ABSTRACT

The Marine Corps is getting back to its expeditionary roots, becoming lighter, leaner, and conversely ever more dependent on power. Until recently, expeditionary power planning has been an afterthought in the Marine Corps. HOMER (Hybrid Optimization Model for Electric Renewables) is a software tool that will enable Logistics Marines to conduct detailed planning to provide efficient expeditionary power. The focus of this thesis is the addition of Marine Corps systems into HOMER. Specific investigations include an analysis of SPACES compared to a control system and rapid-discharge heat testing of lithium ion batteries. Results include performance specifications for SPACES entry into HOMER and partial validation of the use of the Kinetic Battery Model for Lithium Ion Batteries.

EXECUTIVE SUMMARY

As the United States Marine Corps seeks to return to its expeditionary roots, we are confronted by the realization that the modern Marine Corps is more power and energy reliant than ever. As the lethality of each Marine has grown, so has their need to carry more technology, and from radios to night vision devices, the soldiers load keeps growing.

Currently, Marine Corps energy planning for expeditionary power uses peak power to determine the load size for Forward Operating Bases (FOB). A generator is then selected based on the peak power being only 80% of the generator's capacity. Electric loads rarely operate at peak power, resulting in generators experiencing loads at 50% capacity or less almost 80% of their run time. This can cause extra maintenance requirements for diesel generators and forces them to run at the lower end of their efficiency curves, burning more fuel to produce less power.

As the Marine Corps expands its inventory of renewable power sources, expeditionary power planning incorporating those resources into a FOB efficiently becomes a priority. HOMER is a unique software application that is designed to allow users to design a hybrid micro-grid and simulate it in the location it is intended to operate. HOMER (Hybrid Optimization Model for Electric Renewables) then allows the user to optimize the system for performance and cost. HOMER is currently a commercially available tool, and with a few modifications it can become the expeditionary planning tool the Marine Corps needs.

Modifications to HOMER include adding all power systems in the program of record to the component library, the creation and addition of specific unit sized load profiles. These changes will enable a Marine user to design a hybrid micro-grid. Significant changes to HOMER's current capability centers on the optimization feature. HOMER for Marines will enable the optimization a system based on logistics constraints such a fuel, weight, size, and equipment available to transport components. This will empower Marines to create the lightest leanest power system, use less fuel and complete the mission.

The focus of this thesis is on the analysis of the Marine Corps all renewable system SPACES (Solar Portable Alternative Communications for energy System) its performance metrics so that it can be added to the component library of HOMER for Marines. SPACES is a solar system that incorporates a 0.7 m^2 flexible cell solar panel, a DC-to-DC converter, and a lithium ion battery for energy storage.

The lithium ion battery raises several questions on its own. At the time this thesis began, HOMER did not have any lithium batteries in the component library, and it was not entirely clear if the battery model used by HOMER would accurately depict the behavior of lithium ion batteries. As the Marine Corps has added many lithium ion batteries to its inventory, answering this question became central to this thesis.

Related work has shown that the kinetic battery model used by HOMER works well with lithium ion batteries during discharge between 95% and 25% state of charge. Work done in this thesis used lithium iron phosphate batteries and stressed them by discharging them at high current rates. We suspected that internal temperature affected temperature in quantifiable ways, resulting in a possible temperature corrected KBM.

Results from the work done in this thesis found that SPACES is a very flexible system that enables Marines to power communications systems and charge batteries using a variety of adapter cables. In this investigation, we found the Starpower DC-to-DC controller to be highly efficient and the lithium ion battery to have an excellent roundtrip efficiency. However, the solar panel seemed to have a very low efficiency (6 to 8%) relative to what is currently available on the market (up to 12%). Soon flexible solar cells will be over 16% efficient, and it is the author's opinion that the Marine Corps should be investing in better solar technology as it becomes available to meet its energy requirements.

The lithium ion battery investigation vielded interesting results as well. Experiments were designed to show a correlation between voltage behavior and internal temperature. After 25 battery discharges it seems there is a strong correlation. Additionally, a lithium ion battery room temperature is easily modeled by the kinetic at battery model with deviations between the model and data collected of less than 5 mV. A battery that is well above room temperature (over 40 Celsius) deviates from the kinetic battery model by up to 50 mV, a factor of ten difference. While this makes a strong case for temperature dependence, it is the opinion of the author that HOMER does

xxi

not need a temperature corrected battery model at this time. Deviations of 50 mV will not dramatically impact HOMER's energy calculations for a system over the course of a year. Additionally, the batteries in the field will not be discharged at a rate that would increase internal lattice temperature above 40 C very often, eliminating the need for temperature correction at all.

ACKNOWLEDGMENTS

There are many people who helped shape and refine this thesis, and I am grateful to them all. Ι wish to acknowledge my thesis advisors, Dr. Michael and Dr. Nussbaum, whose advice and input has been critical throughout this process. I wish to thank Maj Newell, who has been a mentor and opened many doors to me in the past year. I wish to thank Dr. Coombe at ONR for seeing potential in this project from the beginning.

I am incredibly grateful to all of the amazing people at the Carderock division of NAVSEA, who invested time and effort into this work. Thank you Dr. House, Dr. Shields, and most especially Dr. Miller; it has been a pleasure and an honor to work with you all.

Thank you to all my editors, whose attention to detail and input shaped this thesis into a document that I am proud of. Finally, thank you to my dedicated spouse, whose endless support and patience helped get this work to the finish line. Thank you all, this would not have been possible without you.

I. INTRODUCTION

A. MARINE CORPS EXPEDITIONARY POWER REQUIREMENTS

In 2009, General James T. Conway, the 34th Commandant the Marine Corps (CMC), held the first USMC Energy of Summit in Washington, DC. This summit brought to the fore of conversation the Marine Corps' insatiable appetite for fossil fuels as well as the financial and logistical burdens that appetite has on our finite resources. In his opening remarks the CMC said, "I am unsettled by what I now know with regard to our expeditionary capabilities and 5:00 energy efficiencies...The alarm was set for this morning; at 4:00, I was staring at the ceiling thinking about what we are going to do about this problem"[1].

After the summit the CMC sent a team to Afghanistan to study what the Marine Corps was doing right and where we could do things more efficiently. Shortly after the report from this expedition, the CMC created the Expeditionary Energy Office (E2O) [2]. This office was created to "analyze, develop, and direct the Marine Corps' energy strategy in order to optimize expeditionary capabilities across all war-fighting functions" [3].

Since its creation E20 started the Experimental Forward Operating Base (ExFOB) program, which brings emerging technologies and military minds together to solve expeditionary power problems. E20 has completed multiple efficiency studies, including the BOULDAK study in Afghanistan, which collected Marine Corps actual power use data while operating forward. E20 has commissioned work at

NREL to model improving efficiency in field tents and, among many other things, helped shape this thesis [4].

One of the many concerns E20 is confronting is not simply changing how the Marine Corps uses energy but how we plan for energy use and the perception of energy use throughout the entire Marine Corps. The Marine Corps has an energy planning doctrine that determines the size of a generator we bring to a Forward Operating Base (FOB); that doctrine says the peak load requirement can be no more than 80% of the generator's output capability. While this policy ensures the continuity of operations, it effectively hamstrings our operating efficiency. Loads rarely demand peak power and, therefore, Marines are consistently running generators at low power outputs. This burns fuel at the lower end of a generator's efficiency curve and results in higher maintenance requirements [4].

As the Marine Corps shifts away from expeditionary power that relies solely on burning fossil fuels to alternative energy and hybrid power systems, energy planning becomes exponentially more complex, and we were not doing it well to begin with. This is where HOMER Energy LLC may bridge the gap between expeditionary power requirements and planning for efficient power operations [5], [6].

B. THE ROLE OF HOMER

HOMER (Hybrid Optimization Model for Electric Renewables) is a software application that models hybrid power systems to determine if a micropower system can provide for a particular load and how much the system will cost to install and maintain for the life of the project. HOMER can design an efficient micro-grid for a user. A power system that exists to supply a specific load is called a micro-grid. A micro-grid can be tied to a grid, or independent of a larger grid system.

HOMER is a unique application that enables a user to build a power system in order to supply a load and model it in a specific location over the course of an average year. This allows the user to quickly determine the most efficient power system configuration for a load. The ability to design a system, test it and then optimize it based on user-defined constraints are just a few of the their fingertips. tools HOMER user has at Details а concerning HOMER software capabilities are discussed in Chapter II.

C. PURPOSE AND GOALS

The purpose of the work done in this thesis was to work with the individuals at HOMER Energy to create a tool for the Marine Corps to use for expeditionary power planning. The author's role was to provide the team at HOMER Energy with all the data and information they needed to shape HOMER into a user-friendly application. HOMER will enable Logistics Marines to conduct detailed, location specific power planning and incorporate the optimal mix of renewable and conventional power systems to complete a mission. The goals for a Marine Corps specific application are described in Chapter III.

To that end the author examined an all-renewable power systems that are already in the Marine Corps inventory so that they could be integrated into the component library in HOMER. The Solar Portable Alternative Communications Energy

System (SPACES) is a completely renewable system incorporating a small solar panel, a power controller, and a battery for energy storage. The solar panel was tested in a variety of atmospheric conditions to determine performance characteristics and efficiency.

The battery included in SPACES is a Lithium Ion (Li⁺) chemistry battery. This chemistry added some interesting layers of complexity to this project. HOMER does not have Li⁺ batteries in the component library, and we were not sure if the Kinetic Battery Model (KBM) that HOMER used would be effective for Li⁺ batteries. Li⁺ batteries have peculiar chemistry tendencies that defy standard models. We believe those behaviors are tied to temperature effects, and if the KBM cannot be used, then perhaps a temperature modified KBM might be effective.

Detailed in Chapter IV is the behavior of solar cells, how they work, and how atmospheric conditions affect them.

Background information on batteries is described in Chapter V, where common chemistries, standard battery models and why Li^+ battery behavior defies standard models.

Testing and evaluation of SPACES are detailed in Chapter VI.

Testing and evaluation of lithium ion batteries is detailed in Chapter VII.

Results and conclusions from testing and analysis of SPACES and batteries, as well as recommendations for future work, are detailed in Chapter VIII.

II. HOMER

A. WHAT IS HOMER

1. Introduction

HOMER is a computer simulation software that models and compares micropower systems to aid in the development of cost effective micro-grids. A micropower system is an electrical generation system that serves a specific load. It may draw power from a grid, or it may be an autonomous power system. HOMER models a power system's physical behavior and incorporates life cycle cost (i.e., costs of purchase, replacement, installation and maintenance) to delineate performance and cost metrics to aid the decision making process.

The information in this chapter is drawn heavily from the documentation published on the HOMER Energy LLC website <u>www.homerenergy.com</u> and conversations with personnel within the company itself. The following information is intended to give the reader a conceptual overview of the capabilities inherent to HOMER.

2. A Brief History

HOMER was developed in the National Renewable Energy Laboratory (NREL) as an outgrowth of the Village Power Program. NREL developed a model to aid the rural electrification program in understanding the trade-offs in different micro-grid designs.

By 1997 NREL understood that there was a need for a publicly available model to enhance grid-connected systems with renewable technologies. HOMER became a Windows based

program written in C++, and additions to the model included economic and emissions constraints. In 2009, NREL executed a commercial license, giving HOMER Energy LLC exclusive rights to develop and market HOMER [7].

B. HOW HOMER WORKS

1. Overview

HOMER is a software modeling application that works in three parts: simulation, optimization, and sensitivity analysis. HOMER is particularly useful because of its capacity to model complex systems using a variety of power generation techniques including but not limited to, diesel, solar, wind, hydro and biomass.

