ABSTRACT

This thesis concerns various means of implementing fault tolerance in logic for use in a general payload processor design. The first specific application of this research is a sequencer developed for deploying CubeSats. The sequencer shall be capable of the timing and accurate deployment of multiple CubeSats from a host spacecraft and shall have the capability for quick reconfiguration prior to launch. This research considers a variety of hardware for suitability toward sequencer construction; field programmable gate arrays (FPGAs) are chosen as the primary device. The design further evolves to selection of the Actel ProASIC3 series of FPGAs. Initial logic test configurations are implemented on a development kit with analysis of results provided. Fault-tolerant techniques are compared with a set of experiments to determine optimum resource utilization and timing schemes. Triple modular redundancy (TMR) is selected as the technique for fault-tolerant logic implementation in the sequencer. Preliminary test boards are built via schematic design and printed circuit board layout. The manufacturing, integration and testing of the 'ProASIC3 Test Board' is fully discussed. A follow-on flight prototype board is designed with more extensive hardware allowing for implementation of fault-tolerant techniques and future growth capability. Recommendations for future work are discussed.

EXECUTIVE SUMMARY

The research work contained in this thesis documents a means of implementing fault-tolerant logic for use in a sequencer application developed for deploying CubeSats. The sequencer being developed at the Naval Postgraduate School (NPS) in Monterey, CA shall be capable of the timing and accurate launch of multiple CubeSat platforms from a host spacecraft and shall have the capability for quick reconfiguration prior to launch. This sequencer is one particular application of the general payload processor architecture developed in this work. This payload processor architecture is flexible enough to accommodate future needs and applications with few design alterations required.

The NPS CubeSat Launcher (NPSCuL) currently utilizes host spacecraft resources to control the timing and execution of CubeSat deployment through a simple splitter architecture. Previously manufactured Splitter Auxiliary Device (SAD) versions incorporate wiring harnesses or printed circuit board (PCB) traces to accomplish power and signal splitting and recombining. The developed SAD Version 3 – Flight Prototype Board (SADv3) utilizes a field-programmable gate array (FPGA) device to accomplish the sequencing with primary and secondary power provided by the host spacecraft. Although SADv3 expects to get power from the launch vehicle bus, future versions may be designed with a capability for an internal battery power supply. By utilizing various fault-tolerant design techniques, the need for a fully radiation hardened (rad-hard) FPGA can possibly be avoided. This would save a great deal of money and could result in a product capable of missions beyond low Earth orbit (LEO). While LEO is of primary interest, there may be opportunities to send the general payload processor hardware to geosynchronous (GEO) or perhaps even interplanetary orbits.

Several sequencer design methodologies are investigated. Since the sequencer requires only primary or secondary power, a finite-state machine (FSM) architecture is the appropriate choice. To limit the amount of logic required in the general payload processor architecture, a decision to avoid central processing unit (CPU) designs, such as an ARM processor core, was made. The need for embedded processing lends itself well to an FPGA-based implementation. Types of FPGAs compared include antifuse, static

random-access memory (SRAM), and flash-based designs. The hybrid approach of flash-based FPGAs allows for several benefits such as reconfiguration and live-at-power-on capability, with no boot sequence or secondary support components required, along with increased tolerance to certain radiation effects.

The overall goal of this research is to allow for the operation of a processing circuit in the radiation environment of space. Many of the various single-event effects (SEEs) that may affect the operation of the sequencer logic are considered. Of these, single-event upsets (SEUs), single-event transients (SETs), and single-event latch-ups (SELs) are investigated in further detail. These SEEs along with the amount of total ionizing dose (TID) tolerable by the various classes of FPGAs are an important driver to selection of a particular FPGA. Various forms of radiation fault-tolerant methods are considered for use within the sequencer logic—including scrubbing at set intervals, triple modular redundancy (TMR), quadded logic, triplicated interwoven redundancy (TIR), and quadruple force decide redundancy (QFDR). Since radiation hardening by design (RHBD) is the primary focus of this thesis, further investigation into these types of fault-tolerant methods is justified, and the results become the rationale for selection of a particular fault-tolerant implementation.

A comparison between Xilinx and Actel software and hardware products is made to determine the best applicable development suite for design of the sequencer logic. Of the two software products, Xilinx Integrated Software Environment (ISE¹) 14.3 is the more capable product due to its incorporation of a schematic editor. In addition, the design flow of Xilinx software is more user-friendly and supports rapid re-targeting to different Xilinx FPGA products. Ultimately, the choice of software will depend upon the particular vendor of FPGA product chosen; although, there is a work-around for porting Xilinx schematically designed circuits to Actel instantiations. Since Xilinx devices are primarily SRAM-based, and Actel FPGAs are either antifuse or flash-based, selection of the vendor is primarily dependent on choice of FPGA architecture. In addition to the previously mentioned hybrid advantages of flash-based FPGAs, the Actel ProASIC²

¹ ISE® is a registered trademark of Xilinx, Inc.

² ProASIC® is a registered trademark of Microsemi Corporation.

series has the added benefit of pin-to-pin and timing compatibility between military-grade and rad-hard components. Even with the added difficulty of adopting Actel Libero³ System on Chip (SoC) software over Xilinx ISE, the associated hardware attributes inherent to the ProASIC3 series are beneficial. Therefore, an Actel ProASIC3 is chosen as the FPGA for the sequencer design. Various development boards used in the performance of logic testing included designs from the Xilinx Spartan⁴-3E, Xilinx Virtex⁵-5, and Actel ProASIC3 series FPGAs; these were purchased to allow for all software development platforms to be tested.

Prior to development of the more complex SADv3, a ProASIC3 Test Board (PA3TB) was designed and implemented. This provided significant experience with the Altium Designer⁶ electronic design automation (EDA) development environment. The Altium product suite allows for front-end schematic development, physical printed circuit board (PCB) layout, and FPGA hardware design. Testing of the Joint Test Action Group (JTAG) interface was possible on the PA3TB prior to implementation of an identical JTAG connector interface on the SADv3. The PA3TB incorporates a ProASIC3 nano series FPGA using a core voltage of 1.2 V_{DC}. Bank input and output (I/O) voltages are set at 2.5 or 3.3 V_{DC} levels with CubeSat deployment simulated using light-emitting diode (LED) indicators. The four-layer PCB utilized in the PA3TB serves as a precursor to the eight-layer SADv3 design. Additional experience was realized through surface-mount soldering in the construction of the PA3TB. All power supply circuitry for the PA3TB is located off-board for ease of troubleshooting the main FPGA and JTAG design. JTAG programming is accomplished via a Microsemi FlashPro⁷4 USB-to-JTAG external programmer. A standard USB port is also provided on the PA3TB for interfacing with the design and possible future data-logging capability.

The implementation of a ball grid array (BGA) FPGA in the prototype flight-hardware design is a more involved process than the development of the PA3TB. The incorporation of a BGA into the design limits manufacture to companies with the necessary equipment to accomplish the integration of the PCB. To provide for future expandability and features, SRAM and flash-based memory were added to the design. This added memory allows for additional processing features and data storage. Military-grade Actel ProASIC3E/L FPGAs are used in the design of the SADv3; these devices allow for pin-to-pin replacement with a rad-hard Actel RT ProASIC3 FPGA should a mission require more robust hardware. The complexity of the PCB design is markedly increased due to an increased layer count and the requirement to manage the 484 pins of the BGA FPGA. Due to the increased risk of design error, extensive design review is necessary to prevent errors propagating to the final product. The PCB shape is tailored for optimum fit within the SAD enclosure utilized on NPSCuL. The design is a daughter board configuration for pairing with an associated relay board in the SAD box.

In addition to the memory devices, the increase in SADv3 board area allowed for the inclusion of all power supply and power conditioning circuitry on the PCB. The increase in the number of FPGA I/O pins allow for the inclusion of three 40-pin headers for general-purpose use. A breadboard prototyping area is also provided to allow for future capability development using the PCB. An external crystal oscillator is provided for increased timing accuracy and directly connects to the FPGA for utilization in logic designs. Auto-routing of the design proved difficult as the decisions of the auto-router are not always in the best interest of the overall PCB layout. The fan-out features of Altium work well, after a considerable amount of setup time, to properly distribute the signals lines from the BGA FPGA to the four signal layers and four voltage planes. The majority of signal lines on the SADv3 are manually routed.

To test various fault-tolerant techniques for inclusion in the sequencer, different combinational and sequential logic circuits were implemented. These designs were tested in the Xilinx and Actel software environments. An initial test of redundancy techniques is accomplished by constructing a seven-segment LED counter upon a Xilinx Spartan-3E development board. The design is triplicated schematically with code directives to the

synthesis tool. These directives prevent undesired logic removal by the automatic synthesis tool. Proper operation and timing of the design were seen in the default and triplicated cases of logic. A 16×16-bit array multiplier was constructed to further compare the various fault-tolerant schemes implemented. Fault-tolerant techniques are altered by varying the format of the overall design, mechanisms of full adder instantiation, and the inclusion of voter circuits as necessary for operation. A baseline scheme, TMR, quadded logic, triplicated interwoven redundancy (TIR), and stacked Quad-TMR / TIR-TMR fault-tolerant techniques are developed as versions of the array multiplier. In all cases, the outputs of the array multipliers implemented were identical. Although TIR uses the least resources of any fault-tolerant scheme, TMR has the best combination of device utilization and timing delay for logic design. There is future opportunity for research into different TMR schemes using commercial software such as Precision⁸ Hi-Rel.

Manual insertion of fault injection techniques leads to the comparison of floating-input, ‘stuck-at-0’, and ‘stuck-at-1’ faults. Preliminary research into a method of automatic and random fault injection is conducted, with several methods identified for further inspection. While the baseline FSM produces false timing signals or non-valid signal levels during fault injection runs, the TMR version of the FSM is able to overcome any errors in each of the three fault cases. Timing and resource utilization differences between the baseline and TMR versions of the FSM logic are small. In the future, the additional fault-tolerant techniques that need to be researched are variations in TMR design methods and clocking generation.

Preliminary sequencer logic design is accomplished by developing code and schematics within Xilinx ISE that are subsequently ported to Actel Libero SoC. The initial sequencer logic includes the possibility of setting timing constants either as Verilog parameters or in the FlashROM area of the Actel ProASIC3 FPGA. The logic to be triplicated must be appropriately marked to reduce the possibility of trimming in Libero SoC. The resultant logic design can utilize either case or state switching within

⁸ Precision® is a registered trademark of Mentor Graphics.

Verilog to more fully define the operation of the sequencer logic. Schematic design within Xilinx ISE may be avoided once Actel Verilog techniques are fully developed. The switch from the Xilinx to Actel software environment is an important step toward verification of the design and ease of reconfiguration.

Future mission features of the general purpose payload processor are envisioned to incorporate desired logic in a TMR representation. Due to the remaining logic available on the ProASIC3 FPGAs, there are a considerable number of projects which may be researched for inclusion. These may consist of telemetry and data-logging by the FPGA, two-way communication and charging of the CubeSats within the launcher, video feed and recording of CubeSat launches, and potential networking features to the host spacecraft bus – in addition to the already in-progress sequencer development. A complete signal path verification of the current eight-layer, BGA SADv3 should be accomplished prior to manufacture of the board. This will consist of a series of design reviews by multiple engineers. Future testing within a radiation environment, prior to launch, is also an important step in verifying the chosen fault-tolerant technique of TMR.

In conclusion, there are a number of applications for which the ProASIC3 general purpose payload processor is suitable. The sequencer work contained in this thesis is one application in which a significant gain in the state of current CubeSat deployment technology may be realized. The ability to deploy CubeSats using TMR logic should be quite cost effective when compared to custom, rad-hard components, possibly with no loss of fault tolerance. TMR is useful for protecting both combinational and sequential circuits, especially given the available fault-tolerant software toolsets. Future designs using Actel flash-based FPGA technology may have wide applicability due to its configurability and the flexibility with which the I/O pairs can be assigned. The compactness of the ProASIC3 circuit design, when compared to the more traditional Xilinx Virtex series FPGAs, is readily apparent. It is anticipated that this design, or some evolution of it, will be quickly developed into a flight-ready product.

ACKNOWLEDGMENTS

The author would like to thank Dr. Hersch Loomis and Dr. Jim Newman for their time and devotion to this project. Our bi-weekly meetings were instrumental in keeping this project on track and providing insight and suggestions toward the work. There were several times that a perceived roadblock was avoided, due to the consistently excellent mentorship you both provided. Additionally, thank you for the career guidance and inspiration throughout my time at the Naval Postgraduate School.

Additionally, I would like to thank all the personnel present within the Small Satellite Laboratory—specifically David Rigmaiden and Ernesto Yzquierdo. The time you both spent giving helpful tips on learning Altium Designer and methods of soldering under the microscope were very influential to the success of this project. You are both instrumental to the success of the laboratory as a whole and NPS is lucky to have people like you on staff.

Thank you to all the other excellent professors and Space Systems Academic Group personnel who both instructed and guided my time here in Monterey. Many of the classes were excellent and led to methods and tactics used throughout the performance of this research. I honestly feel as if I have an excellent foundation for future success, based on the knowledge obtained in the Space Systems Engineering curriculum.

I would like to thank my fellow classmates in the program—Matt DeMartino, Pete Firenze, Nolan Semrau, Al Perez, Allan Phillips, Jessie Hallan, Kerri Ackman, Marta Savage, Mike Becker, Travis Bateman, Jason Crane, and Maddie Studholme. You have all become great friends and it was wonderful to feel like a team during our many shared classes and design project. Also, thanks to my friends Mike Smith and Rich Ray. I wish you all continued success in the future. Fair winds and following seas!

Most importantly, I would like to thank my family—namely my wife, Jessica, and son, Michael, for the countless time they donated toward allowing me to finish my work and the thesis writing process. You two are my foundation and reason for every decision I make. I love you both, more than you could ever imagine.

I. INTRODUCTION

A. PURPOSE

The purpose of this research is to determine an effective solution for implementing radiation fault tolerance utilizing inexpensive hardware coupled with a robust logic design. The need for fault tolerant processing drives the development of solutions targeted to the space environment, with particular interest in payload processing designs. By careful exploration of various logic implementations, the developed product will be capable of full operation in a radiation environment through redundancy in logic design.

This research led to the development of a hardware and logic implementation suitable for a general payload processor package. The first specific application of the payload processor is a sequencer for CubeSat launching applications. This sequencer is of primary interest because a low-cost, flight-ready sequencer does not exist. Similar commercial products cost upwards of hundreds of thousands of dollars for space-related applications. The primary cost drivers in the selection of these devices tend to be the amount of non-recurring engineering (NRE) development time and manufacturing that must accompany the design. The additional cost of fully radiation hardened components are not even factored in to these designs. The cost of such devices can easily exceed the budget of all but the largest CubeSat¹ projects. Due to the expense of purchasing radiation hardened (rad-hard), commercial off-the-shelf (COTS) technology, an alternative lower-cost solution is desired. It is expected that development of a sequencer will provide a cost-effective solution for government CubeSat launches.

The technology behind fault tolerance in processors as applied to timing and sequencing devices is presented in this thesis, leading to the development of a sequencer. This sequencer is expected to have many of the same characteristics of more expensive radiation hardened products while using less costly commercial and military-grade

¹ CubeSats are nanosatellites. The term “nanosatellite” is applied to a satellite with a mass between 1 kg and 10 kg (2.2 and 22 lbs) [1].

components. The lack of hardware robustness against upsets is compensated for with fault-tolerant techniques in the logic design itself. Various fault-tolerant techniques are explored leading to the selection of the best logic design suitable for the radiation environment of space. This sequencer must be capable of executing a pre-programmed deployment sequence when the launch vehicle initiates power and deploy commands. The CubeSats may be deployed sequentially at specified intervals, or, in some cases, simultaneously.

The need for the sequencer to be re-programmable prior to launch, to have the capability for future logic growth and the redundancy necessary to deal with space radiation upsets, has led to the use of field programmable gate arrays (FPGAs) in the project. Multiple manufacturers and product lines are considered to determine the particular design configuration for the sequencer design. The developed logic designs are synthesized and implemented on commercial development boards to provide testing and experience with chosen FPGAs and secondary components.

Development of the hardware is carried through the research and schematic design phases. Full printed circuit board (PCB) layout is accomplished with techniques and difficulties discussed along the way. Initial test circuitry was assembled to gain familiarity with chosen components prior to final circuit board manufacture. The final circuit board design will be easily expandable for future projects or substitution into designs requiring a general-purpose processing capability in an easily modified form-factor. In all cases, the design will complement work already completed prior to the initiation of the FPGA-based sequencer research. Though the chosen FPGA technology and fault-tolerant techniques apply specifically to deployment sequencer development in this thesis, the implemented methods have broader applications to space-based processors in general.

B. NAVAL POSTGRADUATE SCHOOL CUBESAT LAUNCHER (NPSCUL) BACKGROUND

1. NPSCuL Objective and History

The Naval Postgraduate School (NPS) in Monterey, CA, uses small satellites for focused research projects of national interest. NPS has several established CubeSat projects along with associated lab support. The Small Satellite Laboratory is equipped with capabilities such as a ‘Class 10k’ cleanroom, thermal vacuum chambers, vibration table, radio frequency interference (RFI) / electromagnetic interference (EMI) testing anechoic chamber, microscope-equipped soldering stations, and a large commercial-scale three-dimensional (3-D) printer. In particular, NPS has recently been involved in the development, integration, and launch of the NPS CubeSat Launcher (NPSCuL). NPSCuL launched on September 13, 2012, as part of the Operationally Unique Technologies Satellite (OUTSat) mission—carrying eleven CubeSats into orbit on NROL-36 [2]. NPSCuL was developed with support of the California Space Education and Workforce Institute (CSEWI) and the CubeSat Program Office at the National Reconnaissance Office (NRO).

2. NPSCuL Physical Design Characteristics

The NPSCuL design uses existing standards such as the Poly-Picosatellite Orbital Deployer (P-POD) from the California Polytechnic University and the EELV Secondary Payload Adapter (ESPA) mechanical interface. As illustrated in Figure 1, NPSCuL is capable of carrying eight P-PODs; each P-POD is capable of deploying up to three 1U CubeSat spacecraft [3]. An ESPA interface ensures compatibility with multiple launch vehicles. NPSCuL itself is a five sided box comprised of a base-plate, four walls, four brackets and the ESPA-compatible, non-separating adapter ring. The non-separating adapter ring could be replaced by a Planetary Systems Mark II Motorized Lightband² [4], allowing NPSCuL to be deployed.

² MKII Motorized Lightband is a registered trademark of the Planetary Systems Corporation.

Figure 1. Final payload configuration and integration of NPSCuL with eight P-PODs.

Deployment signals, either directly from the launch vehicle or via an on-board sequencer box, are required to activate the non-explosive actuators (NEAs), open the P-POD doors, and deploy the CubeSats. To support both these scenarios, NPSCuL can be configured as follows:

- If the launch vehicle has adequate resources (i.e., redundant power and signal lines) then it may be outfitted with a Splitter Auxiliary Device (SAD) to accept eight primary and secondary power signals from the launch vehicle and pass them through to the P-PODs. The SAD also has a pass through for lines monitoring the status of the doors on each of the P-PODs [5].
- If the launch vehicle does not have adequate resources (i.e., only a single primary power, secondary power, and data line are available) then a sequencer is required. This device can be powered by the launch vehicle or by an internal battery and must be capable of providing deploy signals and monitoring the status of the P-POD doors switches [5].

The development of the sequencer is the primary concern of this thesis in order to satisfy the limited resources scenario. Such a sequencer will first be useful for missions to low Earth orbit (LEO). Beyond-LEO applications could include deployment of CubeSats in geostationary Earth orbit (GEO) or for use as a payload processor for interplanetary missions in a greatly increased radiation environment. In any of these scenarios, a fault-tolerant design must prevent radiation-induced upsets in logic.

3. History of Sequencer Requirement

Currently, NPSCuL utilizes the host-launcher resources for the timing and execution of the deployment of the individual CubeSats from their P-POD. The SAD takes the eight lines from each of the launcher-provided primary power, secondary power, and data harnesses and splits them out to eight separate harnesses, each containing one primary power line and one secondary power line for redundancy in actuating the P-PODs NEA, and one data line for monitoring the P-POD door microswitches. Each of eight harnesses is connected to one of the P-PODs, as illustrated in Figure 2. The first iteration of the SAD consisted of an internally harnessed, splitter configuration, as shown in Figure 3.

Figure 2. NPSCuL with associated Splitter Auxiliary Device (SAD) and external wiring visible.

Figure 3. Internal wiring harness structure for SAD depicting power and data line split to eight output ports.

4. Concept of Sequencer Development

The need for a sequencer was realized shortly after the development of NPSCuL was initiated. The design of the sequencer, though simple in principle, should take into account the radiation environment in LEO. There were two approaches envisioned – one, that a radiation and fault-tolerant circuit be designed with the latest in integrated circuit (IC) and manufacturing processes; two, a robust approach involving individual discrete components with feature sizes and voltages that are inherently resistant to radiation induced upsets. This second approach was tailored to industrial parts such as automotive relays and other lower cost components and is the study of a separate, parallel research project. For the purposes of this thesis, only the first approach was considered. The constraints of the fiscal environment precluded the use of the most expensive rad-hard hardware, although, an upgrade path to that technology was considered. Thus, through utilizing lower-cost, commercial and military-grade components, drop-in compatibility of the more expensive rad-hard technology has been maintained. Future processing growth potential was also considered, with emphasis placed on both logic space available and incorporation of subsequent electrical connections.

In modern FPGA applications, especially those dealing with space-based applications, the topic of fault detection and tolerance is often discussed. While there have been a myriad of approaches to sustain the operability of such devices in the past, recent advancements in both FPGA size and application have required updated, or in some cases new, techniques to be developed. Typical methods such as triple modular redundancy (TMR) have been further subdivided into categories based upon application [6]. New methods such as quadruple force decide redundancy (QFDR) [7] are being looked at as a means toward further refinement without the associated overhead of voter circuits. In all of these cases, the aim is to successfully protect the FPGA device from the effects of radiation-induced single-event upsets (SEUs) and multiple-bit upsets (MBUs) which can seriously impact, or even end, a mission.

Various FPGA-specific cost metrics are utilized in comparing the fault-tolerant techniques evaluated. These include device-resource utilization, path-delay timing, ease of implementation, proper logic output, and availability of commercial solutions. The

metrics are assessed after concluding work on a particular fault-tolerant scheme. Logic design software allows for calculation of resource utilization and timing delays. Ease of implementation is more of a subjective realization regarding the time to manually insert the required fault tolerance means. In all cases, the designs are tested for logic accuracy in output under normal operating conditions. Fault injection is used to test for proper logic output in circuit degraded scenarios. Certain fault-tolerant schemes such as TMR are available in many commercial synthesis products; others, like quadded logic, have no commercial implementation and require intense amounts of time and effort to implement. Future testing with commercial, fault-tolerant synthesis software, under a radiation environment, will yield more data for assessing the effectiveness of a particular fault-tolerant technique.

5. Sequencer Requirements and Specifications

For the sequencer application of the general purpose payload processor being developed, there are several requirements that must be considered prior to complete specification of the design and the logic approaches investigated. Specifically, the sequencer will be capable of initiating the door opening of the P-PODs either individually or simultaneously. The application of power, either through primary or secondary power supplies, serves to start the internal timing of the sequencer application. The inputs to the sequencer are minimized, in that application of power serves as both the ‘Arm’ and ‘Deploy’ signal necessary to facilitate the deployment of the payload CubeSats. The removal of power to the sequencer device is sufficient to stop the deployment process. The timing sequencer and deployment of CubeSats will be reinitiated by again supplying power to the device.

There are secondary requirements for the CubeSat launch sequencer which are important in the context of both the environment and application involved. These include radiation tolerance, reconfigurability, low-cost, and suitability toward differing applications. Specifically, the functional requirements of this application require that the general purpose payload processor be capable of operation in the radiation environment of space. This requires careful study of the various methods involved in targeting a

design with fault-tolerant aspects and an understanding of the relevant radiation environment. Several different logic designs will be investigated to determine the appropriate technique for fault-tolerance necessary for the sequencer application. Functionally, the design needs to be capable of operation even in the radiation environment of space. This operation should be indistinguishable from the operation of fully radiation-hardened hardware while allowing for an upgrade path to such hardware if desired. Additionally, the design is targeted to produce the same performance of such hardware, without the overhead of associated expense.

The reconfiguration aspect of the design leads to the choice of FPGA technology, with the associated requirement for the sequencer to be adjusted for timing at any point prior to launch when physical access to the device is still possible. Thus, given the requirements for operation and design, the following specifications for the sequencer can be derived:

- The general purpose payload processor (sequencer application) should fit in the same relative size and form-factor as the previous NPSCuL SAD enclosure space.
- Operation of the sequencer should be indistinguishable from that occurring if the launch vehicle had initiated P-POD door openings.
- A significant reduction in the number of incoming signal and power lines is required occur due to on-board logic taking the place of required external interfaces and data lines.
- The sequencer shall be capable of opening the doors of any of the P-PODs individually, or simultaneously, as the application warrants.
- The sequencer shall be capable of timing reconfiguration at any point prior to launch, when physical access to the device is still possible. This capability may be refined in future revisions to allow for remote reconfiguration. (Low Priority)

- Application of primary or secondary power is sufficient to start the deployment sequencer. Likewise, the removal of these power sources is sufficient to halt the deployment process and power down the sequencer.
- The sequencer shall possess the proper fault-tolerant logic constructs to allow for continued operation in the presence of a radiation environment, particularly while in low earth orbit and possibly out to geosynchronous orbit.
- The sequencer shall utilize commercial or military-grade, off-the-shelf hardware whenever possible to lead to an overall lower-cost. Hardware upgrade to radiation hardened versions should be allowed for with minimal re-design effort.
- The sequencer should have sufficient logic overhead to allow future, secondary functions to be added with no change to the hardware design. This will allow for future expansion and/or the application of the hardware to designs other than the sequencer application.

C. RELATED WORK AND DOCUMENTATION

There have been many theses researching various fault-tolerant techniques, along with past development of FPGA-based hardware [8]–[15]. These works are related in their applicability toward the space environment and various developmental approaches toward the design of FPGA logic and circuitry. In particular, the previous thesis material on the development of the Configurable Fault-Tolerant Processor (CFTP) project was a good starting point for the research contained herein. CFTP was a multi-year, multiple-student research project aimed at the orbital flight of an experimental package designed to test for radiation tolerance properties and mitigation techniques in earlier-generation FPGA technology [8]–[15]. The work on CFTP is still on-going with a second flight scheduled to take place in August 2015, with the launch of NPSAT1 [16]. The CFTP design uses SRAM-based FPGAs and provides a comprehensive guideline for the use of TMR within that type of technology. In this thesis, all available FPGA technologies are compared and evaluated for use in the final sequencer implementation.

Differences between this research and earlier CFTP theses include the type of technology utilized, number of secondary component requirements, transition from combinational to sequential logic, method of power-on configuration, and the transition from a test experiment to practical application. CFTP showed that logic redundancy was an important aspect of design when applied to the LEO radiation environment. It is not a question of if, but of how many, events would occur in LEO due to the radiation environment. The experiment was designed to report radiation events and CFTP's response to them so as to benefit future fault-tolerant logic designs and hardware designs. Lessons learned from that research have led to an evolved selection of technology and logic design for this thesis.

D. CONCEPT OF DEVELOPMENT STRATEGY

Goals of this thesis research include the manufacture and integration of an initial sequencer test board, hardware schematic design and preliminary PCB layout of the flight prototype board, and selection of a particular fault tolerance technique for implementation into the sequencer. Since the sequencer is one specific application of the general payload processor design, the board will incorporate features to allow for easy expansion to other mission sets. All devised logic and prototype hardware will require extensive design review prior to board manufacture. In the future it is hoped to test the design at a radiation test facility to determine fault tolerance effectiveness prior to exposure to radiation in the space environment.

To maximize the amount of time available for sequencer design research, including hardware and logic development, concurrent tasks were undertaken in the course of this research. From comparison of FPGA technologies and fault-tolerant schemes, choices are made regarding applicable devices and logic for implementation. After down-selection to a particular product line, a decision was made to quickly manufacture a sequencer test board. This resulted in considerable design experience with the hardware design software prior to implementation of the more complex flight prototype board. Since the lead time for design of a flight prototype board is vastly greater than the sequencer test board, work on the logic design occurred simultaneously.

This allowed for logic error testing of the chosen fault-tolerant schemes at the same time final hardware layout occurred.

E. THESIS ORGANIZATION

In Chapter I, the history of the sequencer requirement and a concept of application have been presented. This research relates to NPSCuL and follow-on missions, with information provided concerning related projects. The concepts of sequencer design, radiation hardening, and fault-tolerance techniques are discussed in Chapter II. A survey of field programmable gate arrays and selection of the particular FPGA and development boards used are presented in Chapter III. The preliminary hardware design of the sequencer test board and modification of the hardware design to a final sequencer logic board are presented in Chapter IV. A comparison of fault-tolerance methods and implementations, fault injection techniques, and preliminary sequencer logic design, is presented in Chapter V. Conclusions and recommendations for follow-on research are presented in Chapter VI. A comparison of vendor products, including existing software suites, hardware solutions and development kits, are contained in Appendix A. All schematics, circuit board layouts, and data sheets for the sequencer test board are contained in Appendix B. All schematics, circuit board layouts, and data sheets for the final sequencer logic board are contained in Appendix C. Documentation of the HDL source coding and test bench setups are contained in Appendix D.

II. SEQUENCERS, RADIATION HARDENING, AND FAULT-TOLERANCE

A. SEQUENCER DESIGN METHODOLOGY

1. Timing Concerns Specific to Initiating P-POD Deployment

The sequencer design is such that a pre-determined, periodic set of events is triggered in response to the power supplied by the launch vehicle bus. The clocked synchronous state machines within the sequencer must be robust enough to withstand the radiation environment of space, neither permitting premature deployment nor failing to deploy at all. The sequencer must be capable of energizing and de-energizing multiple outputs for variable amounts of time. Additionally, the re-programmable aspect of the sequencer demands that the implementation of the design not be dependent upon the wiring configuration of the overall circuit board or the associated supporting components such as resistors or capacitors. Many commonly used timing circuits are based on technology such as oscillators or 555 timer integrated circuits (ICs) whose timing outputs are fixed once inserted in a certain configuration [17]. These are insufficient for the design of a reconfigurable sequencer, as one should be able to re-program the deployment sequence as long as access to the SAD interface remains available.

There are several options available which would meet the demands of sequencing. The use of a central processing unit (CPU), such as an ARM processor core, running some form of real-time operating system (RTOS) would be applicable to the sequencer development [18]. The resource demands, both in power consumption and protection of the CPU against radiation upset, are limiting factors in the use of this approach toward the sequencer development. Many of the rad-hard designed FPGAs preclude the inclusion of processing units (disabling them in hardware) to prevent these shortcomings in space applications [19].

The other option involves selection between various field programmable devices (FPDs). FPGAs are a type of FPD; ‘field programmable’ refers to configuration capability once installed without disassembly of the circuit. Programmable logic devices

(PLDs) are purely combinational devices while FPGAs provide both combinational and flip-flop logic. PLDs typically consist of two basic types – simple PLDs, which are usually either programmable logic array (PLA) or programmable array logic (PAL³), or complex PLDs (CPLDs), which allow more than one logic block as well as configurable interconnections [20]. The configurable PLA, consisting of logical connections in its and-plane and or-plane, is a good analogue for the manner in which FPGAs are configured [20]. Since simple and complex PLDs are purely combinational and lack the memory devices of FPGAs, they are not suitable for implementing the sequencer finite-state machine (FSM). The mechanisms of operation and the physical characteristics of FPGAs are discussed in Chapter III and Appendix A.

2. Chosen Approach

The FSM to be implemented in the sequencer will allow for the power-on signal to provide an ‘Arm’ situation when the sequencer is first turned on. The sequencer will initiate the ‘Deploy’ signal from its internal logic to begin the CubeSat deployments. Once the command to deploy has been given, the machine architecture will be fully capable of moving from state to state without additional inputs from the host platform. Should there be a desire to stop the sequence for a contingency, power can simply be cut to the sequencer device, which will place it back in a fail-safe configuration. This may be further reinforced with secondary hardware, such as relays for an added layer of protection against misfire. This approach is in line with the derived requirements specified in Chapter I.

The risk of logic upsets in a microprocessor in a radiation environment leads to the decision to utilize FPGA-based technology within the sequencer. FPGAs are a highly flexible means for implementing the sequencer FSM, where complex sequential timing outputs are necessary. The FPGA-based approach gives more flexibility than an embedded microprocessor and is expandable to perform other mission functions besides sequencing. The various PLDs previously discussed are all of combinational logic design and would require external memory devices to allow sequential operation. This would

³ PAL is a trademark of Advanced Micro Devices.

greatly add to the complexity of the design and introduce points of failure between the added memory and interfaces. Since FPGA-based technology is capable of many of the functions of a CPU, without the added requirement of an operating system, FPGAs are the logical choice for incorporation into the sequencer. Some background knowledge about FPGAs and their operation is important before down-selection to a particular product.

B. RADIATION HARDENING

Radiation can ionize atoms and disrupt a semiconductor's crystal structure. High-energy neutrons, which are present in the radiation environment of space, arise from the subatomic particles ejected from the Sun and deep space. A neutron that strikes a silicon atom in a semiconductor IC results in the ejection of heavy ions, as seen in Figure 4 [21]. These heavy ions can further lead to device effects, SEEs, as the possibility of firm or soft errors in logic blocks or the routing interconnect may result. Even in today's low-alpha compounds in FPGA packaging materials, alpha particle emission due to uranium and thorium present in molding compounds can present another significant challenge by making it difficult to protect the devices fully from SEEs [21].

Figure 4. Neutron radiation strike of silicon atom resulting in ejection of heavy ions leading to firm error in transistor (From [21]).

While there has always been a problem of radiation within the space environment, older technologies had the benefit of largely segregated and independent components. The large can-size transistors and low-number integrated circuit counts of the 1960s and 1970s served to protect the computers and equipment placed into space based on their feature sizes alone. As technology-level integration increased, and the number of transistors on ICs grew, the problem of SEEs was seen to manifest itself in ways which were wholly unfamiliar to logic designers of a generation before [22]. New methods of physical shielding and protection from the radiation environment were devised—and differed greatly from those previously developed to combat the strong blast type effects from a nuclear attack. Many of these schemes centered on proper logic operation of the circuit under varying environmental conditions. Such techniques included the use of voter circuits within TMR to correctly provide for functioning of the circuit with erroneous conditions present [23]. TMR has been successfully employed on computers for fault-tolerant behavior since the design of the Saturn V Launch Vehicle Digital Computer in the early 1960s [24].

1. Single-Event Effects (SEEs)

The general term for the effect caused by the interaction of high-energy particles with circuit elements in ICs is the single-event effect (SEE). The charged particles created by the ionization trail along the path of an incoming radiation particle can induce upsets in the states of transistors [25]. These may take the form of logic state changes, current and voltage spikes within the circuit elements, or permanent damage to the transistor itself. In general, SEEs fall into two categories – soft errors and hard errors, as seen in Figure 5. Soft errors are those events that have no damaging effects and are cleared by subsequent device operation, while hard errors are those events resulting in lasting damage [25].

The recoverable soft errors are further categorized into several groups, of which, SEUs (including single-bit errors and MBUs) and single-event transients (SETs) are of the most interest. Likewise, hard errors can be classified into several categories; single-event latch-up (SEL) events are discussed further to provide an example of non-

recoverable errors. Both of these categories of events are of primary interest for the performance of the sequencer.

