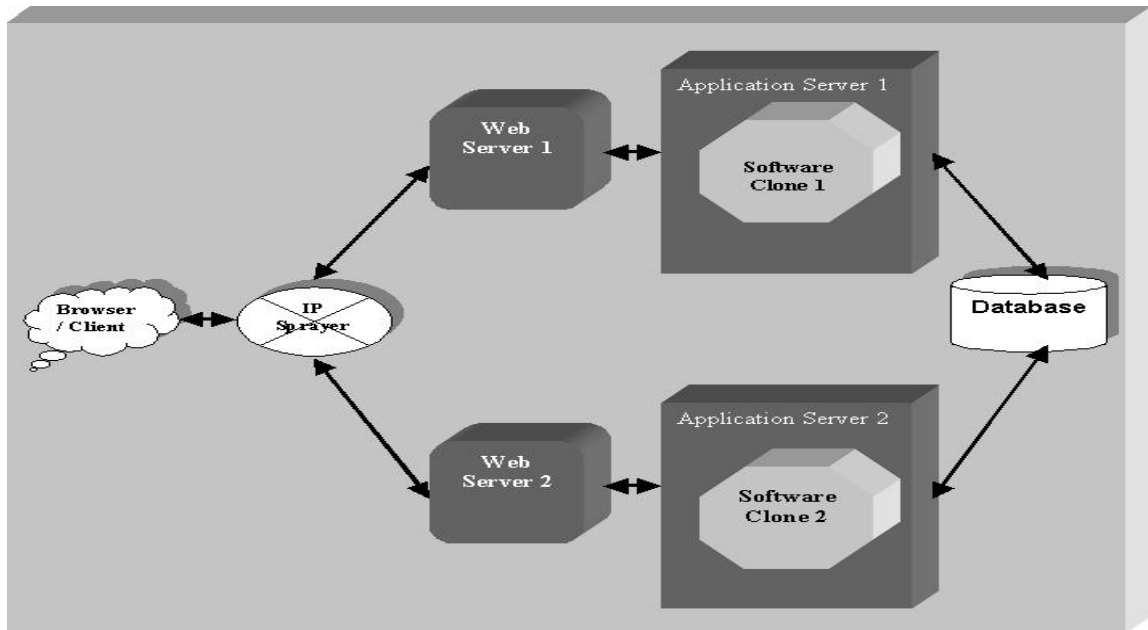

Figure 5.17. Improving Scalability with WLM

Figure 5.17 illustrates WLM across two servers.

Interoperability and Asynchronous Communication

In the prototype implementation, the service components such as DSM, QM, LM, HH, AR are implemented as Java-RMI based services which communicate with each other via JRMP. Alternative implementations could be to structure these services as Enterprise JavaBeans deployed in the EJB container communicating with each other via RMI-IIOP or as SOAP based services communicating with each other via SOAP. These protocols promote greater interoperability than JRMP. Using SOAP for inter-component communication removes the tight coupling that currently exists between the service components. Additionally, SOAP, being a firewall-friendly protocol, will remove the restrictions present in the current implementation of the services having to be located within the same subnet. This is especially a necessity in the case of the *LinkManager* as this will enable federation with external *LinkManager* components (*LinkManagers* in other ICBs) located in different networks.

All inter-component communication in the implementation is synchronous. The users are waiting on the QM to return results and the QM is waiting on the Headhunters to return results. Making these communications asynchronous and using remote event notification will allow a user greater flexibility wherein the user need not wait until the operation completes and results are returned. The use of asynchronous messaging allows the development of loosely-connected systems. These systems are typically more resilient in the event of failures, and more easily extensible as new applications are developed. Additionally, messaging provides an effective means of transmitting events between applications. Asynchronous messaging can be incorporated into the implementation using Java Message Service (JMS). The service components can be structured as EJB components, which integrate with JMS thus allowing the enterprise beans to participate fully in loosely connected systems. The EJB service components can then asynchronously notify other components of the occurrence of events. Remote event notification features will allow the Model to notify the Controller of changes in events in the model, which can be rendered as Views in the system.

Securing the Implementation

In the current prototype implementation users of the URDS discovery services are not authenticated and there is no gradation on the levels of access that the users may possess. However, on a going forward basis, this would be a desired feature, as service providers may not wish to advertise their services to unauthorized users, or depending on the privileges the users possess, they may allow access to only a certain set of functionality as opposed to others. The authentication aspect for users can be handled through a form based userid/password scheme. For supporting users with different profiles, structuring the service components as EJB components allows the implementation to leverage the role based security services offered by the EJB architecture.