When conducting a simulation, HOMER will analyze a system each hour of a year to determine its technical feasibility. It then generates life cycle cost estimates for that system. When optimizing a system, HOMER seeks to determine the most cost effective system arrangement by scaling the various components in the system. The third process is sensitivity analysis, in which HOMER determines the robustness of the optimized system in response to changing variables that are external to the system. For example, a user can ask HOMER to examine how the Net Present Cost (NPC) of the system is affected by fuel prices by analyzing a range of fuel prices that the user defines (i.e., four to ten dollars per gallon). The relationship of these three functions is depicted in Figure 1.

Figure 1. Conceptual relationship between simulation, optimization and sensitivity analysis used in the HOMER software. From [7]

2. Simulation

HOMER modeling centers on simulating a single microgrid configuration over a simulation period of one year. Models analyze a single system configuration with specific component sizes and tie in an operating strategy that guides how those system components interact over the simulation period. There are two main questions that this operation seeks to answer: is the system feasible; and how much will it cost as defined by the inputs and constraints? HOMER considers a system feasible if the power produced, captured, or purchased from the grid meets the identified requirements for each time step of a year. Once a system is feasible, HOMER calculates the costs of initial purchase, operation and maintenance, component replacement and fuel to identify the total system cost in today's dollars (NPC).

HOMER can simulate any system configuration the user defines (e.g., diesel, wind, solar, biomass batteries, etc.). The user can design a system that provides power from AC, DC, and thermal load generators or a system that is a combination of power supplies. To do so, HOMER utilizes a cache of historical worldwide data that enables HOMER's algorithm engine to step through an entire year hour by hour for any location on the globe. As the simulation progresses, HOMER decides what to do with excess renewable power or determines how to generate more if there is a shortfall, while operating within the constraints defined by the inputs. If HOMER detects an unresolved shortfall, it will identify the configuration as not feasible [8]

If the system being modeled has a battery bank and one or more generators, then a dispatch strategy is required. A dispatch strategy is a set of rules that govern the use of available power. It can be thought of as disposable income. Once all the bills are paid, where does the rest of the money (power) go? In deciding where to take power from, HOMER will always attempt to minimize the cost per W. To that end HOMER has two types of dispatch strategies, cycle charging and load following.

In cycle charging the batteries are charged by excess power when the generator runs, thereby, allowing the system to take advantage of the generator fuel efficiency curves (depicted in Figure 2). A generator is more efficient in terms of output power vs. fuel burned when it is run at its maximum load, however, it is also burning more fuel per hour, which may be a logistical or economic burden.

Generator operation and maintenance costs tend to be higher than other components in the system; therefore, deciding when, for how long, and at what output level to run a generator is a critical decision point in each time step[6].

Figure 2. Efficiency vs. Load of USMC Generators. From [9]

The load following dispatch strategy requires the generator to output only enough power to run the load and not charge the batteries. The batteries are required to be charged from another power source, such as solar or wind. The user selects the dispatch strategy; HOMER enables the user to toggle between both strategies to aid the user in the selection process.

HOMER's designers decided to use one-hour time steps for an annual simulation. A time step too large would miss critical intermittent renewable resources (i.e., solar and wind) and fail to provide the level of detail required for a sufficiently accurate model. Conversely, if the time step is too small, the simulation takes too long to make optimization and sensitivity analysis feasible.

HOMER has a simple graphic interface that enables users to select the system configuration and input system constraints. The simple add/remove feature, depicted in Figure 3, allows the modeler to create a system to supply prospective load requirements. Additionally, the the resources section allows the user to input location specific resource data, either from the Internet, personal files, or from HOMER's library. The user can add economic or system constraints, including how long/often they would like the generator to run.

Figure 3. An example system configuration, a screen shot from HOMER.

HOMER evaluates a system's total cost in today's dollars. The NPC includes: initial purchase, replacement, system maintenance, fuel, and the cost of buying power from
a grid. The NPC also includes any revenue that may be generated by the system configuration by selling extra power back to the grid.

3. Optimization

In the simulation function, HOMER models a single system configuration. In optimization, HOMER conducts many simulations to determine the optimal system configuration that meets the input constraints at the lowest NPC. In this function, HOMER can be considered a calculator that gives the best output based on the input of decision variables. It is important to remember that the modeler has to ask the right questions to get the optimum results. The advantage of this modeling system is that running multiple scenarios is quick and easy.

Optimization allows the modeler to answer specific questions about a micro-grid that would otherwise be nearly impossible to answer. Due to the complexity of systems interactions, a user who wanted to add renewable energy sources to a diesel generator power system could be overwhelmed trying to determine how much wind, solar, and batteries to add. Would the cost of the investment be worth the upgrade? Will the improvements meet the load needs over the long term? Decision variables that can be addressed by HOMER include but are not limited to:

- The size of a solar array
- The number of wind turbines
- The size and number of generators
- The number and size of batteries
- The size of the AC-DC converter

- The size of a hydrogen storage tank
- The size of the load

The purpose of optimization is to determine the right system components, the sizes and or quantities of each component, and a power dispatch strategy that meets the needs of the micro-grid without producing power shortfalls or excesses [8].

Consider the following example. A modeler would like to update their diesel generator micro-grid with some renewable power, wind, solar or some combination. Figure 3 from the preceding section is an illustration of the HOMER interface for building such a model. The user can ask HOMER to optimize the decision variables using the search space function. In the search space the user can add scaled variables for each component to be analyzed. The search space for this scenario is depicted in Figure 4. The user has specified five generator sizes, five quantities of wind turbines, seven battery bank sizes, and five sizes of solar arrays. The search space, depicted in Figure 4, displays different system combinations that 2625 HOMER will individuallv simulate. will HOMER disregard any configurations that are not feasible and then rank the remaining configurations from least to most expensive. The tabulated output allows the user to look at decision variables (e.g., project lifetime fuel, project lifetime fuel consumption, operations and maintenance costs). This allows the modeler to look at the trade-offs associated with the each configuration HOMER has determined to be the example of most effective. An HOMER's optimized and tabulated output can be seen in Figure 5. The most cost

effective system is not always the right configuration; other concerns may be carbon emissions, maintenance, or fuel prices.

4. Sensitivity Analysis

Sensitivity Analysis is a means for the user to cope with uncertainty and to determine the robustness of a given optimal system configuration. While the optimization process builds the best system configuration under a single set of input assumptions, sensitivity analysis allows the modeler to run optimizations over various sets of input assumptions.

A sensitivity variable is one for which the user has entered multiple values. A sensitivity variable can be anything that is not a decision variable, including but not limited to: diesel prices, grid power prices, expected lifetime of various system components, variable loads, and carbon credits. For each distinct sensitivity case, HOMER will simulate the sensitivity variable and create an optimized output. The user will then be able to determine which sensitivity variables most dramatically affect the costs of a specific system configuration.

While the most obvious advantage of sensitivity analysis is enabling in-depth cost analysis, sensitivity analysis also gives the user a powerful tool for managing uncertainty. Additionally, the user has the ability to answer a variety of specific questions such as:

- What is the cost and benefit analysis of a 50 percent renewable hybrid system?
- What is the optimal combination of technologies for a specific load at a specific location?
- A policy planner can determine what amount of economic incentive is required to make alternative energies appealing to business and residences.

The user can address these types of questions in the constraints and limitations section of HOMER. Both constraints and limitations have search space dialog boxes that can be used to input variables that can effect each simulation outcome[8].

HOMER uses an array of visual tools to help the system designer recognize how each sensitivity variable affects the NPC. A tabular display shows the optimal system configuration as the sensitivity variable changes. A spider diagram compares the sensitivity variables relative to each other so the system designer can see which variable most directly impacts the system. On a spider diagram, the steeper the curve, the higher the impact of that variable on the system.

Another powerful tool is HOMER's ability to conduct sensitivity analysis on hourly data sets, whether that data set is a variable load, or renewable energy source such as solar, wind, hydro or biomass. This enables the system designer to become informed of the impact on the entire system of several low renewable resource days or several high load demand days. The user can then modify the system to minimize the impact to the load during these occasions of intermittent power variation. Without this analysis tool, system designers often err on the side of caution and accept excess electrical supply for 90 percent of the time, which is a waste of both energy and money. This is one of the major problems the Marine Corps faces today.

C. MODELING PHYSICAL SYSTEMS IN HOMER

1. Overview

The focus of this thesis is on the way that HOMER models physical systems most directly relevant to the United States Marine Corps. The following sections will describe in greater detail the way that HOMER models physical system components and the interaction of the power system and the load(s).

2. Electrical Loads

HOMER models two types of electrical loads: primary and deferrable loads. The primary load is the reason the micro-grid exists and is a load that must be met on a set schedule. A deferrable load is one that can be met within a certain window of time. Primary load is an electrical demand associated with communications equipment, lights, computers, or other equipment that consumes a fairly consistent amount of energy. When the demand exceeds the capacity of the system, HOMER classifies it as an unmet load. Each period of unmet load will be noted in the simulation, and the system designer will know where and why the power supply fell short.

The modeler can generate a primary load in a variety of ways: an excel file can be imported, or HOMER can synthesize daily average load data. Load data is specified in kilowatts (kW) for each hour of the day. The user can specify different loads for each month or season as necessary. Additionally, HOMER can introduce random variability in the daily load profile within limits set by the user. The primary electric load also requires an operating reserve, which is also set by the user. The operating reserve, also called a spinning reserve, is specified as an amount of energy not related to a specific device. It is an amount of energy designated to handle periods of excessive loads or power shortage. The user can set the operating reserve to zero if desired.

A deferrable electric load is a demand that can be met anytime within a specified time interval. Battery charging stations and radios are good examples of deferrable load,

as they have internal energy storage capacity. Deferrable loads are advantageous in regions of intermittent renewable resources. Energy storage is always considered the deferrable load in HOMER. The user specifies the size of the deferrable load in kilowatt-hours (kWh). HOMER models a deferrable load as a storage tank of a defined size. When there is excess power being generated by the system, and the primary load is met, excess energy is directed to the storage tank. HOMER continually tracks the level of energy in the tank. When it is full and the primary load is met, HOMER starts tracking excess energy which is in effect wasted unless it is a grid connected system, in which case excess energy can be sold back.

3. Generators

HOMER can model a variety of electric and thermal generators, including internal combustion, fuel cell, Sterling engines, micro-turbines, and thermoelectric engines. When modeling a micro-grid, HOMER can model up to three generators, each with its own fuel efficiency curve, fuel type, and electrical output either Alternating Current (AC) or Direct Current (DC). It is also possible to model a fuel mixture, such as biomass and diesel.

The principle variables HOMER needs to model a generator are:

- Maximum power output (kW)
- Minimum power output (kW)
- Operating lifetime (hours)
- Fuel consumed (liters)
- Efficiency, which is the rate at which fuel is consumed vs. electrical output produced

HOMER assumes a linear fuel curve if given only two points on the efficiency curve; however, given more data, HOMER will create a best fit. HOMER uses the following equation to model fuel consumption:

$$F = F_0 Y_{gen} + F_1 P_{gen} \tag{2.1}$$

where F_0 is the fuel curve intercept coefficient, F_1 is the fuel curve slope, Y_{gen} is the rated capacity of the generator, and P_{gen} is the electrical output of the generator in kW. The units of F depend on the unit of measure used for the fuel. If the fuel is denoted in liters, then the unit of F is L/h.

The user can specify the intervals during which the generator will run or be shut off. Absent user instructions, HOMER will force the generator on and off based on the needs of the system. According to the dispatch strategy, HOMER will make decisions to set the output of the generator [10].

4. Photovoltaic Cells

Photovoltaic (PV) cells are devices by which incident solar radiation is converted to DC electricity. Commonly known as Solar Cells, PV cells or arrays can vary in size and are characterized in terms of rated capacity. Rated capacity is the maximum power produced by the array in standardized testing conditions. It incorporates the size and efficiency of the array, and therefore, HOMER does not deal with these variables directly. However, it would be a mistake to compile a simulation of a system that claims the best-case power output for all time intervals because PV cells only produce rated capacity output under ideal solar conditions [11]. HOMER uses a modeling tool called a derating factor, which allows the user to scale the available output power from the best case to a more realistic output. The de-rating factor reduces the efficiency of the PV array to take into account things like dust, angle-of-incidence and other factors that may reduce operating performance. HOMER does not automatically account for the fact that PV output decreases as the operating temperature of the cells increase, though the user can incorporate a temperature coefficient when modeling a system in a hot climate.