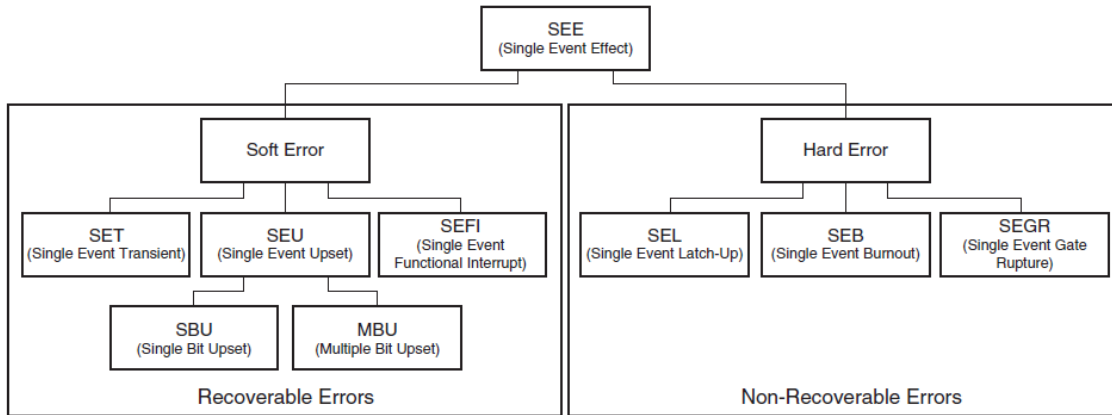

Figure 5. Single-event effects classification diagram illustrating difference between recoverable and non-recoverable errors (From [25]).

a. *Single-Event Upsets (SEUs)*

Single-event upsets are the result of high-energy particles causing a change in the state of a memory element (SRAM, flash memory, FF, or latch) [25]. These can be further subdivided into single-bit upsets (SBUs) or MBUs. SBUs are by far the most common SEE seen in space-related applications [25]. The results of a SEU can lead to the erroneous output of data, which uncorrected can provide little faith in the correctness of the logic circuit in operation.

MBUs are becoming more of an issue with later generations of hardware ICs, including the most recent revisions of FPGAs. As the transistor count has increased on devices, the associated transistor size has decreased. The probability of a particle crossing an individual bit might decrease, but the charge threshold usually also falls [26]. In addition, the number of bits on a device increases due to the increased transistor count, making the device as a whole more sensitive. Thus, a radiation impact upon the devices lattice structure has more of a potential to create cascading effects in the transistors surrounding the impact zone. This is illustrated in Figure 6, where five additional bit cells are upset due to the generation of an oxygen ion by an incident proton in 130-nm

complimentary metal-oxide semiconductor (CMOS) memory [27]. This may lead to MBU issues which are difficult to correct with legacy techniques. Studies have indicated that in one to five percent of SEU cases, MBUs may also be triggered [28].

Figure 6. MBU of six bits triggered by proton induced oxygen heavy-ion in 130 nm CMOS memory cells (From [27]).

b. Single-Event Transients (SETs)

SETs result when a high-energy particle impacts a combinatorial path of a device and can induce a voltage or current spike. Although SETs are temporary in nature, they can lead to long-term effects if they trigger undesirable actions such as power resets. If the pulse width of the spike is sufficient and occurs at the right time, it can propagate throughout the circuit [25]. SETs differ from SEUs in affecting combinational rather than sequential logic. An SET may be indiscernible from a SEU if the transient propagates to the input of a FF during the clocking window of the FF. As a result, SETs can become the primary source of observable errors if hardening is incorporated into an FPGA's sequential logic [29].

SETs pose a potentially serious threat to spacecraft as evidenced by system malfunctions in operational missions. These failures include NASA's

TOPEX/Poseidon satellite, TDRS, Cassini-Huygens and others. In most cases, the SETs caused the satellites to switch into a failsafe mode, in which all nonessential systems were temporarily powered down until the cause was identified [30]. For the sequencer, such an event could be detrimental to the deployment sequence, as a power-down event could greatly impact the mission. Although the sequencer could be resumed after a transient event, this would delay the deployment timing, possibly in an unacceptable manner. For this reason, one must look into not only the SEU mitigation techniques for FPGAs but also the SET tolerance.

c. Single-Event Latch-ups (SELs)

A single-event latch-up (SEL) is a type of circuit latch-up induced by radiation [25]. This is one of the most common CMOS IC failures in the space environment and can degrade IC performance and potentially cause permanent failures [31]. Many space systems cannot tolerate even one SEL. Recent studies indicate that SELs may be caused by nuclear recoil interaction of protons with Tungsten plugs commonly used in high-density ICs [31]. These errors may be cleared by power cycling but in many cases may result in permanent damage and may be non-recoverable. For the FPGA-based sequencer, SELs must be avoided at all costs, with priority given to the technology with the greatest inherent resistance to SELs.

2. Total Ionizing Dose (TID)

Gamma ray photoinduced ionization damage is initiated when electron-hole-pairs (EHPs) are generated along the track of secondary electrons emitted via photo-material interactions such as that with silicon. The density of EHPs generated along the tracks of charged particles is proportional to the energy transferred to the target material. The stopping power or linear energy transfer (LET) expresses the energy loss per unit length (dE / dx) of a particle [32]. It is a function of the energy of the gamma ray photon and the target material's density. The total amount of energy deposited by a gamma ray photon that results in EHP production is commonly referred to as total ionizing dose (TID) [32]. The typical unit of TID is the rad, which denotes the energy absorbed per unit mass of a material. One rad is equivalent to 100 ergs absorbed by one gram of the target material

[32]. An excellent background discussion of the physics behind EHP generation leading to accumulated TID is provided in [32] and [33]. The most common method of protection from TID effects is physical shielding of the PCB. This is accomplished by design of the overall enclosure or protective measures around individual components. Other means of protection from TID effects include the manufacture of specifically targeted radiation-tolerant FPGAs, such as the Xilinx Virtex QV space-rated series of devices. Methods to increase the tolerance of these devices include manufacturing on a substrate such as silicon on insulator (SOI) or silicon on sapphire (SOS) and an increase in feature size to aid in resistance to radiation induced failures.

3. Testing of FPGA Hardware in Radiation Environments

Common means of producing various types of radiation for both SEE and TID testing include the use of a nuclear source, commonly cobalt-60 (Co-60), to produce a collimated gamma-ray beam [34]. Methods to generate broad-spectrum neutrons include bombarding a thick beryllium target with energetic deuterons from a cyclotron [35]. This is a highly-efficient process for testing for neutron SEEs and has been employed by light-ion accelerators for many years.

A common metric for measuring the radiation tolerance of an FPGA device is failures-in-time (FIT). One FIT represents a single failure in one billion hours of operation; a system that experiences one failure in 13,158 hours has a failure rate of $1 \times 10^9 / 13,158 = 76,000$ FITs. Acceptable FIT rates for commercial applications are fewer than 100, while acceptable FIT rates for system-critical applications (including the sequencer) are fewer than 20 [36]. Acceptable FIT rates for the sequencer could possibly be as high as one failure in one hundred thousand hours, equivalent to one failure in about thirteen years of run time. This corresponds to 10^4 FITs, producing a success rate of 99.999% or better for the sequencer's roughly one hour of operation.

4. Radiation Protection Approaches

In looking to safeguard a system against the environment of space, multiple solutions are available to protect electronic systems from radiation in particular. These may be used independently or in combination to provide an optimum solution for the

radiation environment. Commonly utilized techniques include physical shielding of the device or radiation avoidance by mission design [37]. Since the CubeSat Ride Share missions are currently relegated to LEO, the radiation in the outer toroid of the Van Allen radiation belts are beyond the altitude of the mission. The South Atlantic Anomaly, due to asymmetry of the inner Van Allen belt, is closest to the Earth's surface at 200 km (124 mi) in altitude and presents the majority of the radiation received in LEO [38]. These two radiation belts are illustrated in Figure 7. Thus, radiation avoidance by mission design will be somewhat limited based on the planned orbit of the host spacecraft prior to deployment. For future missions extending beyond LEO, the radiation environment of GEO and deep space can be expected to further challenge the sequencer design.

Figure 7. Inner and outer torus-shaped layers of plasma of the Van Allen radiation belts. Energetic electrons form the outer belt; the inner belt consists of protons and electrons (From [39]).

Other radiation protection approaches are beyond the scope of the sequencer project. These protection approaches include radiation hardening by process which

employs specific materials and non-conventional processing techniques and is usually performed on dedicated rad-hard fabrication lines [37]. The protection approaches which are under design control include radiation hardening by architecture and radiation hardening by design. The radiation hardening by architecture technique typically incorporates redundant configurations and component selection. This can be implemented at the component, board, subsystem, or spacecraft level [37]. Some of this will be utilized in the development of the FPGA-based sequencer; the overall architecture of the developed PCB will incorporate as many duplicative protection features to support the FPGA as possible.

Certain forms of radiation faults are protected against, depending on the level of protection required, by selecting the appropriate device line within a vendor's product offering. Devices are often classified as radiation-tolerant when they offer limited resistance to SEL, SEB, and TID effects. Some resistance to these effects is afforded in the commercial and military-grade lines of FPGAs depending on the vendor and production processes. In general, commercial grade devices provide almost no radiation-tolerant properties and are rarely suitable for critical aerospace applications. Certain military-grade level FPGAs provide limited radiation-tolerant properties and can be used with varying degrees of success for critical aerospace applications when combined with other fault-tolerant logic methods. Typically, these military-grade components are used as prototyping devices before purchase of the more robust radiation-hardened FPGAs.

In contrast, the full radiation-hardened devices typically provide much better resistance to SEU and SET effects. This resistance is due to the production processes inherent in the design and manufacture of the FPGAs. The logic cells within the devices are designed with a larger feature size and replicated in hardware to allow for the greatest level of resistance to SEEs as a whole. Coupled with the radiation tolerance afforded by the design of internal fault-tolerant logic, these physical hardware differences combined with fault-tolerant logic development are called radiation hardening by design (RHBD).

The majority of this thesis research considers the protection approach afforded in RHBD. A portion of this technique incorporates fault-tolerant logic design techniques within the FPGA layout to overcome many of the SEU and SET challenges in the space

environment, as covered in Section C of this chapter. After introduction to the techniques in this chapter, the various schemes will be implemented in logic and tested further in Chapter V. Additionally, error correcting memory, parity bits, and watchdog timers are often utilized to provide even more protection. In Appendix A, TID tolerances provided by certain vendors and types of FPGAs are explored with a final selection based upon the best combination of hard and soft fault tolerances.

C. FAULT TOLERANCE

Fault tolerance is the ability of a system to continue to perform its tasks after the occurrence of faults [40]. The ultimate goal of fault-tolerant design is to prevent system failure from occurring. Various requirements satisfied by the introduction of fault tolerance to a system include: dependability, reliability, availability, safety, performance, maintainability, and testability [40].

1. Scrubbing / Re-programming at Intervals

Within the FPGA, the internal logic matrix most vulnerable to SEU effects is the configuration memory. It is this portion of the device that provides the configurable Boolean constructs and memory for operation of the developed FPGA logic. Depending upon the area of the configuration memory affected by a SBU or MBU, the device may have no indications of erroneous output other than transient invalid data being passed. In the worst cases, the FPGA may be altered in such a manner that consistently wrong outputs are generated, or the FPGA may cease to function altogether. Further discussion of FPGA physical configuration memory construction is provided in Chapter III.A.

One of the most common and easiest ways to safeguard an FPGA's configuration memory from SEUs involves the use of scrubbing. To 'scrub' an FPGA, as it is known, involves the complete re-flashing or re-programming of the device at a specified interval to mitigate or prevent the effects of SEUs upon the device [41]. Unfortunately, this requires either that the rate be such that it will not affect the functionality of the FPGA or that it be done regionally, in real time, so that the portion of the FPGA with the upset is reconfigured while other sections continue work. This partial reconfiguration capability is important in real-time operational scenarios. In the case of digital signal processing

(DSP) functions, the complete halt of a processing capability to allow for complete reconfiguration would be unacceptable. Thus, a capability to partially reconfigure based upon the partitioning scheme and fault-tolerance method implemented is desired. If errors are detected in a portion of logic, that section of logic should provide an event trigger to cause partial reconfiguration of the specific partition. This can be implemented via an error detection line with a counter technique to determine repeated errors. Both of these reconfiguration approaches may greatly cut down on the allowable resources of the device, or the quantity of time in which it is fully utilized – therefore, their use should be carefully evaluated before implementation.

2. Triple Modular Redundancy (TMR)

In simplest terms, TMR involves triplicating the logic functioning of the device (in the critical path sections) and including a set or series of voter circuits to determine majority output for proper operation [42]. In majority voting, the best two of three wins the vote and is considered the correct output. Unfortunately, if there is an error in the voter circuits themselves or the output path, then the voting scheme can lead to an overall logic failure. Triplicating voters guards against this type of failure. As such, the voters should be designed with sufficient logic to detect errors when compared to the other voting logic to trigger complete or partial reconfiguration of that portion in the TMR scheme. To better design for the environment of space, and to reflect the increased probabilities of SEUs and MBUs in newer FPGA series, new methods of TMR have been developed [43].

a. Block TMR (BTMR)

The oldest form of TMR is known as Block TMR (BTMR), whereby the three levels of replicated logic are majority voted in one voter circuit [43]. Signal tracing between the triplicated logic outputs and the output of the voter circuit is useful in eliminating the voter as a suspect error source. By limiting the voter circuits to one copy, there is an overhead circuitry requirement to continuously monitor triplicated logic outputs in order to provide this troubleshooting method. Additionally, if one of the triplicated logic circuits should fail completely, then the ability to correct errors in any of

the remaining logic is lost. When coupled with the ever-present radiation environment of space, this leads to a highly increased probability of total failure for a mission.

b. Local TMR (LTMR)

As depicted in Figure 8, an improvement over BTMR is Local TMR (LTMR). In this case, the redundancy and triplication is done only at the Flip-Flop (FF) level where the results of the voted logic are transferred back to the FFs in feedback paths [43]. This has the advantage of masking and correction and greatly increases the overall reliability of the circuit in question. Unfortunately, the problems of clock skew and reset lines are not handled, and Single-Event Transients (SETs), which can lead to SEUs are still a possibility.

Figure 8. Local TMR with all sequential elements tripled and followed by a majority voter (From [44]).

c. Global TMR (GTMR)

As illustrated in Figure 9, Global TMR (GTMR) has the largest overhead of FPGA utilization and is also the most complex. In it, all sections of the FPGA are triplicated – three separate clocks with three separate domains [43]. The upset rate in

such a circuit is very low. This would be at first glance the most advantageous; however it is the most power hungry and wasteful of FPGA resources. It can be difficult to implement if large object libraries are used and difficult to verify and test such large designs. Additionally, the problem of clock-skew and mismatch between the three disparate clocks must be considered in the design methodology [43].

Figure 9. Global TMR with all sequential elements, combinational logic, majority voters, clocking signals and global buffers triplicated (From [44]).

d. Distributed TMR (DTMR)

Lying somewhere in the middle of all these approaches is Distributed TMR (DTMR) – while similar to GTMR in that all logic and sequential elements are triplicated – the clock and resets are not [43]. That is to say, there is only one clocking and reset path. This is illustrated in Figure 10. This is seen to have many of the advantages of GTMR without the clock skew and mismatch concerns of the former. The clock line is still susceptible to effects. Often though, clock drivers are sufficiently less susceptible to SEEs. In all of the TMR techniques, the problem of verification of all nodes is seen to exist and becomes more challenging as feature sizes shrink and logic usage increases [43].

Figure 10. Distributed TMR with all sequential elements, combinatorial elements and majority voters triplicated. Clock signal is shared among resources (From [44]).

3. Quadded Logic

In quadded logic, all involved gates are replicated four times. Errors are corrected soon after they occur, since neighboring good values correct faulty values [45]. Quadded logic does not use voting schemes to determine error values and positions. Rather, it masks errors using logic gates with a particular interconnection pattern.

As illustrated in Figure 11, Tryon conceived of a notion where an error may initially spread through the first series of logic gates but would be corrected further down the circuit. It is in this way that quadded logic can be thought of as a ‘self-healing’ circuit. The absence of voters occurs due to the fact that the logic values at the outputs should all have identical values by the time they reach that stage. The only conceivable failure point would occur should one of the last stage logic gates provide the wrong output due to error in that stage. For that reason, and the desire to recombine the quadded logic signals back into a singular value, voters or other recombination techniques are sometimes reintroduced to provide both of these desired properties. One difficulty with quadded logic is the lack of an error signal to trigger reconfiguration. Periodic scrubbing is necessary.

The interconnection patterns between gates are chosen such that the same pattern is not encountered twice consecutively. This is done in the cases when going from an AND gate to an OR gate or vice versa, as seen in Figure 11. There is an exception to this rule when connecting like gates. When driving an AND gate by an AND gate or an OR gate by an OR gate, the connecting patterns to the first and second identical gates must also be identical. This is not the case, however, when connecting NAND or NOR gates. In these cases, like NAND or NOR, repeating gates should have differing interconnection patterns.

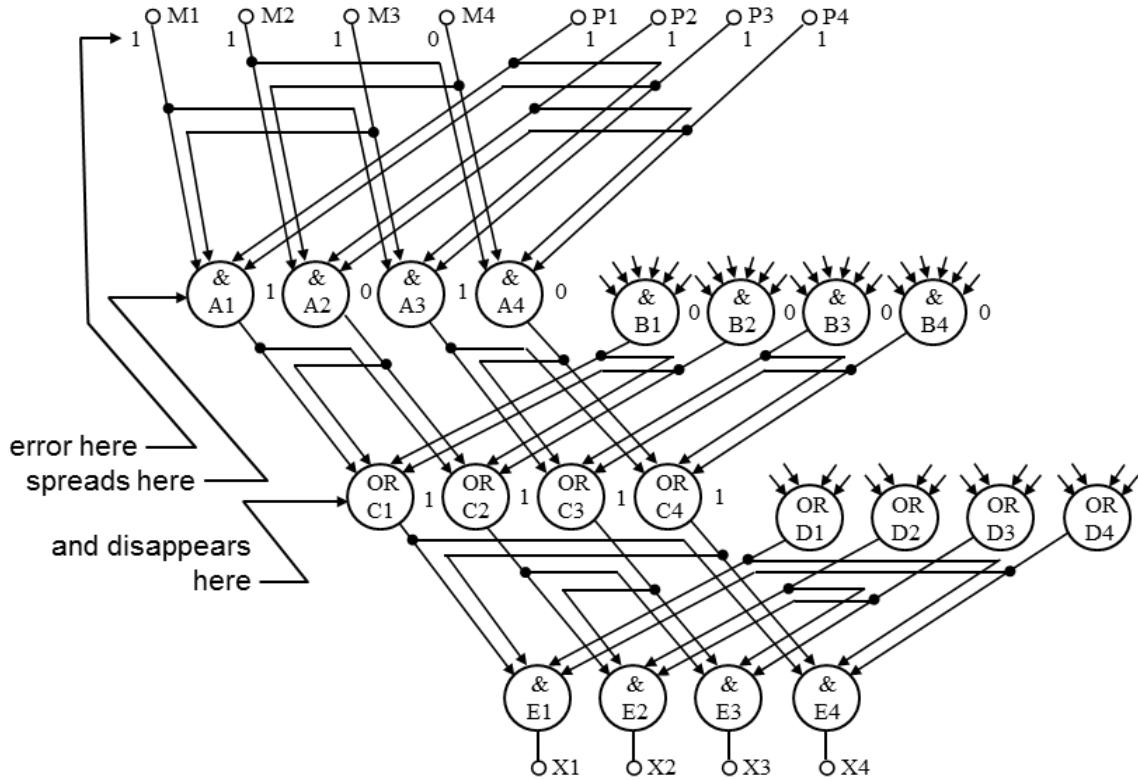

Figure 11. Quadded logic illustrating error propagation and masking (From [46]).

4. Triplicated Interwoven Redundancy (TIR)

As the simplest form of random interwoven redundancy, triplicated interwoven redundancy (TIR) exists as a useful comparison to the techniques of TMR and quadded

logic. There are some of the interwoven benefits of quadded logic combined with the triplicated nature of TMR. Similar to TMR designs, TIR requires a voter at the outputs as a restoring device. The design of a TIR half-adder, without the associated voting logic, is represented in Figure 12.

The general procedure for constructing a TIR circuit involves starting with the non-redundant form of the circuit, triplicating each gate, and then using the interconnection pattern of the non-redundant circuit – randomly selecting a gate from each triplet pair to use as an input for a gate that has no other inputs from the same triple. That is to say, the output of a gate in a pair of triplets is paired with the output of a gate in another pair of triplets to form the inputs of a gate in the next stage. This last step is repeated until all of the gates are connected in the TIR circuit. The method would be identical to TMR if the connection pattern utilized repeating inputs from the same triplet. Thus, TIR is a generalization of TMR to allow for random interconnections.

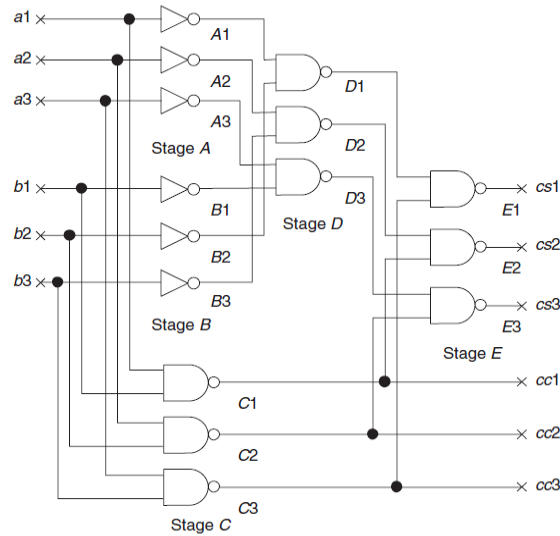

Figure 12. Design of TIR half-adder implementation illustrating interwoven connections (From [47]).

Previous work and simulations have shown that the reliability of TIR circuits with random interconnections are comparable to their TMR equivalent circuits [47]. For certain interconnection patterns, the TIR structure would present weaker performance

than TMR where a single error's effect in a circuit is not confined only to one set of outputs. The interconnection pattern used for experimental testing in the thesis was selected to alleviate much of these concerns. As with quadded logic, no error detection signal is provided, so periodic scrubbing is necessary.

5. Quadruple Force Decide Redundancy (QFDR)

Much of past logic research has dealt with the concept of quadded logic as it applies in the historical context of interest—dealing with AND and OR gates. Quadruple Force Decide Redundancy (QFDR) takes this idea further by applying it to larger general Boolean constructs—namely, the LUTs and FFs present on FPGA devices, as illustrated in Figure 13. The differences between quadded logic and QFDR allow for the FPGA resources to be allocated manually in a more efficient manner than allowing synthesis to auto-allocate resources. By specifying both the number and attachment point of the individual LUTs and FFs, one has greater control of the synthesis effort. This is accomplished by taking the output of the map phase and manually making edits to the layout before the place and route phase occurs [48]. This can be a very time intensive application of fault-tolerance. There are some software tools to aid in this approach; although, none are fully autonomous.

Figure 13. QFDR substituting LUTs and FFs constructs for logic gates (From [48]).

6. Advantages and Disadvantages of Various Fault-Tolerant Techniques

There are many inherent advantages and disadvantages of the above techniques when implemented in logic. Scrubbing of an FPGA usually guarantees a clean working state of the device; however, it typically incurs large time penalties. These can be somewhat mitigated if partial reconfiguration is applicable to a certain device. TMR has the advantage of a long history of application and testing in the space environment. While the utilization requirements for the circuit are slightly more than three times the amount of logic when compared to a non-TMR design, the timing requirements for the design should only incur a modest penalty due to the addition of the voter circuit. The various subsets of TMR will be further studied to determine the appropriate instantiation for the particular type of circuit in development.

Quadded logic and QFDR techniques have the disadvantage of utilizing even more logic resources than TMR. The elimination of a required voter circuit may be an advantage since that eliminates a single point of failure from the design, as the implementations mask any faults by the time the logic values reach the output state. Another advantage may come from increased MBU resiliency. Overall, both quadded logic and QFDR appear to be viable techniques; although, the automated methods of implementation have yet to be developed. TMR insertion using software such as Xilinx TMRTTool⁴ or Mentor Graphics Precision⁵ Hi-Rel remains the only automated means for fault-tolerance insertion into existing logic designs [49], [50]. These logic design software packages are discussed in Chapter V.

TIR exists as a hybrid approach between TMR and quadded logic, with the TMR design being a special case of a TIR solution. An inherent disadvantage is the uncertainty in the proper output unless the proper interwoven pattern is chosen. Timing conclusions for TIR, as compared to the TMR-case, remain to be seen. The suitability of the various fault-tolerant techniques compared in this study is assessed fully in Chapter V.

D. CHAPTER SUMMARY

The concepts of sequencer design, radiation hardening and fault tolerance were discussed in Chapter II. An FSM logic design was chosen for its suitability in the sequencer. Considerations unique to the CubeSat launching application are contributing factors to the FSM approach. Different types of programmable logic devices were analyzed with the FPGA being chosen as the most applicable hardware type. Trends in FPGA development were discussed with an emphasis placed on the evolution of the technology into different subcategories of underlying architecture.

Background information regarding radiation effects in semiconductors was provided with a full description of recoverable versus non-recoverable errors. SEEs are subdivided into categories of SEUs, SETs, and SELs with an emphasis placed on those events which could impact the FPGA-based CubeSat deployer in a LEO radiation environment. TID resiliency is seen as another common metric for comparison between FPGA vendors' products with the means of conducting testing for SEEs and TID introduced. RHBD is considered the focus of research within this thesis.

Various means of fault-tolerant logic implementation were discussed with a breakdown of particular approaches. The particular advantages and disadvantages of scrubbing, TMR, quadded logic, TIR, and QFDR were presented. Initially, TMR is seen as the preferred choice due to software availability and a long history of use in space applications.

III. FIELD PROGRAMMABLE GATE ARRAYS AND SELECTION OF SEQUENCER TECHNOLOGY

A. FIELD PROGRAMMABLE GATE ARRAYS

The field programmable gate array is an IC designed to be configured by the end-user after manufacture of the chip is completed [51]. The configuration process is aided by the use of various hardware description languages (HDLs) including VHDL, Verilog and schematic design. These HDLs are translated to actual FPGA layout configuration via various logic computer-aided drafting (CAD) software suites. These CAD software tools are usually vendor specific; although, generic toolsets are available. FPGAs have largely superseded custom application-specific integrated circuits (ASICs) as the method of choice for rapid prototyping of logic circuits [52]. Though custom ASICs are still often designed for large-quantity or application critical situations, FPGAs are rapidly becoming the primary device all the way to manufacture. This is largely due to the low-cost of FPGAs relative to the development costs inherent in ASIC production [52]. When ASICs are still required, the FPGA is an important tool in prototyping logic circuits that will eventually be laid out during very-large-scale integration (VLSI) logic design. There are even FPGAs onboard the most recent Mars rover, Curiosity [53].

1. Physical Construction

The typical FPGA is internally configured as a matrix of logic blocks, input / output blocks (I/O), and programmable interconnects [54], as illustrated in Figure 14. In all cases, the internal configuration is programmable and, in many FPGA hardware types, re-programmable. This reconfiguration may take place as a wholesale re-programming of the device or a partial reconfiguration of certain sections of the FPGA. The partial reconfiguration capabilities of a particular FPGA device are dependent on the vendor and particular series of device utilized. In all cases, the particular reconfiguration characteristics of a device should be fully understood to allow for a combination of partial reconfiguration simultaneously with other fault-tolerant techniques.

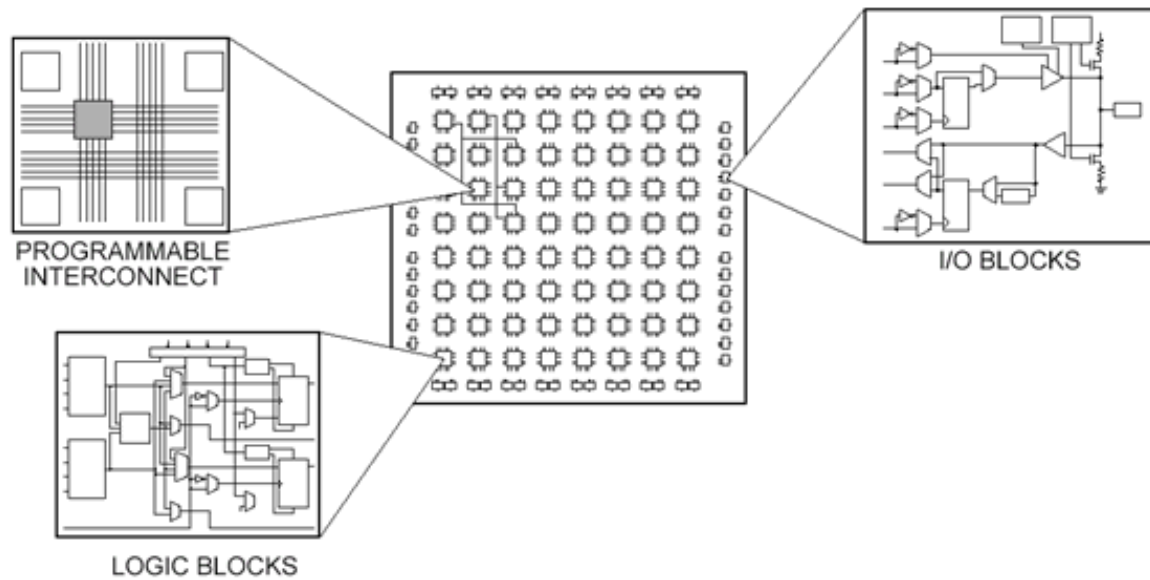

Figure 14. Typical FPGA internal architecture consisting of configurable logic blocks, I/O blocks and programmable interconnects (From [54]).

a. Internal Fabric

FPGAs are usually structured in a two-dimensional array with corridors dividing the rows and the columns used for global interconnects between the logic cells of the array [20]. Each cell consists of a combination of logic functions and flip-flops that can be programmed to perform a desired function. Logic functions are often implemented as lookup tables (LUTs) since they are basically small, programmable random-access memory (RAM). Newer FPGAs may contain more sophisticated building blocks such as adders and RAM. RAM blocks can be further used to build register files [20] as shown in Figure 15. Together these cell clusters of LUTs, gates, adders and RAM blocks can be termed configurable logic blocks (CLBs) or ‘slices.’ FPGAs that contain 16 and 32-bit CPU cores can often be found in commercial use; however, the use of FPGAs with built-in CPU cores are extremely limited in space-based applications. This is due to the previously mentioned difficulties with radiation and power consumption.

onboard the device, allowing for connection to ball grid array (BGA) device pins [56]. These I/O blocks allow for various data lines to be routed to the appropriate pins of the device with reconfiguration possible at a later point. I/O blocks provide buffering and the appropriate voltage and current levels necessary to drive externally interfaced components at the signal level required. Often, these I/O blocks are grouped into I/O banks with differing voltage levels possible for various bank clusters.

b. Programmability and Reconfiguration

In general, the method of programming FPGAs involves writing HDL such as Verilog or VHDL and is known as configuration. Schematic diagrams may also be developed to do the same function. In most cases, the schematic designed is translated into an intermediate HDL format through the programming interface. This allows one to create a schematic representation of a logic circuit and later instantiate it through a code representation. After synthesis of the HDL code, the developed design is ready for translation, mapping, and place and route phases of implementation. It is at this point that a programming file can be generated for construction of the logic upon the desired device. The actual configuration of FPGAs takes place when the bitstream format of the programming file is loaded onto the device. All of the logic block, I/O block, and interconnect logic is configured on the device at this point in the development cycle. This configuration cycle may be repeated at any point in the future, dependent upon the nature of the technology with which the FPGA is constructed.

Arguably, the largest benefit stemming from the development and rapid adoption of FPGA technology is the short time-span in which reconfiguration of devices is possible. Akin to a software upgrade within a computer, or firmware upgrade within a flash memory device, the re-programmable aspect of FPGAs allows for quick and easy maintenance of hardware logic. This ‘field programmable’ capability changes much of the traditionally held notion that once hardware was deployed, one would have to replace that hardware in order for capabilities upgrade or bug corrections. Many of the current approaches to FPGA reconfiguration involve “over-the-air” (OTA) re-programming, often at a remote location from the actual physical location of the FPGA device [57].

Partial reconfiguration allows an FPGA to implement many concurrent functions and to change those functions while the system is running [58]. This is done by partitioning the device into several regions which may be re-programmed without impacting the other sections of the device. This dynamic reconfiguration during runtime is the real advantage of partial reconfiguration. Each vendor's FPGAs have significant differences in the partial reconfiguration technique, advantages and perceived benefits due to the close coupling of the underlying FPGA fabric with the ability to partially reconfigure [59]. One of the largest benefits for partial reconfiguration would come in communications—the field of software-defined radios (SDRs). The partial reconfiguration of such a device, to allow for more modes or channels in specific frequency ranges, while the radio continues to operate on other areas of the FPGA, is extremely attractive.

Applied to the CubeSat deployer, such a reconfiguration technique could be utilized to reconfigure the sequencer portion of the FPGA while another region of the device is still operating. This would be useful in future scenarios where expected feature upgrades to the sequencer will allow for multiple secondary functions. These functions could include such features as remote CubeSat monitoring via telemetry, video feed of the launch sequence occurring, and overall monitoring and data collection for NPSCuL. The ability to execute these mission areas simultaneously while still allowing for remote OTA re-programming is recommended for future study. For the first iteration of the sequencer, only the ability to execute the deployment sequence reliably is researched. This initial design will be reconfigurable through an interface on the SAD, with future designs possibly incorporating OTA reconfiguration. Another function of partial reconfiguration is configuration-fault repair, which was presented in more detail in Chapter II.

2. Historical Overview of FPGA Technology

PLD development was a new industry in the early to mid-1970s, developed by companies such as Motorola, Texas Instruments, and IBM [60]. The ability of PLDs to have not only programmable logic but programmable interconnection fabric gave rise to

the FPGA industry. Much of the groundwork for programmable logic arrays, gates and logic blocks are found in the two patents by David W. Page and LuVerne R. Peterson filed on January 11, 1983 [61], [62]. These patents were the first to incorporate the aspects of dynamic re-programmable PLAs. This gave way to the notion of devising a high-density programmable logic device from an SRAM cell in the mid-1980s. Ross Freeman founded the Xilinx Corporation in 1984 and successfully obtained a patent for a ‘Configurable Electrical Circuit Having Configurable Logic Elements and Configurable Interconnects’ on September 26, 1989—the first FPGA [63]. Seiko Epson—Semiconductor Division manufactured the first FPGAs for Xilinx in 1985 with a 1,000 gate ASIC equivalency and clock speed of 18 MHz. This FPGA, the XC2064⁶ had both programmable gates and programmable interconnects—64 configurable logic blocks (CLBs) each with two 3-input lookup tables (LUTs) [64].

Recent advancements in IC manufacturing techniques have led to a series of devices with feature sizes that were unthinkable in years before. These advancements have extended to FPGA families with some of the more advanced series (Xilinx Virtex⁷ 6 or 7) containing millions of logic devices onboard. In contrast to the XC2604, a Virtex 7 with a clock speed of 1.866 GHz, may contain up to 305,400 CLBs with a total logic cell count of 1,954,560 and 1,221,600 6-input LUTs [65].

With the reduction in feature size comes the added burden of an increased probability of SEUs occurring. Indeed, the smaller the feature sizes of the devices, the larger the problem and associated probability of failure [66]. Additionally, the newer problem of cascaded SEUs occurring in a section of a device, or an MBU occurring, has been seen to markedly increase over the past couple of generations of devices. The specifics of SEEs and MBUs, challenges of radiation-induced failures, and the associated mitigation techniques were previously discussed in Chapter II.

For every generation of FPGA developed—the time it takes to fully space qualify an FPGA is seen to increase markedly. The physical differences between commercial and

⁶ XC2064® is a registered trademark of Xilinx, Inc.

⁷ Virtex® is a registered trademark of Xilinx, Inc.

space-grade devices, and various radiation effect challenges, are presented in Chapters III and IV. Even though the Xilinx Virtex 7 series has been released for some time, only the Virtex 5QV series has been developed as a rad-hard variant of its commercial counterpart [67]. This is a lag time on the range of three to five years from release of their commercial counterparts. Obviously, a new method of fault tolerance is desired—to allow commercial or military grade devices to produce similar performance as a fully rad-hard, flight tested FPGA, in an identical environment. This change could reduce the need for the product lines of rad-hard devices from various manufacturing companies (Xilinx, Actel, Altera); however, it would readily open up their more recent and capable products to the space environment where they are currently not targeted.