This chapter presented an implementation for the URDS architecture and the experimental results. The chapter also discussed enhancements that could be made to the prototype.

The next chapter concludes the thesis by presenting a comparison between the URDS architecture and other resource discovery protocols discussed in Chapter 2. The chapter also discusses possible future extensions to this work.

6. CONCLUSION

This thesis presented the architecture and an implementation for a resource discovery service, the “UniFrame Resource Discovery Service”. The resource discovery service itself forms a part of a framework, “UniFrame”, which aims at providing a platform for building DCS by integrating existing and emerging distributed component computing models under a common meta-model that enables discovery, interoperability, and collaboration of components via generative software techniques. Section 6.1 discusses the features of URDS and compares it to other resource discovery services. Section 6.2 discusses possible future enhancements to the URDS architecture.

6.1 Features of URDS

A discussion of the features of URDS and how these compare with other resource discovery protocols is presented here:

6.1.1 Interoperability

Various resource discovery protocols available today adhere to different “standards” and there is little interoperability between them. These protocols have been designed to provide services for very specific models. For example, the CORBA Trader services offer directory services only for CORBA objects, or the JINI discovery services spontaneously discover only other JINI enabled devices. For these protocols to be logically compatible, they need to be mapped by implementing equivalent protocols or bridges and proxies. This defies the underlying goal of “discovery” being universal. It is

this interoperability gap that URDS is trying to bridge by providing discovery and directory services for components developed using diverse distributed computing models.

URDS tackles the issue of non-uniformity with the assistance of the ICB and Headhunter components (explained in Chapter 3 and Chapter 4). The Headhunters discover heterogeneous components. Since the components discovered by the Headhunters do not share common semantics for communication, the ICB provides the capability to generate the glue and wrappers for components implemented in diverse models to collaborate across the Internet. The ICB will eventually use standard component mappings and component model adapters to bridge the conceptual model disparity. Thus, URDS addresses the issue of bootstrapping between components implemented in diverse architectures, which is not found in other resource discovery protocols.

The Headhunter and ICB components together are responsible for allowing a seamless integration of different component models and sustaining (managed) cooperation among heterogeneous components.

6.1.2 Discovery Mechanism

It is essential that Discovery Services effectively manage the bandwidth usage. It is easy to saturate the network if the services implement protocols, which do not consider bandwidth as a critical issue (e.g., “if services and clients discover each other by multicast/broadcast once per second”). Protocols that are based on a purely advertisement or purely request strategy may use a great deal of bandwidth [GUT99]. If all services keep advertising their availability periodically and if clients keep sending service requests to all possible services, the network will saturate with advertisements and requests, and may also overload service providers. It is, therefore, imperative that multicast be used carefully and the number of messages exchanged be limited.

The fundamental difference between other Service Discovery Protocols and URDS is that, in the URDS architecture, the Clients and Services are not ‘active’ i.e., they do not directly participate in the multicast communications of the discovery process. It is the native registries that have a handle to the services that participate in the discovery process and not the services themselves. The advantage of this approach is two fold:

1. network usage is reduced as the Services and Clients are not participating in active discovery, which cuts down on the multicast messages periodically being broadcast/multicast by Services, Clients, and Lookup Services wanting to be discovered by each other.
2. service providers do not need to add additional functionality to their components to make them ‘active’ i.e., communication-aware. The components can be constructed in any desired component model and still be discovered in the URDS environment.

The URDS architecture of combining a Directory Service with a Discovery service, presents another unique advantage in reducing communication overhead. The ICB acts as the directory for brokering client requests. Clients contact the ICB with their service requests, and the ICB responds with a list of services matching the service requests. This avoids the situation of the client being swamped with responses from arbitrary services. URDS also supports Federation of the ICBs, which further helps to localize traffic and reduce the number of parties involved. The idea of Federation or Hierarchical organizations is common in Directory Services, and this can prove very efficient when combined with a Discovery service.