The voltage at which current is drawn from a PV array significantly impacts the efficiency of the array. This will be discussed in more detail in Chapter IV. For modeling purposes, HOMER assumes that a PV array has a Maximum Power Point Tracker (MPPT) included in the system to ensure that the PV has current drawn at the most efficient voltage and, therefore, is generating the most energy for the time, location, and system configuration [11].

5. Batteries and Battery Banks

HOMER can model a single battery or an entire bank of batteries, which HOMER treats as a DC storage device. A string of batteries denotes that one or more batteries are connected in series, and a bank of batteries is one or more strings. In the system component library, there are a variety of specific batteries the user can add to their system, mostly variants of a lead acid chemistry or other more common chemistries. The system designer is able to select the number and size of the batteries that HOMER is to consider in its system analysis. If the user is unable to find a suitable battery in the library, HOMER does have the option of allowing the user to create a battery, and select the way that battery is modeled. Currently, there are two models that HOMER uses in its calculations, the KBM and the simple battery model. The KBM is much more robust and detailed than the simple battery model. The KBM will be discussed in more detail in Chapter V [12].

Batteries are capable of storing a fixed amount of DC electricity at certain round trip efficiencies. Each individual type of battery has limits as to how quickly it can be charged and discharged, how deeply it can be discharged, and how many cycles it can undergo prior to failing. The depth of discharge directly affects the number of cycles a battery can endure. The cycles to failure is inversely related to the depth to which a battery is discharged.

The key parameters HOMER uses to replicate battery behavior are:

- Nominal voltage, which is the rated voltage for each battery.
- The capacity curve, which shows the discharge capacity (available energy) in Ampere-hours (Ah) at a particular discharge current.
- Lifetime curve is the number of cycles to failure verses the depth of discharge.
- Minimum state of charge is the minimum voltage a cell can be discharged to and not suffer permanent damage.
- Round trip efficiency is the amount of energy that can be discharged from a battery compared to the amount of energy it takes to fully charge a battery.

HOMER uses the KBM to track energy going into and out of each battery in the bank. Each of the key parameters enables HOMER to determine the current state of charge and whether energy is stored in or discharged each hour of the year [8].

6. Converters

Converters are devices that can change DC electricity to AC electricity and back. When converting from DC to AC, the process is called inverting, and from AC to DC, the process is called rectifying. The capacity of a converter is always given in terms of AC power throughput (kW). The size of the converter is a decision variable in HOMER. Additionally, output capacity for rectification is а percentage of inversion capacity; the user sets the rectification percentage variable. HOMER assumes that the inversion and rectification capacities are not surge capacities but continuous capacities that the device can withstand for long periods of activity.

When dealing with converters, HOMER does have the capability to model several power sources in parallel. Doing so requires the inverter to have the capability to match AC frequencies, which some converters do not have.

D. ENERGY RESOURCES IN HOMER

1. Defining Resource

The term "resource" is defined in HOMER as something outside the system that provides a means to produce electrical power. Renewable resources include solar, wind, hydro, and biomass. Conventional resources are fuels such as diesel, natural gas, and liquid hydrogen. Renewable resources create a complex problem set for a system modeler because they are location dependent, and highly variable [8].

2. Solar Resources

Solar energy is dependent on several key factors: the latitude, the clearness factor (which denotes how readily the solar energy can traverse the atmosphere) and diffuse radiation (which is sunlight reflecting off nearby surfaces). The user must supply HOMER with the solar data for any given location. HOMER currently has many locations' data already collected, and the correct file need only be imported. If a specific location is not available, there are a variety of websites where the user can find appropriate solar data, such as the NASA website. The data can be inputted in any of three forms: hourly average global solar radiation on the horizontal surface in kW/m², monthly average global solar radiation on the horizontal surface in kW/m^2 , or monthly average clearness index, which is a ratio of the radiation striking the surface to the radiation striking the upper atmosphere. HOMER synthesizes the data and generates an 8760-hour data set that spans each hour of the year [8].

3. Fuel

There is a library of predefined fuels in HOMER. Should none of the available fuels prove sufficient to match the user's needs, it is possible to create a new fuel. The user need only input the fuel density, the lower heating value, the carbon content, and the sulfur content. The last two values are needed only if the modeler wishes to monitor carbon and other waste emissions. THIS PAGE INTENTIONALLY LEFT BLANK

III. PROPOSED MODIFICATIONS TO HOMER

A. INTRODUCTION

HOMER in its current form is an excellent micro-grid modeling tool and economic calculator for determining the most efficient and cost effective system for a user's location. The proposed modifications to HOMER will enable a Marine to design the lightest, smallest, most efficient FOB power system for any location and duration with the tools and systems already in the Marine Corps inventory.

B. BACKGROUND

1. Previous Work

Military interest in the capability set of HOMER started in 2010 with a Naval Postgraduate thesis by then-His work Captain Brandon Newell. was intended to demonstrate the viability of using a tool like HOMER to do a thorough pre-deployment energy planning analysis [3]. Since that time HOMER Energy LLC's vision for what its software can do has grown into a more dynamic and userfriendly tool. This, together with the Marine Corps' need to curtail energy waste and simplify the logistics burden of moving fuel around the battle space makes HOMER Energy a meaningful partner moving forward.

2. Collaborative Partners

There are several stakeholders in this endeavor. The Office of Naval Research (ONR) and the Marine Corps Expeditionary Energy Office are both actively engaged in creating a HOMER application specifically for the military.

Additional help and interest has come from individuals in the Carderock division of the Naval Sea Systems Command (NAVSEA). All parties have worked with HOMER Energy to create a coherent plan to create such a tool.

C. HOMER FOR MARINES

1. Marine Corps Power Modifications

The proposed changes to HOMER are intended to create a simple, user friendly tool that any Logistics or Utilities Marine can use to design a micro-grid that can support the Camp Commander and the mission.

The proposed user interface will be a simple, directed set of questions. These questions allow a user without a comprehensive understanding of power systems to design a feasible micro-grid. For more advanced users, such as Utilities Marines who already understand power distribution, a more detailed interface with additional user-specified variables will be created. The intent is that anyone can build a solution to a complex problem set.

The system library will be updated with all current Marine Corps inventory power supplies, such as the Tactical Quiet Generators (TQGs), the next generation power systems Advanced Medium Mobile Power Systems (AMMPS), as well as all renewable systems such as Ground Renewable Expeditionary Energy System (GREENS) and SPACES. Additionally, Jet Propulsion 8 (JP8) must be added to the fuels library because all Marine Corps systems run on that particular diesel blend.

GREENS and SPACES present a unique modeling situation because they are a complete power system already, including

power generation, conversion, and storage[6]. In HOMER's current form, each component is modeled separately. However, the intent is for a user to select GREENS in the component library, and HOMER will know to add each component of the system into the micro-grid.

A load library will also be created. The Marine Corps will need to develop an average 24-hour load profile for each item in its inventory that requires power to operate. The user will be able to specify the load equipment and quantity going to the FOB, and HOMER will synthesize the load profiles into a location and mission-specific primary load. To simplify the process HOMER will have a menu of pre-defined primary loads of varying unit sizes. The predefined loads will be in the form of actual equipment lists from which the user will be able to add and remove items as necessary. Environmental Control Units (ECUs) are seasonally dependant loads that require different profiles for spring, summer, and winter.

While there is renewable resource data available on the Internet for most global locations, the user does have to know where to look if the location profile does not already exist. To simplify this task for the Marine Corps, HOMER will add Marine Corps specific training and operating locations to the resource library, starting with Camp Pendleton, Twenty Nine Palms, and Camp Lejuene.

Other modifications include adding the family of Lithium Ion Batteries to the component library and improving modeling of inverter efficiencies.

2. Logistics Modifications

Currently HOMER does not have any logistics planning tools. HOMER's primary baseline for comparing separate systems is the total NPC, which includes the lifetime cost of fuel, operations and maintenance, and acquisition price of the system. Once a system is through the Marine Corps acquisition process, the NPC is not a driving factor. What is important is how a system is transported to a training area or theater of operations and how it is maintained and supplied. The following modifications seek to provide the Marine Corps with a tool to design an optimal hybrid power system that is as light and lean as possible, as well as an optimal packing method to get the system to the operating area.

Changes in HOMER will start with creating a logistics algorithm that will optimize a system based on logistics requirements. The variables that need to be included are the size (in cubic inches) and weight (in pounds) of each power system. HOMER will also incorporate logisticsspecific information about each type of vehicle in the inventory including cargo capacity dimensions, fuel tanker capacity, trailer capacity, and cargo container dimensions.

These proposed modifications will enable the modeler to optimize a system based on logistics concerns and still meet the mission requirements for power generation and distribution. Additionally, the modeler will be able to do sensitivity analysis on the system to determine the best resupply cycle, such as how often a given FOB will require fuel and or batteries.

3. Marine Corps Energy Planning

Currently, the Marine Corps deals with power planning by addressing how much power needs to be produced in order to meet peak loads for a particular FOB. The modified version of HOMER will enable any Marine to consider energy planning as a whole concept. The purpose is a culture shift away from planning for peak power to planning to generate, store, and use only the total energy required to complete the mission. The whole concept approach is the ability to do an analysis quickly each time the Marine Corps needs to erect a camp. The modified version of HOMER enables the user to analyze all the pieces of a system, power sources, loads, and energy resources for any location necessary, based on available equipment and the mission profile. The user will be able to drive the optimization process for each system based on the most pressing concerns of the mission commander, whether those concerns are weight and space or resupply intervals. HOMER will enable the Marine Corps to be lighter, leaner, and more ready for the next fight.

D. AQUISISTIONS ENGINEERING

1. Engineering Analysis

Acquisitions is a complex process that takes many competing ideas for a material solution and prunes them down to a single concept, for which a contract is written to develop a prototype. Often this system lacks the modeling capability to provide direct systems comparisons and a detailed capabilities assessment.

ONR has requested a detailed engineering analysis tool to aid in the assessment of proposed power systems. HOMER is developing an application that will allow the modeler to build a power system from the ground up and then insert it into a micro-grid for performance analysis. The user will able to build a hybrid system comprised of be many different technologies including a diesel generator, PV, solar concentrator, flywheel, wind, hydrogen fuel cell, will and many others. The user batteries, have the flexibility to manipulate variables such as fuel efficiencies, battery depth of discharge, state of charge requirements, power dispatch strategy and much more.

Once the user has designed and "built" the proposed systems in a HOMER file, each power system can be simulated and optimized under actual load profiles to determine which system has the best performance. The acquisitions modeler can even choose the best-proposed system and make modification requests to the system designer to reflect the optimized system HOMER produced.

This application of HOMER will have a separate interface from the Marine Corps Power Planning Tool. The engineering application will retain the user-friendly visual interface, allowing the user to combine the system components in a fashion similar to the proposed item.

E. PROGRESS REPORT

With the help of ONR and E2O, HOMER Energy has developed a three-phase acquisition strategy. Phase one is prototype development; phase two is bringing the total software system online and conduct fielding tests. Should

this tool have value to the Marine Corps, phase three will be distribution of the software and training for the Marines.