3. Types of Modern FPGA Technology

The method of FPGA construction has evolved in recent years to one of three primary forms of design and implementation. Depending on the method of operation, these various FPGA technologies all possess their own set of strengths and weaknesses. In order to properly compare the three technologies: antifuse, SRAM-based, and flash-based FPGAs—the relevant design features and differences are presented.

a. Antifuse-based FPGAs

Antifuse technology is a type of permanent configuration that allows a connection to be made or broken once, upon initial programming. The antifuse FPGAs, while configurable, are not re-configurable types of devices. The permanent connections involve the creation or destruction between two wires. Antifuse-based FPGAs use a small piece of dielectric, usually smaller than $1\ \mu\text{m}^2$, as an open switch between the two lines. Layers of amorphous Silicon in the vias provide isolation between metal layers. Where a connection between the two metal lines is desired, a programming pulse is used to short out the dielectric. When this configuration voltage is applied, the amorphous silicon changes to a low impedance state, creating a metal-to-metal interconnect [68].

There are some benefits to this type of technology since it does not need to be configured each time power is applied to the device. It is this live-at-power-up capability that makes antifuse FPGAs a true single-chip solution for circuit design,

similar to ASICs. In addition, antifuse FPGAs do not suffer from radiation-induced configuration faults as their SRAM-based counterparts do [69].

b. SRAM-based FPGA Implementations

Reconfigurable FPGAs store their configuration in some form of memory. This memory is often static random-access memory (SRAM) in its implementation. In SRAM-based FPGAs, the configuration is downloaded at power-on with the contents controlling the setting of various switches. These switches in turn determine which metal lines are connected within the FPGA interconnects and logic blocks [20]. There are three primary disadvantages of SRAM-based FPGAs—one, that the configuration is volatile and must be re-loaded at each subsequent power-on; two, the use of active transistors for switches slightly increases the resistance of such connections; and three, SRAM technology is more susceptible to SEUs due to its inherent structure and design [20]. Vendors of SRAM-based FPGAs typically offer higher logic densities when compared to antifuse based solutions with nearly the same performance and speed levels [69]. This makes them an attractive option for space-based implementations.

The design decisions related to the use of SRAM-based FPGAs include the selection of secondary components to support boot configuration and the manner in which to configure within the time allocated for system startup. When a SRAM-based FPGA experiences a brownout or power-glitch, dedicated circuitry such as voltage supervisors and CPLDs must be in place to capture these events and force a reset and reconfiguration of the FPGA [69]. All of these design factors lead to a greater system cost, higher associated mass, increased circuit complexity, and higher power consumption. Since the sequencer is a resource intended for the space environment, weight and power consumption are important issues for consideration.

Previous thesis work done at NPS regarding CFTP utilized Xilinx Virtex I and II FPGAs for the experimental componentry. These types of devices are SRAM-based technology and required additional components for support such as synchronous dynamic random-access memory (SDRAM), programmable read-only memory (PROM), and electrically erasable PROM (EEPROM), as well as the discrete devices to support

those, including resistors, capacitors, voltage regulators, and an oscillator [9]. The EEPROM and PROM provide the configuration storage for the two FPGAs.

c. Flash-based FPGAs

Existing as a hybrid of antifuse and SRAM-based FPGA technologies, flash-based FPGAs offer many of the benefits of the two previously discussed types. These FPGAs utilize flash cells to store configuration information. Positive or negative charge stored on floating-gate transistors is used to hold pass transistors in either “on” or “off” states. This either opens or closes connections between routing tracks and logic resources [70]. This is similar to the method utilized for storage in typical flash-based memory, as illustrated in Figure 16. The flash cells are nonvolatile due to the storage of charge within the floating-gates, even when power is removed from the circuit.

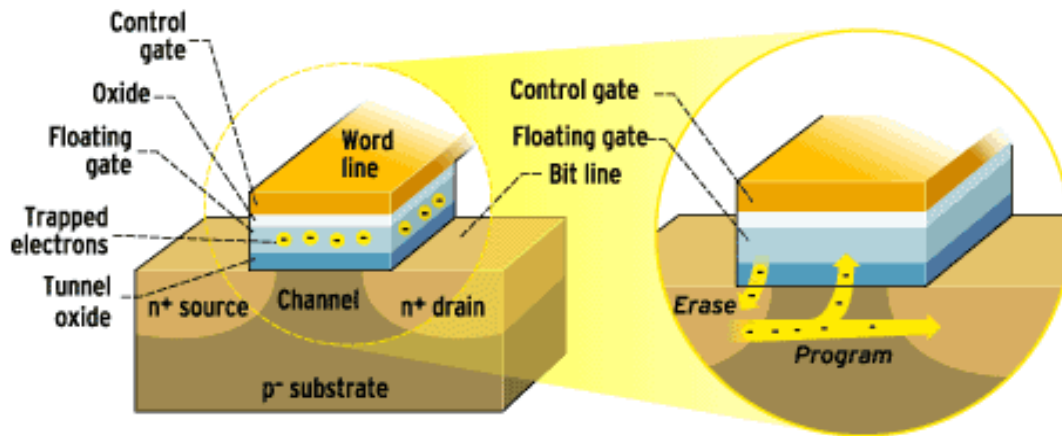

Figure 16. Internal flash transistor configuration with charge build-up in floating gate allowing for reconfiguration and nonvolatile storage (From [71]).

The flash-based technology allows the logic blocks, I/O block, and reconnect matrix to emulate reconfiguration capabilities of SRAM-based FPGAs while retaining the nonvolatile aspects of antifuse FPGAs. This allows the flash-based FPGA to have an operating mode almost instantaneously at power-up with no boot sequence or secondary components necessary to support. The inherent reduced SEU vulnerability of flash memory also makes them more desirable than SRAM for configuration memory.

4. Design Concerns

There are some concerns that arise due to the differences in FPGA manufacturing. The primary concern for the sequencer is the FPGA's radiation tolerance. Though not necessarily required for the sequencer application, a secondary interest is the ability of the general payload processor application to be re-programmable any time prior to launch. Reprogrammability demands that one of the two types of FPGAs incorporating re-writable characteristics in their logic blocks and interconnect matrix be utilized. Reconfiguration capability prior to launch for the general purpose payload processor design rules out using antifuse technology as the design would be permanent after the first configuration event.

In comparing the SRAM to flash-based FPGAs, the difference must be carefully considered. Since the majority of FPGA use at the Naval Postgraduate School has been with SRAM-based products, there is a strong desire to remain within those product lines to benefit from the experience of past designs. The use of SRAM technology, however, makes the overall design more complex in schematic layout, microcontroller interfaces, and power provisioning. This is related to the requirement to restore the configuration of the SRAM-based FPGA at initial power-on from an external memory device. This increases the time from power-on until operation and the need to protect secondary components from the effects of the space environment. Radiation is a challenge no matter how many components are utilized, however, increasing the secondary required devices and interfaces only add to these difficulties. Inherently, SRAM-based FPGAs are more vulnerable to SEUs than flash-based products.

On the basis of simplicity, with an eye toward speed and reliability, the initial viewpoint of the author is to take the flash-based FPGA route. This will yield a simple, reconfigurable circuit while providing the added speed benefit of operation at power-on. For the sequencer, this should eliminate any added "wait" time that would be necessary to account for before the deployment sequence proceeds. Due to the harsh environment and desire for very precise timing constraints, a sequencer that is ready to start deployments immediately upon receiving 'Arm' and 'Deploy' signals is of most interest. The final decision as to the type of FPGA technology to utilize is presented in the next

section of this chapter. The differences between the Actel and Xilinx FPGA technologies are more fully discussed in Appendix A.

B. FINAL SELECTION OF ACTEL PROASIC3 SERIES FPGA

1. Required FPGA Characteristics

There are several important characteristics that an FPGA must possess for applications related to the space environment. When choosing the appropriate device, several factors must be taken into consideration: non-recoverable hard errors such as SELs and SEBs, TID tolerance, choice of technology utilized, computing power concerns, and the cost of the device. Within these, the tolerance of the FPGA chosen to SEL and SEB effects, along with its accumulated TID tolerance, are among the most important factors for consideration in the choice of a device. Since non-recoverable hard errors may lead to a complete electronic failure of the FPGA, these must be protected against at all cost. The gain in survivability with regards to these effects is often worth the higher cost rad-hard technology when utilized for mission critical applications.

Following this, the computing power necessary for the proper operation of the logic necessary for a specific FPGA application is of immediate concern. If the FPGA is sufficiently protected from non-recoverable errors but unable to perform its desired function due to speed concerns, it will be of little use once on-orbit. Closely related to the speed of the device is the reconfigurable technology selected for the application. SRAM-based FPGAs tend to have inherent speed advantages over their flash-based counterparts; however, many of the speed increases come at the added cost of reduced reliability for radiation tolerance. Additionally, the added circuitry and support components required for the SRAM-based designs greatly impact the overall cost of the platform as a whole. In many cases, cost may become a large driver on the selection of the technology as certain payload requirements call for multiple FPGAs to be utilized, along with any space-grade support circuitry. This may greatly limit the options available to the designer on smaller scale programs such as this sequencer project.

2. Overall Sequencer and Processor Characteristics

When focusing on the specific sequencer application of this research toward a general-purpose payload processor, there are considerations that factor into selection of a particular FPGA. These include the resistance of the FPGA to recoverable, soft errors such as SEUs and SETs and the selection of a device with the lowest SWAP (size, weight, area, and power) requirements; the choice of a particular vendor and product line must take all these factors into account.

In general, flash-based FPGAs are more resilient to SEU and SET effects than SRAM-based devices. Also, due to the lack of a requirement for secondary support circuitry, flash-based FPGAs again save SWAP when taken in comparison to SRAM-based devices. The flash-based FPGAs are live-at-power-on, take almost no power during idle periods due to lack of a need to refresh the devices, and typically are smaller in SWAP requirements. This has the added effect of producing less of a thermal load, with less heat being produced by flash-based FPGAs. All of these factors typically lead to an overall smaller cost for flash-based FPGAs than SRAM-based FPGAs. The advantages of flash-based FPGAs over the SRAM-based products greatly sway the decision for these reasons.

3. Comparisons of Xilinx and Actel FPGAs

While the Virtex-5 series may provide more overall logic area for expansion, slightly increased TID radiation performance, and additional DSP functions not present in the ProASIC3 devices—for a sequencer designed to deploy CubeSats reliably, overall device utilization should not be the predominate factor. Even given the added logic overhead of TMR or quadded logic implementation, the ProASIC3 FPGA should be fully capable of configuration with the targeted design. A brief comparison of both the Virtex and ProASIC3 series FPGAs is provided in Table 1. More information concerning specifics of each device type is found in Appendix A.

With the Xilinx FPGAs utilizing SRAM-based technology versus the Actel flash-based FPGAs, the prominent difference between these two implementations exists at the hardware level. This equates to the need for secondary memory components required to

support the FPGA both during power-on configuration and subsequent operations. While the number of user I/Os is considerably less for the Actel ProASIC3 series, the provided 270 maximum is more than enough for the sequencer application within the general-purpose payload processor design.

Table 1. Overall hardware comparison between Actel ProASIC3 and Xilinx Virtex-5 series FPGAs illustrating strengths and weaknesses.

	<i>FPGA Device Series</i>	
	Actel RT ProASIC3	Xilinx Virtex-5QV
<i>Device Type</i>	Flash-based	SRAM-based
<i>Quantity of Logic Cells</i>	13,824 VersaTiles	20,480 Slices
<i>Number of User I/Os</i>	270	836
<i>Number of Clocks</i>	6	18
<i>Clock Speed Frequency (MHz)</i>	350 @ 1.5 VDC / 250 @ 1.2 VDC	450
<i>SEL Immune (MeV-cm²/mg)</i>	68	> 100
<i>TID Immune</i>	55 Krad	1 Mrad
<i>External Memory Required</i>	No	Yes
<i>Number of Package Pins</i>	484	1,738
<i>Price (US Dollars)</i>	\$63.87	\$4,352.40

If the goal of the general purpose payload processor were limited to DSP functions, or faster operation, the Xilinx Virtex-5 series would be a better solution. Since only comparing the number of logic gates is not meaningful when comparing different vendors, it is more useful to compare the baseline logic cell architectures. The equivalency for Xilinx logic slices to Actel VersaTiles is listed in Table 2 [72]. From this data, one may conclude that one Virtex-5 slice is equivalent to approximately eight Actel VersaTiles. Though the Virtex-5 slices have more logic capability than the Actel VersaTiles, there should be sufficient overhead in the Actel FPGAs for design of fault-tolerant logic for a sequencer design. Testing of different fault-tolerant schemes for FPGA logic utilization factors is conducted in Chapter V.

Table 2. Approximate relationship between different vendors FPGA logic blocks (After [72]).

Logic Block	Virtex-4 Slice Equiv.
Xilinx Virtex-4 Slice (Ref.)	1
Xilinx Virtex-5 Slice	2
Actel VersaTile	0.25

The volatile nature of SRAM-based FPGAs and the overall requirements for secondary componentry result in the choice of Actel flash-based technology over the Xilinx product. Even considering the reduced schematic capabilities of adopting Actel SoC over Xilinx ISE⁸, the associated hardware benefits inherent to the ProASIC3 series are worth the effort. The difficulty in learning a new software package for logic design is more than compensated by the strengths of the single-chip Actel solution. This Actel ProASIC3 series is the clear choice for simplicity, due to the reduced number of secondary components, and the potential for reduced cost.

Given the need for a low-power, low-cost general purpose fault-tolerant processor design, the Actel ProASIC3 FPGA is the suitable choice for the development of hardware in this thesis. This differs from earlier work done on CFTP by limiting the amount of secondary component design necessary for completion of a PCB. The overall technology behind the FPGA has changed from SRAM to flash-based in this implementation. As previously discussed in Section A.3 of this chapter, this flash-based technology also has the added benefit of increased SEU resistance in the configuration memory. Since one of the goals of this sequencer design is simplicity, the ability for the sequencer to function immediately upon power application of the ProASIC3 fits better with the desired sequencer operation. This should allow for an ‘Arm’ signal to be passed to the sequencer by the power initiation, with the ‘Deploy’ signal coming from the internal sequencer logic. Further detailed comparisons between the Xilinx and Actel products which result in the selection of the Actel ProASIC3 FPGA may be found in Appendix A.

⁸ ISE® is a registered trademark of Xilinx, Inc.

Initial work will be done to develop a ‘ProASIC3 Test Board’ using the Actel ProASIC3 nano series of FPGAs in Chapter IV. This will allow for design software familiarity prior to development of the flight prototype board. Altium Designer will be used for the schematic and PCB design of the ProASIC3 Test Board and SAD Version 3 – Prototype Flight Board. All prototype flight hardware schematic and PCB design work will be accomplished using the Actel ProASIC3 military-grade component (A3PE600L-FG484M) in Chapter IV. Drop-in compatibility with the lower-cost, commercial-grade FPGA (A3PE600-FG484) should allow for several prototypes to be manufactured. By staggering the design, one is able to quickly develop and manufacture a test board to become familiar with the Microsemi product lines, datasheet representations, and skill-set necessary to develop the more complete design.

C. SELECTION OF DEVELOPMENT BOARDS FOR LOGIC DESIGN

In addition to developing an in-house test board, various vendor manufactured development boards were purchased in tandem with this research. This allowed for a known working configuration to proceed with logic development parallel to hardware design and manufacture. Since past familiarity was with Xilinx FPGAs and software, a decision was made to purchase a Virtex-5 development board in addition to a ProASIC3 variant. If unexpected results with logic area utilization were to occur, the Virtex-5 series would provide a backup choice for work to continue. For quick logic development and testing, a Spartan-3E series development board was utilized. This development board was USB powered, allowing for portability and rapid testing. Finally, a ProASIC3 development board was purchased, with the same series of FPGA as the final BGA design—to allow for complete logic design testing. The comparison between the various boards is provided in Table 3.

Table 3. Comparison of FPGA development boards used in logic design and testing.

	Board #1	Board #2	Board #3
FPGA Device	Spartan-3E 100	Virtex-5 LX50T	ProASIC3L 1000
FPGA Part No.	XC3S100E	XC5VLX50T	M1A3P1000L
System Gates	100,000	Not Specified	1,000,000
Logic Cells	2,160	50,000	24,576
Total CLBs	240	3,600	N/A
Total Slices	960	7,200	N/A
VersaTiles	N/A	N/A	24,576
Distrib. RAM bits	15,360	491,520	147,456
Block RAM bits	73,728	2,211,840	147,456
Number of Clocks	2	6	6
User I/Os	66	480	300
Differential I/O Pairs	30	240	74
Max. Clock Speed	100 MHz	550 MHz	350 MHz
FPGA Size	16 x 16 mm	35 x 35 mm	23 x 23 mm
Number of Pins	100	1136	484

D. CHAPTER SUMMARY

In Chapter III, the Actel ProASIC3 FPGAs were seen as the best solution to the sequencer application. This is a result of the increased resilience to soft-error effects, reduced secondary hardware required for operation, ease of design, live at power-up operation, and pin-for-pin compatibility between versions. Antifuse FPGAs were discarded as a design choice due to the non-availability of reconfiguration. SRAM and flash-based FPGAs were contrasted with the differences in design considerations realized. Conclusively, flash-based FPGAs seem the most promising choice due to their configuration memory's reduced SEU vulnerability, reduced system complexity, and live-at-power-on capability. The ProASIC3 Test Board will be developed in Chapter IV; follow-on development of the SAD Version 3 – Flight Prototype Board will also occur in Chapter IV.

IV. HARDWARE DEVELOPMENT – PROASIC3 TEST BOARDS AND PRELIMINARY FLIGHT PROTOTYPE

A. PROASIC3 TEST BOARD

Due to the need to obtain test hardware as rapidly as possible, a decision was made to build a set of ProASIC3 test boards prior to the development of a more challenging flight hardware prototype. This would serve two purposes—one, that a ProASIC3 Test Board (PA3TB) would quickly allow for rapid prototyping of logic designs; two, that familiarity would be gained with the hardware development package, Altium Designer 10. The ProASIC3 nano FPGA selected allowed for familiarity with the Actel Libero⁹ SoC software environment while retaining the ability to manufacture the test board in the Small Satellite Laboratory. The goal of the PA3TB design was to minimize the secondary components required and to realize the most basic design that could accomplish the requirements of the sequencer application.

Altium Designer provides a unified product development environment including: front-end design and capture, physical PCB design, FPGA hardware design, FPGA system implementation and debugging, embedded software development, mixed-signal circuit simulation, signal integrity analysis, and PCB layout [73]. The standard development environment can be seen in Figure 17, where schematic, two-dimensional (2-D) PCB layout, and 3-D board placement views are visible on the separate monitors.

Figure 17. Altium Designer interface with separate schematic, 2-D PCB layout, and 3-D component placement views visible on separate monitors (From [73]).

⁹ Libero® is a registered trademark of the Microsemi Corporation.

An added benefit to obtaining the preliminary hardware was experience gained in the manufacture and testing of the design. This allowed for in-house soldering skill to be gained with the smaller surface-mount components as well as the baseline FPGA device. A complete testing of the JTAG interface to be utilized on the flight prototype board was also possible to ensure all design difficulties were worked out prior to scaling up the design.

1. Derived Requirements

There were several derived requirements determined for the ProASIC3 Test Board. The particular requirements utilized for design are as follows:

1. Use of ProASIC3 FPGA with flash-based architecture;
2. Core voltage of 1.2 V_{DC} to reduce power consumption;
3. Specification of I/O bank voltages at core voltage or higher rating;
4. External JTAG (IEEE 1532) interface, compatible with standard hardware programmers;
5. Simulation of CubeSat P-POD deployment via indicators;
6. Expandability, in terms of additional I/O availability and extra interfaces such as USB;
7. Implementing the design in the smallest form-factor available, which implies utilizing surface-mount components.

2. Selection of Board Size and Layer Count

Since the actual ProASIC3 nano FPGA has a relatively small footprint, the PCB size was chosen to minimize the size of the board—allowing associated secondary components the minimum amount of room for layout. This decision allowed for effective resource usage when placing desired components. The overall dimensions of the board chosen are 1.87 inches \times 1.87 inches (3.497 in²). This allows for center placement of the FPGA upon the PCB with secondary components surrounding.

Since the SAD Version 3 Flight Prototype Board (SADv3) will use a BGA with hundreds of pins, the routing difficulties inherent to that technology mandate the use of a multi-layer PCB. To prepare for the evolution to that hardware, it was decided to manufacture the PA3TB using a four-layer design. Although the number of signal and power lines was such that a two-layer board could have been used, the experience gained from the four-layer PCB design will be valuable in the layout of the six to eight-layer SADv3. As is standard, the internal layers consisted of the ground (GND) and positive voltage (V_{CC}) plane. By placing V_{CC} and GND copper polygon-filled areas internal to the PCB, the signal lines for data were visible on the top and bottom planes of the PCB. This allows for more flexibility in the case where signal lines are misrouted due to design-error or manufacturing defects. Additionally, there are capacitive and signal-noise issues that are resolved when designed in this fashion. The overall layer structure of the PA3TB is illustrated in Figure 18. Through-hole vias were used throughout the design for coupling between layers.

Figure 18. Four-layer stack of the ProASIC3 Test Board with internal power planes and external signal layers.

3. Selection of Components

In Chapter III it was decided that the ProASIC3 architecture was the best approach; the decision was made to utilize a comparable FPGA technology without the overhead of BGA manufacturing for test board development. Actel's ProASIC3 nano has the advantages of being a low-cost, single-chip solution utilizing flash-based technology

coupled with a 100-pin Very Thin Quad Flat Package (VQFP). The VQ100 package of the chosen A3PN250 FPGA, which allows for manufacture utilizing a microscope soldering station in the Small Satellite Laboratory, is illustrated in Figure 19. The particular characteristics of the chosen ProASIC3 FPGA are specified in Table 4. Specific schematic decisions, PCB layout and component placement choices, and the physical construction and testing of the PA3TB are fully described in Appendix B.

Figure 19. ProASIC3 nano VQ100 package of VQFP-type (From [74]).

Table 4. Characteristics of ProASIC3 nano FPGA (A3PN250) utilized in development of ProASIC3 Test Board (After [74]).

	PA3 Test Board
FPGA Device	ProASIC3 nano
FPGA Part No.	A3PN250
System Gates	250,000
Logic Cells	2,048
VersaTiles	6,144
Distrib. RAM bits	36,864
Block RAM bits	36,864
Number of Clocks	8
User I/Os	68
Differential I/O Pairs	N/A
Max. Clock Speed	350 MHz
FPGA Size	14 x 14 mm
Number of Pins	100

The full 2-D PCB layout can be seen in Figure 20. Individual electrical and mechanical layouts for the various layers are presented individually in Appendix B.

Figure 20. ProASIC3 Test Board 2-D PCB layout with all component footprints, signal lines, and vias visible.

After the 2-D layout was concluded, the various 3-D Standard for the Exchange of Product Data (STEP) models were imported into the design the check for fit. These components were viewed in a 3-D representation of the integrated PCB design, allowing for any fit issues to be quickly resolved, as illustrated in Figure 21. There were a few cases where vias or traces were moved to better accommodate the physical representation of the PCB. This is an important prototyping tool and saves a great deal of work prior to receiving the initial run of PCBs. The entire layout process took place over the course of approximately six weeks.

Figure 21. ProASIC3 Test Board 3-D isometric view with component models indicating approximate sizing and spacing of integrated board.

Further 3-D views of the top and bottom face of the PCB are available in Appendix B.

B. SAD VERSION 3 – FLIGHT PROTOTYPE BOARD

While work was proceeding with the fault-tolerant logic design, described in Chapter V, modification of the FPGA-based sequencer hardware design occurred in parallel. Concurrent design of the SAD Version 3 – Flight Prototype Board was undertaken to allow sufficient time for logic development and testing, with the anticipated long lead-time in PCB layout for a BGA FPGA. The means of implementing the more extensive BGA form-factor FPGA into a prototype, flight-hardware design is presented in Appendix C. The design of this board is not meant to be all-inclusive of the final general purpose processor design, as some necessary hardware revisions will understandably occur; the overall context of the schematic design along with supporting circuitry is expected to remain relatively constant. There is a desire for a design which can be easily expanded to incorporate future feature requests as necessary for future

missions. Though the sequencer is the first practical application of the general purpose payload processor, future iterations of the design may require extended logic and memory usage. As such, the developed BGA design incorporates several features such as additional SRAM and flash memory, along with general purpose and differentially paired I/Os to support future requests. The board developed is termed SADv3 for the purposes of the sequencer, however, it may be renamed in the future to indicate its general purpose feature set.

As in the previous section, all work done on the design of the SADv3 was accomplished with Altium Designer. A great deal more schematic development was required in the implementation of this more extensive design. Additionally, the added work in PCB layout, when transitioning from a six to eight-layer PCB, was seen to increase almost exponentially. As such, the final design presented in the course of this research will require multi-person design panel review before manufacture—there are simply too many connections and possible failure points to risk production without extensive oversight on the development of the board. To initiate production prior to complete design review would invite an expensive redesign should an error be present.

1. Discussion of Specific FPGA

In the transition to a larger FPGA fabric to incorporate additional logic and I/Os, the need for switching from a VQFP to BGA became readily apparent. In the development of the PA3TB, the largest resource-area FPGA was chosen in the design of that board. Although the quantity of gates in that design are more than suitable for the instantiation of the sequencer logic, any additional features would quickly expand past the resources of the device, especially once TMR is implemented. As discussed in Chapter III, all prototype flight hardware schematic and PCB design work will be accomplished using the Actel ProASIC3EL military-grade component (A3PE600L-FG484M). Drop-in compatibility with the lower-cost, commercial-grade FPGA (A3PE600-FG484) should allow for several prototypes to be manufactured. The FG484 package of the chosen A3PE600L FPGA is illustrated in Figure 22. The particular characteristics of the chosen ProASIC3EL FPGA are specified in Table 5. Again, should

there be a need for the fully rad-hard FPGA in future missions, the RT ProASIC3 (RT3PE600L-CG484B) is compatible with the defense-grade ProASIC3EL (A3PE600L-FG484M).

Figure 22. FG484 BGA package of the Actel ProASIC3L A3PE600L FPGA (From [75]).

Table 5. Characteristics of ProASIC3L BGA (A3PE600L) utilized in development of SAD Version 3 – Flight Prototype Board (After [75]).

	Flight Prototype
FPGA Device	ProASIC3EL
FPGA Part No.	A3PE600L
System Gates	600,000
Logic Cells	4,608
VersaTiles	13,824
Distrib. RAM bits	110,592
Block RAM bits	110,592
Number of Clocks	8
User I/Os	270
Differential I/O Pairs	135
Max. Clock Speed	350 MHz
FPGA Size	23 x 23 mm
Number of Pins	484

In using the BGA FG484 form-factor, the complexity of the design is increased markedly with a corresponding increase in requirements for PCB design. Due to the BGA package, soldering of the PCB is impossible utilizing equipment in the lab; manufacture of the board and placement of surface-mount components for reflow soldering will take place with an outside PCB production company. The design of the PCB necessarily takes into account the required sizing and layer count to properly locate and support the BGA FPGA and all supporting components.

The initial layout of the board shape with FPGA, headers, and prototyping area visible is illustrated in Figure 23. The ribbon-cable connector for attachment to the relay board can be seen toward the top edge of the PCB. As specified previously, the sequencer board is approximately half the width of the relay board (taking up area from the bottom to middle bolt-holes). This design allows for additional area in future revisions if the footprint is modified to be identical to the relay board.

Work continues on the appropriate component placement and wiring of traces. Placement of the power de-coupling capacitors is somewhat problematic with relation to the FPGA footprint; careful selection of appropriate capacitors to place closest to the footprint is imperative for ease of trace laydown. After wiring, extensive design reviews must be accomplished to verify not only the schematic but also the layout of the PCB in 2-D signal trace layers and 3-D component placement and sizing.

Figure 23. Initial 2-D PCB layout of FPGA, three 40-pin I/O headers, prototyping area, and ribbon-cable connector for relay board attachment.

Recent representations of individual electrical and mechanical layouts for the various layers are presented individually in Appendix C. Further 3-D views of the top and bottom face of the PCB are also available in Appendix C.

2. Additional Modifications Considered

Since the board developed is the first initial prototype of the eventual flight sequencer, there are some features included for bench testing which can be removed in the final representation of the design. For this design a +5 V_{DC} connector was utilized to provide V_{IN} to the LDO voltage regulators for conversion to the appropriate voltages. Since the relay board will be receiving a +28 V_{DC} supply from the host spacecraft bus, there will be a way to incorporate this conversion on the relay or sequencer board itself. As such, the +5 V_{DC} connector can be removed from the final flight design with the +5V net replacing the V_{IN} net. The SRAM and flash-memory can be left off the footprint since they are not required in the sequencer design and can be installed as necessary for future missions.

Additional modifications to the design include possible future incorporation of two-way telemetry concerning board and CubeSat status back to the host spacecraft, a video camera feed of CubeSat deployments with data saved in memory, smart charging and maintenance of CubeSats within NPSCuL prior to launch, and experimental payloads for testing of logic in a general payload processor design. One of the desired short-term features is the inclusion of an Ethernet port and standard for testing in radiation environments. Data provided over this port could be used in data logging the radiation upsets and recoveries during testing events.

C. CHAPTER SUMMARY

The reasons for the development of the ProASIC3 Test Board prior to design of the SAD Version 3 – Flight Prototype Board were discussed in this chapter. Development of the PA3TB was accomplished using Altium Designer 10 for the schematic and layout portions of board design. The design was implemented with a set of derived requirements to enable the rapid production of a hardware product; the PA3TB serves as a model for evolution to a more complex PCB. Minimization of PCB area and secondary components

were important in troubleshooting the device when problems were discovered. Other design decisions are presented concerning the manner in which they drove PCB component selection.

In addition, the design modifications for the SAD Version 3 – Flight Prototype Board were also discussed in this chapter. Again, development of the SADv3 was accomplished using Altium Designer for the schematic and layout portions of board design. The work in this chapter on the SAD Version 3 – Flight Prototype Board continues with all of the circuitry having been schematically represented. Component placement and trace layout for the support devices on the board is still on-going. Specific considerations for future board development and expansion were provided.

V. COMPARISON OF FAULT-TOLERANCE METHODS FOR USE IN SEQUENCER LOGIC DEVELOPMENT

A. TMR VERSUS OTHER FAULT TOLERANT APPROACHES

For this portion of the thesis, the Xilinx Spartan-3E development board was used to simulate logic designs. The specifics of the FPGA utilized are listed in Chapter IV, Table 2. This device allowed for the utilization of the Xilinx ISE 14.3 WebPACK toolset so that all logic constructs could be created schematically and in VHDL or Verilog. A 16×16-bit array multiplier was constructed to test for the proper operation of the device using different redundancy techniques. All designs were carried through the synthesis, map, and place and route phases to ensure accurate timing information was obtained in the simulation. Additionally, the Xilinx techniques were manipulated to program Microsemi ProASIC3 devices. These altered designs will be incorporated into the final sequencer logic using Microsemi Libero SoC 10.1. In Chapter III, a decision was made to use the Actel products due to hardware concerns of the SRAM-based Xilinx technology versus the flash-based FPGA technology.

1. Maintaining Logic Structures within HDL Languages (Verilog / VHDL and Schematically)

To test for proper operation and characteristics of the Xilinx ISE 14.3 software, it was first necessary to create a test circuit which could be successfully duplicated and verified. This was accomplished via a combination of synthesis and simulation with follow-on hardware testing. The design chosen for the test consisted of a simple seven-segment LED counter. This design is a state-machine counter with sixteen states (0 through F) with the added functionality of push button and switch status. The counter design is implemented in VHDL with the overall clocking setup and top-level design applied in a modular fashion. As illustrated in Figure 24, the design was implemented on a Digilent, Inc. BASYS2 development board. This board incorporates the Xilinx Spartan-3E 100. Code for this state-machine counter is in Appendix D.

Figure 24. Digilent BASYS2 development board counting with proper state logic.

a. Baseline Design – Seven-Segment LED Counter Example

The resource utilization for the baseline LED counter design was found to use 19 of 960 available slices (2%) with a corresponding 1% utilization of FFs and 1% use of LUTs. As depicted in Figure 25, the overall gate layout of the design in a technology schematic is visible for the unaltered design. This provided a good baseline for comparison once modification to the design evolved.

Figure 25. Default gate layout for baseline seven-segment LED counter.

b. Triplicated Design – Seven-Segment LED Counter Example

Upon initial synthesis, there were some issues with ISE overly trimming the redundant logic from the design. This manifested itself in the removal of two of the three triplicated counter circuits and the voter circuit being marked as unnecessary in some cases. To alleviate these issues, ‘Resource Sharing’ in HDL Options and ‘Equivalent Register Removal’ in Xilinx Specific Options must be disabled in the Synthesis – XST ‘Process Properties.’ This alone was insufficient to prevent logic trimming of desired redundant circuits, so the following lines were added to the VHDL code:

```
attribute equivalent_register_removal: string;  
attribute equivalent_register_removal of signal : signal is "no";
```

The preceding lines must be added to the architecture structures within the logic that is being trimmed after the signal names are defined.

For the operational test, the design was altered such that the top-level depiction occurs schematically, as seen in Figure 26. This was done by instantiating the seven-segment LED counter into its own schematic symbol. All signal lines were placed manually in the same fashion that they occurred in their VHDL depiction. The counter was triplicated, and a voter circuit was added at the output to test for proper operation and recombination of the signals.

This produced the proper, anticipated results as illustrated in Figure 27. The logic of the unaltered design can clearly be seen as triplicated in the technology schematic view of the gate structure. The resource utilization for the triplicated design was found to use 61 of 960 available slices (~6%) with a corresponding 4% utilization of FFs and 5% use of LUTs.

In the FPGA layout view, Figure 28, one of the three counters is highlighted in red with the triplicated counters occurring in the upper portion of the graphic. Since this occurs after the place and route phase, one can confidently say that the logic trimming of the redundant circuits has been prevented. This is an important step before continuing with the implementation of different fault-tolerant techniques.

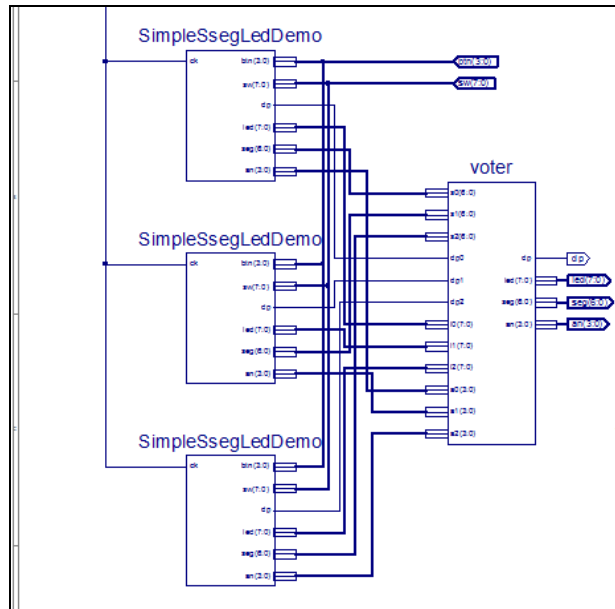

Figure 26. Triplicated seven-segment LED counter example with voting logic.

Figure 27. Triplicated gate layout with voting logic - seven-segment LED counter.

When testing onboard the physical device, the functionality of the development board was seen to be identical in the triplicated logic case to the non-fault-tolerant design. The FPGA continued to count in the proper state sequence with all push button and switch controls working as before. Finally, the design was altered to enable improper operation of one of the counters by reordering the states within that counter. This resulted in the mismatch of the output vectors between that counter and the other two, properly functioning counters. The voter was seen to work properly, as no discrepancies were noted in the operation of the development board FPGA.

Figure 28. FPGA layout view illustrating placement of three counter structures.