6.1.3 Service Description

Every resource discovery protocol specifies its own standards for describing services. The Object Management Group (OMG) specifies the standard Interface Definition Language (IDL) for defining service contracts. W3C has focused on standards

for exchanging information using the Internet infrastructure (HTML, XML, HTTP, XSL). URDS aims to discover and achieve interoperability in an open, dynamic network environment where the communicating parties (clients and services) are implemented in diverse architectures each conforming to their own standards of service description. It was realized that it would not be possible to implement a meta-protocol of service types. The solution adopted in URDS is to allow the components to follow their own standards for service description but also provide a UniFrame specification in XML outlining the computational, functional, co-operational, auxiliary attributes and QoS metrics. Since, XML is designed to support an automatic translation and transformation between XML languages, it is well suited for providing interoperability between diverse services. The UniFrame Approach also provides capabilities for auto-generating the XML based UniFrame specifications from the natural language specification of the component.

6.1.4 Client Query and Matchmaking

In URDS, the users (clients) present a query to the system in natural language-like style. This query is passed through a natural language query processor, which extracts the key words, constraints, and preferences (see Chapter 4) from the query and constructs a structured query language statement. The matchmaking is achieved by comparing the structured query language statement against the repository of service information. This method of query and matchmaking allows a user a large degree of flexibility in formatting queries, which is not found in any of the other discovery or directory services. The JINI searching mechanism uses the Java serialized object-matching mechanism, which is based on exact matching of serialized objects, making it prone to false negatives due to class versioning problems [CZE99]. The SSDS searching mechanism is based on XML tag matching while SLP is based on matching of service types all of which require the client's query to adhere to a standard format in order to obtain a match.

6.1.5 Domain of Discovery

The discovery protocol of the URDS architecture is “administratively scoped”, i.e., it locates services within an administratively defined logical domain. *Domain* in the UniFrame Approach refers to industry specific markets such as Financial Services, Health Care Services, Manufacturing Services. In URDS, the Headhunters and Active-Registries are associated with specific domains and they register and detect services developed for the specific industrial sector with which they are associated. This kind of logical partitioning also allows for a contextualization of the search space. Other discovery protocols too have the notion of “administrative scope” but the difference in their case is that scope is associated with the topology of the network domain. The resources detected in these cases are those that are logically located ‘nearby’ within the network topology.

6.1.6 Security

Most Directory Services do not have a built-in security framework. Security is not as essential in these cases because of the centralized management schemes. Discovery protocols however need to address this issue because of their decentralized nature. Discovery protocols are faced with the challenge of providing a robust, yet lightweight, and automatic security protocol that does not consume network resources.

The UniFrame architecture addresses a majority of the security threats faced in the scenario of a discovery process. The security model provides for authentication of the principals involved (Headhunters and native registries) through a userid-password based authentication scheme. URDS uses access control lists to restrict access to multicast address resources. URDS also ensures the security of the multicast data transmitted through the use of a secret-key based data encryption scheme. The model does not at this stage provide for elaborate protocols for establishing keys and passwords. It uses a

centralized controller (the Domain Security Manager), which is responsible for authenticating the principals and distributing the secret-keys.

The Ninja: SSDS, outlined in Chapter 2, is a good example as it uses several different security protocols and services. SSDS uses Certificates and a Certificate Authority structure to authenticate all principals. The authenticity of the discovery service is maintained through Public Key authenticated SDS server announcements. Privacy and authenticity of service descriptions are ensured through one-way encrypted service announcements (combined public and private key protocol). SSDS uses Secure RMI for a two-way authenticated and encrypted remote method invocation.

The other protocols like JINI and SLP have support for authentication, but no provisions for encryption.

6.1.7 Quality of Service

A unique feature of URDS is the incorporation of the notion of QoS as applied to software components. Although QoS parameters and associated metrics have been widely used in networking, there is no standard vocabulary for discussing QoS as it relates to distributed computing and component based solutions. The UniFrame research aims at outlining an approach to a QoS-based framework for creating distributed heterogeneous software components [RAJ01]. This work leverages work by Zinky, Bakken & Schantz [ZIN95] with the goal of providing a catalog of QoS parameters, indicating how parameters might be described, and providing a list and brief description of the QoS parameters being cataloged along with a detailed sample description. The discovery services of the UniFrame integrate this notion of QoS into the specification of services and the matchmaking process. The UniFrame specification of a component indicates the various QoS metrics supported by a component and the clients issue requests for components possessing desired levels of QoS. The matchmaking process then uses the

QoS metrics as an additional level of filtration to return the appropriate match to the client.