Currently, HOMER is in phase one, at the end of which a functional prototype will be demonstrated to ONR. The prototype will have several basic load profiles; all current power systems programs of record will be in the component library. HOMER will be able to demonstrate design of a FOB power system for a company sized unit or a Marine Expeditionary Unit (MEU). The power system can be optimized for fuel, weight, or size at any of three locations: Camp Lejuene, Camp Pendleton, or Twenty Nine Palms. Finally, HOMER will produce a written report that includes the best packing arrangement for transportation of the system. THIS PAGE INTENTIONALLY LEFT BLANK

IV. SOLAR CELLS AND POWER SYSTEMS

A. INTRODUCTION

1. PV Basics

A photovoltaic cell is essentially a p-n junction in which electrons and hole pairs, generated by light energy, are separated by the bandgap of the material utilized in making the p-n junction. The visible solar irradiance spectrum is most commonly associated with photovoltaic cells, which is why they are often called solar cells. However, artificial light, infrared light, and even ultraviolet light can be used to generate electricity given the right material in the photovoltaic cell. There are three basic attributes to a functioning PV cell[13]:

- The absorption of incident light generates electron-hole pairs.
- Charge carriers are separated from parent atoms.
- Charge carriers are extracted to an external circuit.

B. SOLAR SPECTRUM AND SOLAR RADIATION

1. Electromagnetic Waves

The electromagnetic (EM) spectrum refers to the entire frequency range of EM radiation. The EM spectrum extends from the Extremely Low Frequency (ELF) bands used for radio communication to gamma radiation, which has a wavelength the size of an atom, and extremely high frequency.

EM waves are generally referred to by three variables; frequency (f), wavelength (λ), and photon energy (E). These three physical descriptive properties are related by the following equations:

$$f = \frac{c}{\lambda} = \frac{E}{h} \tag{4.1}$$

$$E = \frac{ch}{\lambda} \tag{4.2}$$

where c is the speed of light and h is Planck's constant $(4.135 \times 10^{-15} \text{ eVS})$. These equations relate the wavelength and frequency of EM radiation to the amount of energy each photon has. Grouping wavelengths that behave similarly into "bands" further delineates EM radiation. These bands of EM radiation are shown in Figure 6.

Figure 6. A diagram of the entire EM radiation spectrum. (From [14])

The bands or classifications of EM energy are sifted into seven categories. From highest energy to lowest, they are:

- Gamma radiation
- X-ray radiation
- Ultraviolet radiation
- Visible radiation
- Infrared radiation
- Microwave radiation
- Radio waves

The bands of EM radiation can be even further broken down into specific EM frequencies. In Figure 7, the specific frequency of radiation is directly associated with wavelength and photon energy. These numbers can be solved for mathematically using Equations 4.1 and 4.2.

CLASS	FREQUENCY	WAVELENGTH	ENERGY
V	300 EHz	1 pm	1.24 MeV
¥ цу —	30 EHz	10 pm	124 keV
□^ _	3 EHz	100 pm	12.4 keV
SX —	300 PHz	1 nm	1.24 keV
	30 PHz	10 nm	124 eV
	3 PHz	100 nm	12.4 eV
	300 THz	1 µm	1.24 eV
	30 THz	10 µm	124 meV
	3 THZ	100 µm	12.4 meV
	300 GHz	1 mm	1.24 meV
	30 GHz	1 cm	124 µeV
	3 GHz	1 dm	12.4 µeV
	300 MHz	1 m	1.24 µe∨
	30 MHz	10 m	124 neV
	3 MHz	100 m	12.4 neV
	300 kHz	1 km	1.24 neV
	30 kHz	10 km	124 peV
	3 kHz	100 km	12.4 peV
	300 Hz	1 Mm	1.24 peV
	30 Hz	10 Mm	124 feV
	📕 3 Hz	100 Mm	12.4 feV

Figure 7. The EM Spectrum, the respective wavelengths and photon energy in eV. From [14]

2. Solar Radiation

The Sun emits EM radiation across almost the entire spectrum. Gamma radiation photons are created by nuclear fusion within the Sun. They are such high-energy photons that they are converted to a lower energy band by the time they reach the surface of the Sun through interactions with the solar gas. Therefore, the Sun does not emit all EM frequencies, but it is very close to being a blackbody object, which is a theoretical object that does not absorb EM waves and radiates the entire EM spectrum [15].

The EM radiation travels unattenuated through a vacuum Sunlight that strikes the top of in space. earth's atmosphere has a power of 1366 W/m^2 , 50% of which is in the infrared band, 40% is in the visible light band, and 10% is in the ultraviolet band. The ultraviolet light is absorbed by the upper atmosphere, specifically the lithosphere. As sunlight travels through the various levels of atmosphere, it is attenuated and refracted; photons reaching the ground are less energetic. Where sunlight has to penetrate the least amount of atmosphere and where the direction the waves are traveling is perpendicular to the surface of the earth, the amount of energy at the surface is about 1000 W/m^2 [16]. The energy breakdown is about 53% in the infrared range, 44% in the visible range, and 3% remains in the ultraviolet range. The variation between the top of the atmosphere and the earth can be seen in Figure 8. In Figure the solid curve is the EM 8 spectrum emitance of a blackbody [15]. The yellow shaded area is the radiated EM spectrum of the Sun in space just outside the earth's

atmosphere, and the red shaded area is the portion of the EM spectrum that reaches the surface of the earth [14].

Figure 8. A comparison of the EM spectrum at the top of the atmosphere and the surface of the earth. From [15]

3. Air Mass

Air Mass coefficient (AM) is a reference system that assigns a value to the distance sunlight has to travel through the atmosphere. AM is commonly used to characterize solar cell performance at the surface of the earth. At the top of the atmosphere, the reference starts with AMO, where the available power in a square meter is 1366 W. As sunlight travels through the atmosphere, it is scattered, refracted and absorbed by particulates in the atmosphere.

When the Sun is directly overhead, commonly referred to as the zenith, EM radiation travels the shortest distance, defined as AM1. As the angle of the Sun deviates from the zenith, the atmospheric thickness increases, and the AM reference assigned goes up. AM for a specific path length is defined by

$$AM = \frac{1}{\cos z} \tag{4.3}$$

where z is the angle away from the zenith. This is a simplistic model that does not account for the curvature of the earth. A more accurate assessment of the distance sunlight has to travel through a round atmosphere is given by [15]

$$AM = \sqrt{((r\cos z)^2 + 2r + 1) - r\cos z}$$
(4.4)

where r is ratio of the radius of the earth over the height of the atmosphere, which is 708. Once the coefficient has been determined for a specific location, the solar intensity can be estimated useing

$$I = 1.1I_o 0.7^{(AM0.678)} \tag{4.5}$$

where I_0 is the solar intensity at the top of the atmosphere, 1366 W/m². Depicted in Table 1, a sample of various AM coefficients and surface solar intensities can be viewed. The values in Table 1 were calculated using Equation 4.4 [15].

Ζ	AM	W/m^2
	0	1353
0	1	1040
23	1.09	1020
30	1.15	1010
45	1.41	950
48.2	1.5	930
60	2	840
70	2.9	710
75	3.8	620
80	5.6	470
85	10	270
90	38	20

Table 1. A representation of the AM coefficient and the resulting solar intensity at the earth's surface.

It is important to note that Equation 4.4 is an ideal representation and does not take into account weather, pollutants, humidity and other air mass particulates that solar intensity the may reduce the at surface. Additionally, seasonality affects solar intensity. Monterey is 36 degrees north of the equator; in the summer the Sun is 36 degrees away from zenith at noon providing approximately 1000 W/m^2 of solar energy. However, it is usually overcast during the summer months in Monterey. In October, it is beautifully sunny, and the sun at noon, is significantly closer to the horizon, 23 degrees closer. The best day for solar intensity in Monterey in the winter months is estimated to be 840 W/m^2 .

C. SOLAR CELLS

1. How Solar Cells Work

Solar cells are a form of PV cell that utilize the visible portion of the EM spectrum. Solar cells are simply

semiconductors, similar in nature to a diode. Elements that are used to make solar cells are those that have only four electrons in the valence band. The most stable atoms are those that have a full valence band of eight electrons. Semiconductors make very structured crystal lattices where each atom in the lattice shares the four electrons in its valence band with four neighbors. Thus, electrons in the valance band are moving between two atoms and are not entirely bound to either. Next, the primary element, most commonly silicon, is doped with impurities [17]. Doping is the addition of an element that has one more or one less electron in the valence band. Therefore, doping adds more charge carriers, either positive or negative. Ιf the silicone is doped with a material that has five electrons in the valence band, then one electron does not have a specific place in the lattice and is free to move through the structure. The lattice is now said to be an n-type material, because the charge carriers are predominantly negative electrons. If the primary element is doped with an element that has three electrons in the valence band, then some atoms are left with an incomplete outer shell, and those atoms appear positively charged. Thus, the lattice is said to be a p-type material [17], [18].

Semiconductors are junctions between n-type and p-type materials in which the excitation of the lattice in one material causes movement of the charge carriers in both materials. These semiconductor junctions require the right amount of energy to break the charge carriers free of the atoms to which they are bound. That specific energy is called the bandgap and is measured in electron volts (eV). The bandgap energy of silicon is 1.1 eV. Refer to Figure 7, to see that 1.1 eV is the energy of photons in part of the visible light spectrum [18].

2. Factors Affecting Output Power

The size of a solar cell is one of the main factors that determines the current of the particular cell. The voltage is minimally affected by the intensity of the sun. The maximum voltage a solar cell can produce is designated as the open circuit voltage (V_{oc}) and is the potential across the cell when a path for electrons to move does not exist. The intensity of the sunlight is proportional to the amount of current a cell or string of cells produces. The maximum amount of current a cell can produce depends on the intensity of the sun and the area of the cell and is called the short circuit current I_{sc} . The short circuit current is only available when the two terminals of the solar cells are shorted. These characteristics can be seen in Figure 9 [18].

Figure 9. The behavior of a solar cell at various solar intensities. From [13]

Common solar cell behavior is described in the figure above. The current remains relatively set over a range of voltages then drops quickly over the 'knee' of the curve. The solar cells' most efficient operating point is the point on the knee where the current and voltage produce the maximum power. Tracking the Maximum Power (MP) point of a solar cell is the substance of a whole subset of solar research. Figure 9 is an I-V curve; it is a simple matter to measure the V_{oc} , I_{sc} , and MP and then plot the I-V curve [16].

3. Efficiency and Fill Factor

The efficiency of a solar cell or solar panel is the ratio of the maximum output power of the solar cell to the available input incident power. Solar cell efficiency can be defined as:

$$\eta = \frac{MP}{P_{input}} \tag{4.5}$$

where η is the solar cell conversion efficiency. The input power is measured in W/m², so care must be taken to scale the input power to the array size.[16]

The theoretical maximum output power of a solar cell is $V_{OC}I_{SC}$. Fill Factor (FF) is a ratio of the MP point and the theoretical maximum. Fill factor is defined as:

$$FF = \frac{MP}{V_{oc}I_{sc}} . \tag{4.6}$$

Other factors that affect the overall efficiency of solar cells are temperature and dirt/dust. To function, a solar cell must absorb light; most of the light is absorbed at the surface of the cell. Those photons, which have either too much or not enough bandgap energy, generate heat. As the cell temperature increases, the V_{OC} of individual solar cells decreases by approximately 2 mV/C, reducing the overall power output [16].

Solar cells must be cleaned from time to time in order to allow the fully available light spectrum reach the cell surface. This must be done regularly in the desert where dust can quickly build up on a static panel.

Solar cell technology development has been something of a grueling process. Traditional rigid solar cells have been the focus of solar development for 50 years, advancement being driven by satellite power requirements. The most efficient and expensive solar cells on the planet have now broken the 30% efficiency barrier.

D. THIN FILM SOLAR CELLS

Rigid solar cells that are commonly found on roof and building tops tend to be heavy. They are mounted on an aluminum substrate and encased in glass.

Thin film solar cells are made by depositing layers of semiconductor material on a substrate that is nanometers to micrometers thick. The semiconductor material is deposited as a gaseous vapor onto the substrate and then covered with an anti-reflective coating. There are several material combinations that make effective thin film solar cells; one of the most common is Copper Indium Gallium Selenide (CIGS). Silicon is still a popular choice for thin film, as well as Cadmium-telluride [19].