2. Implementation of Various Redundant Techniques in Combinational Logic Designs

a. Baseline Design – 16×16-bit Array Multiplier

The design chosen for further testing of fault-tolerance is a 16×16-bit array multiplier which has been implemented in a tree structure consisting of 4×4-bit array multiplier subsections. The output of the array multiplier is a 32-bit unsigned integer value which correctly represents the product of the two input vectors. The 4×4-bit array multipliers are carry-save-adder versions with 7-bit sum and 5-bit carry output vectors. They are combined in the following fashion to generate proper multiplication:

$$\begin{aligned}
 P = A \times B &= \left(\sum_{k=0}^3 a_k 4^k \right) \times \left(\sum_{l=0}^3 b_l 4^l \right) = \sum_{k=0}^3 \left[a_k 4^k \left(\sum_{l=0}^3 b_l 4^l \right) \right] \\
 &= 4^6 (a_3 \times b_3) + 4^5 [(a_3 \times b_2) + (a_2 \times b_2)] + 4^4 [(a_3 \times b_1) + (a_2 \times b_2) + (a_1 \times b_3)] \\
 &\quad + 4^3 [(a_3 \times b_0) + (a_2 \times b_1) + (a_1 \times b_2) + (a_0 \times b_3)] \\
 &\quad + 4^2 [(a_2 \times b_0) + (a_1 \times b_1) + (a_0 \times b_2)] + 4^1 [(a_1 \times b_0) + (a_0 \times b_1)] + 4^0 (a_0 \times b_0)
 \end{aligned} \quad (1)$$

As illustrated in Figure 29, the 4×4-bit array multipliers are internally wired with a combination of 4-bit partial product generators and full adders configured to give the proper sum and carry output vectors. These adders were initially configured in the logic structure seen in Figure 30. Each of these full adder blocks were replaced in subsequent iterations to yield proper comparison with this baseline design.

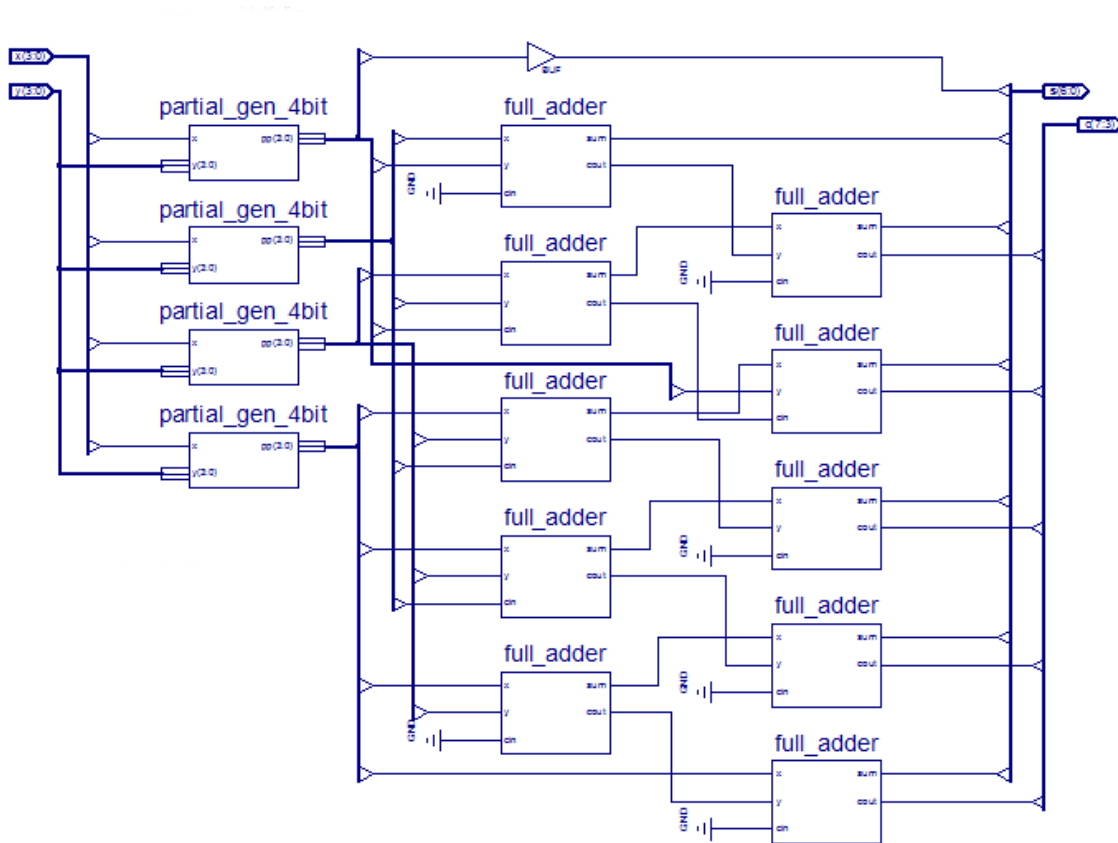

Figure 29. 4×4-bit array multiplier internal structure using partial product generators and full adders.

The 4×4-bit multiplier modules are combined with carry-save adders and ripple-carry adders to form the 16×16-bit multiplier in the top-level structure of the design. Specifics of the code and the overall top-level block diagram of the default 16×16-bit array multiplier structure are presented in Appendix D. This design is modified

slightly in the specific fault-tolerant schemes tested throughout the remainder of this chapter.

Figure 30. Full adder gate structure for the 16×16-bit array multiplier, baseline design.

The resource utilization of the FPGA after layout is seen in Figure 31. It is important to note that the layout of the FPGA can be manually edited at this stage.

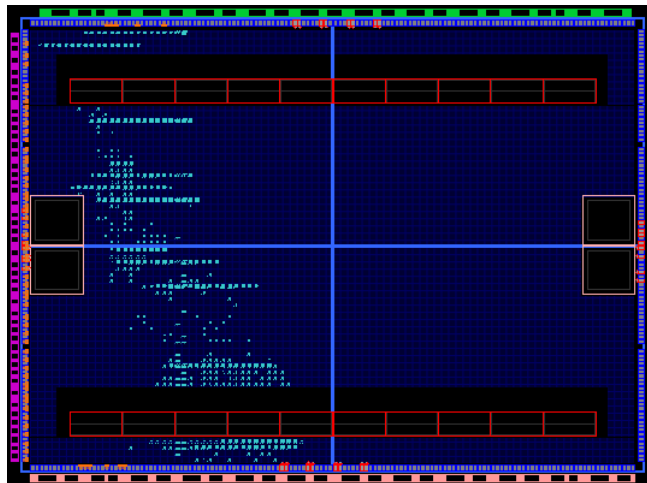

Figure 31. FPGA physical layout of default 16×16-bit array multiplier logic.

b. Triple Modular Redundancy (TMR)

The next iteration of design involved the implementation of the 16×16-bit array multiplier in TMR format. As illustrated in Figure 32, the design was modified in a similar fashion as that accomplished in the previous seven-segment LED counter example, with all Verilog code instantiated as schematic symbols. These were wired together with a voter on the output for a majority voting scheme of the output vectors.

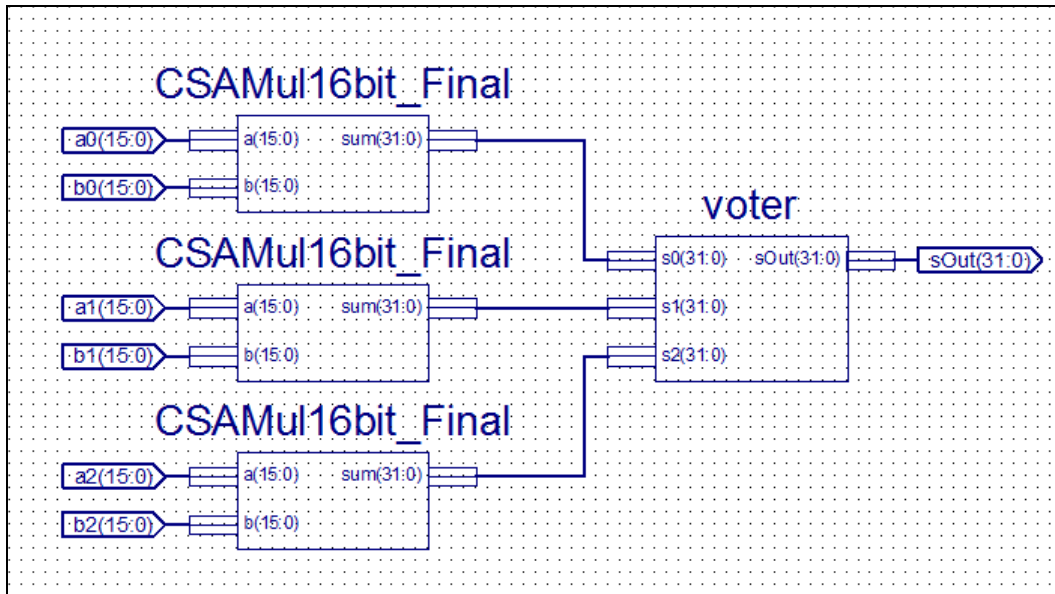

Figure 32. 16×16-bit array multiplier implemented in TMR with voting logic.

Again, with Verilog, some modification to the code is necessary to prevent trimming of logic that is desired for fault-tolerant purposes. In the case of Verilog, the code addition necessary is:

```
(* equivalent_register_removal = "NO" *)
```

This line must be placed immediately before the module declaration line in the Verilog file of each part of the design one does not want trimmed. In doing so, the FPGA layout of the device was seen to vary greatly from the unaltered case, as seen in Figure 33.

The input vectors for this design were left as three separate pairs, which allowed a differing input product to be injected into one of the array multiplier blocks.

This allowed for quick testing of the voting logic and overall multiplication when analyzed through simulation. In all cases, the proper simulation results were obtained and those of the mismatched multiplication discarded by the voting scheme. This initial simulation run was important in later fault-tolerance schemes to determine proper operation of the overall circuit.

Figure 33. FPGA physical layout of 16×16-bit array multiplier using TMR logic.

c. *Quadded Logic*

To implement the quadded logic form of the 4×4-bit array multiplier, a NAND implementation of a half adder was constructed, as seen in Figure 34. This provided a good baseline for comparison and simulation to the quadded logic implementation; the half adder circuits were completely tested and simulated prior to being implemented in full adder combinations. To properly construct the OR gate for recombination of the carry output lines, a quadded NAND gate was also designed, as depicted in Figure 35.

Once the NAND configuration of the half adder and quadded format were determined, modifications to the half adder to generate a quadded logic implementation were made. This can be seen in Figure 36. Again, this half adder was fully tested and compared to the non-quadded logic format before insertion into full adder structures. Once the quadded logic full adder was complete, the structure was substituted in for the

full adder blocks in the overall 4×4-bit array multiplier schematic. The follow-on recombination into the appropriate 16×16-bit array multiplier structure then took place.

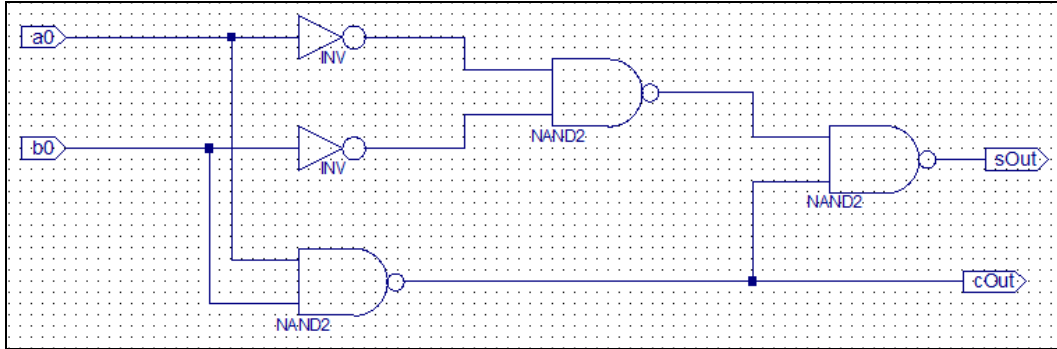

Figure 34. Baseline NAND implementation of half adder.

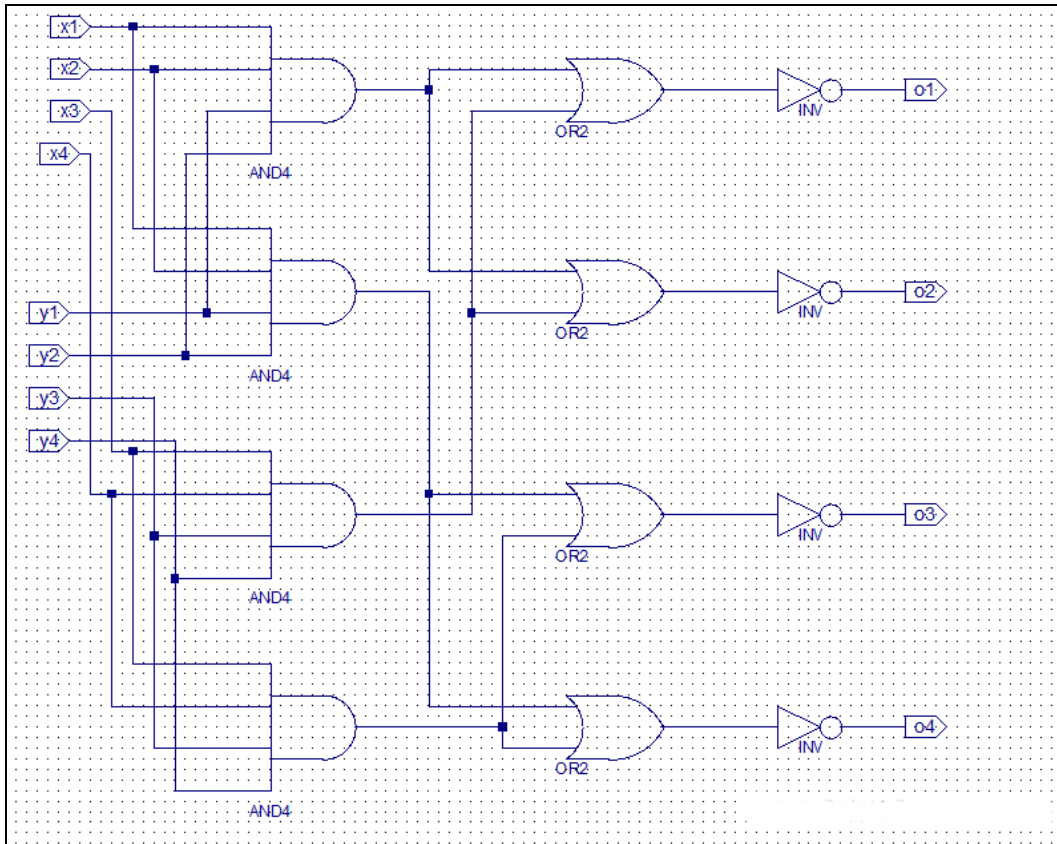

Figure 35. Quadded logic version of NAND gate.

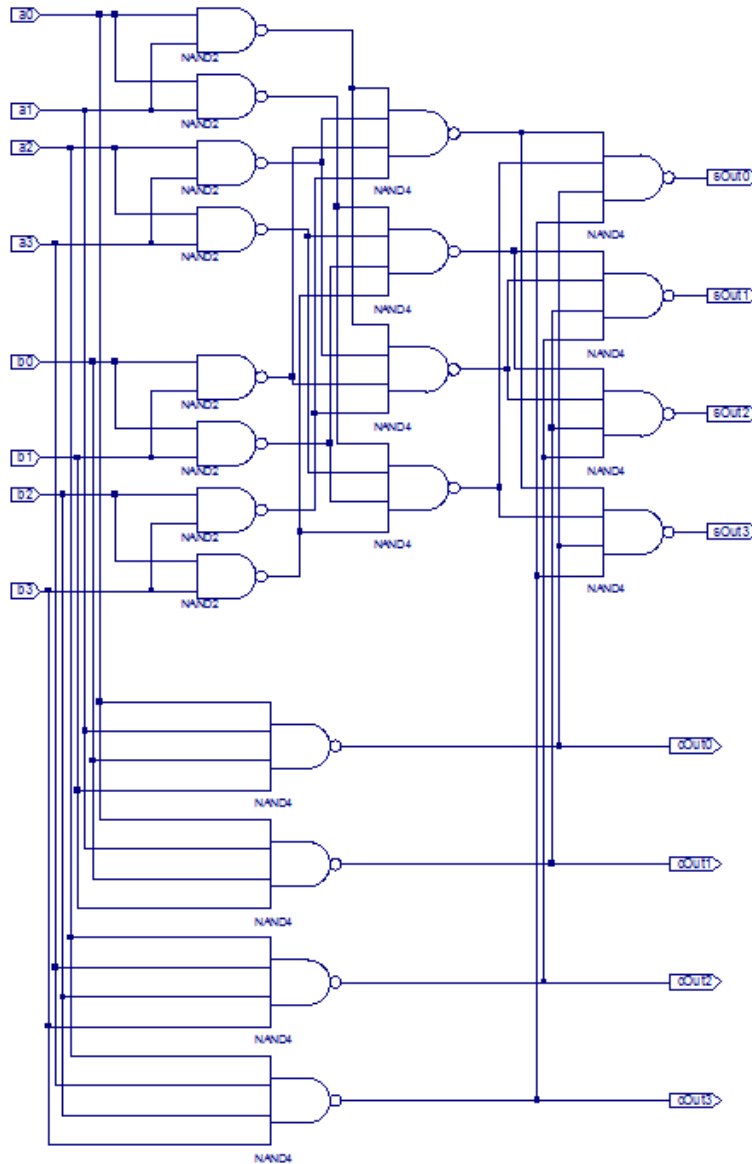

Figure 36. Quadded logic version of half adder.

As in the previous test cases, full simulation of the design was accomplished to account for proper outputs from the multiplier circuit. In all cases, the output product vectors were seen to match the baseline design. Further testing to alter the internal structure of the quadded logic half adders took place (i.e., tying certain gates to high or low logic values) to simulate internal errors. The quadded logic was seen to overcome these errors in all single and certain multiple upset cases. The outputs from the overall quadded logic circuit were identical to the non-error case.

It was particularly interesting to note the large amount of FPGA resources utilized in the layout view, as illustrated in Figure 37. This overhead is completely due to the quadded logic implementation of the full adders and should be approximately four times the resources as in the baseline 16×16 -bit array multiplier.

Figure 37. FPGA physical layout of 16×16 -bit array multiplier using quadded logic.

d. Triplicated Interwoven Redundancy (TIR)

In the construction of the triplicated interwoven redundancy (TIR) case, the half adders within the 4×4 -bit array multiplier tree were replaced with the TIR half adder design, as depicted in Figure 38. These half adders were combined into a full adder configuration with the signal lines recombined with a voter on the output. This allowed for a quick insertion into the 4×4 -bit array multiplier tree, as previously indicated. The 4×4 -bit array multipliers were again recombined into the overall 16×16 -bit array multiplier tree structure to obtain the desired circuit.

Simulation was accomplished to verify the design against the unaltered multiplier configuration; simulation results were identical in both cases. The resource utilization of TIR in FPGA physical layout is illustrated in Figure 39.

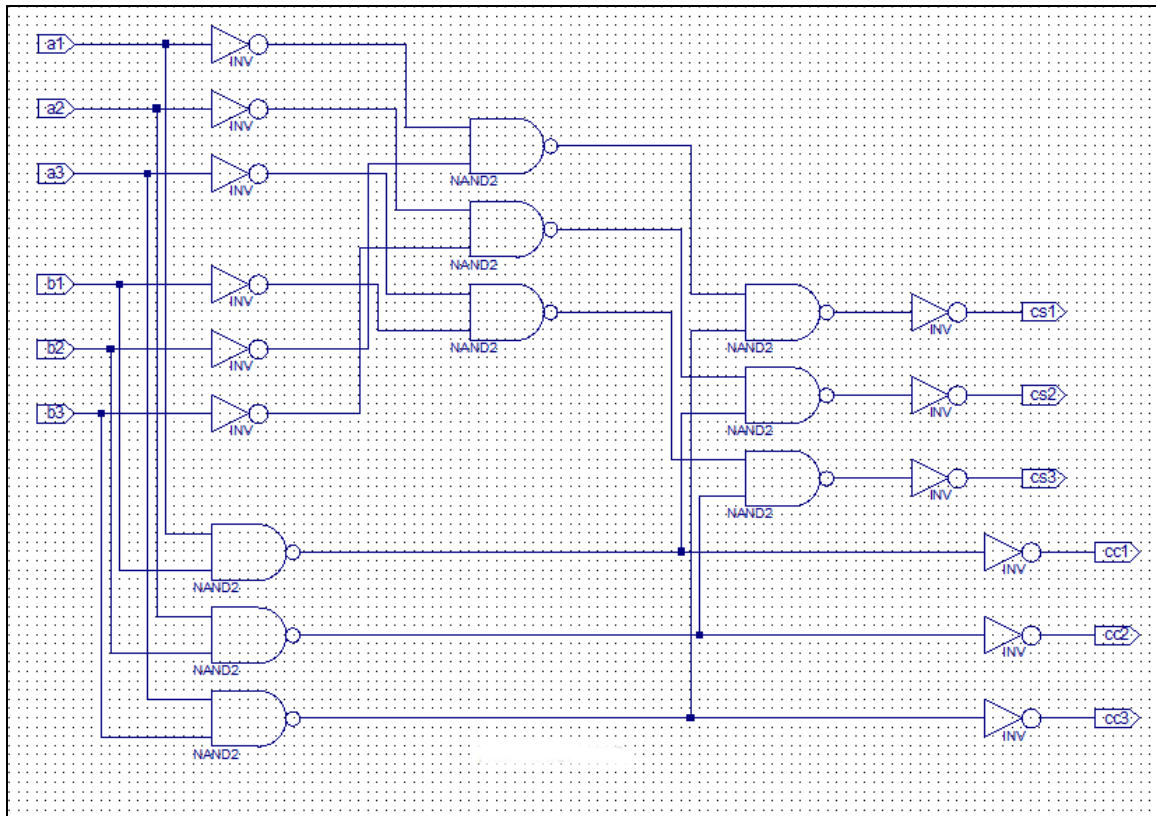

Figure 38. TIR logic version of half adder.

Figure 39. FPGA physical layout of 16x16-bit array multiplier using TIR logic.

e. Stacked Techniques – Quad-TMR & TIR-TMR

Since there was additional logic area on the FPGA for synthesis, a decision was made to attempt stacked fault-tolerant techniques to determine the limits of logic capacity and speed. This is similar to the manner in which encryption algorithms are stacked upon one another to increase the security of the encrypted electronic data. By stacking the fault-tolerant techniques, one should produce a more stable circuit in the event of multiple bit upsets or cascaded faults.

In the first case, the attempt to place the quadded logic implementation of the 16×16-bit array multiplier into TMR layout failed due to the physical constraints of the target FPGA. The overall resource utilization was such that ‘OVERMAPPED’ errors occurred in the map / place and route phases of the implementation. This was due to the volume limitations of the selected Spartan 3E FPGA device. The simulation of the device could still be accomplished and the results matched those of previous runs, indicating that both the multipliers and voter scheme were functioning properly.

Figure 40. FPGA physical layout of 16×16-bit array multiplier using stacked TIR-TMR logic.

Finally, the TIR implementation of the multiplier was stacked upon the TMR layout for the final synthesis and implementation run. The FPGA physical layout

for this combinational technique is illustrated in Figure 40. Again, the simulation runs of the design indicated all circuits were functioning properly and as anticipated.

When utilizing these stacked fault-tolerant methods, it is difficult to predict the amount of logic resources that will fit in an FPGA's logic matrix. This is mostly due to the manner in which the software toolsets attempt to auto-optimize logic by combining and trimming for either speed or resource area utilization. Should one desire to target a design with these techniques, care must be taken to account for sufficient logic resources once the stacked fault-tolerant methods are employed.

3. Data Results and Analysis

The results of all six methods of fault-tolerance implementation were compared to obtain both FPGA resource utilization and timing information. The post-place and route (P&R) timing analysis consisted of a worst-case path measurement. The resources looked at consisted of the 4-input LUTs, number of occupied slices, number of logic LUTs, number of route-thru LUTs, and the average fan-out of the circuits. The results of both of these comparisons are presented in Tables 6 and 7, respectively.

Table 6. FPGA worst-case path timing for various fault-tolerant designs.

	Worst-Case Path [ns]
<i>Default</i>	38.54
<i>TIR</i>	42.15
<i>TMR</i>	38.71
<i>Quadded</i>	53.37
<i>TIR-TMR</i>	45.52
<i>Quad-TMR</i>	Fail to Map / P&R

Table 7. FPGA resource utilization for various fault-tolerant design methods.

	4-Input LUTs	Occupied Slices	# of Logic LUTs	# of Route-Thru LUTs	Avg. Fanout
<i>Default</i>	762 of 9,312 (8%)	389 of 4,656 (8%)	643	119	2.15
<i>TIR</i>	1,836 of 9,312 (19%)	949 of 4,656 (20%)	1,717	119	2.94
<i>TMR</i>	2,318 of 9,312 (24%)	1,196 of 4,656 (25%)	1,961	357	2.14
<i>Quadded</i>	4,445 of 9,312 (47%)	2,614 of 4,656 (56%)	4,325	120	3.29
<i>TIR-TMR</i>	5,540 of 9,312 (59%)	2,828 of 4,656 (60%)	5,183	357	2.93
<i>Quad-TMR</i>	13,361 of 9,312 (143%)	6,688 of 4,656 (143%)	13,001	360	3.28

These results are also presented graphically in Figures 41 and 42. The failed case for timing in the Quad-TMR scenarios was due to the aforementioned failure to map / place and route the design into the Spartan-3E FPGA. A retargeting of the design to a Xilinx Virtex 4/5 series was met with success; however, the resource utilization for this type of device was still high.

Figure 41. Timing analysis for worst-case paths in various fault-tolerant implementations.

Figure 42. FPGA LUT and slice resource utilization in fault-tolerant implementations.

4. Discussion of Results

In looking closer at the timing analysis, it was interesting to note the variance in the TIR versus TMR design. Though both are similar (TIR being a version of modified TMR), the default and worst-case path timings were less in the TMR case. This extra 3.5 to 16.1 ns difference may not impact the design of a simple 16×16-bit array multiplier but could have greater implications in a more complex circuit or sequential logic. Likewise, the quadded logic and stacked fault-tolerant techniques were seen to have an even greater increase in timing delays. Again, these would have to be weighed carefully, dependent upon timing criticality and SEU tolerance benefit of the various techniques.

Similarly, the results of the FPGA resource utilization indicate that the TIR case, while having the increased timing requirements, uses less logic than the TMR case. The TMR case is fairly close to the TIR case—and has the added benefit of timing being fairly close to the baseline 16×16-bit array multiplier circuit. In the quadded logic case, the FPGA utilization was actually seen to consume more than the anticipated four times the amount of resources. This is likely due to the types of gates and LUTs necessary to synthesize this type of design. This is important to note, in that the extra work of wiring the quadded logic implementation of gates may not lead to the anticipated logic utilization. This, in combination with the markedly increased timing path delays, would preclude any but the simplest logic designs. One suspects that there would be added difficulties and overhead when incorporating quadded logic into sequential machines.

If the FPGA device family has sufficient resources, a better approach may be to choose the TIR-TMR stacked fault-tolerant technique. Both the path timing delay and resource utilization are similar to the quadded logic implementation. Any fault-tolerant benefits of stacked techniques would have to be compared to existing, baseline techniques both through fault injection simulations and in the presence of a radiation environment. Synthesis and implementation of the design through the map / place and route phases would be necessary before conclusively knowing the required FPGA resources; however, the construction of this design is greatly simplified when compared to quadded logic. Since the stacked techniques can be implemented without much

difficulty, future testing for possible benefits of stacked fault-tolerant schemes may be accomplished in a cyclotron.

Due to the path timing and FPGA resource utilization results, the best approach appears to be the complete TMR implementation of a design. This has almost exactly three times the required logic use plus the addition of the voting scheme. The timing being so similar to the non-modified case should yield excellent results in both combinational and sequential circuits. Future research should look more into the varying TMR techniques such as distributed versus global approaches. The different methods of clocking should produce varied results when used with sequentially clocked circuits. These methods should be combined with partial reconfiguration techniques, if necessary, to yield an optimal design for a particular scenario.

Additional work needs to be done in the realm of QFDR as it compares to quadded logic. Past research has shown some benefit to the application of this technique both with regards to timing and resource utilization. An open-source toolset known as RapidSmith exists to assist with this implementation. This should be a useful toolset—however, knowledge of Eclipse Java IDE and the interfaces between it and Xilinx ISE are necessary.

B. SELECTION OF A FAULT-TOLERANT TECHNIQUE

As a result of this study, the design of the sequencer being developed for NPSCuL will utilize Actel ProASIC3 flash-based FPGA logic in a TMR configuration. The sequential finite-state machines to control the timing and execution of deployments should benefit most from the decrease in path timing results and reduced logic utilization relative to other fault-tolerant techniques. Future work will analyze probabilities of failures, both in simulation and physically, in a radiation-exposed environment. Special attention needs to be given to the overall reliability measurements of the various fault-tolerant techniques, with particular emphasis placed on TMR versus quadded logic and the benefits of stacked combinational techniques.

One benefit to selection of the TMR technique in obtaining practical designs is the amount of commercial software available for implementation of these methods in

logic. While testing the TMR instantiations of redundant logic on combinatorial circuits, all designs were manually wired together in schematic form to achieve the results mentioned. One would desire to have these methods automatically inserted into a baseline design for quick implementation and comparison to manually developed methods. As such, a quick comparison of commercial products to manual TMR development is appropriate.

1. Xilinx TMRTTool and Mentor Graphics Precision Hi-Rel

Two of the commercially available, fault-tolerant synthesis products available for the design of TMR logic are Xilinx TMRTTool and Mentor Graphics Precision¹⁰ Hi-Rel. The purpose of both these products is similar; an increase in designer productivity by reducing errors and speeding the time for TMR implementation. The main difference between the two tools is the family of products the software is intended for. TMRTTool is only targeted toward Xilinx FPGAs; although, it works with all entry methods including schematics and HDLs [49]. Precision Hi-Rel, however, is a multi-vendor, multi-mode product [50]. While TMRTTool is listed as an ITAR-controlled product [49], Precision Hi-Rel does not appear to have similar restrictions. Since the design of sequencer logic is taking place upon Actel ProASIC3 hardware, Precision Hi-Rel is the most suited application for further use.

Precision Hi-Rel offers fault recovery and fault-tolerant FSM encoding through a variety of features. This FPGA synthesis product was developed under NASA guidance. Precision Hi-Rel provides an enhanced form of safe FSM that offers full SEU detection and recovery [50]. The generated FSM, when it detects an invalid transition, must still go through a recovery process including an operational reset that may consume one or more clock cycles. Thus, Precision Hi-Rel also includes fault-tolerant FSM implementations which can absorb an SEU and continue operation without interruption [50]. Precision Hi-Rel also allows for selection of LTMR, DTMR, and GTMR methods and handles all embedded resources.

¹⁰ Precision® is a registered trademark of Mentor Graphics.

The Precision Hi-Rel synthesis tool is not included as part of Microsemi's Libero SoC package. Instead, the default synthesis tool provided with Libero SoC is Synplify Pro. Synplify Pro does not have any of the added TMR capabilities of Precision Hi-Rel. Application of Precision Hi-Rel to the sequencer project will require a separate software license, as an academic or trial version is not available for educational institutions. The author recommends that future design work on the sequencer incorporate the use of this software package, as it would allow for testing and comparison with the manually inserted TMR methods. The ability to quickly switch to LTMR, DTMR, and GTMR modes in logic would be greatly beneficial when testing the final design in a radiation environment. Additionally, it will allow for ease of migration of more complex logic designs to TMR instantiations once expanded features are added to the sequencer.

2. Manual Insertion of TMR with Schematic and HDL Techniques

Due to the lack of available commercial software during the performance of this research, all designs were implemented manually using the LTMR methodology. In this method, all logic elements were triplicated with error correction performed by one voter on the output path. Certain features of DTMR were carried forward into the sequential logic development, such as feedback path voting being triplicated and tied to all triplicated structures. The clock input to the sequential logic and single voter output can still be seen as limiting factors in the application of this technique to the final sequencer logic design. It would be greatly beneficial to obtain the benefits of full DTMR with the triplicated clock signals of GTMR in the final representation of this sequencer logic.

C. APPLICATION OF TMR TO SEQUENTIAL LOGIC DESIGNS

After deciding upon TMR as the appropriate fault tolerance method, based on the experimental results in the combinational logic testing earlier in this chapter, the TMR technique was implemented in sequential logic. Many of the means of constructing TMR sequential logic were very similar to that utilized previously. All logic elements within the FSM design were triplicated with a voting scheme on the output. There was one important difference due to the addition of logic to the feedback paths within the FSMs. The FSM chosen for triplication was a clocked synchronous state machine of Moore

design, similar to that found in [76]. This allows for a predictable state transition with plenty of points to test circuit output or allow for fault injection in testing. The schematic representation of the FSM under test is illustrated in Figure 43.

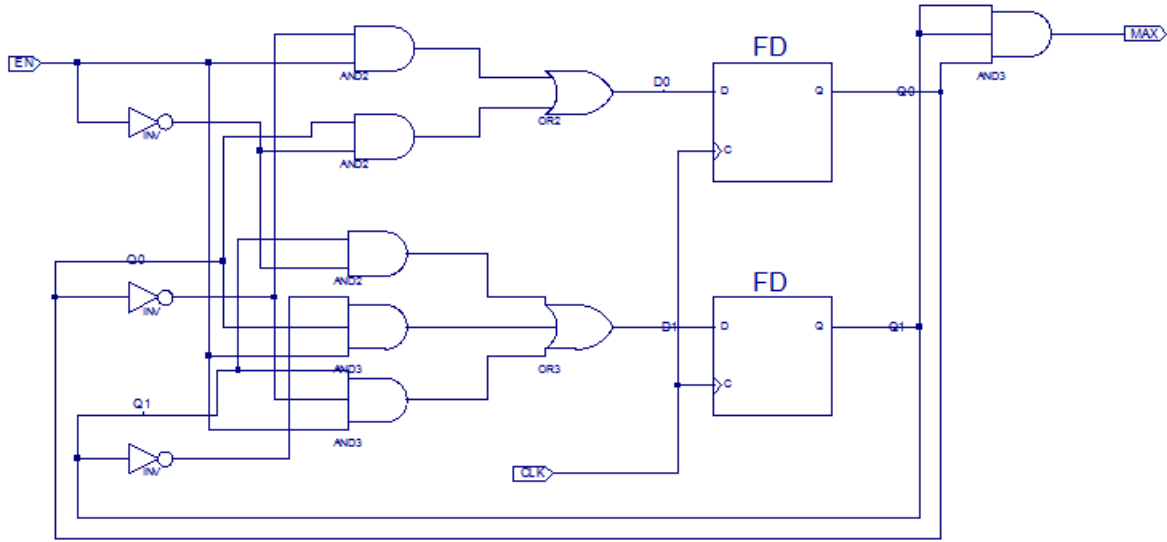

Figure 43. Moore design, clocked synchronous state machine utilizing positive-edge triggered D flip-flops (After [76]).

The resultant output of the post-place and routed design was run through a simulation utilizing a testbench file. The code for the testbench can be found in Appendix D. The resultant timing diagram is illustrated in Figure 44. The top lines of the timing diagram corresponds to the output of the FSM (MAX), with the clock signal (CLK) and enable (EN) signal lines following. The next four signal lines of the timing diagram (highlighted in blue) are the inputs and outputs of each of the two D-FFs – D0, D1, Q0, and Q1. The output of the circuit is seen to go high whenever Q0 and Q1 are high, corresponding to D0 and D1 falling on the positive-edge of the clock signal. The fault-free case of this timing diagram output appears as anticipated with the state transitions expected.

Figure 44. Timing diagram for the Moore-type FSM developed with output, clock, enable and D-FF input/output signals visible (fault-free case).

After sequential behavior for the fault-free case of the FSM was obtained through simulation, a decision was made to implement fault cases for comparison in the non-TMR circuit.

1. Manual Insertion of Faults

For the initial testing on logic timing results due to error cases, there were three trials done to determine effects of error: floating-input, ‘stuck-at-0,’ and ‘stuck-at-1.’ These were inserted into the circuit on the second input of the second AND gate tied to the top OR gate. This would lead to an error in D0, dependent upon the combination of fault with the other passed logic values.

a. Floating-Input Case

For the floating-input case to the AND gate, the second input line was disconnected with no attachments, as illustrated in Figure 45. Breaks in the circuit similar to this case commonly result in non-valid logic values in the output represented by ‘x’ and a red floating line in timing diagrams.

Figure 45. Floating-input case of AND gate second input disconnected, simulating break in circuit or disruption in input.