6.2 Future Work

This thesis proposed an architecture for discovering services developed in different component models. The proposed architecture was validated through a prototype. The prototype implements the following features of the URDS architecture: i) Dynamic Discovery of components, which are developed using the Java-RMI, distributed computing model, ii) Servicing Component Assembler's requests presented in natural language-like style, and iii) Security features outlined in the URDS architecture.

Future extensions to this research involve more comprehensive and complete implementation and a more rigorous validation of the features proposed in the URDS architecture, which are not currently implemented in the prototype. This is outlined in Section 6.2.1. Section 6.2.2 outlines research possibilities to extend the URDS architecture.

6.2.1 Extensions to the Prototype Implementation

Many extensions are possible of the current prototype. A few of these are:

- Discovery of components developed using other distributed computing models such as CORBA, Voyager, etc., by extending the native registries of the respective models in accordance with algorithms outlined in Section 4.8.1 of Chapter 4.

- A support for Federation of ICBs by providing for an implementation of the Link Manager Service in accordance with the algorithms outlined in Section 4.4.1 of Chapter 4.
- A support for Adapter Component Services. This will require further research in the area of developing adapter components by using glue and wrapper technology. The URDS architecture provides the Adapter Manager Service (refer Algorithms outlined in Section 4.5.1) for the discovery of these adapter components.
- A support for the failure detection capabilities in the Headhunter outlined in algorithm 4.6.1.6 of Chapter 4.
- The performance of the prototype can be optimized by fine tuning various parameters such as the time between periodic multicast announcements by the Headhunter, the time period between successive purge cycles to maintain the ‘freshness’ of the information returned as a result of a search, and the number of Headhunters present in the system per domain, etc.
- The performance of the prototype from an implementation perspective can be enhanced using alternative technologies for implementation. Section 5.5 in Chapter 5 outlines implementation strategies for enhancing the prototype.
- Testing the scalability and incorporating the feedback.

6.2.2. Enhancements of the URDS Architecture

Possible areas for enhancement of the current architecture are:

- *'Intelligent' Search Process:* The search propagation process in URDS can be made 'intelligent' i.e., the search process can use decision making capabilities to restrict the search space and perform more 'selective' searches. The URDS architecture proposed the use of query propagation policies, search scoping policies and function scoping policies to restrict the search space (See Section 4.3 of Chapter 4). The process can be further improved if the search process utilizes heuristics such as: a) past history and statistical results, and b) notion of acquaintances to narrow the search space. The QM can use heuristics to propagate a search to Headhunters and Link Managers. The QM can base the decision to propagate a query on parameters such as past history of availability, response time, number and quality of search results obtained from a Headhunter/Link Manager.
- *Mobile Headhunters:* The Headhunters in the current implementation use the network communication to gather information from the Active Registries. A possible enhancement could be to make the Headhunters 'mobile' i.e., the Headhunters move to the machines hosting the registries to gather information from the registries. The performance advantage of such an approach over the current approach needs to be carefully weighed out as it raises several security concerns.
- Usages of alternative schemes for techniques such as Security to create domain-specific (and restricted) versions of URDS are other directions of enhancement.

6.3 Summation

The thesis has presented an architecture and an implementation for the part of an infrastructure facilitating a semi-automatic construction of a distributed system that provides for the dynamic discovery of heterogeneous components and selection of

components meeting the necessary requirements, including desired levels of QoS. The URDS architecture addresses essential design issues such as interoperability, QoS of software components, scalability, fault tolerance, security and network usage. These issues, considered in the design of URDS, make it unique as compared to other existing approaches. Interoperability is achieved by discovering components developed in several different component models. The discovery mechanism uses multicasting to detect native registries/lookup services of various component models that are extended to possess 'active' and 'introspective' capabilities. The specifications capture the computational, functional, co-operational, auxiliary attributes and QoS metrics of their registered components. Flexibility in query formatting is achieved by providing support for natural language-like client requests. URDS is organized in a federated hierarchical structure as a scalability mechanism. Failure tolerance is handled through periodic announcements by failure prone entities and through information caching. Security is provided through authentication of the principals involved, access control to multicast address resources, and encryption of data transmitted. The URDS architecture coupled with the UA presents a promising solution for creating DCS by integrating geographically scattered, heterogeneous software components.