Thin film solar cells function the same way as rigid solar cells, absorbing light and allowing the energy of a photon to break an electron free of its valence band bond to move into the higher energy conduction band. However, thin film solar cells tend to have a number of damaged electron bonds that do not allow the electron to break free. Additionally, since there are fewer atoms in the solar cell structure, the net result is there are fewer charge carriers in the structure. Therefore, thin film solar cells tend not to be as efficient as their rigid 2000 thin film counterparts. Since solar cells have struggled to exceed 10% efficiency. Emerging technologies offer the exciting promise of thin film efficiencies in the 16 to 20% range in the near future [20].

Thin film cells are aggressively researched and designed because they are cheaper to make and, even with the reduced efficiencies, are very competitive in the market. The solar cell will be considered ready for mass installation and use when the price per W drops to about one U.S. dollar [21].

E. ARTIFICIAL LEAF

The concept of modeling nature to produce energy is not new. Scientists and researchers have successfully converted sunlight and water into energy in a variety of ways since the seventies using rare earths and expensive metals as the catalysts for photo-electrochemical reactions. However, the so-called "holy grail" of the artificial leaf is making a system economical and robust enough to enable full-scale competition with fossil fuels and coal burning power plants. A professor at MIT and his research team believe they have done just that.

The last ten years have seen several major leaps forward in this field, and the number of research groups working worldwide on these ideas has ballooned from two to Researchers understand the chemical 29 since 2001.[22] that takes place in a leaf very well. Leaves process utilize the chemical compound chlorophyll as a catalyst that enables the leaf to use sunlight to split water molecules. Freed electrons bind oxygen and carbon dioxide to produce glucose. The remaining electrons from the chemical split are used to repair the chemical makeup of the chlorophyll in the leaf so that it can continue to produce energy. However, chlorophyll itself is a poor choice for the artificial leaf because when directly exposed to Carbon Dioxide in the atmosphere it breaks down rapidly.

An artificial leaf would work in much the same way, simply producing a different chemical output, hydrogen gas. In theory it works like this: a collector is used to gather photons and convert them into electrons, an electrolyzer then uses the energy contained in the electrons to split water molecules, and some chemical or metal catalyst is used to speed the process. According to the Department of Energy, in order for this kind of operation to be scalable to meet National energy demand, each unit will have to last 10,000 hours of use [22].

In 2008 Dr. Daniel Nocera and his team at MIT discovered an inexpensive way to split water molecules using silicon nano-tubes combined with a cobalt/ phosphate catalyst. However, cheap and abundant these materials are, they only freed the oxygen to a gaseous state; the hydrogen

atoms were not able to combine with electrons in order to produce hydrogen gas. At that time Dr. Nocera and his team determined that they would need a separate catalyst for the Hydrogen atoms.

In March 2011, at the National Meeting of the American Chemical Society, Dr. Nocera and his team unveiled a design the size of a playing card that is able to catalyze both oxygen and hydrogen into their gaseous forms ten times more efficiently than a plant can. On one side of the 'card', the cobalt phosphate catalyst drives the chemical reaction for oxygen, and on the other side, а different drives (undisclosed) catalyst the hydrogen chemical reaction. His team asserts that all the materials are cheap and abundant, but the most astonishing news is that the catalysts are self-annealing and that his prototype has lasted for 45 hours of continuous activity thus far [23].

F. SOLAR CONCENTRATORS

Solar Concentrators are systems or arrays that use mirrors or lenses to amplify the solar intensity a solar cell experiences. They are often used in large solar farms in the southwest. With solar concentrators, a smaller number of more efficient solar cells can be used to produce a large amount of power [16].

G. DC TO DC CONVERTERS

The SPACES Starpower controller is a DC-to-DC device that enabled the voltage output of the solar panel to be raised or lowered to meet a loads need. The following sections describe the electronics necessary for these conversions. DC-to-DC power converters are a class of
switched mode power electronics that enable voltages to be raised and lowered as necessary. DC-to-DC converters are important in solar cell technology because solar cells tend to provide a varying output, and a DC-to-DC converter can provide a stable output voltage at the required level. Switched mode power supplies have very high conversion efficiencies, generally around 95% or better. The two primary converters will be discussed in the following sections.

1. Boost Converter

A boost converter is a voltage 'step-up' converter. Boost converters use a switch, either a diode or a transistor, and an energy storage device, a capacitor or an inductor. This device relies on the principle that inductors resist change in current. Figure 10 is a diagram of a typical Boost converter circuit.

Figure 10. A typical boost converter circuit configuration. From [24]

When the switch is closed, the load is shorted out of the circuit. The inductor is able to store energy in the magnetic field from the voltage source. When the switch is open the load is reintroduced to the circuit; the rapid addition of a load demands an increase in either voltage or current. The inductor resists the demand for more current and, therefore, temporarily appears to the load as a voltage source in series with the input voltage, giving the load the higher voltage that is required. If the switch is cycled fast enough, then the inductor will never fully discharge, and the load will always perceive it as a voltage source. Additionally, while the switch is open, the capacitor in parallel with the load is charged to the boosted voltage level. When the switch is closed, the capacitor then becomes a voltage source for the load [25].

The period of time the switch is open compared to the time it is closed is called the duty cycle. Since the duty cycle describes the fraction of time the circuit is on verses the time it is off, the duty cycle is always less than one and can be defined as:

$$D = 1 - \frac{V_i}{V_o} \,. \tag{4.7}$$

When Equation 4.7 is rearranged, it can be seen that the output voltage is always larger than the input voltage: [25]

$$V_{O} = \frac{V_{i}}{1 - D} \,. \tag{4.8}$$

2. Buck Converter

A buck converter is similar to a boost converter except that it is a voltage 'step-down' converter. Like the boost converter, the buck converter circuit depends on the reluctance of an inductor to change current rapidly. Figure 11 is a representation of a typical buck converter.

Figure 11. A typical buck converter circuit. From [26]

When the switch is open, the circuit is 'off', and there is no current across the load. When the switch is closed, current starts to flow towards the load; however, the inductor resists this increase in current. In order to maintain the state of energy, the voltage on the load side of the inductor drops. Since the inductor is an energy storage device, as long as the switch opens before the inductor magnetic field is fully charged the load will always perceive a voltage lower than the voltage source. Again the capacitor in parallel with the load ensures the load maintains a constant V_0 at a lower voltage than V_i . The buck voltage relationship can be described in terms of the duty cycle: [25]

$$V_o = DV_i (4.9)$$

V. LITHIUM ION BATTERIES

A. INTRODUCTION

The Marine Corps is shifting away from disposable energy storage systems to rechargeable batteries in the lithium ion family. The Marine Corps has many mobile communications systems that run on batteries, and the need to understand the capabilities and limitations of our power systems increases with our reliance on them.

1. History of Batteries

The term battery was first used by Ben Franklin to describe a collection of Leyden Jars electrically connected, a reference to an artillery battery. Leyden Jars were the first energy storage devices, and while revolutionary at the time, they were little more than capacitors [27].

An Italian physicist named Alessandro Volta stumbled upon the first known battery in 1799. During some experiments he sandwiched a brine-soaked piece of cardboard between two metal plates and was surprised to discover they conducted electricity when connected [29]. Further work by Volta led to his Voltaic pile; a stack of alternating materials: a zinc plate, brine soaked pasteboard, and a silver plate, repeated several times. This arrangement is depicted in Figure 12. While this was not the first device to produce electricity, it was the first to produce a steady and lasting current. Volta did not appreciate that electricity was created as a result of chemical reactions; he believed the pile to be an inexhaustible power source that suffered degradation because of the oxidation of the zinc and silver plates. He did not realize that oxidization was the inevitable result of the chemical reactions that enabled electrons to move [27].

Figure 12. A depiction of Volta's Voltaic Pile. From [28]

After the Voltaic Pile amazed the world, the race to improve the battery was on. People explored many different chemistries and configurations. The next major breakthrough came from English chemist John Fredrick Daniell. Daniell created his cell using a zinc plate, a copper plate and two chemical electrolytes, zinc sulfate and copper sulfate. Daniell's cell was not very mobile but became a common way to power stationary devices. This cell's primary advantage over previous batteries was its ability to produce a longlasting reliable voltage source.

2. How Batteries Work

Batteries are electrochemical devices; through a chemical reaction, electrons are freed from their bonds and are able to move through a circuit as a result of a chemical reaction.

Though there are many different battery chemistries, all batteries essentially work same way. A battery has four main components, an anode, a cathode, an electrolyte, and a collector. Most batteries have a positive and negative terminal which, when connected to a load via a circuit, allows electrons to flow from the negative to the positive The negative terminal is where the anode is terminal. located. When a load is connected, the anode experiences an oxidation reaction where ions from the electrolyte combine with the anode freeing electrons to the circuit. The positive terminal has a similar chemical reaction that creates holes, which enable the electrons to recombine as they complete the circuit. The collector allows the electrons to flow from the battery to the circuit [30].

3. Description of Common Battery Chemistries

The sodium-sulfate cell is a rechargeable molten metal battery with a high energy density and a round trip efficiency of 89 to 92 %. It has a long lifetime, up to 2500 cycles, and a shelf life of up to 15 years [29]. A primary disadvantage is that its operating temperature is over 300 C.

Lithium sulfur is a light battery chemistry that has the potential to replace lithium ion and lithium polymer cells due to its extremely high energy density. Experiments

so far have been able to create a battery with an energy density of 84% of the theoretical limits, which is four times greater than current lithium ion cells. Another advantage of these cells is that sulfur is a cheap and abundant material [29]. Some issues with lithium sulfur cells include capacity fading over time and limited (about 100) charge/ discharge cycles.

Nickel-cadmium cells have been around for over 100 years. They eventually were enhanced to a sealed battery that responds well to pulse charging and high current rapid discharges. Unlike other batteries, the nickel-cadmium cells require the occasional deep discharge in order to prevent loss of capacity due to memory effects. Modern nickel-cadmium cells have lifetime capacity of over 1000 charge/discharge cycles [29].

Modern nickel-metal-hydride batteries have gained in popularity because of their easily available and environmentally friendly components. These batteries offer an energy density up to 40% higher than nickel-cadmium batteries. However, they are less durable than, and do not handle large loads as well, as nickel-cadmium cells [29].

Lead acid batteries are one of the most commonly known cell chemistries, used in many vehicles for electric turnover of the engine. Lead acid batteries are the oldest rechargeable batteries. They tend to be heavy and have a low energy to weight ratio but can provide very high surge currents. Described in Table 2 are the electrochemical properties of a variety of common battery types.

Chemistry	Cell Voltage	Specific Energy (MJ/Kg)			
Lead-Acid	2.1	0.14			
Nickel-Cadmium	1.2	0.14			
Nickel-Metal-Hydride	1.2	0.36			
Lithium-Sulfer	3	0.35			
Lithium-Ion	3.6	0.46			
Lithium-Iron-Phosphate	3.3	0.4			

Table 2. A comparison of various battery cell chemistries.

B. LITHIUM ION CHEMISTRIES

Lithium is one of the primordial elements created in the big bang; it is the third element on the periodic table after hydrogen and helium. When trying to store and generate electricity, what is actually occurring is the storage and use of electrons at a relatively high potential. Electrons, however, come with the baggage of the atoms they are attached too. Compare the atomic weight of lead (202.7) to the atomic weight of lithium (6.94). Lithium is 30 times lighter than the material we use to make lead acid batteries. Add to this the fact that lithium, a metal half the density of water, is highly unstable and reacts explosively with water and air. This instability can be perceived as eagerness by a lithium atom to shed its outer electron easily. All of these factors, coupled with its natural abundance, make lithium an excellent element for energy storage devices.