The resultant timing diagram for the floating-input case is seen in Figure 46. As anticipated, the logic values for both the overall circuit output and the intermediate D-FF inputs and outputs are inconclusive logic values. This floating break in the circuit leads to complete break-down of the overall FSM with inconclusive data returned. A disabling error such as this in the non-TMR case could produce erroneous or no output.

Figure 46. Timing diagram for the Moore-type FSM developed with output, clock, enable and D-FF input/output signals visible (floating-input case).

b. 'Stuck-at-0' Logic Fault

For the constant logic '0' or 'stuck-at-0' case to the AND gate, the second input line was pulled down with a biasing resistor tied to ground, as illustrated in Figure 47. This simulates a constant value of binary zero to the second input of the AND gate, leading to incorrect output to the OR gate in certain cases.

Figure 47. Second input of AND gate tied to logic '0', simulating constant logic zero or short in circuit to ground plane.

The resultant timing diagram for the 'stuck-at-0' case is seen in Figure 48. There are some noticeable differences in this timing diagram in comparison to the fault-free case in Figure 44. While the output (MAX) appears to go high in the expected manner, a closer look at D0 and Q0 reveal the error injection as they do not always go

high where anticipated. As such, the output does not remain high over the last 150 ns as in the fault-free case. An error such as this in the circuit, where a line is shorted to ground by an SEL, could lead to erroneous output timing for the sequencer. This could lead to individual CubeSats being deployed at the inappropriate time or missed deployments altogether.

Figure 48. Timing diagram for the Moore-type FSM developed with output, clock, enable and D-FF input/output signals visible (constant logic '0' case).

c. 'Stuck-at-1' Logic Fault

For the constant logic '1' or stuck-at-1 case to the AND gate, the second input line was pulled up with a biasing resistor tied to V_{CC} , as illustrated in Figure 49. This simulates a constant value of binary one to the second input of the AND gate, leading to incorrect output to the OR gate in certain cases.

Figure 49. Second input of AND gate tied to logic '1', simulating constant logic one or short in circuit to positive voltage plane.

The resultant timing diagram for the 'stuck-at-1' case is seen in Figure 50. Again, there are some noticeable differences in this timing diagram in comparison to the fault-free case in Figure 44. The output (MAX) appears to go high in many unexpected

places as the incorrect value is passed forward by the AND gate through to D0 and Q0. D0 and Q0 get stuck at a logic high value which creates oscillations in the output state of the circuit. These outputs eventually affect D1 and Q1, as Q0 is tied to the second OR gate tree via a feedback path. This will most assuredly lead to individual CubeSats being deployed at the inappropriate time and a complete loss of sequencer function. An SEL of a signal line creating this type of condition is a catastrophic event.

Figure 50. Timing diagram for the Moore-type FSM developed with output, clock, enable and D-FF input/output signals visible (constant logic '1' case).

2. Modification of FSM Design to TMR Representation

Once the methods of fault injection were developed and fully tested for the non-TMR FSM implementation, work was done to develop the design to a TMR instantiation. This was done by voting on the output path, similar to the combinational logic methods utilized earlier. In addition, voters were added to the feedback paths to each FSM in the triplicated logic. This negated any errors generated in propagating back to the next state. The triplicated version of the Moore-type FSM is illustrated in Figure 51.

Initial testing of the TMR FSM yielded results identical to the non-TMR version of the circuit, as seen in the timing diagram of Figure 52. This verified the proper operation of the modified circuit with exact timing sequences matching the non-TMR case. To properly test for the fault cases, scenarios were run using each of the three manual, fault-injection test cases as previously specified. For the constant logic '0' and constant logic '1' cases, the output was seen to correct itself regardless of the intermediate states of D0, Q0, D1, and Q1. The more interesting of these cases, constant logic '1', which yielded so many timing errors in the non-TMR instantiation, is illustrated in Figure 52.

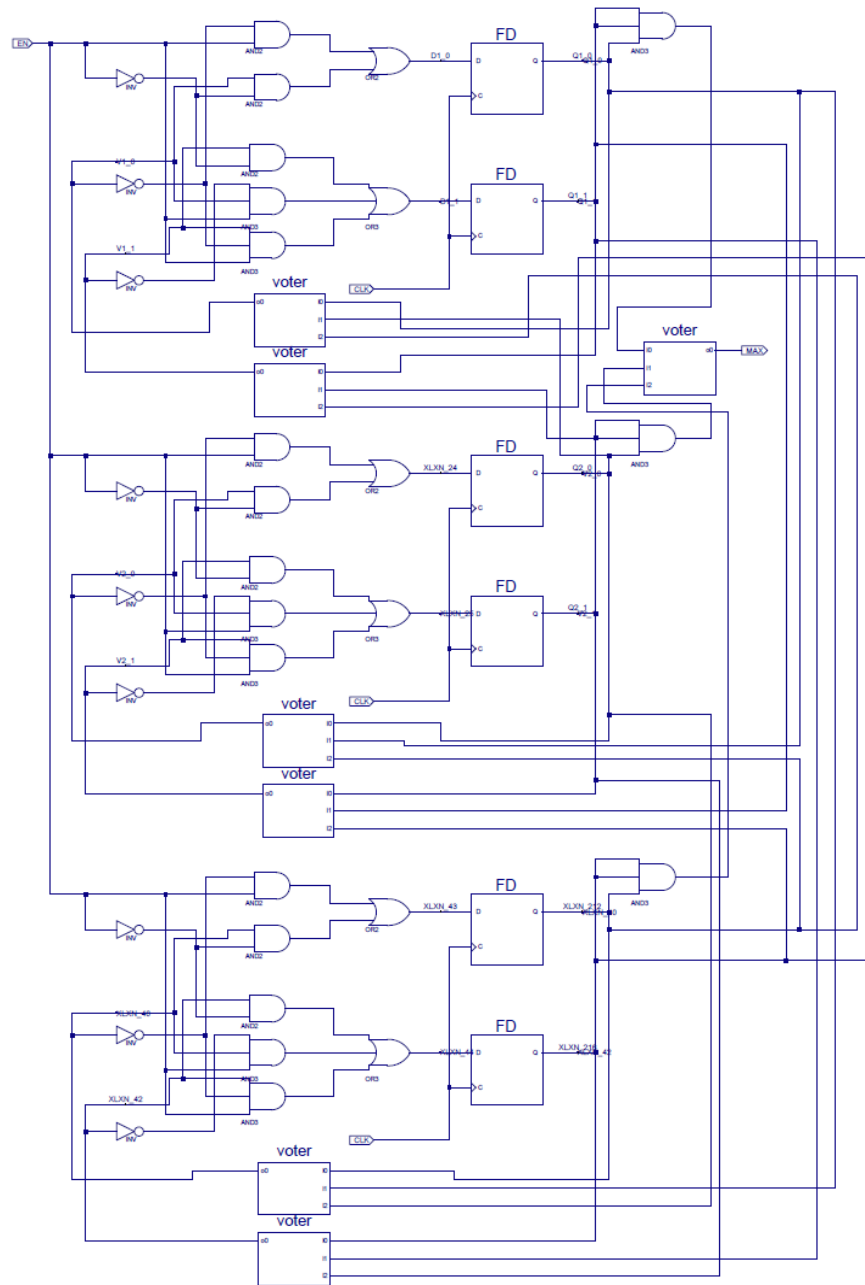

Figure 51. TMR representation of the Moore-type FSM with voting logic.

Figure 52. Timing diagram for the Moore-type, TMR version of the FSM developed showing output signal correction regardless of errors (constant logic '1' case).

Equally as interesting was the manner in which the TMR version of the FSM corrected for the floating-input case. While the floating input lines may still be seen in the D0 and Q0 input and output of the first D-FF, the signal is corrected by the time it reaches the output, MAX. Additionally, the voting logic is working on the D0 and Q0 signals to restore proper operation when possible. The amount of time left in the non-valid logic states was minimized. This is illustrated in Figure 53.

Figure 53. Timing diagram for the Moore-type, TMR version of the FSM developed showing output signal correction regardless of errors (floating-input case).

3. Timing and Resource Comparison for Sequential Circuits

Another analysis of the timing and resource utilization between the two designs was made prior to proceeding to the next phase of logic design. Once verification of the TMR technique was made for a general Moore-type FSM, one desires to obtain accurate timing information to further validate the approach. In the case of the non-TMR representation of the FSM design, an average delay of 4.9 ns across three levels of logic was measured. This corresponds to a clock frequency of up to 204 MHz. Worst case delay across four levels of logic was found to be 5.5 ns due to the input and output buffer delays on the FPGA. After the place and route phase, net skew was measured as 0.0 ns with a maximum delay of 0.2 ns. Setup time was 1.9 ns and hold time 1.3 ns; thus, considering the sequencer will be under-clocked to conserve power at a frequency of approximately 50 MHz, any necessary timing constraints are met.

For the TMR version of the FSM, the same measurements were conducted after the synthesis and place and route phases of design. An average delay of 6.5 ns across four levels of logic was measured. This corresponds to a clock frequency of up to 154 MHz. Worst case delay across four levels of logic was found to be 6.8 ns, again due to input and output buffer delays. After place and route, net skew was measured at 0.0 ns with a

maximum delay of 0.2 ns. Setup time was 3.1 ns and hold time 2.0 ns; again, any timing constraints necessary for the design are met.

The data above indicated that the added delay of the voter circuits introduced in the TMR version of the FSM is responsible for the increased timing results and subsequent reduction in clock frequency. This may be somewhat further affected by the delays of the output buffers, as they do not appear in the feedback paths of the TMR version. Most interesting was the increase in setup and hold times between the non-TMR and TMR versions of the FSM. While the increase of approximately 0.5 to 1 ns should not affect the operation of the simple sequencer application considered in this research, more complex functions such as DSP algorithms or more complex processing schemes may have to take similar timing increases into account. Complete verification of the data timing sequences would need to be carefully analyzed in either of these two scenarios.

A difference in resource utilization between the two designs was as anticipated. The non-TMR, baseline version of the FSM design utilized two of 9,312 FFs, three of 9,312 LUTs, and two of 4,656 slices with an average fan-out of 2.00. The TMR version used six of 9,312 FFs, eleven of 9,312 LUTs, and six of 4,656 slices with an average fan-out of 2.50. In both these baseline and TMR instantiations, the resource utilization for FFs and LUTs was well under 1% of the total available quantities. These resource utilization values should maintain an approximately three factor increase of TMR over the baseline design, as the complexity of the logic design increases. The three-fold increase of the TMR design in resource utilization from a baseline version will be readily apparent in percentages the larger a logic circuit becomes.

The timing and resource utilization comparisons between the non-TMR and TMR forms of sequential logic revealed that either design may be used for the sequencer design. The additional setup and hold time, slower clock speed available, and slightly increased path delay will have little to no effect on the sequencer operation. The additional fault-tolerant features of TMR make it the best solution for the sequencer project while requiring a factor of three to four times the resource utilization for the design.

D. PRELIMINARY SEQUENCER LOGIC DESIGN

After testing the validity of the TMR approach in sequential logic, design work proceeded with specific development of logic for use in the sequencer application. Transition of design work was carried over from the Xilinx test cases to Actel specific designs using Libero SoC. The Actel ProASIC3 development board was used for the first sequencer logic testing, as seen in Figure 54.

1. Conversion of Xilinx HDL to Actel HDL

One of the first challenges in carrying schematically-designed circuits from Xilinx ISE to Actel SoC is the manner in which logic primitives are specified in the two products when HDL is generated. This requires manual editing when porting the HDL specifying a Xilinx schematic design over to the Actel SoC development suite. For example, in Xilinx ISE the instantiation of a two-input NAND gate is as follows:

```
NAND2 XLXI_4 ( .I0 (XLXN_4) ,  
               .I1 (XLXN_3) ,  
               .O (XLXN_5) );
```

Figure 54. Actel ProASIC3 development board showing sequencer LED testing with TMR logic implemented.

To properly port this design over to an Actel equivalent representation of the two-input NAND gate, the signal inputs and output must be renamed to the appropriate variable term. In this instance, .I0 becomes .A, .I1 is renamed .B, and .O translates to .Y for the following representation:

```
NAND2 XLXI_4 ( .A (XLXN_4) ,
               .B (XLXN_3) ,
               .Y (XLXN_5) ) ;
```

While the instance can be renamed from XLXI_4 to something else, leaving this device name helps with the realization that the code is ported from Xilinx to Actel representation. Comparing the two source code equivalents aids in troubleshooting the automatically generated HDL should errors occur. This may not seem like a great deal of work until one considers the amount of logic typically involved in complex designs. Since the design of the sequencer is implemented on the ProASIC3 family, knowledge of Verilog is critical to the success of the project; once the initial work is done schematically, time must be taken to understand any generated HDL code prior to porting the design to Actel SoC.

2. Synplify Pro Representations of FSM Logic

Once logic for an FSM is implemented in Actel SoC, there are a variety of synthesis tools available in Synplify Pro to aid in the realization of circuits. Instantiated logic can be viewed as a register-transfer level (RTL) or technology schematic. These views within Synplify Pro are illustrated in Figures 55 and 56 for a simple FSM.

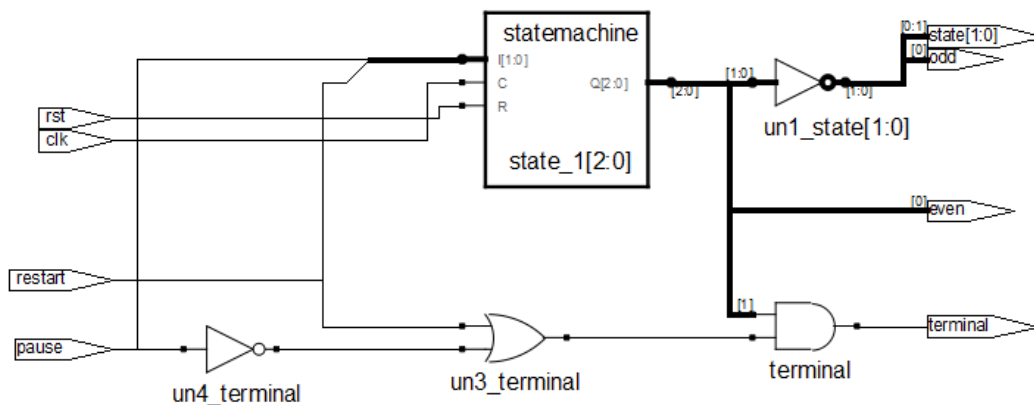

Figure 55. Synplify Pro RTL view of instantiated FSM logic.

Table 8. Synplify Pro generated state table for FSM logic.

Number of states: 3			
Number of inputs: 2			
Inputs:			
0: restart			
1: pause			
Clock: clk			
Reset: rst to state S2			
Transitions: (input, start state, destination state)			
1-	S0	S2	
00	S0	S1	
01	S0	S0	
1-	S1	S2	
-0	S1	S2	
01	S1	S1	
1-	S2	S2	
-1	S2	S2	
00	S2	S0	

Figure 57. Synplify Pro generated state diagram for FSM logic.

3. Designation of Timing Constraints within Logic

In defining the timing variables for use in deployment, there are two possibilities for storage—saving the timing constants as parameters in Verilog and using the FlashROM feature of the ProASIC3 FPGA to store constant values.

a. *Parameter Constants in Verilog HDL*

In Verilog, parameters are constant values and do not incorporate any other data types such as nets or registers. In defining these parameters during the initial portion of Verilog code, one is able to rapidly change the values and operation of a module prior to re-synthesis and configuration of a target FPGA device. These parameter values are not modifiable at runtime and can act as the timing constants necessary to control the deployment sequence. The following code illustrates the use of parameter values within a Verilog module:

```
// Module - Test Module
module test_Mod (Clk, D, Q);
    parameter    width = 2,
                  delay = 10;
    input  [width - 1 : 0] D;
    input  Clk;
    output [width : 0] Q;
    assign #delay Q = D;
endmodule
```

In this manner, all eight of the timing constants defining the deployment sequence for the various P-POD deployments may be specified. Once the ‘Arm’ power signal activates the sequencer and the ‘Deploy’ command is internally generated, the sequencer FSM will execute the deployment sequence using the constant variables defined at the start of the Verilog declarations. To modify the timing sequence, only a quick re-declaration of parameters must occur prior to re-synthesis and implementation. The generated bitstream file for FPGA reconfiguration takes only minutes to produce. All interfacing and reprogramming may be accomplished through the JTAG port at any time prior to launch, when physical access to the sequencer is available.

b. *Constant Declarations in ProASIC3 FlashROM*

The ProASIC3/E devices have a dedicated nonvolatile Flash ROM (FROM) memory of 1,024 bits for storage of constant values or serial number identification. This FROM can be read, modified, and written using the JTAG interface; however, it can be read but not modified from the FPGA core. The FROM is logically organized as eight pages of 16 bytes and physically organized 8×128 bits [77]. Actel

ProASIC3/E devices are the only FPGA to support this feature as only flash-based technology supports reconfigurable, nonvolatile memory.

The advantage of this FlashROM is immediately seen in any application utilizing the FROM. Since the FPGA can be configured using HDL code with a portion referring to the constants stored in FROM, any changes via JTAG interface to the constant values do not require complete reconfiguration of the FPGA. The main portion of the synthesized and implemented FPGA configuration can be left untouched with only a simple flash re-programming of the FROM. This reduces the time required to redefine variables for sequencing from minutes to seconds.

Designation of FlashROM contents from within Actel SoC is a simple process of adding the appropriate module ('FlashROM_cmp') to a project requiring its use. The IP core is then instantiated as follows to call the FlashROM variables from the HDL code:

```
----- FlashROM ip core instantiation -----  
-----  
--FlashROM_cmp_inst: This FlashROM block is configured  
--to generate different time intervals between launch  
--select signals  
-----  
  
FlashROM_cmp_inst: FlashROM_cmp port map  
(  
    CLK  => from_en_sig,  
    ADDR => addr_sig,  
    DOUT => dout_sig  
) ;
```

The above example is modeled after an eight chip power sequencer reference design provided by Actel [78]. The decimal values stored in the first eight bytes of page zero in the FlashROM are illustrated in Figure 58. The design of this reference power sequencer is very easily modified to fit the requirements of the CubeSat launching application. All that remains is the modification to TMR implementation of logic using manual or commercially available means along with radiation testing. Preliminary code for the CubeSat sequencing application is provided in Appendix D.

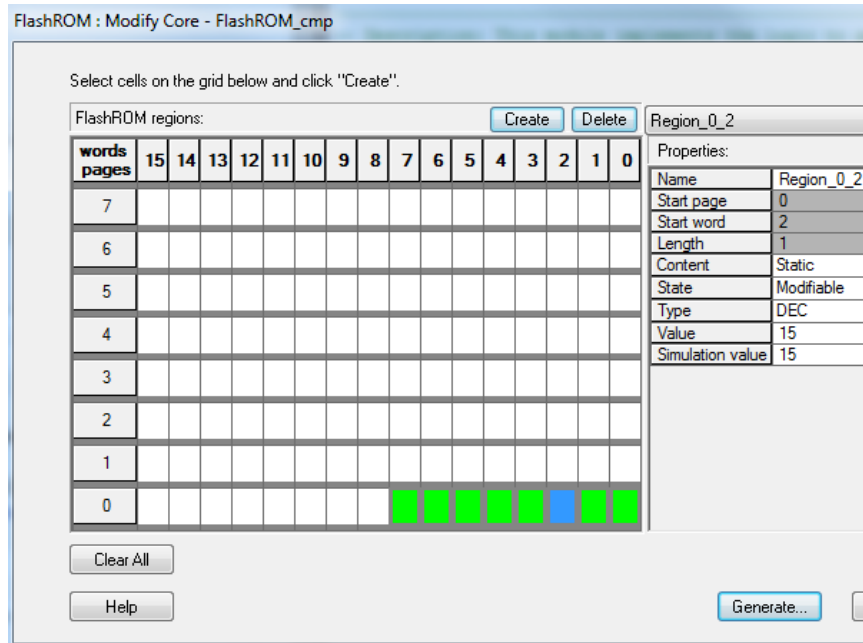

Figure 58. FlashROM storage of eight bytes defining sequencing timing; the third value (0x2) is highlighted containing decimal value '15.'

E. CHAPTER SUMMARY

The methods of implementing fault-tolerant techniques within logic leading to final selection of a particular method were presented in Chapter V. All combinational and sequential circuits were compared for accuracy in output, FPGA resource utilization, timing characteristics, and reliability for correcting errors. TMR was seen as the best solution for both combinational and sequential circuits due to small overhead requirements and small increases in logic delay. Discussion of manual and automatic fault injection techniques was provided.

Further research was conducted toward developing the sequencer logic for use in the developed ProASIC3 design. Work was carried over from Xilinx ISE to Actel SoC with porting methods discussed. An overview of Actel SoC requirements for logic development was provided with suggestions for future code design. Differences in storage methods for sequencer timing values were discussed, including storage of variables within HDL code or in the internal FlashROM of the FPGA. The use of a power sequencer reference design for the ProASIC3 family, coupled with TMR logic, is seen as the way forward for the sequencer application.

THIS PAGE INTENTIONALLY LEFT BLANK

VI. CONCLUSIONS AND RECOMMENDATIONS FOR FUTURE RESEARCH

A. CONCLUSIONS

During the development of a general payload processor, there were several items noted which vary from work done in the past. The research conducted to discern the appropriate type of processor suitable to the sequencer project led to a complete review of all available FPGA technology on the market. One of the most important differences between the development of the sequencer and work done previously on CFTP concerns the type of device utilized. While CFTP focused on SRAM-based FPGAs, with all of the inherent requirements for supporting secondary componentry, the fault-tolerant FPGA-based sequencer project utilizes Actel ProASIC3 flash-type FPGAs for embedded processing. This has several benefits including a large reduction in the number of secondary components required to operate the device, a low-power operating mode that reduces power consumption by up to 40%, live-at-power-on processing capability, and the inherent radiation tolerant properties of flash-type technology [79]. This type of FPGA has not been previously utilized in space-systems projects at NPS, and future research should incorporate this design. While the Xilinx Virtex-5 series has certain clock frequency and quantity of logic resources advantages, the Actel ProASIC3 series is suitable in all but the most demanding DSP applications. The ability to have one flash-based FPGA take the place of up to a dozen components on a SRAM-based platform is of great benefit in the radiation environment of space. When only one device is involved, protection of the design from radiation induced faults becomes a more manageable challenge.

In researching the various means of fault tolerance available, one is faced with the task of choosing between several competing schemes—each of which promises to accomplish the same end-state of reducing radiation-induced errors in logic. While there are certain benefits to the quadded logic approach, such as the elimination of the voter circuitry, the combined effects of greatly increased resource utilization coupled with a significant timing delay reduce the suitability of this approach. Additionally, the time-

intensive manual wiring of logic that accompanies the quadded logic approach is disproportionate to the returns in error masking. Similarly, TIR offers many of the same benefits of TMR in a slightly more resource efficient design; however, the lack of certainty in error correction coupled with delay path differences in the circuit negatively affects its usefulness. TMR offers the best combination of logic utilization and timing path delay for any of the circuits investigated.

The development of the PA3TB was instrumental in developing skills necessary for effective use of Altium Designer. Altium was found to be a highly capable platform for development of schematic and PCB layout. The ability to easily try out circuit implementations while linking 2-D footprint and 3-D models to their associated components is of great interest to any circuit designer. Many errors were avoided by careful planning of the schematic before layout and placement fitting of components. There were excellent results obtained in the development of the first PA3TB design; it served as a familiarization with not only the design software toolset but also the manufacturing and integration of multi-layer PCBs and SMT components. There was a general realization of what features would work or be too difficult to manufacture on the more complex SADv3 design after gaining hands-on experience with the integration of the PA3TB.

Design work and implementation of the SADv3 is seen as the most time-intensive portion of work occurring in this research. The complexities involved when moving from a four to eight-layer PCB design with a 484-pin BGA FPGA are easily the most daunting task accomplished. Overall design complexities involved with supporting the FPGA require pre-planning in the number and type of supporting circuitry such as capacitor and resistor banks. The automatic trace routing choices made by Altium Designer are not always in the best interest of the PCB layout. The traces and escape patterns provided by the auto-router may be permissible once extensive work is done to manage the settings and parameters of the layout options. The addition of the SRAM and flash-based memory components to the design is done in the best interest of future operations and mission sets. Although not necessary for the sequencer application, any additional data logging or data processing application will find these devices useful.

In both combinational and sequential circuits, the logic outputs of the TMR instantiated circuit under test were identical to the non-triplicated version. Additionally, the timing path differences between the two versions of circuitry were negligible. In all but the most complex circuits, this should remain the case. The ability to quickly represent HDL code within a schematic or Verilog representation, triplicate the instantiation, and combine with voting logic is a simple means of providing logic redundancy to any design. Sequential circuits take a bit more work, as the feedback paths providing next-state logic must also be properly protected to prevent error propagation. In all cases of TMR testing upon sequential logic, the designed circuit was able to correct any introduced fault prior to affecting the output. This is a clear benefit for the sequencer application, the greatest advantage of which is guaranteed timing and CubeSat deployments during the periods specified.

The ability to manually inject faults for testing, while applicable to the work in this thesis, is a time-intensive proposition. To test all possible fault points within a circuit, a more automated version of the fault injection technique must be developed. Additionally, the manner of TMR development and insertion has great implications concerning time available to pursue other logic research, development, and testing. With the availability of commercial software products, a great deal of time and effort can be saved by automatically configuring different forms of TMR for logic implementation using software packages such as Precision Hi-Rel. Use of this commercial synthesis software will allow for comparisons between the manual TMR methods developed and automated TMR generation. This program should be licensed to allow for continued testing of the various subsets of TMR implementations.

Any transitions from Xilinx to Actel Verilog HDL code require reformatting all instantiated logic components into the proper syntax for use by the Actel synthesis tools. This process is lengthy and tedious with regards to the appropriate syntax for transition from one software toolset to the other. Since Precision Hi-Rel can be targeted toward any vendor's devices generically, it should also aid in automating syntax exchange to some degree. Even if the logic has been designed schematically in Xilinx, the Precision Hi-Rel package will be able to TMR the design and adapt it for Actel FPGA usage.

The development of HDL sequencer logic is an important step toward the realization of the integrated payload design. Through careful application of various techniques, including Verilog variable declarations and ProASIC3 FlashROM utilization, there are a variety of options available for logic implementation on the sequencer. The ability to quickly realize an FSM design using Verilog case and state assignments saves a great deal of time and effort. This is in contrast to attempt to reproduce a complex FSM design schematically with logic gate equivalency.

The design work in developing a general-purpose payload processor has many real world applications. Specifically, the work contained in this thesis sequencer design is applicable to a real-world, CubeSat deployment application for potential use on future missions. In developing a novel approach to processing and timing management operations, a low-cost solution to a difficult problem is realized. There is still research to be conducted and testing necessary to validate the design prior to manufacture and launch. This additional research should allow for several subsequent theses to be prepared on the topic. The general-purpose payload processor is flexible enough both in configurability and logic capacity to target new implementations. The TMR techniques and logic implementations for the sequencer are only a single example of an application.

B. FOLLOW-ON RESEARCH AND TESTING

There are several avenues available for development of the general payload processor design. One of the first tasks to accomplish is final component placement and subsequent trace verification of the SADv3 by a design review committee. This team of engineers must work to ensure that the design of the eight-layer PCB and all associated components are verified prior to board manufacture. As there are a large number of signal lines on the design schematic, care must be taken to verify all traces to ensure proper endpoint termination and routing. The choice of power supply may also be combined with current means of power conversion to obtain the required +5 V_{DC} voltage for down-conversion to other voltages. VPT Incorporated manufactures DC-DC converters for space applications which are rated to 30 krad TID and SEE characterized to 44 MeV-cm²/mg with up to 85 MeV-cm²/mg parts available [80]. They also manufacture an

associated electromagnetic interference (EMI) filter for use with the DC-DC converters [81]. These will work well in converting the +28 V_{DC} power supplied by the host spacecraft into a more manageable +5 V_{DC} for further regulation on the PCB. Their use has already been space-qualified in several previous mission hardware designs.

Another desired feature for inclusion on the SADv3 design is the incorporation of Ethernet for data logging during radiation testing. Preliminary research into the incorporation of Ethernet standards, in combination with ProASIC3 FPGAs, indicates that there is a Microsemi available 10/100 Ethernet Media Access Control (MAC) core to connect to local area networks (LANs) [82]. Work will need to be done to interface the appropriate pins of the FPGA and determine logic area utilization and suitability for triplication. Actel provided 10/100 MAC core specifications for the ProASIC3 series that specify an estimated 44% device utilization with a corresponding 49 MHz clock performance [82]. This utilization factor precludes TMR instantiation of this portion of the FPGA logic on the ProASIC3 series of devices.

The addition of SRAM and flash-based memory to the SADv3 design opens up new possibilities in both processing and video feed features. Implementation of the FPGA into a general payload processor arrangement for other applications can utilize such features. There are a multitude of cores available for processing available directly from the vendor [83]. While much of this IP may cost extra to license, there are open-source cores available which may serve an equally useful purpose [84]. The available open-source cores include communications controllers, processors, systems controllers, and video controllers. Research into these IP options should be conducted to find suitable items for possible inclusion into the SADv3 design. There are display reference designs available including video and still-shot camera design and programming files [85]. It should be noted that the large relative device utilization of such proprietary cores may make it impossible to TMR such features on the FPGA while leaving sufficient logic resources to TMR the sequencer portion of the design. Additional difficulties are incurred in trying to TMR proprietary IP with regard to timing constraints and power requirements. Some testing of this may be possible with the Precision Hi-Rel software

packages, although, there is still a logic resource utilization challenge as seen in the 10/100 MAC core specified previously.

The majority of remaining work involves radiation testing of a flight-ready SADv3 board with various fault-tolerant schemes. This is necessary to determine the best combination of FPGA hardware and configuration logic. The various forms of radiation introduction to the PCB need to be investigated, including FPGA dose rates and the possibility of whole board testing. Radiation levels need to be sufficient to push the FPGA to specified limits and beyond to determine suitability for the space environment. For the nuclear source chosen for testing, coordination between NPS and the cyclotron provider needs to be managed up-front to avoid testing errors in setup.

In conclusion, there are a number of applications for which the ProASIC3 general purpose payload processor is suitable. The sequencer work contained in this thesis is one application in which a significant gain in the state of current CubeSat deployment technology may be realized. The ability to deploy CubeSats using TMR logic should be quite cost effective when compared to custom, rad-hard components, possibly with no loss of fault tolerance. TMR is useful for protecting both combinational and sequential circuits, especially given the available fault-tolerant software toolsets. Future designs using Actel flash-based FPGA technology may have wide applicability due to its configurability and the flexibility with which the I/O pairs can be assigned. The compactness of the ProASIC3 circuit design, when compared to the more traditional Xilinx Virtex series FPGAs, is readily apparent. It is anticipated that this design, or some evolution of it, will be quickly developed into a flight-ready product.

APPENDIX A. FPGA HARDWARE PRODUCTS AND SOFTWARE DEVELOPMENT TOOL DIFFERENCES

A.1 COMPARISON OF XILINX AND ACTEL PRODUCTS

The goal of this appendix is to look at all of the considered hardware vendors to determine the optimal solution to the choice of FPGA for use in the CubeSat deployment sequencer. A variety of features are compared, including software packages and hardware feature sets. In past chapters, the choice of the FSM type, FPGA types considered, radiation challenges faced, and fault-tolerant logic implementations were discussed. The choice of a SRAM-based or flash-based FPGA using a Moore machine FSM was settled upon as the desired configuration for the sequencer. This appendix looks to further that choice to a specific product, having considered the software suites available and the particular hardware configurations which may fit a chosen fault-tolerant scheme.

In both cases, Xilinx or Actel products, design choices are limited to those devices with a full upgrade path to rad-hard technology. The devices compared are those that would have pin-to-pin compatibility between commercial and military-grade products with their rad-hard counterparts. Both vendors' software products are compared in terms of feature sets, usability, and ease of hardware interface. In all cases, attempts are made to test various logic designs upon the hardware compared using vendor provided development boards. These experimentation results were discussed previously in Chapter VII.

1. Software Feature Set

For the purposes of this research, two of the most prominent vendors of SRAM-based and flash-based FPGAs were compared in hardware and software features. Xilinx Corporation is known for its Spartan¹¹ and Virtex series of devices - with legacy Virtex I FPGAs being flown on CFTP during MidSTAR-1 and the upcoming NPSAT1 satellite missions. Xilinx devices are SRAM-based with all of the previously mentioned design challenges. Xilinx devices are best programmed with the Xilinx Integrated Software

¹¹ Spartan® is a registered trademark of Xilinx, Inc.

Environment (ISE¹²) development package [86]. Meanwhile, Actel (now a division of Microsemi) Corporation has long focused on antifuse technology but has recently made strides in configuring their ProASIC¹³/L flash-based FPGAs for the space environment. Similar to ISE, Microsemi provides a software environment known as Libero¹⁴ System on Chip (SoC) targeted to its various FPGA product lines [87].

a. Xilinx ISE 14.3

ISE WebPACK¹⁵ design software is the name of the free Xilinx PLD development suite made for Linux, Windows¹⁶ XP, and Windows 7. ISE WebPACK is a downloadable solution for FPGA and CPLD design offering HDL synthesis and simulation, implementation, device fitting, and Joint Test Action Group (JTAG) programming. It consists of the software development kit (SDK), MicroBlaze¹⁷ controller system, project navigator, CORE Generator¹⁴, PlanAhead¹⁴, ChipScope¹⁴ Pro, Xilinx Power Analyzer (XPA), ISE Simulator (ISim), and Xilinx Synthesis Tool (XST). The software package is upgradable to more extended editions including the Logic, Embedded, and DSP versions of the package [86]. The use of Xilinx ISE has a long history at NPS, an earlier version being the toolset utilized for the development of CFTP. Xilinx ISE, having used Mentor's ModelSim¹⁸ in the past, now defaults to its proprietary ISim simulator. The primary interface of Xilinx ISE can be seen in Figure 59.

Figure 60. ISE ‘Design Summary’ window listing FPGA utilization and design flow.

The options within the toolset allow for easy customization of the programming options for FPGA synthesis. Logic designs can be tailored for speed, area optimization (size), or further customized to fit individual needs. The ability to rapidly reconfigure a target design to other FPGA target devices is as simple as changing a configuration option and was used extensively in the testing in Chapter VII. This allowed for selection of Spartan versus Virtex products in the development of stacked methods of fault tolerance to test sizing constraints.

Furthermore, the transition from schematic diagrams to generate HDL was seamless, as Xilinx ISE allows for HDL generation to Verilog or VHDL. In all cases, the

generated code was easy to follow due to the naming scheme and instantiations matching the schematic labeling. Actual synthesis of a design was very informative in the case of errors generated by XST. XST provided enough context help to locate the line of code in error or the schematic discrepancy. HDL files and schematic files can be checked for concurrency with standards prior to implementation.

b. Actel Libero SoC 10.1

Libero SoC is a comprehensive design software toolset for use with Microsemi's SmartFusion¹⁹, IGLOO¹⁶, ProASIC3 and Fusion¹⁶ FPGA families. This software suite allows for entire design flow from design entry, synthesis and simulation, through place-and-route, timing and power analysis, with enhanced integration of the embedded design flow [87]. Libero SoC consists of the product design flow and management system including a 'Core Catalog' with commonly configurable cores and the SmartDesign²⁰ creation tool for building high level modular systems and subsystems. Additional software tools provided include Synplify Pro²¹ AE, Symphony Model²² Compiler AE, ModelSim AE, physical design layout, SmartTime²³, and SmartPower²⁰. The primary interface of Libero SoC can be seen in Figure 61.

In contrast with Xilinx ISE, the Actel Libero SoC package seems more tailored to system level design, especially once the baseline HDL is written for the FPGA logic. While product literature indicates that SmartDesign is tailored to assemble and connection Microsemi intellectual property (IP), user-generated IP, and custom HDL modules [88], the development of initial HDL models (especially schematically) is troublesome within Libero SoC. Since Xilinx ISE is able to create schematic symbols for synthesized Verilog and VHDL, the product is more easily suited to wiring those instantiated symbols graphically.

²³ SmartTime™ and SmartPower™ are trademarks of the Microsemi Corporation.