Lithium-ion describes a family of lithium chemistry batteries; they share many qualities, advantages, and disadvantages. Various chemistries differ in performance, cost, and safety considerations.

Lithium Ion Batteries (LIB) operate differently from other batteries. LIBs have similar components to standard batteries, an anode, a cathode and an electrolyte. In the anode, lithium is combined with carbon, most commonly graphite. In the cathode a lithium-metal oxide is used; the metal oxide is what defines the battery chemistry. For example a lithium iron phosphate battery contains lithium and carbon in the anode and lithium iron phosphate in the cathode. The electrolyte used is a lithium salt in an organic solvent [30].

When LIBs are connected to an external circuit a chemical reaction in the anode separates a lithium ion (Li⁺) from the carbon, and it migrates through the electrolyte to the cathode. The insertion of the lithium ion into the metal-oxide is called intercalation. The electron that is freed in the process is able to flow to the external circuit. Because the lithium ions move from the anode to the cathode, there is no oxidization in the carbon; this is why lithium batteries do not suffer from memory effects. When the battery is charged, the lithium ions are removed from the metal-oxide and migrate through the electrolyte back to the anode, this process is called deintercalation [31].

The electrolyte is often a liquid lithium salt in an organic solvent. The electrolyte conducts the lithium ions as they migrate. The conductivity of the electrolyte is temperature dependent, making the internal resistance of the battery also a function of temperature.

1. Advantages

Lithium ion batteries can be packaged in a variety of ways, from hard packs of plastic containing multiple cells to very thin and light aluminum. Because they do not necessarily require a metal housing, LIBs are much lighter than other batteries. As mentioned before, LIBs suffer no memory effects. These batteries self-discharge at a much than lead acid or nickel lower rate metal-hydride batteries, prolonging their shelf life. Finally, LIBs generally have a higher open circuit voltage, which provides a higher output power under relatively low current draws. The higher open circuit voltage and lightweight of these batteries contributes to their higher specific power, which is a ratio of the available output power to the weight of the battery [32].

2. Disadvantages

Lithium is an inherently unstable substance; it does not exist in nature in pure form. If overheated a LIB may suffer thermal runaway and cell rupture. Often LIBs contain multiple cells packed into a single battery; if thermal runaway occurs, one or more cells in the pack can rupture violently and in some cases breach the metal or plastic encasement. In extreme cases overheating can lead to combustion. Battery monitoring circuits are included in many cell packs to disconnect the battery in the event unsafe conditions exist, but this adds weight, complexity and expense [32], [33].

During the deintercalation process deposits can form in the electrolyte, which increases resistance over time. Increased resistance reduces the cell's ability to deliver current, which is more apparent at high current discharges. Internal resistance also increases with age.

C. EXISTING BATTERY MODELS

A variety of battery models exist that predict battery behavior. Each model has its strengths and weaknesses. Models differ in complexity and in the nature of the testing needed to build out and parameterize. The following discussion compares the model that HOMER uses to simulate battery behavior to the electric circuit models, which tend to be simpler and more intuitive for a variety of reasons. Both of these types of models address battery performance and non-linearities such as the relationship of the SOC to VOC, runtime, and state of health [34]. However, neither of these model categories addresses temperature effects; LIBs have performance variations tied to temperature effects.

1. KBM

The kinetic battery model is an analytical model that uses some heuristic or empirical techniques to derive battery behavior [34]. The KBM uses a two-tank reservoir analogy using water to illustrate the flow of electrons to a circuit; this is shown in Figure 13. The KBM depicts the relation effect in batteries in which the open circuit voltage rises after the battery is disconnected from the circuit. This is represented in the analogy by the two tanks returning to equilibrium.

Figure 13. A visual representation of the KBM.

HOMER uses the KBM to determine the state of charge for the battery, or battery bank, for each time step in a simulation. Manwell and McGowan developed the KBM in 1993; KBM models a battery as a two-tank storage system. Both tanks contain the theoretical maximum capacity of the battery (Q_{max}) . The first tank describes the energy that is chemically bound (Q_1) , the second tank describes the energy that is available (Q_2) for use. The model connects both tanks with a fixed pipe that enable a controlled amount of bound energy to move to the available energy tank. These two tanks seek to be at equilibrium. The total sum of energy stored in a battery at any time is:[12]

$$Q_{\rm max} = Q_1 + Q_2 \,. \tag{5.1}$$

For each simulation hour, HOMER calculates the maximum amount of power that can be discharged from a battery or bank of batteries from: [12]

$$P_{batt,d\max,kbm} = \frac{-kcQ_{\max} + kQ_{1}e^{-k\Delta t} + Qkc(1 - e^{-k\Delta t})}{1 - e^{-k\Delta t} + c(k\Delta t - 1 + e^{-k\Delta t})}$$
(5.2)

where

- Q₁ is the available energy (kWh) in the battery at the beginning of the time step,
- Q is the total energy available in the battery at the beginning of the time step,
- Q_{max} is the total capacity of the battery (kWh),
- C is the battery capacity ratio (unit-less),
- k is the battery transfer rate constant (h^{-1}) , and
- Δt is the length of the time step (h).

The available capacity in each tank at the end of each time step are determined by: [12]

$$Q_{1,end} = Q_1 e^{-k\Delta t} + \frac{(Qkc - P)(1 - e^{-k\Delta t})}{k} + \frac{Pc(k\Delta t - 1 + e^{-k\Delta t})}{k}$$
(5.3)

$$Q_{2,end} = Q_2 e^{-k\Delta t} + Q(1-c)(1-e^{-k\Delta t}) + \frac{P(1-c)(k\Delta t - 1 + e^{-k\Delta t})}{k} .$$
(5.4)

HOMER imposes three limitations on charging. The first limitation is to determine the maximum power going into the battery or bank of batteries per time step using:

$$P_{batt,c\,\max,kbm} = \frac{kQ_1 e^{-k\Delta t} + Qkc(1 - e^{-k\Delta t})}{1 - e^{-k\Delta t} + c(k\Delta t - 1 + e^{-k\Delta t})} \,. \tag{5.5}$$

The second limitation HOMER places on the charging power relates to the manufacture set charge rate. The third

limitation relates to the manufacture limitation set on maximim charge current [35].

2. Resistive and Capacitive Battery Models

Electric circuit models in which resistive, capacitive and inductive elements are used to represent the circuit offer flexibility and are most suitable for electrical engineering purposes where battery capacity is not the primary modeling concern. A few of the available battery representations are depicted in Figure 14. The electric circuit models can classified into be three main categories: the Thevinin-based, impedance-based, and runtime-based models [34]. These models are unable to describe the dynamic and transient behavior of batteries.

The computer software modeling application SIMULINK uses a Thevinin-based model to describe battery behavior in its simulations. This model was used by Chen, a graduate of the Naval Postgraduate School (NPS), while modeling the impact of adding solar cells to the RAVEN UAV (Un-manned Aerial Vehicle) [29]. SIMULINK is a great tool for circuit analysis and modeling circuit behavior. However, SIMULINK cannot account for the total amount of energy available in a battery.

Impedance-based models are perhaps the most important this field because describe in they dynamic battery behavior the best. An understanding of dynamic behavior is for essential Battery Management Systems (BMS). The impedance of a battery can be used to derive other valuable information about the battery condition such as State of Charge (SOC), temperature, life-cycle, charge and discharge current to name a few [34].

Figure 14. The three main categories of electric circuit models; (a) Thevinin based, (b) impedancebased, (c) runtime based models. From [34]

Yet another way to use electric circuits to model batteries is the resistive approach. This model breaks the internal resistance of a battery into two categories, ohmic resistance and polarization resistance. Ohmic resistance consists of the electrode resistances and the resistance of the electrolyte. Polarization resistance has to do with the chemical composition of the electrolyte. The ohmic resistance of a battery can give a BMS critical information regarding battery voltage, ohmic loss, discharge time and power available.

3. Challenges of Lithium Ion Batteries

All models are an approximation; the level of accuracy needed in a simulation determines which model will be used.

Both the KBM and the resistive/capacitive models described in this chapter model some battery behaviors and neglect others.

LIBs tend to defy both these standard models for various reasons. LIBs are unique because the Li⁺ ions must traverse the graphite lattice, the electrolyte and move into the cathode. The internal lattice structure allows for the relatively free movement of those ions when the battery is fully charged. However, as the battery is depleted the lattice starts to collapse, trapping the ions. This collapse is reversed once the battery is charged. Once a load is attached to a LIB, the SOC drops dramatically; as the battery discharges a slight voltage recovery can be observed, then the battery enters the linear region which the KBM tracks effectively [31]. When discharged at high currents, LIBs have the appearance of additional capacity, something we have termed thermal crossover. Since the parameter 'k' (Equations 5.2-5.4) is largely dependent on battery capacity, this behavior is at odds with the KBM. Initial attempts to parameterize a LIB for the KBM resulted in the chemically bound energy tank appearing much larger than the size available energy tank. It is important to remember that parameter 'c' (Equations 5.2-5.4) is the ratio of the bound energy to the total energy of the battery [33], [37].

The KBM is a good representation of battery behavior for the specific purpose of power modeling as long as the battery is not deep-cycle discharged. We believe that LIB behavior is dependent on the following parameters: temperature, voltage recovery after the initial discharge,

thermal crossover, and the apparent capacity of tank one (available energy). If these behaviors can all be tied to temperature, then it may be possible to create a temperature dependent KBM by adjusting the variable 'k' as the internal temperature of the battery varies [29], [38].

VI. TESTING AND ANALYSIS OF SPACES

A. INTRODUCTION

The Marine Corps has two all renewable power systems Both are solar-based in inventory. the power, with controllers, and energy storage. The large system is the Ground Renewable Expeditionary Energy System (GREENS). GREENS has eight large 200-W solar panels, four Lithium Phosphate (LiFePO₄) batteries, and an integrated Iron controller. GREENS is not a man portable system. The solar panels are rigid glass coated and are transported in protective metal cases. The batteries are approximately 80 pounds each. Two complete systems fit into a standard USMC shipping container (quadcon). The second all-renewable system is SPACES, which consists of a single folding solar panel, a DC-to-DC power converter, and a single LIB for energy storage. There are a number of adapters and cables that can be used to power various radios or small systems.

HOMER's current modeling method takes individual components and combines them into a single system to model. HOMER and SPACES are complete systems; however, they physically can be incorporated into larger systems. The intent is to add both SPACES and GREENS to HOMER as complete systems that can be modeled on their own or combined with other power systems and loads. Most importantly, the user will be able to select 'GREENS' or 'SPACES' in the menu, input the number of systems, and HOMER will populate all the components into the workspace.

The following experiments were designed to understand the operating limits of the SPACES system under various sunlight intensities, with the end goal of making engineering recommendations to the team at HOMER for the inclusion of SPACES into the Marine Corps HOMER model.

B. DESIGN AND METHOD FOR SPACES

1. Design

The Carderock division of NAVSEA loaned a SPACES system to the NPS solar lab. The manufacturer rated the SPACES solar panel at 62 W; the Starpower controller is rated for an input of 9-32 V and will boost the output to 15 to 32 V depending on the load requirements. The controller is compatible with multiple systems, and the complete system comes with many cable adapters. The manufacturer specification for the controller efficiency is 96%. Finally, the energy storage in SPACES is the DS-BT70791A, which is a battery common to many Marine Corps systems. The battery is a LIB, with a nominal voltage of 28.8 V and a 9.4-volt absolute minimum state of charge.

The first step toward modeling this system in HOMER was determining the performance specifications of the folding solar panel in actual light conditions. The second set of tests involved determining whole system performance. Both series of tests would require a control system to compare and validate SPACES performance. All solar testing took place on the roof of Spanagel Hall at NPS.