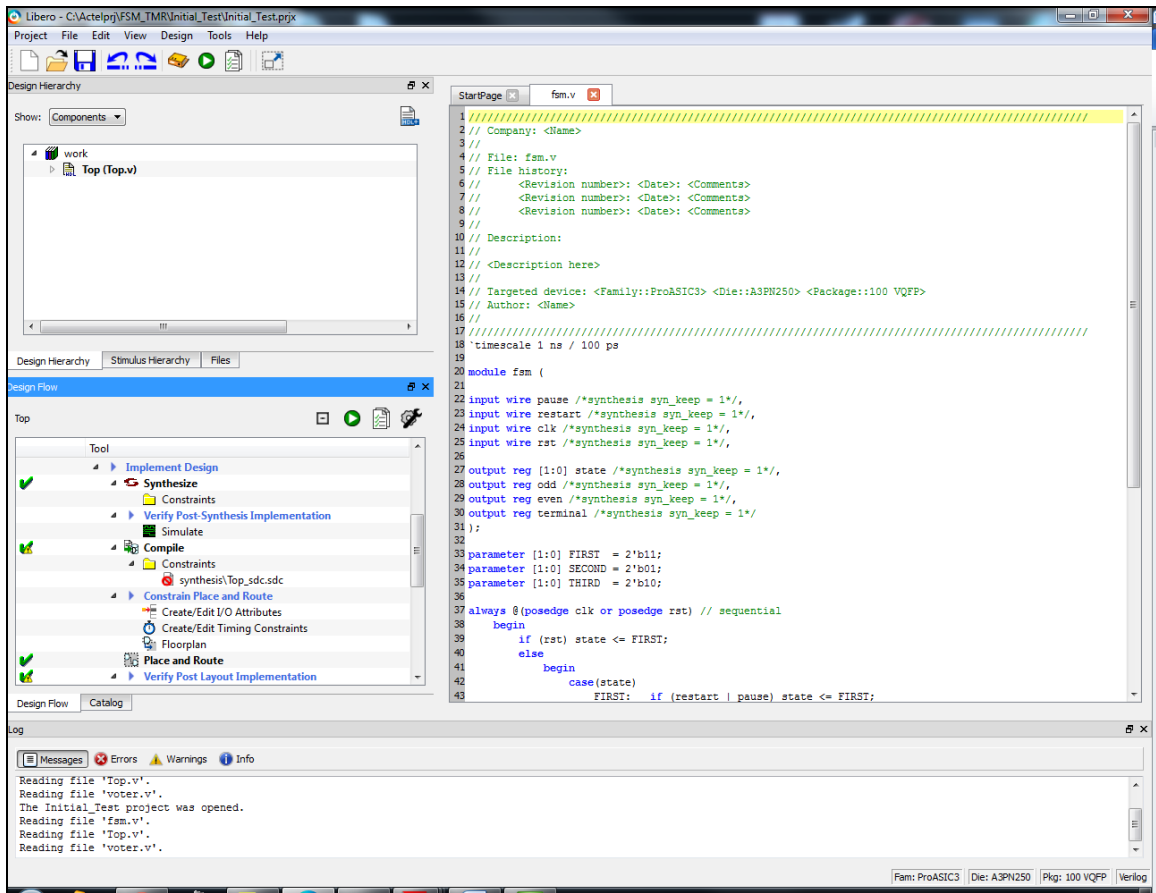

Figure 61. Interface of Libero SoC 10.1 showing Verilog HDL and design flow.

Both Xilinx and Actel have strong chip planning toolsets when looking at device pin-outs and logic floor plans. Much of the chosen product depends upon comfort with simulation software available for the two suites. Actel SoC defaults to Synplify Pro as its simulator of choice. Any reasonable experience with either of these two simulators could lead to a tendency to choose one software package over the other. The author has found, in extensive testing, that the feature sets of both ISim and Synplify are quite similar with logic timing diagrams generated being almost identical. Users of either simulation product should not have any difficulty switching from one to the other. Overall choice of software package comes down to comfort level of HDL versus schematic design and choice of FPGA. Both are fully capable in their synthesis, simulation results, and final output of bitstream files for FPGA configuration.

c. Results of Software Comparison

Overall, Xilinx ISE appears to be a more robust and feature-filled software suite. The ease of transition from HDL instantiation, to simulation, to synthesis and implementation is seamless and requires only a few hours of experimentation to grasp the basics. In contrast, Libero SoC seems very difficult to grasp, especially considering there are logic flow difference between versions 9.1 and 10.1 of the package. It appears as if Actel is trying to utilize a more contextual menu interface for design flow (similar to Xilinx) in its newer product, however, the graphical flow diagrams of the 9.1 software suite made a great deal more sense. On the basis of software alone, Xilinx ISE is a clear winner in feature set, configuration options, and the usability of the software package.

2. Hardware Feature Set

Significant differences in the Xilinx and Actel series of FPGAs are apparent in the choice of hardware for design. The SRAM-based implementations of Xilinx compared to the flash-based FPGAs of Actel are significantly different in their utilized technology. While the initial research in Chapter II led to the conclusion that flash-based FPGAs are superior in their simplicity, there is much left to be considered including their suitability in space-applications. For the sequencer developed for CubeSat deployment applications, one desires a re-programmable, low-power device of the most simplistic nature available. SRAM-based FPGAs, due to their requirement for external PROM type devices for configuration and microcontrollers to enable the power-on configuration, are significantly more challenging in the secondary component requirements.

Experience with Xilinx FPGAs shows that at least 90% of SEEs cause configuration faults rather than logic faults. Configuration faults can cause persistent errors in computation. The error-correcting technique used in the logic must detect as well as correct any errors in the computation. Detection of a repeated error in the computation then should signal the need for reconfiguration. Until reconfiguration of that portion containing the configuration error, the error-correction capability maintains correctness of the result [89].

A comparison between the radiation tolerant properties of both devices is necessary for down-selection to a specific product line. While many of the overall features, include logic real-estate, configuration methodology, and use in the final circuit are similar, clearly the differences in radiation tolerant properties and secondary component requirements have the most impact upon selection. The two product lines considered for use in the research are the Xilinx Virtex and Actel ProASIC3 series of FPGA devices. Experiments conducted on logic development in Chapter VII were targeted to both vendors' products, allowing for the earlier software feature comparison and subsequent testing of development boards.

a. Xilinx Virtex Series FPGAs

The Xilinx SRAM-based Virtex series of FPGAs are consistently utilized devices with long heritage in space applications. Their product familiarity, coupled with many years of on-orbit lifetime utilization, has led to a product line extending almost a decade. The space-rated rad-hard versions of the Virtex-I/II gave rise to the Virtex-4QV that has, in turn, led to the development and fielding of the radiation hardened Virtex-5QV. One must suspect that their more recent product lines, including the Virtex-7 series FPGAs, are undergoing modification and certification for use in the space environment.

For the rad-hard Virtex-5QV device, the FPGA consists of 131,072 logic cells, 87,920 internal fabric FFs, 87,920 real 6-input LUTs utilizing greater than five million LUT bits, 450 MHz system performance, up to 18 total clock generators, 836 user I/Os, and 20,480 configuration logic blocks (CLBs). Each CLB slice contains four LUTs and four FFs (an increase from earlier generation devices). There are also 320 DSP slices consisting of a 25×18-bit multiplier, an adder, and an accumulator [61]. The internal structure of a Virtex-5 CLB slice is illustrated in Figure 62.

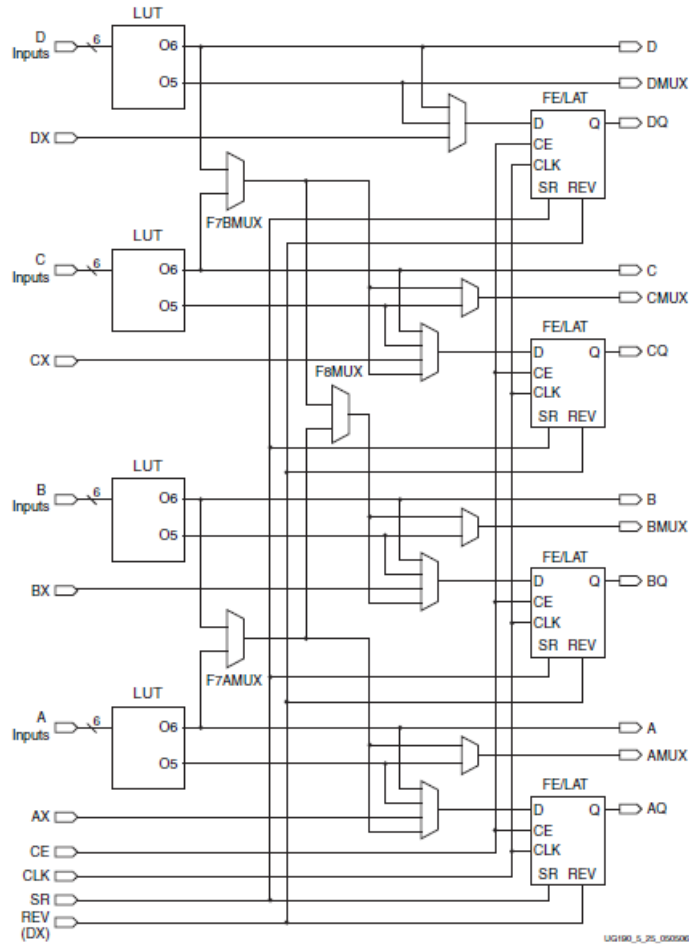

Figure 62. Each Virtex-5 CLB slice contains four LUTs and four FFs (From [79]).

The Virtex-5QV series advertises guaranteed SEL immunity to LET greater than 100 MeV-cm²/mg, 1 Mrad TID, SEU hardened configuration memory cells and control logic with 3.8×10^{-10} errors/bit/day, and SEU and SET hardened CLB flip flops and internal data paths [61]. The SRAM cells used for the configuration memory of the Xilinx FPGAs are larger and more robust than the SRAM cells used for general-purpose memory, which are optimized for speed and cost [25]. These configuration memory cells are optimized for SEU resistance by a combination of their feature size and manufacturing technique.

The Virtex-5QV is listed as compatible with the commercial and defense-grade Virtex 5 FPGAs, allowing for low-cost, rapid prototyping and easy design migration to flight hardware. For the purposes of a component comparison, the Virtex-

5QV (XQR5VFX130) rad-hard version is compatible with the commercial-grade Virtex-5 (XC5VFX130T) [90]. The embedded microprocessor of the Virtex-5QV is disabled when compared to the commercial versions. Also, there are some pin differences, as the rad-hard version contains 1,752 pins, while the commercial version utilizes 1,738 pins [61], [90]. There are compatibility guides provided by Xilinx for the correct pin conversions from one design type to the other. The lowest cost for a commercial-grade Virtex-5 is \$4,352.40 [91].

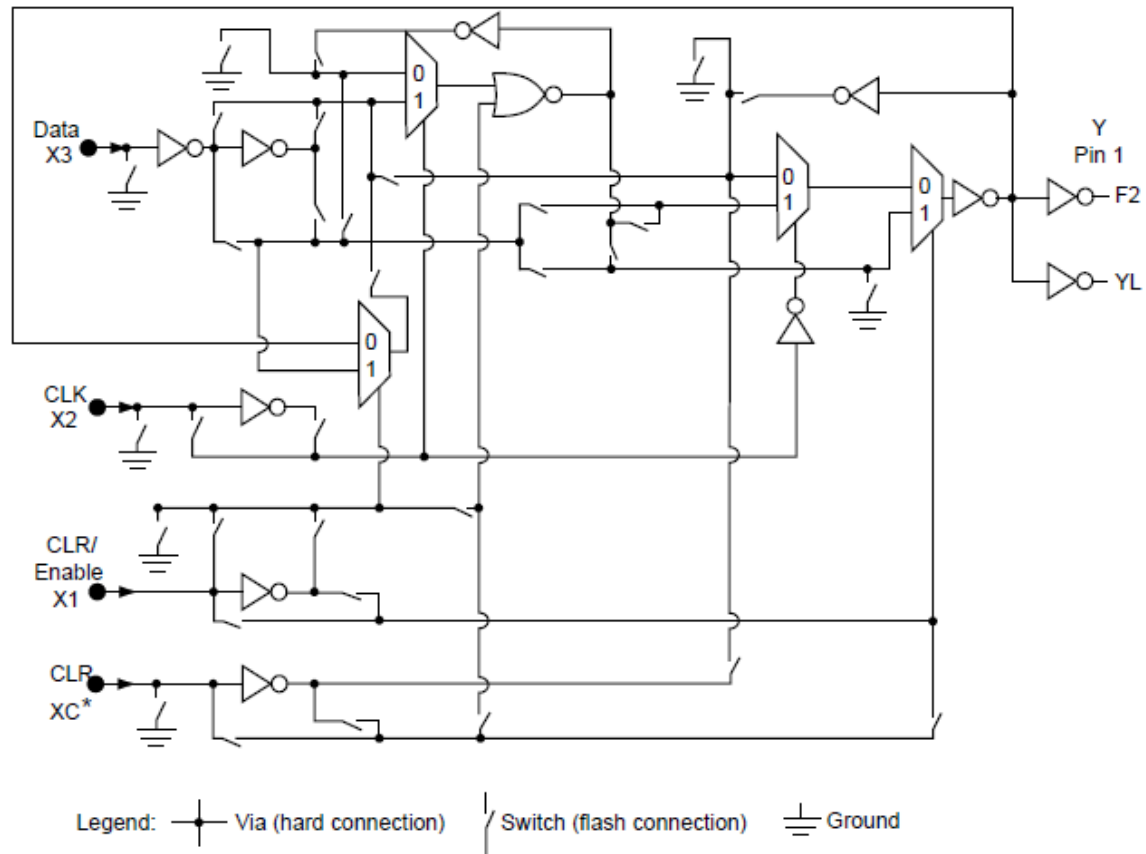

b. Actel ProASIC3 Series FPGAs

A more recent development in FPGA manufacturing stems from the use of flash-based FPGA technology to provide operational capability at power initiation and reprogrammable aspects, as previously discussed. The use of flash technology is a great enabler for the reduction in secondary components required for operation. Additionally, one may benefit from the inherent radiation tolerant properties of flash-memory when compared to SRAM-based FPGA configurations. In this sequencer research, the RTAX²⁴ and RTSX antifuse products from Actel were discounted for lack of reconfiguration techniques previously discussed. Therefore, only RT ProASIC3 devices, with pin-compatibility to the ProASIC3L defense-grade of FPGAs, were considered for use in the project. With lack of a reconfiguration requirement, however, RTSX-SU devices, which implement TMR in hardware, could be ideal [92].

In the RT ProASIC3 device, the FPGA consists of 600,000 logic gates including: 13,824 VersaTiles²⁵ (D-FFs), 350 MHz system performance at 1.5 V_{DC} or 250 MHz at 1.2 V_{DC}, six clock-conditioning circuits (CCCs) with integrated phase-locked loops (PLLs), 270 user I/Os, and 135 differential I/O pairs. Each VersaTile can be configured as a three-input logic function, a D-flip-flop (with or without enable), or a latch by programming the appropriate flash-switch interconnections. There is also 108 kbit of RAM and 1 kbit of non-volatile ROM provided [19]. The internal structure of a ProASIC3 VersaTile is illustrated in Figure 63.

²⁴ RTAX™ is a trademark of the Microsemi Corporation.

²⁵ VersaTile™ is a trademark of the Microsemi Corporation.

* This input can only be connected to the global clock distribution network.

Figure 63. Configuration of low-power ProASIC3 device core VersaTile (From [93]).

The RT ProASIC3 series advertises SEL immunity to a projected LET threshold of $68 \text{ MeV-cm}^2/\text{mg}$, D-FFs and internal SRAM SEU limits of 63.5 MeV protons, and heavy ion transients on the global clock networks and I/O banks greater than $70 \text{ MeV-cm}^2/\text{mg}$ [43]. SEE mitigation strategies mentioned include TMR of the clock network, I/O banks and D-FFs. This may not be the most efficient manner to mitigate SEEs in the combinatorial logic and embedded SRAM memory; strategies for these logic types are explained in more detail in Microsemi's radiation reports [29].

RT ProASIC3 devices have been tested for TID effects under x-ray and gamma ray environments [94]. There is an observable effect of increase in propagation delay through pass transistors as TID increases. This is due to floating gates being less able to hold interconnection pass transistors in their 'on' state. With a dose rate of 5

krad/min, an increase in propagation delay of 10% has been observed at a gamma ray TID of 25 to 30 krad. The results of this analysis are indicated in Figure 64. At 1 rad/min, which is more representative of the space environment of LEO, the 10% propagation delay occurs at a TID level of approximately 40 krad. A 15% propagation delay was seen at a TID level up to 55 krad [83]. Microsemi is working to alter Libero SoC to include propagation delay increase for designers wishing to incorporate these delays into simulation and static timing analysis prior to deployment [83].

Figure 64. Degradation of propagation delay versus TID for RT ProASIC3 (From [83]).

The RT ProASIC3 is listed as pin-to-pin and timing compatible with the defense-grade ProASIC3EL FPGAs. For the purposes of a component comparison, the RT ProASIC3 (RT3PE600L-CG484B) rad-hard version is compatible with the defense-grade ProASIC3EL (A3PE600L-FG484M). The use of the M version (military temperature range) ensures that timing can be verified in hardware across the full temperature range from -55 C to 125 C [83]. The lack of pin differences between the rad-hard and military-grade components is of great benefit in comparison to the Xilinx Virtex-5QV. This should allow for one standard design in which schematics can be developed and not modified if utilizing either the rad-hard or military-grade FPGA. Since the overall goal of this thesis is to select lower-cost componentry, with the possibility for

future upgrade dependent on mission, the Actel series devices are more design friendly in this regard. The individual cost for both these devices require product quotes; a logic compatible device in the 484 pin-package can be purchased for as little as \$63.87—this device (A3PE600-FG484) should be sufficient for initial prototype testing [95]. Depending on the results of future radiation testing, this prototype FPGA may be reliable enough with redundant logic to utilize on final flight hardware.

3. Associated Hardware Requirements

There are many associated benefits with the ProASIC3 and ProASIC3L FPGAs related to supporting hardware. These devices can be powered from a single 1.2 V_{DC} or 1.5 V_{DC} supply for core voltage and I/Os. There is no requirement for a 2.5 V_{DC} or 3.3 V_{DC} supply for power-up; although, these are added as necessary to supply I/O bank voltages. Running the entire system on a single supply saves costs and area associated with voltage regulators [90].

Since there is no boot PROM or flash microcontroller required to load the FPGA at system power-up, the ProASIC3 line is a single-chip solution [90]. Since CPLDs are not required, ProASIC3 FPGAs are live at power-up. Again, this saves on board layout area and total system cost. Additionally, no power-up monitor chip is required; unlike SRAM configuration bits, flash configuration switches do not brownout [90]. Clock management is also simplified by live at power-up CCCs and PLLs, allowing for the removal of additional clock distribution chips often used to boot SRAM FPGAs or microcontrollers during system start-up [90].

A.2 APPENDIX SUMMARY

The comparison of Xilinx versus Actel software and hardware products was discussed in Appendix A. Xilinx ISE 14.3 was compared to Actel SoC 10.1 with ISE being realized as the more complete design suite due to its' integrated schematic editor. Both software suites were seen to have capable synthesis and simulation toolsets.

APPENDIX B. PROASIC3 TEST BOARD – REFERENCE, SCHEMATICS, AND PCB LAYOUT DIAGRAMS

The design files for the ProASIC3 Test Board are divided into four sections: the bill of materials, schematics for electrical connections, the 2-D PCB layout documents, and 3-D component placement views. All of the associated documents were constructed using Altium Designer 10 during the development portion of this research.

B.1 PROASIC3 TEST BOARD DEVELOPMENT METHODOLOGY

1. Detailed Discussion of ProASIC3 Test Board Design Decisions

Since one of the objectives of this test board was to minimize the amount of secondary components placed upon the PCB, the power regulation circuitry for the PA3TB was not implemented on the PCB. A wiring harness configuration was determined to be the proper method for providing power to the board. A bench-top Agilent E3632A DC power supply was utilized for the power supplied to the FPGA core with an Agilent E3631A triple output DC power supply used to supply secondary voltages. By using external power supply and conditioning, any design errors could be localized to the FPGA design rather than the power circuitry. This greatly aids in trouble shooting, should the PA3TB not operate as anticipated upon integration.

For the power supply harness, a six wire configuration was chosen as it would supply the required voltages and ground for proper operation of the FPGA in various manners. As seen in Figure 65, pin 1 is tied to ground, pin 2 is USB voltage (optional), pin 3 is V_{CCPLF} (tied to $1.5 V_{DC}$ or GND dependent upon analog PLL usage) [96], pin 4 is V_{CC} ($1.2 V_{DC}$), and pins 4 and 5 provide I/O bank voltages (1.2 , 2.5 , or $3.3 V_{DC}$). This allows for maximum flexibility in testing of the PCB, as one desires to enable certain features or drive I/O lines at different voltages depending on connections. A Molex 43045-0614 2×3 Micro-Fit 3.0²⁶ connector was chosen as the six wire header [97].

²⁶ Micro-Fit 3.0™ is a trademark of Molex.

Figure 65. Footprint of Molex Micro-Fit 3.0 6-pin header for power supply to FPGA core and I/O bank voltages.

Similarly, the JTAG header was chosen for ease of interface to the Microsemi hardware programming device, a FlashPro4²⁷. The FlashPro4 provides in-system programming for all series of Actel FPGAs including the ProASIC3 (nano and rad-hard variants). The FlashPro4 supports IEEE 1149 and IEEE 1532 standards for programming [98]. This allows for easy programming when coupling the Libero SoC IDE and FlashPro software. The JTAG interface is a 10-pin header in a 5×2 configuration. The footprint of this connector as seen on the PCB layout as illustrated in Figure 66. The straight pin header used on the PCB board for JTAG interface is manufactured by TE Connectivity (P/N 5103308-1) [99]. This part is the replacement for the discontinued components specified in the FlashPro4 user's guide [100].

Figure 66. Footprint of FlashPro4 JTAG 10-pin header for programmer interface.

²⁷ FlashPro is a trademark of the Microsemi Corporation.

To allow for future debugging and interfacing with secondary data logging equipment, a USB connector was added to the PA3TB design. This interface was useful in adding experience in interfacing secondary standards with the FPGA I/O banks. A standard USB 1.1 Series-B receptacle was added. A Tyco Electronics receptacle assembly was chosen as the device for implementation (P/N 292304-1) [101].

The emulation of CubeSat P-POD deployment is simulated by the inclusion of eight ‘bit’ light-emitting diodes (LEDs) which light to indicate activity on that particular I/O pin of the FPGA. These were labeled BIT0 through BIT7. The specific LEDs chosen were green, surface-mount of standard brightness in the 0603 form-factor (P/N QTLP601C-4) [102]. These were coupled with current-limiting resistors also in the 0603 form-factor. By utilizing these LEDs, we can realize a visual representation of sequencer timing. Four additional LEDs were added on a different bank for testing and indication purposes, labeled PWR and TST0 through TST2.

Since the LEDs and resistors chosen were of 0603 type, all power-decoupling capacitors required for the FPGA power inputs were also selected as 0603 form-factor. This minimizes board area necessary for wiring while still allowing for soldering under the microscope. These small LEDs, chip resistors and capacitors can be manipulated with tweezers while soldering with a fine-tip so long as magnification is available. In addition, the VQ100 package of the ProASIC3 nano is able to be soldered under the microscope.

The remaining requirement of expandability is met by adding as many copper pads to the PCB as will fit. This will be discussed during the PCB layout section of this appendix. The full ‘Bill of Materials’ for the ProASIC3 Test Board is provided in Appendix A.

2. Discussion of Schematic

For the development of PA3TB, the schematic portion of Altium Designer was utilized to develop the circuit design. The ProASIC3 nano was laid out first, with the banks not utilized in construction (‘Bank 1’ and ‘Bank 3’) placed with non-connected I/Os. These are additional connections that can be implemented in future designs with this device. Concerning ‘Bank 0’, very few of the available I/O resources were utilized;

I/O_00 through I/O_03 were tied to the PWR and TST0 through TST3 indicators. I/O_04 through I/O_19 were seen as points to implement future electrical connections. These I/Os are tied to copper pad areas on the PCB for expandability. ‘Bank 2’ I/O_38 through I/O_40 were utilized for the USB connection with resistive values allocated as per the datasheets [101]. The BIT0 through BIT7 LEDs were also implemented on this bank via I/O_41 through I/O_48; resistor values of 390 Ω were utilized as per specifications for LED protection. A close-up schematic view of the USB and LED connections are illustrated in Figure 67.

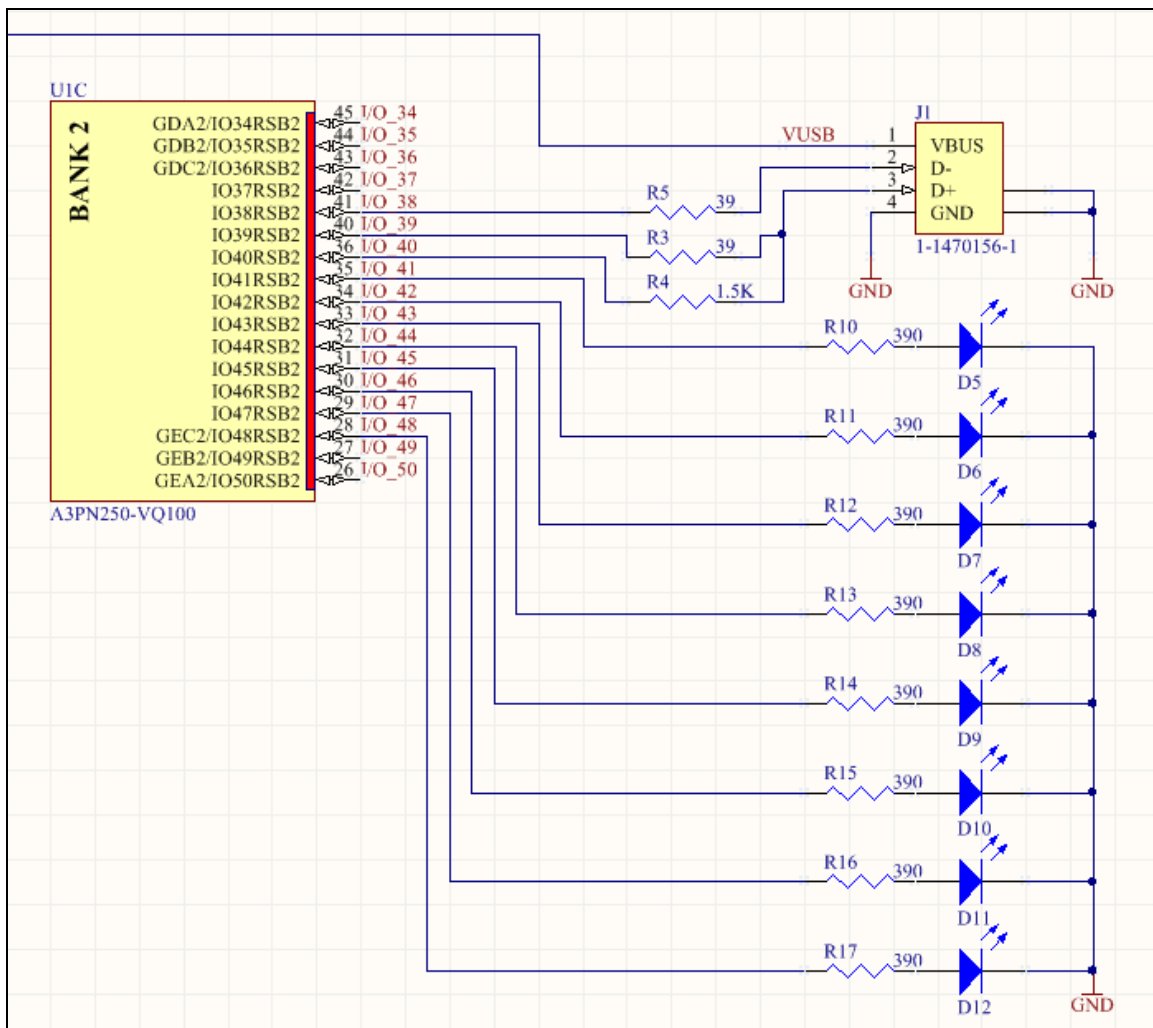

Figure 67. Schematic view of PA3TB ‘Bank 2’ connections to USB connector and BIT0 through BIT7 LEDs.

All power de-coupling capacitors for the FPGA were tied to the appropriate V_{CC} inputs for proper operation. Again, this was done in accordance with the ProASIC3 datasheet to reduce noise from the power supply to the FPGA [74]. The 6-pin 2×3 Micro-Fit 3.0 connector was placed on the schematic and wired to the appropriate power and ground lines on the FPGA and USB header. In placing the JTAG connector on the schematic, a 5×2 header was utilized for the electrical connections as seen in Figure 68. Proper biasing of the V_{PUMP} connection was done in accordance with the datasheet [74].

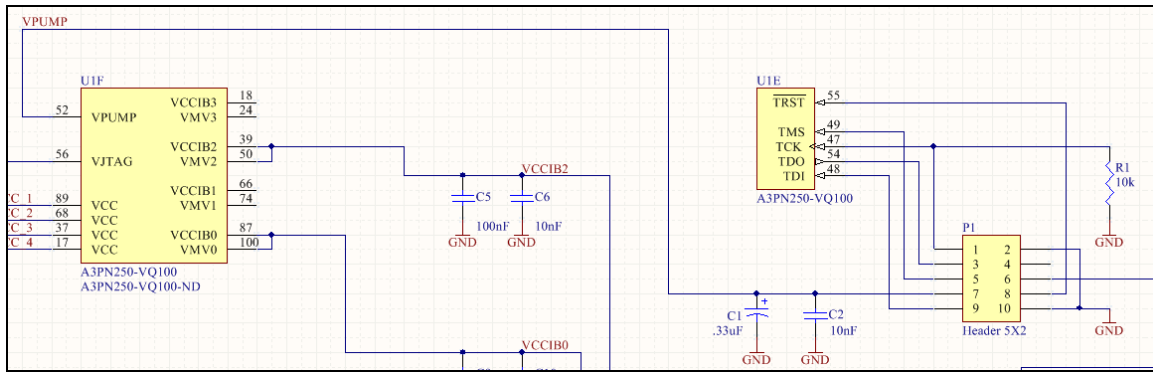

Figure 68. Schematic wiring diagram of JTAG interface header to ProASIC3 nano connection points on PA3TB.

The complete ProASIC3 Test Board schematic is presented in Appendix A.

3. Discussion of PCB Layout and Component Placement

After schematic design of the ProASIC3 Test Board was complete, development moved into the PCB layout and board management phase. The PCB was setup with the previously specified dimensions and layer configuration and all components from the schematic phase brought into the layout view for placement. Initial work concentrated on placing the ProASIC3 nano FPGA toward the center of the board design to obtain area utilization data. The FPGA was seen to require approximately 12% to 15% of the available board area on the top face of the PCB (including fan-out pad fingers). Work was then done to place the de-coupling capacitors as close to the FPGA as possible, in line with the manufacturer recommendations. Thus, the capacitors were placed within the footprint of the FPGA on the bottom face of the PCB. They are staggered in a

configuration which allows them all to fit and utilize vias for connection from top to bottom signal layer planes to their associated V_{CC} and GND connections.

Placement of the USB, power header, and JTAG header occurred next as these were the next largest components on the PCB. The headers and connector were also placed on the top face of the PCB to allow for the bottom face of the board to rest flat upon a surface. When associated with their required resistors and capacitors, the combination of USB, headers, and FPGA utilize approximately 50% of the available PCB area. This is before any wiring was accomplished to tie electrical connections together. The USB and power header were placed near the top of the PCB; since the power harness extends quite a distance from the PCB to the associated bench power supply, this reduces wiring clutter with the JTAG interface. The JTAG interface was placed at the bottom of the PCB, allowing for electrical connection to the FlashPro4 programmer via ribbon cable.

Layout of the PWR, TST0 – TST2, and BIT0 – BIT7 LEDs with their associated resistors was then undertaken. These components were seen to fill another 25% of the PCB top layer area. All of the BIT indicators were placed on the left side of the PCB so that any prototyped sequencer timings could be quickly visualized on LED indication. The power indicator and TST LEDs were placed at the top-right of the PCB to keep them separated from the BIT indicators. This also has the benefit of tying these lines to their ‘Bank 0’ electrical connections on the FPGA without any complicated routing requirements.

The sixteen copper pad areas were placed in the middle and lower-right section of the PCB. These are used in the connection of the PCB to any external equipment desired; the first iteration of the sequencer relay board can be tested with these I/Os for prototyping of the sequencer logic. This allows for a quick breadboard type setup to be accomplished while work is completed on the SADv3 design.

All of the remaining board area was used for the connection of signal lines between the FPGA, secondary components, and required resistors and capacitors. The large diameter vias for power and ground supply were tied to the internal V_{CC} and GND

planes, which connected the internal power planes to their associated nets. With this method, extraneous wiring from component ground points to localized vias is minimized.

Most of the top face traces are associated with the LED indicators or copper pad fingers. The bottom face traces are associated with the various capacitor and resistor banks. Wiring was accomplished with 8.0 mil traces. Care was taken to avoid any right angle routed traces. All PCB footprints and component identifications were placed on top and bottom silkscreen layers, with board identification information filling the remaining space.

4. Physical Construction and Testing

After completion of PCB layout, the design was exported in mechanical and electrical Gerber Computer-Aided Manufacturing (CAM) files for fabrication. These files were verified by automated design checking tools by Advanced Circuits [103]. This allowed for any mechanical or electrical deficiencies to be detected prior to manufacturing; several issues were reported as potential errors and these were corrected with corrected CAM files re-exported. Since the initial PA3TB run consisted of only three boards, these were sent to a local PCB manufacturer for production [104]. This was a lower-cost option for small production runs of non-flight, non-ITAR (International Traffic in Arms Regulations) hardware restricted PCBs. The turn-around time for the manufacturing of the PCBs was approximately two weeks. One of the manufactured PCBs prior to integration appears in Figure 69.

Figure 69. Manufactured four-layer PCB with gold surface pads and through-hole vias.

One the PCBs were received, work began on the integration of surface-mount components onto the PCB. This was accomplished with a PACE PRC 200 Process Control System station equipped with a microscope and video camera output, as seen in Figure 70. The soldering iron was equipped with the smallest tip available, a 1/64 in. conical sharp tip set at an 800 F operating temperature.

Figure 70. External camera view of ProASIC3 nano soldering to PCB board as seen through the microscope.

All soldering was done under the microscope with the finest diameter solder in the laboratory, Kester “44” 0.38 mm lead-tin (Sn 63% / Pb 37%) rosin-core. This fine diameter solder was very well suited to the 0603 surface-mount component size and VQ100 FPGA package pins. A Luxo 150-watt fiber optic illuminator provided extra lighting under magnification for ease of assemble. Thorough wetting with a Kester #186 rosin flux, type RMA Flux-Pen²⁸ was necessary to prevent oxidation of surfaces and ease of solder flow. The assembly of all three PCBs, as seen in Figure 71, took approximately five days.

²⁸ Flux-Pen™ is a trademark of Kester.

Figure 71. All three ProASIC3 Test Boards soldered and integrated—ready for testing.

After assembly of the PCBs, electrical testing of the PA3TB proceeded with the test bench setup illustrated in Figure 72. The ProASIC3 Test Board was connected to the bench-top power supplies with the FlashPro4 programmer attached to the JTAG interface. Initially, there were issues with the configuration of the FPGA, as the device would pass the JTAG scan chain with a returned identification (ID) code; however, erasing and configuration of the FPGA failed. The problem was determined to be in the power wiring to the PCB. Once a new power harness was constructed, using the appropriate end connector and clamped pin sets, the problem with erasing and configuration of the FPGA was resolved. All device tests passed and programming of several test bitstream files succeeded.

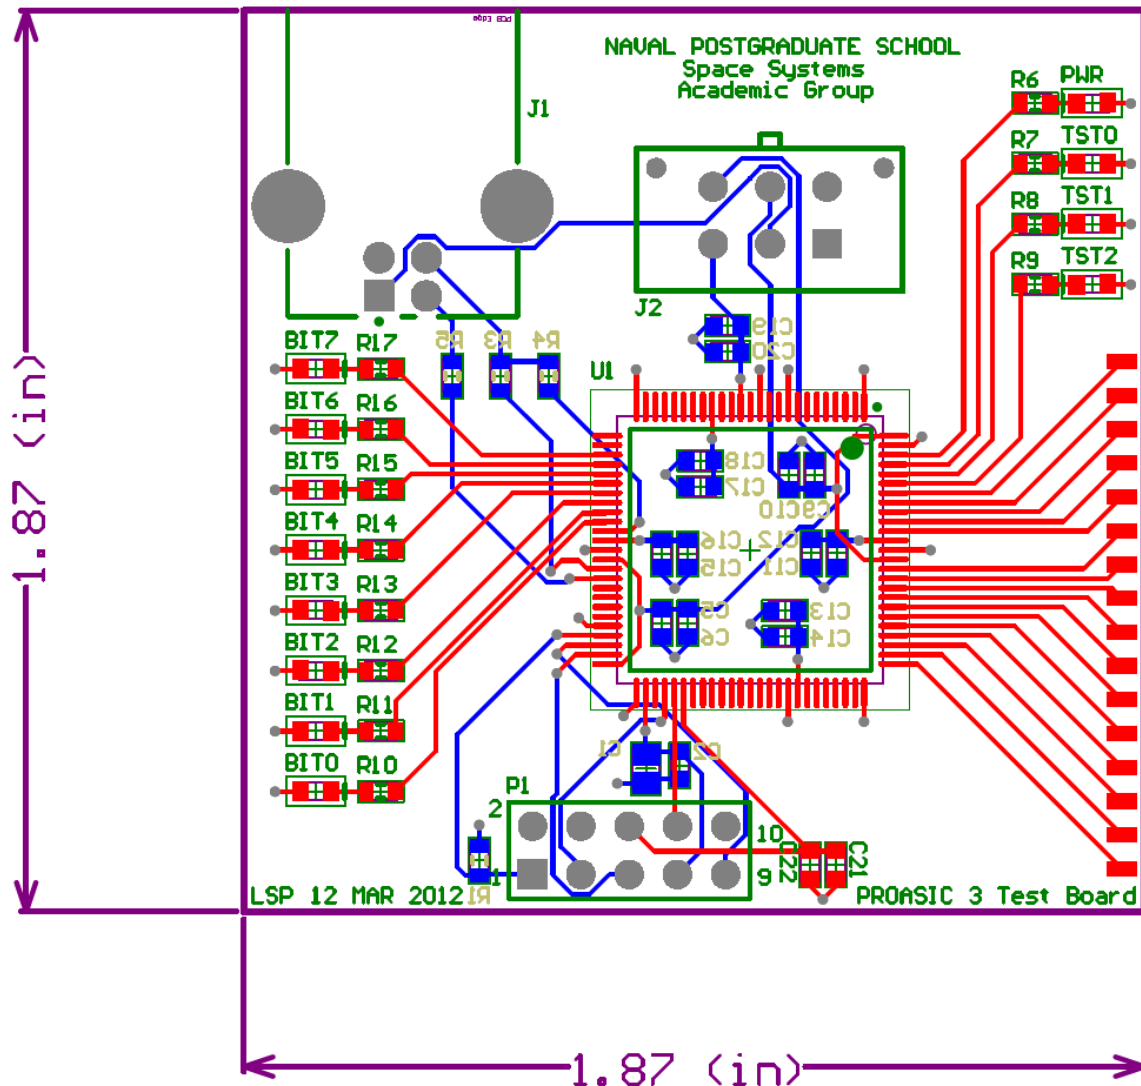

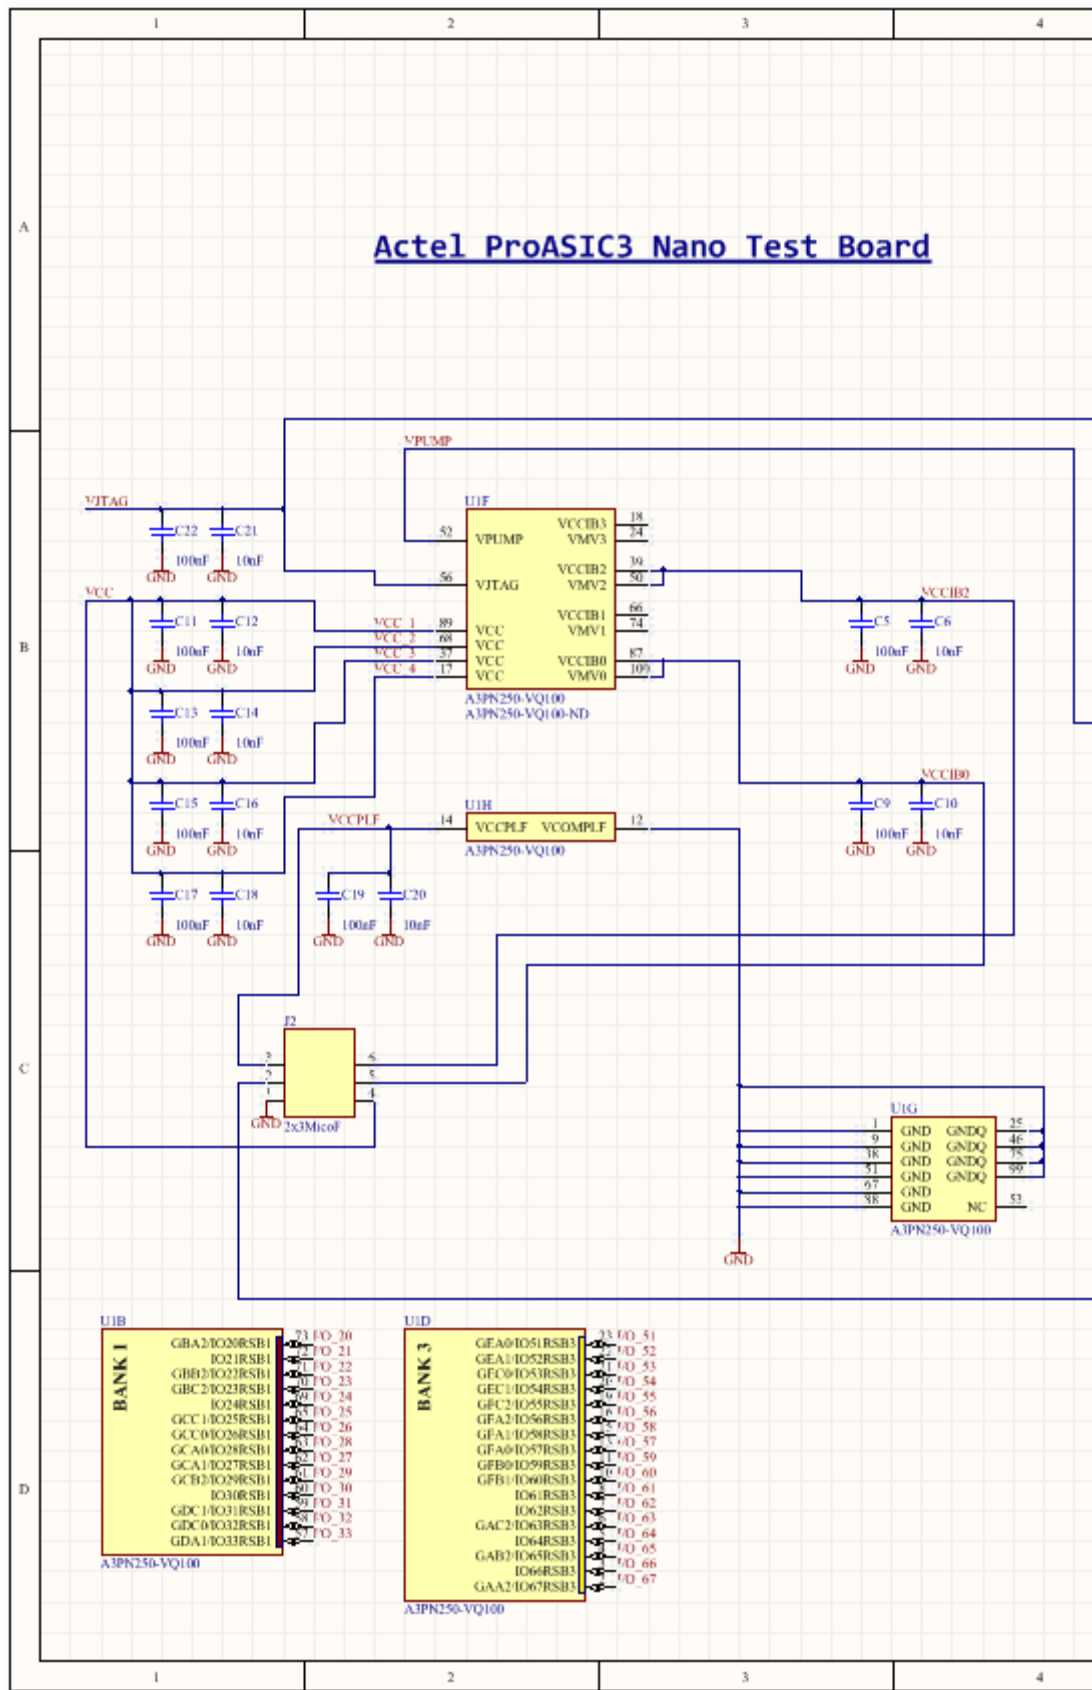

Figure 72. Test bench setup of ProASIC3 Test Board wired to power supply; FlashPro4 interface via USB to desktop computer station and programmer interface.

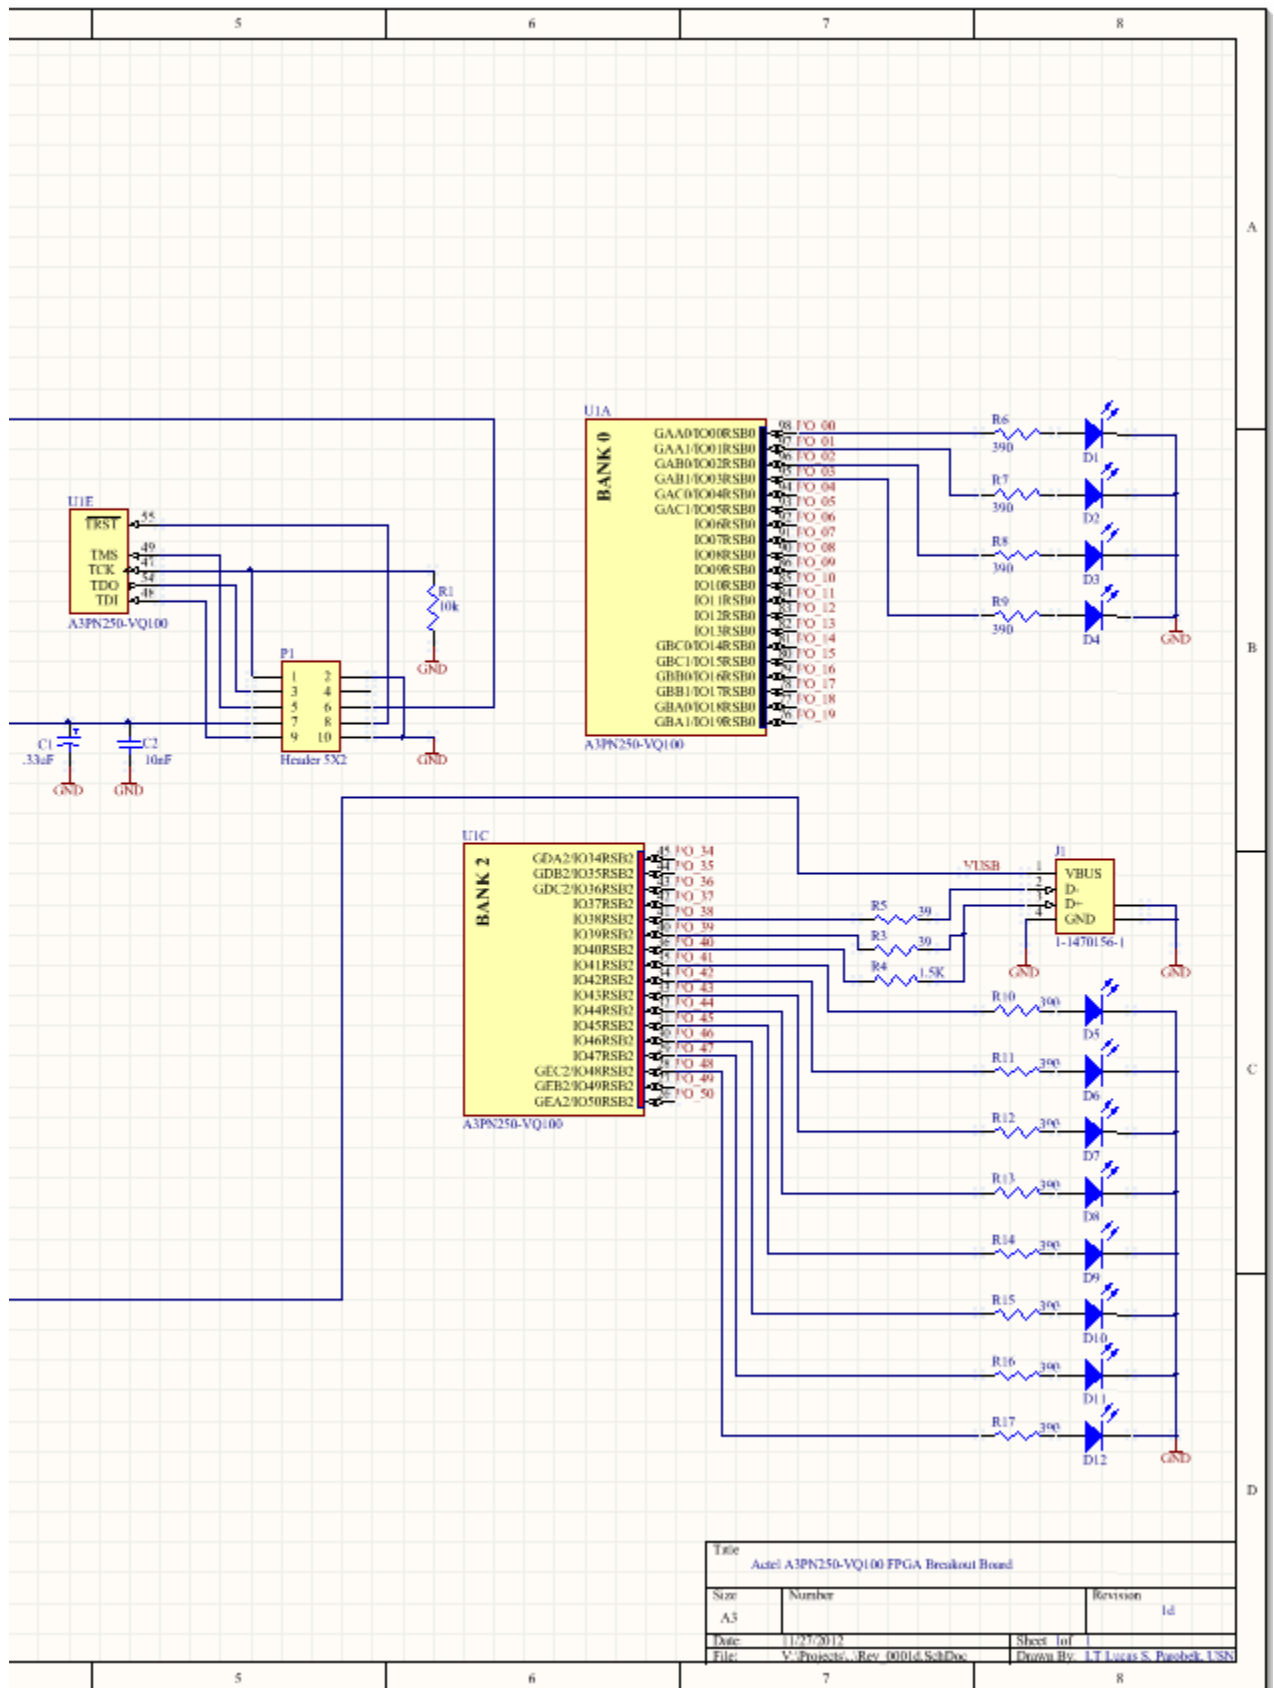

Initial testing of LEDs for verification through Verilog coding was successful, all initial pin-out specifications and PCB layout graphics for the trial design are located in later sections of this appendix. For the Verilog test code for LED testing, see Appendix D.

B.3 MECHANICAL DIMENSIONS AND ELECTRICAL SCHEMATICS

The following diagrams illustrate the mechanical sizing constraints and electrical schematics for the PA3TB. The schematic is broken up into left and right-halves to fit the size constraints of the page. The schematics are available electronically for import into Altium, for reproduction or modification of the design as necessary.

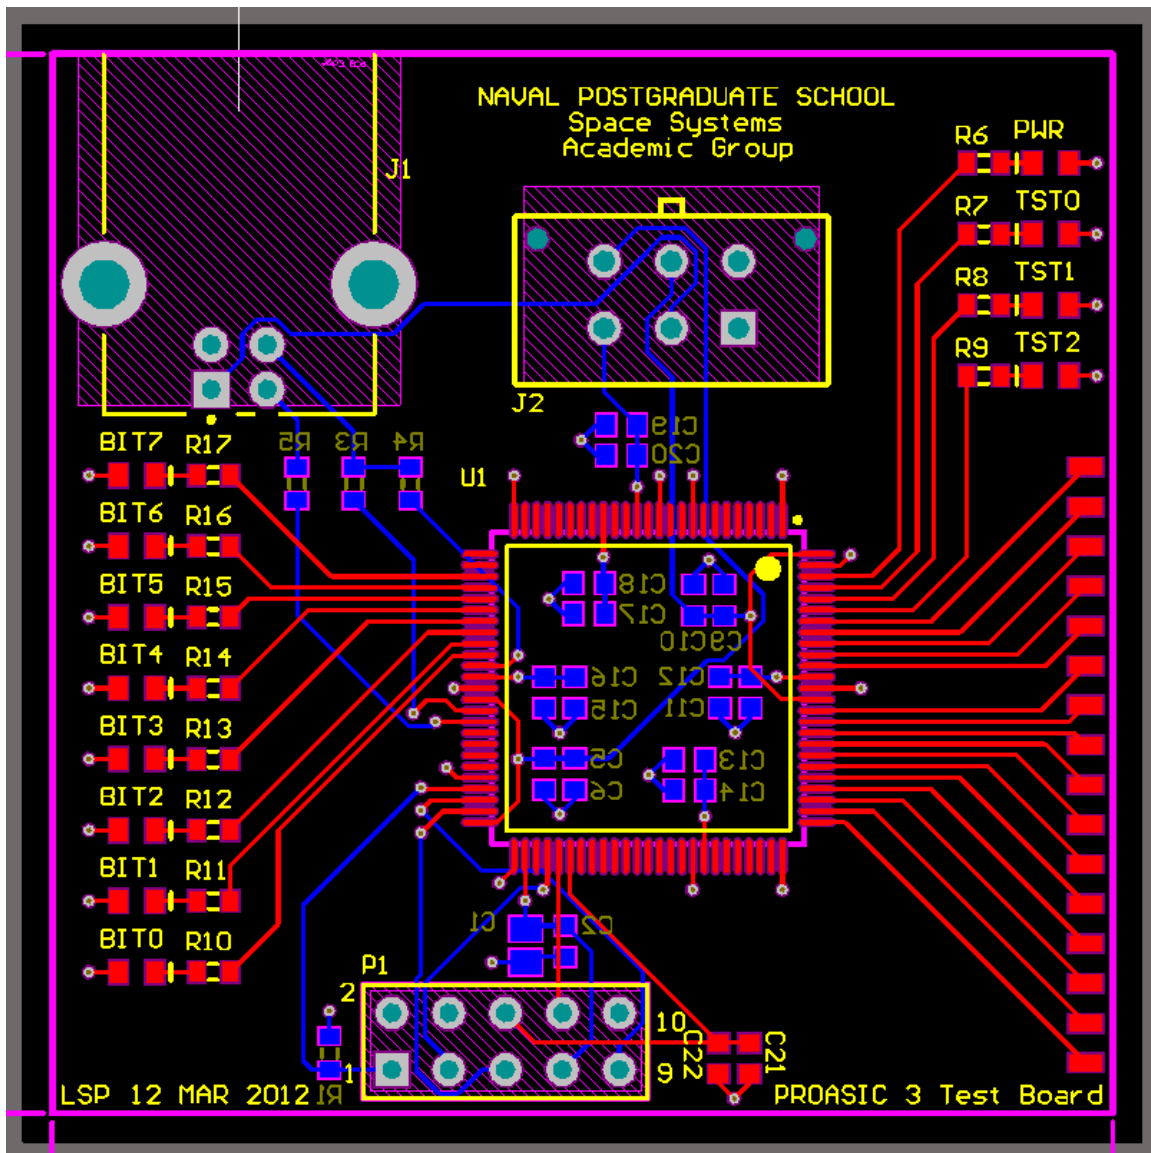

B.4 2-D PCB LAYER DIAGRAMS

The following PCB layer diagrams illustrate the layout decisions in the PA3TB placement of components. The various diagrams included are the overall layer set, signal layer, plane layer, non-signal layer, and mechanical layer. These layouts are available electronically for import into Altium, for reproduction or modification of the design as necessary.

B.5 3-D PCB COMPONENT PLACEMENT

Top and bottom face 3-D views of the PA3TB are provided to depict component fit and placement upon the PCB. These layouts are available electronically for import into Altium, for reproduction or modification of the design as necessary.

B.6 APPENDIX SUMMARY

In Appendix B, the development of the design was presented from schematic to PCB layout with reasons presented for component selection and placement. A complete description of the board assembly process was provided, with difficulties in manufacture specified. An overview of the PCB testing process for programming was outlined with the initial power supply harness issue resolution. The work in this appendix led to the development of the SADv3 presented in Chapter IV.

THIS PAGE INTENTIONALLY LEFT BLANK

APPENDIX C. SAD VERSION 3 – FLIGHT PROTOTYPE BOARD – REFERENCE, SCHEMATICS, AND PCB LAYOUT DIAGRAMS

The design files for the SAD Version 3 – Flight Prototype Board are divided into four sections: the bill of materials, schematics for electrical connections, the 2-D PCB layout documents, and 3-D component placement views. All of the associated documents were constructed using Altium Designer 10 during the development portion of this research.

C.1 SAD VERSION 3 – FLIGHT PROTOTYPE BOARD DEVELOPMENT METHODOLOGY

1. Selection of Board Size and Layer Count

The transition of sequencer from the PA3TB to SADv3 necessitates an increased board size and layer count to support the BGA FPGA and fit within the confines of the SAD enclosure. The scope for interface within the enclosure incorporates the sequencer as a motherboard. The relay firing circuitry is attached as a daughter-board via ribbon cable. The overall dimensions of the SADv3 board utilized are 9.81 in. \times 3.28 in. (32.177 in²). These dimensions, however, do not take into account the reduced area due to cut-outs for possible inclusion of battery packs, bolt holes, and rounded corners to fit within the enclosure. The size and shape of the board were chosen to conform to the already specified size of the relay board. The relay board will fit underneath the sequencer board, attached with the same bolt-hole pattern and ribbon cable for signal transmission. This board is in the process of being developed with primary work on it accomplished by another student [105]. The current PCB design for the relay board is shown in Figure 73. Manufacturing and testing of this relay board had not occurred at the time of publication of this thesis.

Figure 73. Current 2-D layout and 3-D component placement of SADv3 Relay daughter-board with size and shape for proper enclosure fit (From [98]).

Since the SADv3 has an increased board size, there were additional areas for expansion upon the PCB itself. These were targeted for the incorporation of additional SRAM and flash-memory devices and a breadboard prototyping area. Additionally,

headers were desired for ease of connection to the various general and differential pair I/Os. These were accommodated by three 40-pin headers (20×2).

To properly develop the SADv3 layer design, the move to a six-layer PCB was accomplished. Attempting to fan-out the BGA FPGA was possible at this layer count; however, there were insufficient power planes internal to the PCB to fit the overall voltage scheme. Due to the requirements for a 3.3, 2.5, and 1.2 V_{DC} power supply, plus the addition of a ground plane, the decision was made to transition to an eight-layer design. This allows for the incorporation of the ground and power planes internal to the PCB with the outer four planes consisting of signal layers. The power planes and ground plane were structured in a manner to limit the capacitance between layers or any inductive effects that may impact signal lines. The overall layer structure of the SADv3 is illustrated in Figure 74. Through-hole vias were used throughout the design for coupling between layers.

Figure 74. Eight-layer stack of the SAD Version 3 – Flight Prototype Board with internal power planes and external signal layers.

Figure 75. Final fanned-out configuration of the ProASIC3EL FPGA with multiple signal layers and all vias visible.

The final fan-out configuration of the ProASIC3EL FG484 BGA FPGA is shown in Figure 75. This configuration was chosen as the optimum solution once the additional power planes were added to the footprint of the FPGA design. This allowed for through-hole vias connecting to the necessary pins of the device while still allowing for enough room to route signal lines. This was not possible with the previous six-layer PCB design as there were certain pins trapped within the footprint. In addition, the revised eight-layer PCB allowed for the proper fan-out configuration of a crossed middle-channel open beneath the footprint of the FPGA, as illustrated in Figure 76. This allows enough room for various power decoupling capacitors to be placed immediately below and near the BGA footprint vias on the bottom plane of the board. To properly fit these surface-mount technology (SMT) capacitors within the footprint of the center-channel left, sizing of the capacitors must be equal to or less than 0603. Fortunately, many of the secondary required components to support the FPGA could be maintained at the 0603 footprint; although, some of the smaller resistors chosen necessitated 0402 sizing. Past experience shows manually soldering at less than 0603 size to be problematic.

Figure 76. Bottom plane pattern of vias within FPGA footprint on eight-layer PCB with room for center-channel power decoupling capacitors.

2. Selection of Components

In contrast to the off-board power supply scheme of the PA3TB, the SADv3 requires all associated power supply hardware to be co-located upon the PCB for proper operation. Due to the increased requirement for multiple voltage levels, the supporting circuitry designed for power distribution included 3.3, 2.5, and 1.2 V_{DC} levels. Texas Instruments low-dropout (LDO) low-power linear voltage regulators (P/N TPS79601) were chosen as the means of reducing the +5 V_{DC} input voltage to the required levels. These devices feature high power supply rejection ratio (PSRR), ultralow-noise, fast start-up, and excellent line and load transient responses [106].

For future expansion purposes, the inclusion of SRAM and flash-based memory was necessary to allow for more data handling capability by the FPGA. Choice of the memory devices used was done in concert with the reference design for the ProASIC3 development board. This was done to allow for design modifications where necessary while allowing for similar pin specification and design constrain files to be utilized. In the case of the sequencer, these devices will not be necessary for inclusion on the PCB, and the footprints can be left open if not included. For the CMOS Static RAM, 4-Mbit

(256k words \times 16-bit) devices were chosen from Cypress Semiconductor (P/N CY7C1041DV33) [106]. The logic block diagram of these SRAM chips can be seen in Figure 77 with proper address and data lines specified.

The embedded flash-memory used for this design consisted of two Intel / Numonyx™ 0.13 μ m NOR-based, 64-Mbit density devices (P/N JS28F640J3D-75). Specified features include reliable, low-voltage capability (3 V_{DC} read, program, and erase) with high-speed, low-power operation [107]. These feature 75 ns initial access speed and operation at the 3.3 V_{DC} voltage level. The 64-Mbit capacity (8 Mbyte) is configured as sixty-four 128-kbyte erase blocks. Security features are also present on the device that prevent altering of code through different code protection schemes that can be implemented based on user requirements [107]. The logic block diagram of these flash-memory chips can be seen in Figure 78. All lines indicated are utilized as per specification in the manufacture's datasheet [107].

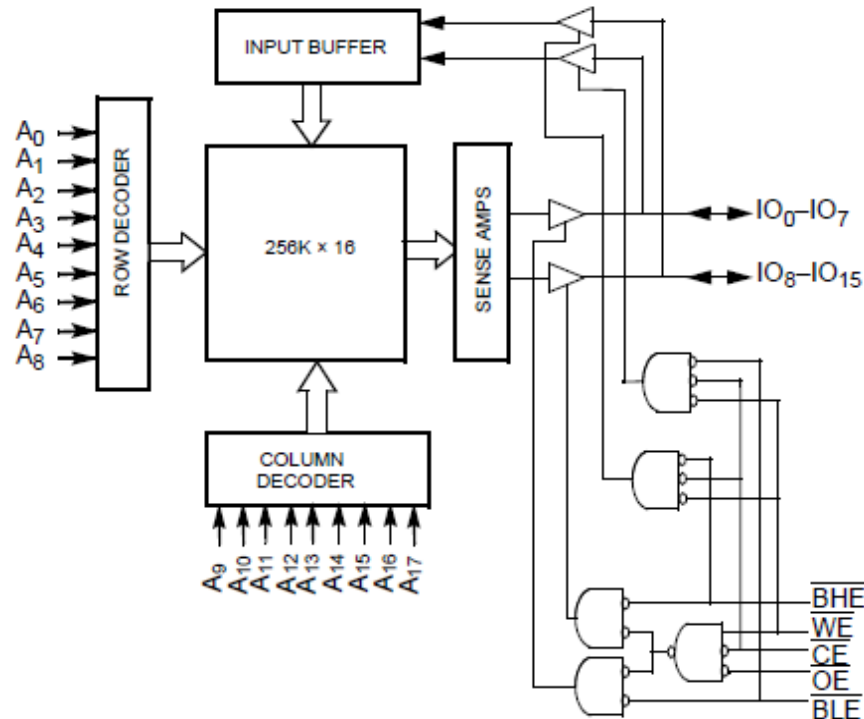

Figure 77. Logic block diagram of Cypress Semiconductor 4-Mbit (256k words \times 16-bit) SRAM devices illustrating address and data line use (From [99]).

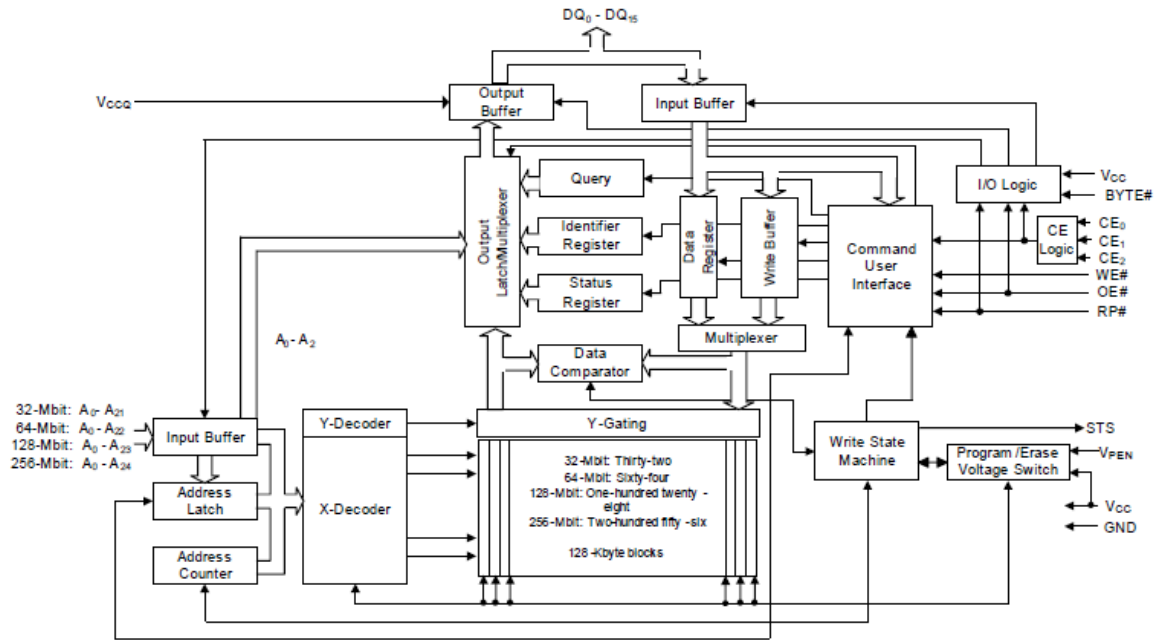

Figure 78. Logic block diagram of Numonyx™ 64-Mbit embedded flash-memory devices illustrating address, data, and signal line use (From [107]).

The incorporation of a crystal clock oscillator was necessary to allow for future timing accuracy as a secondary clock signal source for the FPGA. Similar to the reference design, an Abracon 48.0-MHz through-hole oscillator was chosen for inclusion (P/N ACHL 48.0MHz-EK). This design features a compatible 3.3 VDC supply voltage, CMOS and transistor-transistor logic (TTL) compatibility, and tight frequency stability on the order of ± 30 parts per million (ppm) [108].

The remainder of components chosen was done to maximize the design similarities between the PA3TB and the SADv3. The JTAG interface design was reutilized with capacitor differences utilized where necessary. Additionally, the test LEDs of the PA3TB were included for troubleshooting purposes. An ‘always-on’ power LED was substituted for the PWR LED of the PA3TB; this change was made for easy of seeing the board power application, as a commanded signal should not be necessary for board power indication.

The full ‘Bill of Materials’ for the SAD Version 3 – Flight Prototype Board is provided in Appendix B.

3. Discussion of Schematic

The first component placed on the schematic was the ProASIC3EL BGA FPGA, with instantiation provided via the Altium Hobart vault. This online design vault specifies many of the FPGA devices made by vendors and greatly simplifies the inclusion into a design. The schematic layout of the FPGA consisted of seven banks, four of which were the associated ‘Bank 0 through 4’ as provided in datasheet specifications. The remaining banks were either non-connections or power and ground supply for core and bank voltages. A great deal of time was spent specifying the signal lines in a similar format to the ProASIC3 development board reference design.

The setup of the TPS79601 power supply circuitry was accomplished as specified in the datasheet, as illustrated in Figure 79. Within that diagram input voltage (V_{IN}) and output voltage (V_{OUT}) points lie at the left and right of the diagram respectively. Additionally, the unregulated input to the device (IN), enabling pin to turn on the regulator (EN), regulator ground (GND), output of the regulator (OUT), and feedback input voltage for adjustment (FB) terminals are all visible [109]. Specification of the desired output voltage utilized the following:

$$V_{OUT} = V_{REF} \times \left(1 + \frac{R_1}{R_2}\right) \text{ where } V_{OUT} = 1.2246 \text{ V}_{DC} \quad (2)$$

and

$$R_1 = \left(\frac{V_{OUT}}{V_{REF}} - 1\right) \times R_2. \quad (3)$$

As per Equation (2), R_1 and R_2 must be chosen for approximately 40 μA of divider current [109]. The recommended design procedure is to choose $R_2 = 30.1 \text{ k}\Omega$ to set the divider current at 40 μA , set $C_1 = 15 \text{ pF}$ for stability, and then calculate R_1 using Equation (3). The output capacitor was changed from the 1 μF value to 2.2 μF , as per datasheet specifications [109]. There were three difference circuits schematically wired to meet the positive voltage requirements of the FPGA and associated circuitry. All three voltages were placed into nets for inclusion in the internal power planes of the PCB. This

will allow for local power to be provided rather than tracing out long power lines to the FPGA and secondary components.

Figure 79. TPS79601 adjustable LDO regulator programming schematic for proper specification of R_1 and R_2 values (From [109]).

After development of the additional power circuitry necessary to power the board concluded, work was done to add the additional SRAM and flash-based memory to the design. The devices were wired with address and data lines as specified in datasheets [106], [107]. The schematic layouts of the SRAM and flash-memory devices are seen in Figure 80. The various data and address lines are wired to the appropriate pins of the FPGA with data control lines included as applicable. Both types of memory devices are wired to the 3.3 V_{DC} net, which allows for via coupling the associated voltage plane. A more complete representation of these layouts with their associated power decoupling capacitors may be found in Appendix B.

The general purpose and differential pair I/Os were next placed on the schematic with the various data lines being coupled to the 40-pin headers as appropriate. The general purpose I/Os utilize the 3.3 V_{DC} voltage net, while the low-voltage differential signaling (LVDS) signal lines utilize the 2.5 V_{DC} net. The schematic representation of a subset of these connectors is illustrated in Figure 81.

All of the remaining power de-coupling capacitors, JTAG circuitry, resistor banks, and clock oscillation circuitry were wired as in the PA3TB case or as specified by datasheets. The complete SAD Version 3 – Flight Prototype Board schematic is presented in Appendix B for further reference if modification to the design is desired.