2. Building a Control System

The solar lab has a small quantity of thin film, flexible solar cells to work with. The first step in building a control system to compare to SPACES was to determine what size array to build. SPACES is approximately

0.73 m^2 , and each cell in the control array is 210 cm^2 . Using 36 cells, we built an array that is 0.75 m². The control panel cells needed to be mounted on a flexible substrate, and we needed to determine how to cover and protect them. In recent laboratory work, thin film solar cells have been attached to rigid boards with simple clear packing tape, which provides both protection from the elements and increases the efficiency of the solar cells by reducing the amount of light reflected. However, using tape to attach cells to a flexible substrate increased the chances of ripples and air pockets trapped in the panel. Our idea was to laminate the cells, sealing them between two flexible sheets of plastic and in the process squeeze all the air out. One big concern was that the cells would not survive the 230 Fahrenheit that is the operating temperature of most laminators.

To heat-test the solar cells, we used three $210-cm^2$ cells and tested their output in series. Then they were cut into nine cells that measured 10 cm by 7 cm and were connected in series. We cut the cells to attempt to increase the output and found that the current decreases per cell a little, but now we had nine voltage sources in series, theoretically increasing the output. Once they were mounted on a small flexible substrate, we tested them outside once again to ensure that the cells had not been damaged while being cut. Lastly, the cells were laminated using a standard one-meter wide laminating machine with the thinnest plastic sheeting. Depicted in Figure 15 is the per-single-cell I-V curve before and after laminating the cells. Note the open circuit voltage improves slightly after lamination as expected. The notable drop in short

circuit current is due to the difference in sunlight from 20 September to 21 September. The shape of the two curves are almost identical, there were no discernible losses in the power of the cells due to the heat of lamination.

Figure 15. The I-V curve of the heat test cells before and after lamination per single cell.

The standard laminators available were not large enough to build a control panel the same size as the SPACES, but the idea of heat-sealing solar cells was a valid one. Using two yards of medium thickness flexible plastic sheeting, we built a 36-cell control panel using the standard 210-cm² cells.

One yard was stretched and attached to the worktable to prevent wrinkling of the material. The 36 cells were fixed to the plastic sheeting with two-sided tape and connected in series. Mounting the cells in three strings of 12 cells meant the positive and negative terminals were on opposite ends of the panel. To facilitate easier lead connections, copper tape was run from the negative terminal along the edge to the 'top' of the panel. In Figure 16, the control panel manufacture process is depicted.

Figure 16. Manufacturing a control panel in the Solar Lab.

Once the cells were in place, connected and terminal leads attached, it was ready to be covered. We used the second yard of plastic sheeting; we stretched it over the cells and bottom sheeting and attached it to the worktable. It was left overnight stretching on the table to prevent the plastic from shrinking, causing the cells to be warped or uneven. The next day, the two sheets of plastic were sealed together using a clothing iron. While sealing the top and bottom sheets together, we pressed as much air out from between the two sheets as possible.

C. EXPERIMENTATION AND DATA COLLECTION

1. Experiment One

October in Monterey is one of the sunniest months of the year. Using the AMPROBE solar meter, we made side-byside comparisons of the SPACES solar panel and the control panel over several weeks. The AMPROBE solar meter is a commercial-off-the-shelf device that quickly and accurately measures the open circuit voltage, the short circuit current, and the output power of a solar panel. This piece of equipment collects many data points for a solar array, producing a detailed I-V curve and allowing the users to export the data to a spreadsheet file. The AMPROBE solar meter is depicted in Figure 17. On each day of clear skies, we went out to the roof and measured each panel's output I-V curve.

Figure 17. AMPROBE Solar-600, solar meter.

To evaluate the performance of each panel, it is useful to know the input power per square meter. We know from research that during October in Monterey the bestinput power we can expect is roughly 850 W/m^2 . By comparing a string of standard cells to a small silicon cell and taking a ratio of the output power at the unit size (1 cm²), we were able to create a ratio that allows us to estimate each day's solar intensity. A standard cell is one that was hermetically sealed and measured under laboratory conditions with a known input power. The cells are shipped with an attached data sheet that details the output power, V_{OC} , I_{SC} , FF, I_{MP} , V_{MP} , and their I-V curve. The standard cells we used were measured at 1015 W/m² and consisted of a string of nine 210 cm², for a total of 1890 cm². In 2009, the standard cells produced an MP output of 20.46 W; for at least 5% losses over time, the MP output under an input power of 1015 W/m² would be 19.44 W/m². When measured on the roof, the standard cells produced only 13.87 W. The ratio of the standard cell's best output under known input power conditions vs. the output power produced in Monterey is:

$$\frac{13.87}{19.44} = \frac{x}{1015} \tag{6.1}$$

where x is an approximation of the day's solar irradiation input. This approximation does not take into account the variation of the EM spectrum by distortion in the atmosphere or some of the factors that affect cell performance. Knowing the input conditions, the current and voltage of the cell, we can then use a similar ratio to estimate each day's input power.

2. Experiment Two

The second experiment used both the control and SPACES solar panels, the Starpower controller, and two identical Li⁺ batteries that are the energy storage components of

SPACES. The purpose of this exercise was to see which panel would charge a battery from zero SOC to a full SOC most efficiently.

We used the battery that is included in SPACES, the DS-BT70791A. This particular battery is nominally a 28.2 V (maximum 33.8V) battery arranged in two cell packs. Each cell in a pack has a maximum output voltage of 4.2 V and a minimum voltage of 2.4 V. Internal electronics monitor the state of charge in each cell; when a single cell drops to the minimum voltage the cell pack is disconnected. Each cell pack has a visible meter denoting the percentage of remaining state of charge.

For this set of data collection, we used two identical batteries and drained them until both cell packs were at a zero state of charge. Once the fog cleared at noon on 2 November, we set the systems up on the roof and let the batteries charge.

3. Data

Side-by-side panel data shows that, although the control panel operates at a lower open circuit voltage, it consistently generates a higher maximum power output than the SPACES panel. The control panel performed better under all test conditions. Output power was consistently 5.0 W higher, and the fill factor was consistently better. Shown in Table 3 are the data highlights from the days that measurements were taken. The data in the table show the better performance of the control panel over SPACES blanket with as much as 35% improvement in the output power for the same size blanket.

Date	Input (W/m^2)	Control				SPACES

Table 3. Performance of both the Control Panel and SPACES each day of measurement in October, 2012.

The input power is a rough estimation that was calculated using the ratio mentioned in Section C.2. Depicted in Figure 18 is the solar irradiance measured at the Del Monte costal station over the course of a single day in Monterey. The input power over the course of the month can be seen in Figure 19.

Figure 18. Measured solar irradiance for 24 hours in Monterey, CA, on 4 October.

Figure 19. Calculated and measured solar irradiance in Monterey for the month of October, 2012.

The I-V curves in Figures 20-27 depict the daily performance of both panels. All measurements were taken within five minutes of each other. On 8 October, the heat of the current and the warmth of the day caused the plastic substrate of the control panel to shrink. The plastic shrank enough that two columns of solar cells started to touch. This caused a short circuit, removing half of the cells and their voltage from the output. As a result of the short circuit, a minor fire minimally involved six cells. In order to prevent future short circuits, we opened the panel and trimmed the cells. This action reduced the maximum output by approximately three W, and the fill factor was never as good as my initial measurements. As a result only the first few days of data collection represent the true potential of the control panel.

Figure 20. The I-V curve of both SPACES and the control panel, collected on 4 October.

Figure 21. The I-V curve of both panels on 5 October.

Figure 22. The I-V curve of both panels on 8 October.

Figure 23. The I-V curve of both panels on 13 October.

Figure 24. The I-V curve of both panels on 15 October.

Figure 25. The I-V curve of both panels on 18 October.

Figure 26. The I-V curve of both panels on 24 October.

Figure 27. The I-V curve of both panels on 26 October.

Figure 29. The performance of SPACES each day measurements were taken in October.

In Figures 20-27, the triangles are located at each panel's maximum power point. In Figures 28 and 29, each panel's daily variation and performance is depicted. Note

that in both figures the open circuit voltage does not vary much; it is the current that changes with the light spectrum.

Figure 30. The output power vs. input power of both panels for the solar spectrum in Monterey, CA.

D. ANALYSIS OF RESULTS

In Figure 30, we note the pattern of output powers for both panels is very similar. That similarity is due to the panels operating in the same solar spectrum each day. The variation in output power each day when the input power is so similar is due to atmospheric conditions, moisture, and other air particulates. The important take away from Figure 30 is that on the best day in Monterey, SPACES may produce 38 W. If located on the best spot on earth for solar cells, sub-Saharan Africa or some locations in Australia, we expect SPACES would produce as much as 50 W. That estimate is based on the maximum efficiency that SPACES performed at NPS here in Monterey, which was 7.8%. In order to produce the advertized 62 W at the best solar location on earth, the efficiency of the SPACES panel would have to be 8.8%. The control panel consistently operated at 8.5 to 9.5% efficiency before it was damaged by fire and subsequently being trimmed. After the damage, the control panel consistently performed over 6% efficiency, which was only slightly better than the SPACES panel, which consistently performed at just under 6% efficiency. These efficiencies were calculated taking the size of each array and each day's estimated input power into account. The efficiencies were calculated from:

$$\eta = \frac{P_{Out(W)}}{P_{Input(W/m^2)}Area_{Panel(W)}} .$$
(6.2)

Looking at Table 3 (p.73), we see that when the control panel was performing at its peak, it produced 10 to 12 W more power than SPACES with virtually the same area of solar cells.

Using SPACES to charge a battery can be time consuming in Monterey. The lithium ion battery included in the system is a 207 Wh battery. Depicted in Figure 31 is the charge time of the Battery using a controller and battery that are ideal and have zero losses. The second curve depicts charging time accounting for the controller's 96% efficiency and the battery's round trip efficiency of 93.3%. We note that the curves are not significantly different, and the losses in the controller and battery are not significant.

Figure 31. The time to charge energy storage using the SPACES controller and a solar power input to the controller.

Set up on the roof on three consecutive days, it took SPACES 12.3 hours to fully charge the lithium ion battery that comes with the system. Generating on average 3 to 4 W more took the control system 10.2 hours to charge the same battery.
VII. ANALYSIS OF LITHIUM ION BATTERIES

A. INTRODUCTION

As discussed in the previous chapter, batteries in the Lithium Ion family have the strange behavior that when discharged rapidly they appear to have increased capacity. As the battery temperature increases, there is often a small voltage recovery in the SOC. This provides the appearance of a higher potential energy in the battery as temperature increases. The experiments outlined in this designed to discover chapter were if there is а deterministic correlation between temperature effects and battery behavior which could be used to develop a simple model. Whether that model could be a modified KBM or a new model is a separate discussion.

B. DESIGN AND METHOD

1. Batteries Used

We had three types of lithium ion batteries at our disposal. One 26 V, six cell lithium battery that was current limited to 20 A. We also had one 28.8 V LIB from SPACES. Neither of these were good options for strenuous testing because they did not belong to the Naval Postgraduate School; therefore, we could not destroy them, which was a remote possibility. Additionally, we only had one of each type, and without redundant testing robust conclusions could not be drawn.

The third battery type was LiFePO₄ batteries, commercial off-the-shelf products, of which we tested five. These were chosen because they have the same battery

chemistry as the GREENS batteries, though they are significantly smaller. These were single cell 3.2 V, 3.4 Ah batteries, а standard battery capacity (C). The manufacturer rated maximum charge rate is 1.6 A, maximum rated discharge rate is 12 A, and the energy density is 127.2 Wh/Kg. The charge and discharge rates are representative of the capabilities of lithium batteries.

2. Constant Current Circuit

In order to conduct discharge experiments, we needed to be able to control the current. We designed a circuit that used an operational amplifier, two bipolar junction transistors (BJT), several 2.0 W power resistors, and a large power source. The circuit described is depicted in Figure 32.

Figure 32. The high power constant current circuit used to discharge LiFePO₄ batteries.

The circuit in Figure 32 uses the high input impedance and output gain of the operational amplifier to power this circuit. The input voltage drives the voltage on the feedback loop. Therefore, the input voltage is the voltage on the node above the resistor and forces the current through the resistor to ground. By varying the input voltage, we can set the current to desired levels. Kirchhoff's current law demands that the current through the battery to the BJT collector be essentially the same as the current in the emitter leg. The circuit is governed by the following equations:

$$I_{collector} = I_{emitter} + I_{base}$$
(7.1)

$$I_{base} \cong I_R$$

$$I_{collector} \cong I_{battery}$$
(7.2)

$$V_R = I_R R = V_{in} \tag{7.3}$$

$$\frac{I_{collector}}{I_{base}} = \beta \tag{7.4}$$

$$I_{battery} = \frac{V_{in}}{R} + I_{base} \tag{7.5}$$

$$\frac{V_{in}}{R} = I_{battery} \left(1 - \frac{1}{\beta} \right) \cong I_{battery} .$$
(7.6)

Equation 7.1 governs the behavior of BJT's, and Equation 7.2 simply obeys Kirchhoff's law that current in a loop is constant. By following Kirchhoff's Voltage law, we arrive at Equation 7.3. By algebraic rearranging of Equation 7.1 and inserting the substitutions of 7.2, we arrive at Equation 7.5. The symbol β is an operational amplifier constant that relates to amplifier gain; it is usually much greater than one. Substituting Equation 7.4 into Equation 7.5, we arrive at the conclusion that varying the input voltage drives the current through the battery. Once we determined that the circuit would work, we simulated it in PSPICE and found there would be losses in the BJT's, which are to be expected when discharging a battery's energy and then dissipating that energy as heat. However, the end state of a controlled constant current discharge was feasible. The simulated system is depicted in Figure 33. Additional PSPICE model data is available in Appendix A.

Figure 33. The PSPICE model of our constant current circuit.

3. Temperature Measurements

Temperature was recorded using a FLIR Systems camera model SC 620. It is a portable long wave infrared camera with a temperature range that extends from -40 C to 500 C. It registers EM waves from eight to twelve μ m. The camera has an industry standard 24 C lens and a screen with a resolution of 640 by 480 pixels. This camera takes video and uses an SD memory card slot to store that video.

C. EXPERIMENTATION AND TESTING

The circuit was set up in the power lab on a bench. We kept the battery isolated from the circuit so the heat from the circuit did not interfere with temperature readings from the battery. Depicted in Figure 34 is the laboratory set up.

Figure 34. The discharge battery test circuit and measurement equipment.

Using a small power supply, we rigged a homemade charging system; in addition we adapted a standard battery charger to fit the size of these particular batteries. We were able to charge four batteries simultaneously; each battery took approximately six hours to charge. The time to charge allowed only a single round of discharges per day, and we set the batteries up for an overnight charge. For these reasons we did not collect charge data. It should be noted though, that as dangerous over-charging a lithium battery is, we never managed to overcharge one. As long as the voltage of the power source remained constant, the current gradually decreases as the charge on the battery increases until there is no longer any current going into the battery.

The five test batteries were labeled A-E and had positive and negative leads attached. The first test used battery Alpha, the purpose of which was to determine if varying the input voltage did affect the current of the battery. We found that the circuit performed consistently well and that specific input voltage settings would produce consistent current. We found the relationship of V_{in} and the battery current to be linear; therefore, we were able to preset the input voltages for a specific current. After the first experiment, battery Alpha would no longer hold a charge. We suspect that it was a weak battery that had been sitting on the shelf for a few years.

Once the circuit had been tested and was proven to work, we began the tests. Each of the four remaining batteries were discharged at the rate of C, 2C, 3C, and 4C, where 'C' refers to the capacity of the battery; each discharge was recorded using high definition video to record the voltage as the battery discharged, and the FLIR camera was used to record the radiated temperature of the battery. Each of these batteries were discharged once at C (3.4 A), once at 2C (6.8 A), three discharges per battery at 3C (10.2 A), and three discharges per battery at 4C (13.6 A). After each discharge, we collected the voltage data as the battery cooled and returned to equilibrium. To help measure temperature effects, each battery was rapidly cooled using a can of quick-freeze after a 3C and 4C

discharge. Depicted in Table 4 are the number of discharges and rates of discharge for each round of battery testing.

		RATE OF DISCHARGE									
Battery	Variable	C/2=1.7A	C=3.4A	2C=6.8A	3C=10.2A	4C=13.4A					
А	Х										
В			Х	Х	XXX	XXX					
С			Х	Х	XXX	XXX					
D		Х	Х	Х	XXX	XX					

Table 4. Delineation of battery testing cycles for each battery.

After the second round of discharges, battery Echo would no longer hold a charge, and the data collected with it was deemed suspect. Only batteries Bravo, Charlie, and Delta were discharged at 3C and 4C. For these experiments a total of 25 discharges and cool-downs were observed and recorded

D. DATA

The following two subsections depict the graphical representation of the data that was collected in the laboratory and the data calculations done to analyze the results of the experiments in Figures 35-45. Each of the figures depicted below are described in the following section along with an explanation of the process calculations and analysis.

1. Discharge

E. ANALYSIS

1. Discharge

Of the five batteries we purchased to conduct these experiments, only three were viable in the tests; the other two failed to hold a charge. Of the three that were discharged in the 25 tests only one, battery Charlie, gave reliable and expected results. Battery Charlie provided almost 3 Ah of energy for most discharges and a minimum of 2.6 Ah of energy at worst.

These batteries had been sitting on the shelf for two years, and some degradation was to be expected. Though degraded, each of the three remaining batteries displayed the tendencies toward thermal crossover that has been seen in so many other Li⁺ chemistries. Thermal crossover is the point on Figures 35, 36, and 37 where it seems that more energy can be removed from a battery the faster it is discharged. This behavior does not lend itself to the KBM. The KBM hinges on the value of 'k' which restricts the flow of energy from the chemically bound 'tank' to the available energy 'tank'. When a battery is rapidly discharged, it should not have more energy than when it is discharged slowly.

2. Cool Down

It can be shown that for Li^+ batteries there exists a large region of the discharge curve where the voltage is linearly proportional to the SOC. Therefore, the voltage is linearly proportional to Q_1 . This region typically runs from about 98% SOC to 25% SOC. This region can be described by:

$$VOC_{0} = E_0 + E_1 Q_1 - IR \tag{7.7}$$

where E_0 and E_1 are empirical constants that fit the discharge curve. The internal impedance of the battery is designated R. When the circuit is disconnected and there is no current, Equation 7.7 can be reduced to

$$VOC_{Q_1} = E_0 + E_1 Q_1$$
 (7.8)

For a battery having completed a charge or discharge event and where the voltage and SOC was in the linear region, the equilibrium of Q_1 has the following relationship with voltage:

$$V(t) = VOC_{Q_1}(t) = E_0 + E_1QC + (Q_1 - Q_2)e^{-k\Delta t}$$
(7.9)

Equation 7.9 is obtained by rearranging Equation 7.2 and substituting the result into Equation 7.8. Taking the limit of Equation 7.9, we arrive at the equilibrated voltage of the battery:

$$\lim_{t \to \infty} V(t) = E_0 + EQc = V_{eq} \tag{7.10}$$

Equation 7.9 can now be rewritten as:

$$V(t) = V_{eq} + V_{conc} e^{-k\Delta t}$$
 (7.11)

where V_{conc} is the over/ under potential of the battery at the initial time due to the disequilibrium in the cell. It has a value of:

$$V_{conc} = (Q_1 - Qc) . (7.12)$$

The values of V_{eq} , V_{conc} , and k can be fit to the open circuit equilibration voltage curve of a battery. The resulting value of k can be used as part of the parameterization for the KBM. The benefits of this is that k can be determined at specific SOC using a single curve, and it does not require repeated charge and discharge cycling, which is normally required.

Table 5. The Parameter values of battery discharges using Equation 7.11 from discharge experiments.

	V _{conc}	V_{eq}	k
B 3C Un-cooled	-0.165282293	3.208693719	0.002442694
B 3C Cooled	-0.014353445	3.220411896	0.003333333
B 4C Un-cooled	-0.046607662	3.268605204	0.004192852
B 4C Cooled	-0.012072473	3.287081337	0.002
C 3C Un-cooled	-0.070397154	3.257218754	0.007941791
C 3C Cooled	-0.026957585	3.085923091	0.001212341
C 4C Un-cooled	-0.012072473	3.287081337	0.002
C 4C Cooled	-0.071013631	3.169218963	0.000625

We used Equation 7.11 to fit equilibrium curves to the batteries as they recovered from being rapidly discharged. The batteries that were forced to room temperature rapidly after the discharge was a complete fit to the KBM model within one or two mV for each cooled battery discharged. The cooled fitted models, depicted in Figures 38, 40, 42 and 44, began at the time when the battery reached room temperature. For the each of the batteries that were allowed to cool over time, the fitted voltage recovery followed the general trend of the measured voltage recovery. However, the fitted curve deviated from the measured data by as much as 50 mV. The widest model deviations come at the points on the curve where the temperature of the battery is the warmest. This suggests that the battery cooling off affects the voltage recovery in a dynamic manner. These observations are consistent in all of the recoveries depicted in Figures 39, 41, 43 and 45.

From these results we have concluded that there is a significant temperature effect on battery behavior. Though the 50 mV deviations during recovery are not significant enough to warrant a new model, a temperature corrected KBM could be very useful.

VIII. CONCLUSIONS AND RECOMMENDATIONS

A. RESULTS

1. Solar Experiments

In each solar experiment the control panel outperformed the SPACES panel. The solar cells that the control panel is comprised of are three years old and were properly stored, resulting in not some performance degradation. In the process of the experiments, the control panel also caught on fire due to a short circuit. The rated output power of the SPACES is 62 W; the estimated best output of SPACES is approximately 50 W, only 80% of its rated capacity. Systems like GREENS and SPACES are very important to expeditionary power, but the technology is improving constantly. Those systems need to improve as the technology becomes available. In the next two or three years, promising research has the strong potential to yield flexible thin film solar cells that are 16% efficient. Such an improvement would double SPACES output without adding weight or size. A two-fold increase in GREENS output power, while reducing the weight of the system several hundred pounds (by switching ridged cells for new improved thin film cells), will vastly improve expeditionary power systems.

2. Battery Experiments

A complete tabulation of the data collected can be viewed in Appendix B. These tables depict the behavior of

the batteries as they are discharged, including the current at which they are discharged, their temperature rise, and their V(t).

Once all the data was collected, we applied the KBM equations to the equation for the linear region. We found model fitted а battery voltage recovery the nearly perfectly battery was at room temperature. when the Moreover, this behavior was repeated in three different batteries of the same design and chemistry. This suggests a strong correlation between temperature and battery behavior; the internal lattice temperature affects battery voltage.

B. CONCLUSIONS

The KBM needs to be tested and verified for both charging and discharging. We think there is strong evidence based on work done previously and our work in the lab that the KBM is a valid working model for Li⁺ when the battery is operating in the linear region. Additionally, the Marine Corps will not likely be discharging batteries at high enough currents to be concerned with temperature effects. From the data collected, temperature does not appear to affect battery behavior until it is over 40 C. Internal temperature is driven by excessive discharge rates.

SPACES is a well-designed system that provides small units with a micropower system. However, it is important that SPACES improves as solar cell technology improves in order to meet the demands of the modern expeditionary Marine Corps.

C. RECOMMENDATIONS FOR FUTURE WORK

There is a lot of work left within HOMER to meet the Marine Corps' requirements. We need to collect 24-hour load profiles for our most common FOB structures. A system analysis of GREENS should be conducted in order for that system to be incorporated into HOMER.

The KBM needs to be validated for Li⁺ batteries (during both charging and discharging) in order to determine if temperature is the most dynamic variable and, if so, to develop a temperature dependent model. THIS PAGE INTENTIONALY LEFT BLANK