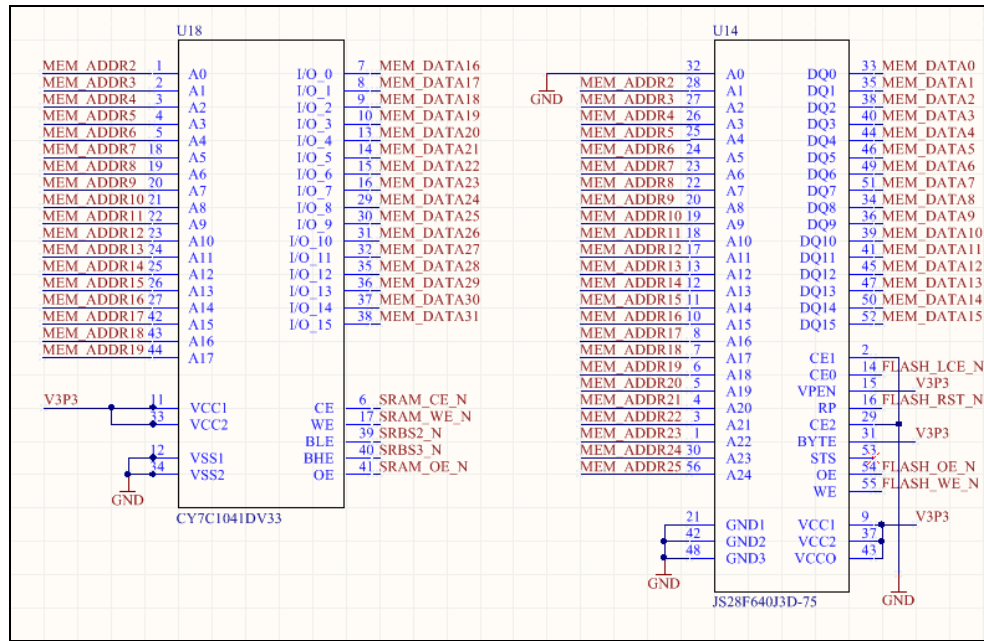

Figure 80. Schematic wiring of SRAM and flash-memory devices with address, control, and data lines as specified by design documents.

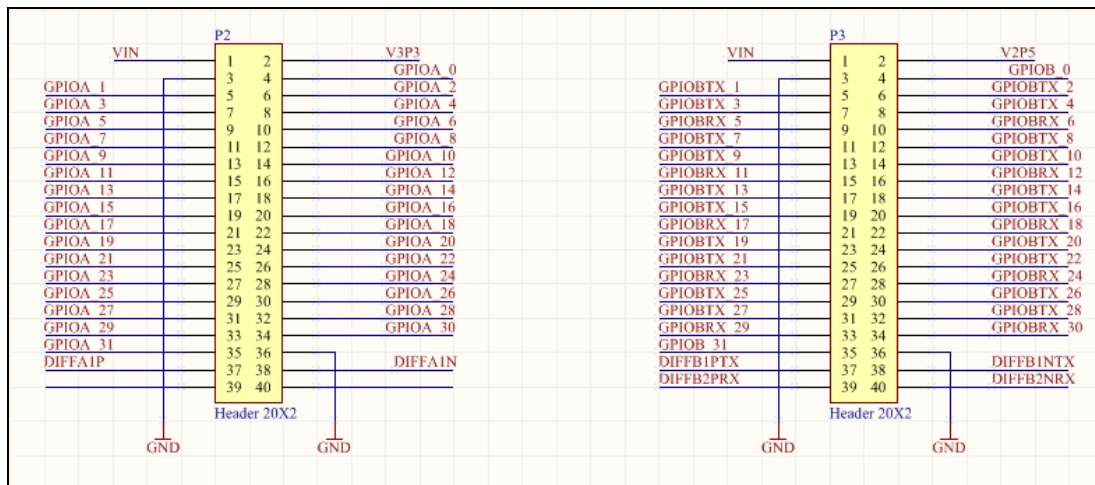

Figure 81. 40-pin general digital and LVDS headers as placed on the schematic.

4. Discussion of PCB Layout and Component Placement

After placement of the ProASIC3EL BGA FPGA, 40-pin I/O headers, breadboard prototyping area, and relay board connector as previously discussed in this chapter, the placement of the SRAM and flash-memory was accomplished. These were placed as close to the FPGA as practical to limit signal line losses between the components. The

orientation of these devices was done to best position the connectors of the memory chips to their respective pins on the FPGA. Fan-out of the memory devices was done to better route signal traces upon the four signal layers of the PCB. The flash-memory devices are located to the bottom of the FPGA when viewing the top plane, while the SRAM chips are located to the right of the FPGA footprint. The flash-memory devices come in 56-lead thin small-outline packages (TSOPs); the SRAM devices are 44-pin TSOPs (Z44-II). These devices required custom footprints and pin-outs to be built in the schematic and footprint editors in Altium. The location of these chips relative to the FPGA is seen in Figure 82.

Figure 82. Location of SRAM and flash-based memory chips relative to BGA FPGA device; JTAG header visible in lower-right corner.

All of the required power supply decoupling capacitors, LDO voltage regulators, resistor banks, JTAG circuitry, crystal clock oscillator, and any additional components were then added from the schematic to their associated PCB footprint. The LDO voltage regulators used the SOT223-6 footprint, which required additional custom footprint and pin-out specification in Altium. Placement of these individual components is a tedious process, requiring many weeks of locating components to their best electrical and physical separations. Wiring of these components will require at least one to two months of concerted work to associate all traces amongst the four signal layers.

Initial test cases were run to test various Altium settings on the auto-routing of the design. In all cases, the auto-router is limited in the choices it makes regarding traces. Though there are a myriad of settings available (including trace widths, bend radius, via allocations, and placement strategies), the output of the auto-router is not optimum in the decisions it makes regarding traces. There are many instances where shorter traces could be shortened or run across less signal layers. Portions of the initial auto-route 2-D and 3-D test cases of the PCB are illustrated in Figures 83 and 84. Certain features of the auto-router, especially fan-out, will be utilized in the final PCB board design; however, the majority of signal lines must be manually routed.

Figure 83. Auto-route testing of SRAM and flash-memory connections to ProASIC3EL FPGA across four-layer signal planes.

Figure 84. Initial 3-D footprint placement of FPGA and memory devices in isometric view of PCB top plane.

C.2 BILL OF MATERIALS

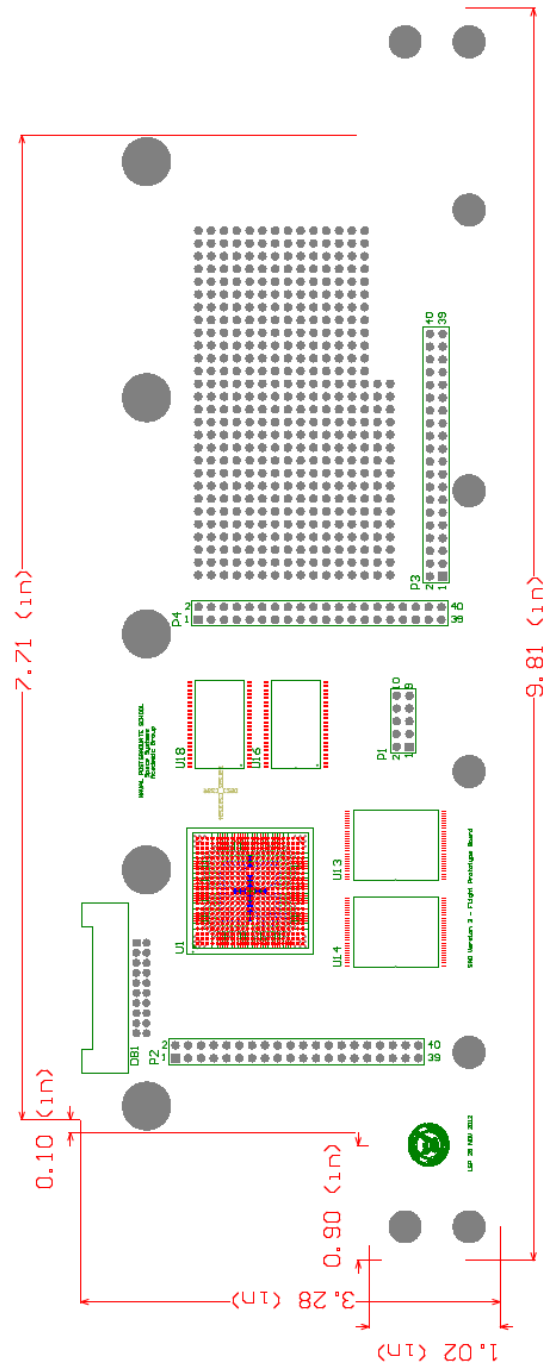

The following bill of materials specifies the required components necessary to construct the SADv3 in the same configuration specified schematically and in PCB layout. Values for the associated components are located on the schematics.

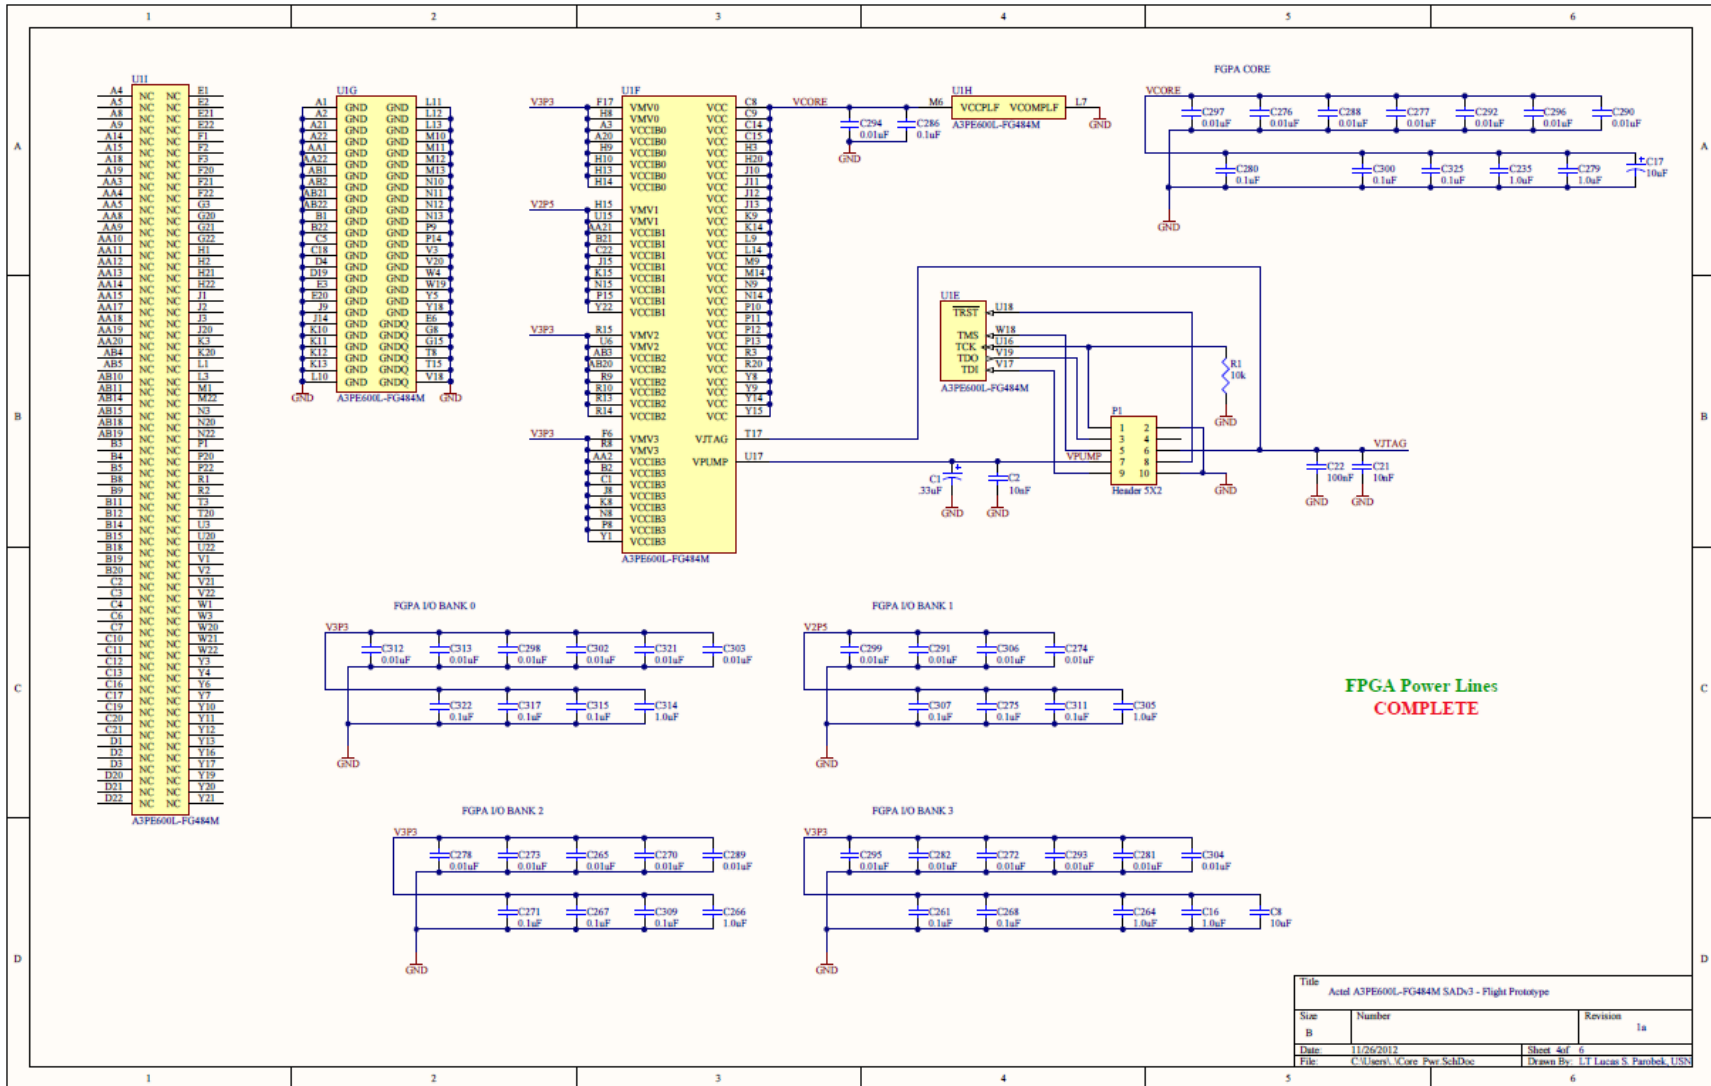

Comment	Description	Designator	Footprint	LibRef	Quantity
Cap Pol3	Polarized Capacitor (Surface Mount)	C1, C8, C11, C13, C14, C17, C227, C230, C243, C246	C0805	Cap Pol3	10

C.3 MECHANICAL DIMENSIONS AND ELECTRICAL SCHEMATICS

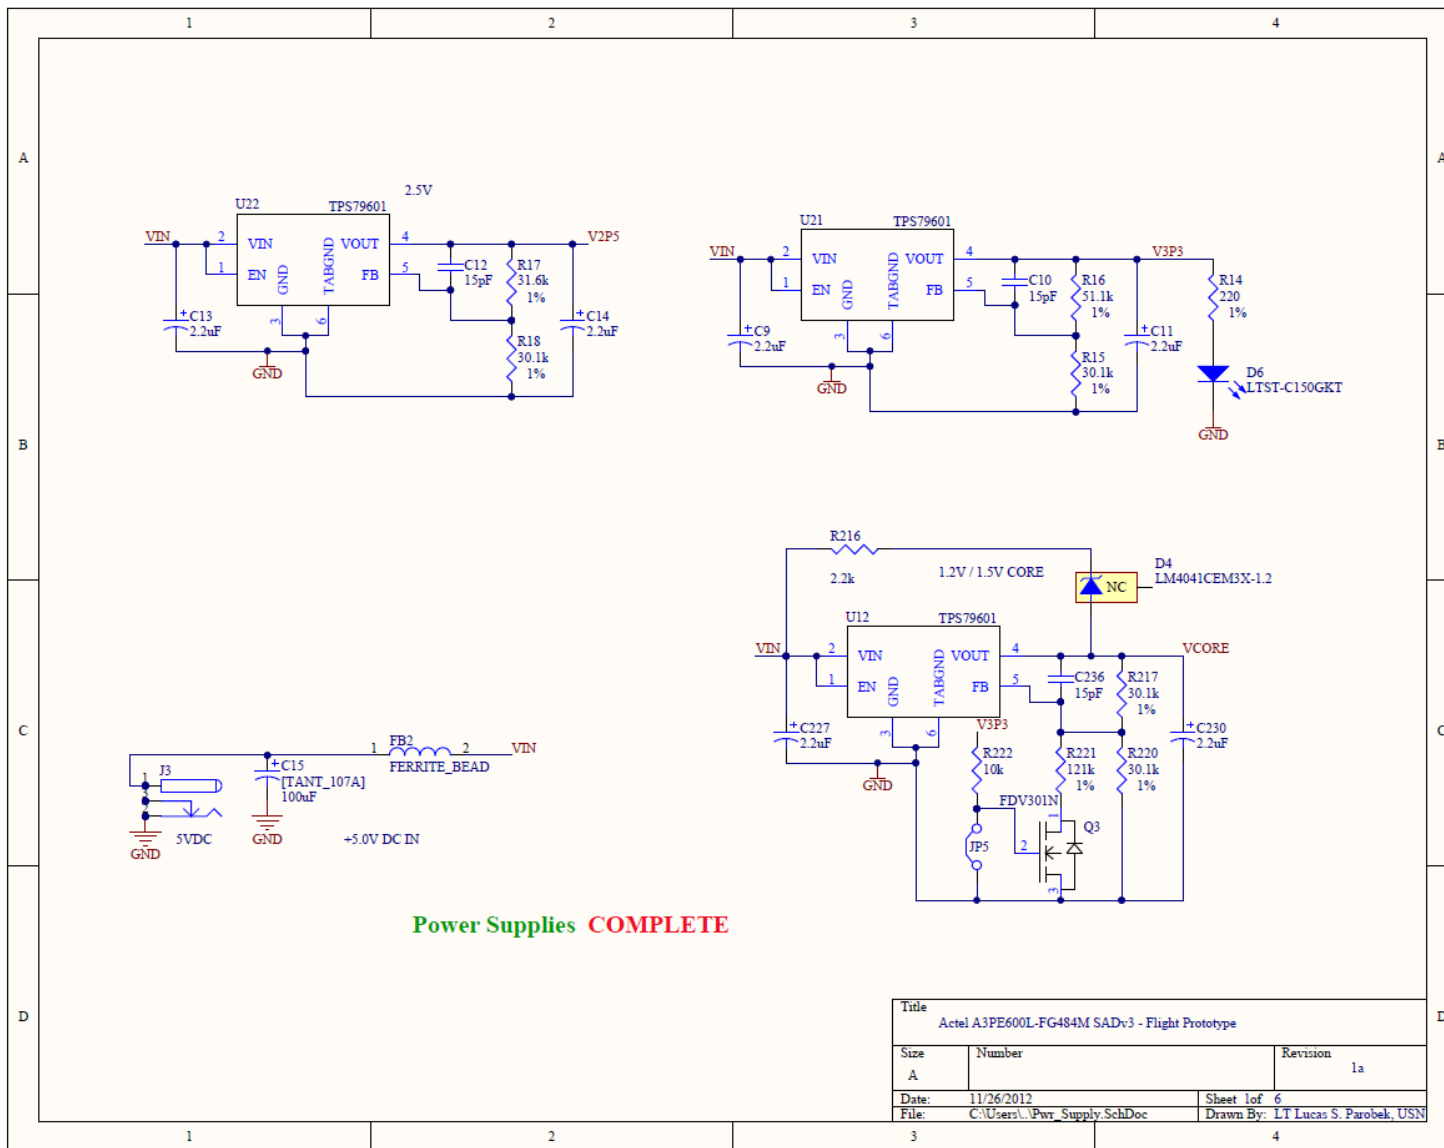

The following diagrams illustrate the mechanical sizing constraints and electrical schematics for the SADv3. The schematic is broken up into multiple pages for ease of viewing in this thesis format. An overall schematic is available electronically for import into Altium, for reproduction or modification of the design as necessary.

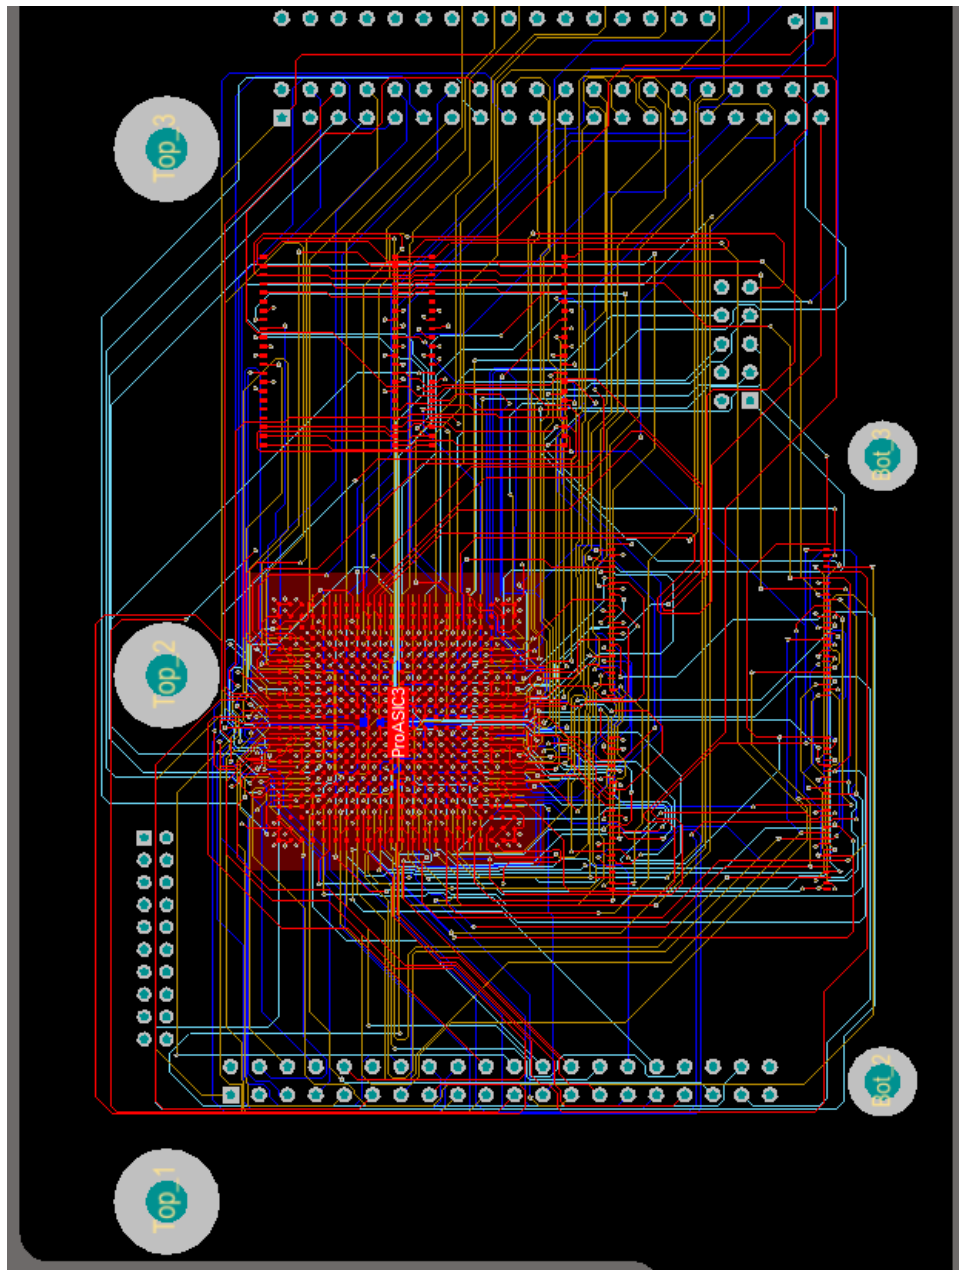

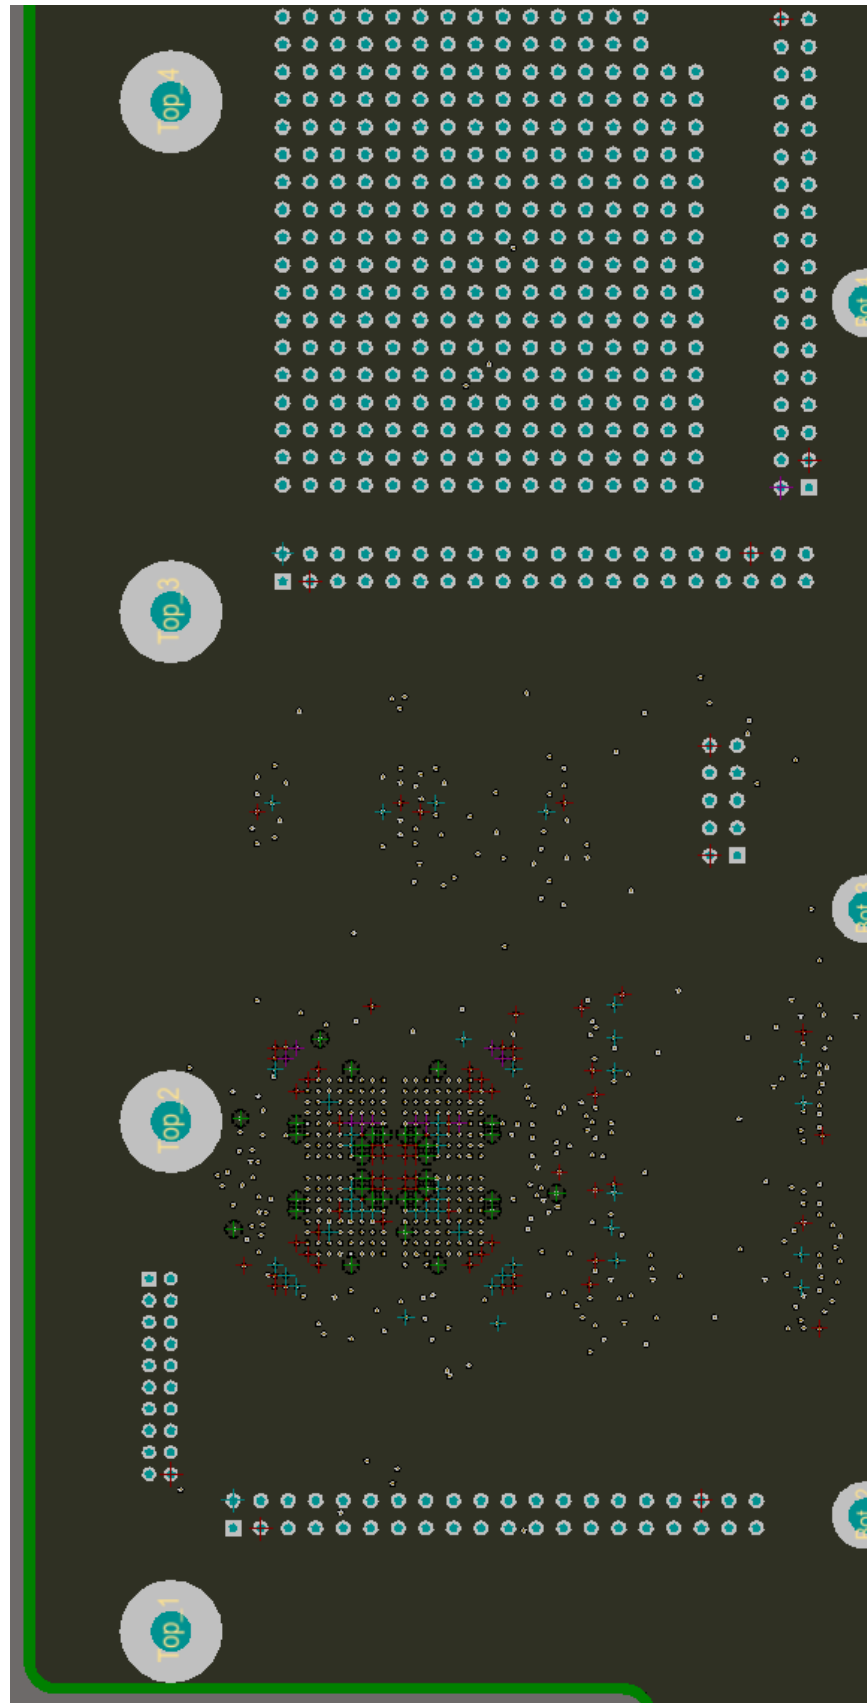

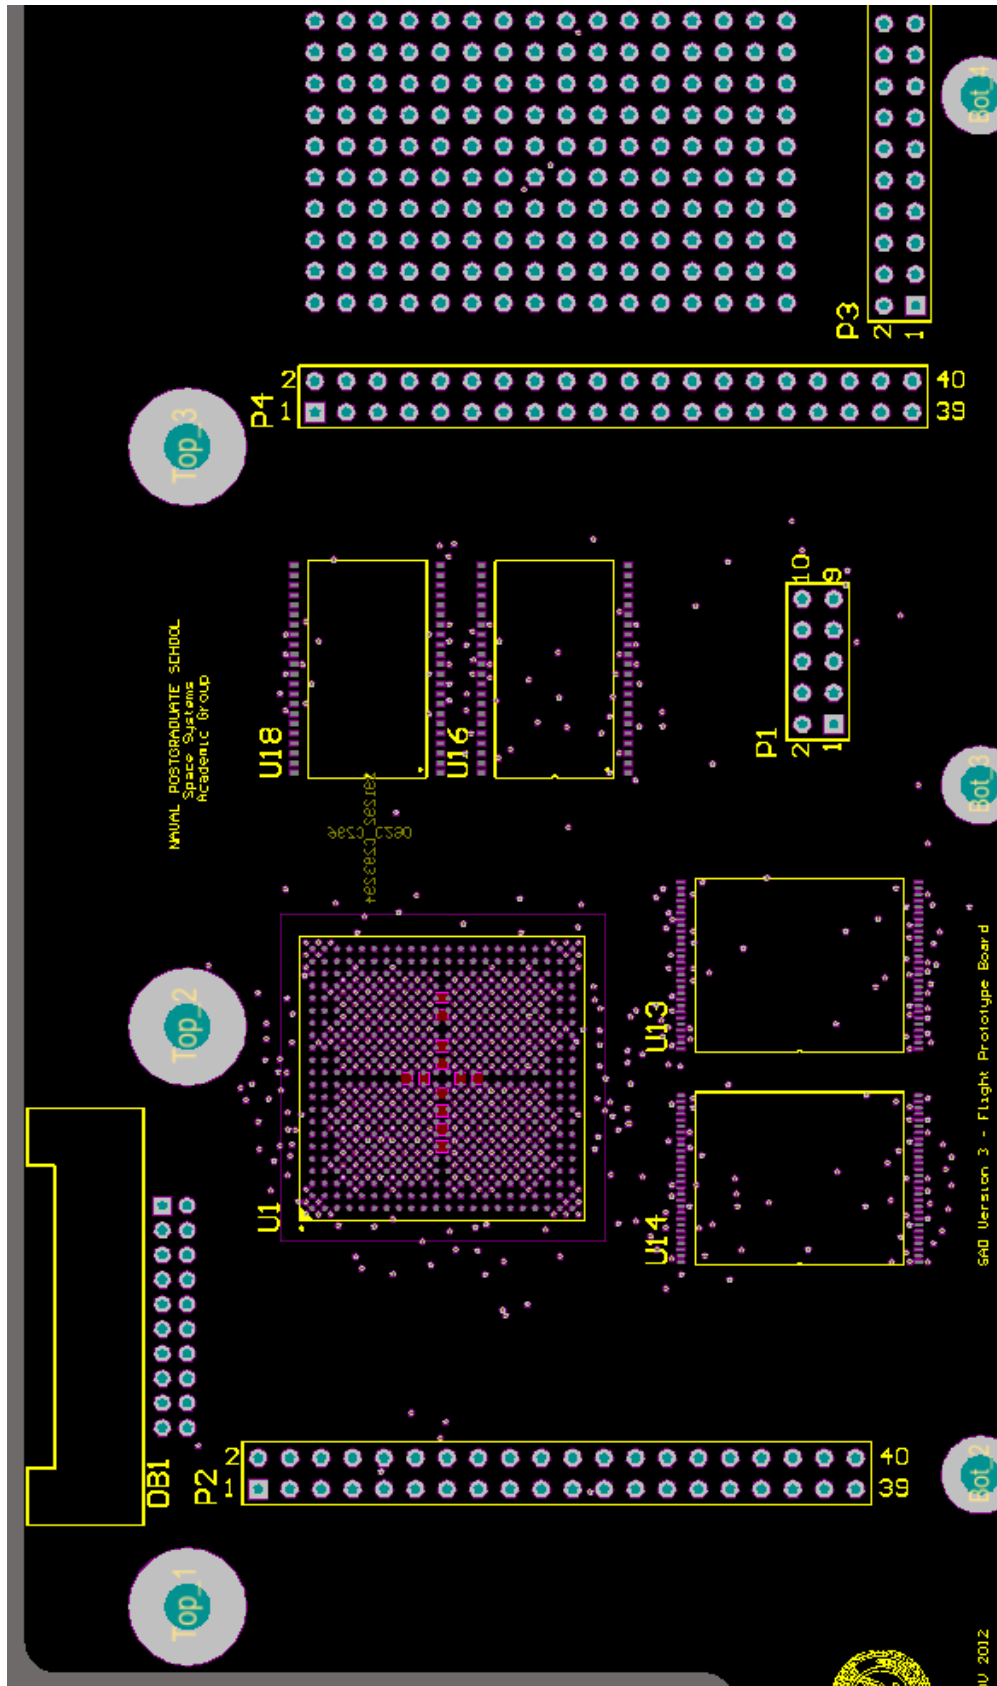

C.4 2-D PCB LAYER DIAGRAMS

The following PCB layer diagrams illustrate the layout decisions in the PA3TB placement of components. The various diagrams included are combined signal layers, plane layer, non-signal layer, mechanical layer, top plane layers, and bottom plane layers. These layouts are available electronically for import into Altium, for reproduction or modification of the design as necessary.

C.5 3-D PCB COMPONENT PLACEMENT

Top and bottom face 3-D views of the SADv3 are provided to depict component fit and placement upon the PCB. These layouts are available electronically for import into Altium for reproduction or modification of the design as necessary.

C.6 APPENDIX SUMMARY

In Appendix C, design decisions were presented concerning the manner in which they drove PCB component selection. Development of the design was presented from schematic to PCB layout with reasons presented for component selection and placement. Difficulties in schematic design with associated PCB layout complexities were presented.

APPENDIX D. SEQUENCER HDL PRESENTATION

The source code to generate the various bitstream files for testing of FSM and TMR logic was developed utilizing Verilog and VHDL. The code was synthesized using Xilinx ISE 14.3 and Libero SoC 10.1 and was executed on a Windows 7 PC with 8 GB of RAM and an Intel® i7™ 2600K CPU operating at 4.2 GHz. The code is designed for implementation onto the various Xilinx and Actel development kits and can be easily ported to the final SAD Version 3 - Flight Prototype Board.

All source code was formatted for presentation using Notepad++.

D.1.1 SEVEN-SEGMENT LED COUNTER (BASYS2USERDEMO.VHD)

The following code is a modified form of the top-level module for instantiation of a seven-segment LED counter with the clocking required:

```

D.1.3 SEVEN-SEGMENT LED COUNTER (VOTER.V)

The following code is a the voter module for instantiation of a seven-segment LED counter in TMR and corresponding switch and button inputs:

```
////////////////////////////////////
// Company: Naval Postgraduate School
// Engineer: LT Lucas S. Parobek
//
// Create Date:      19:48:32 10/23/2012
// Design Name:      Seven-Segment LED Counter - TMR Version
// Module Name:      voter.v
// Project Name:      Basys 2
// Target Devices:    Spartan 3E 100 (250)
// Tool versions:     ISE 14.3
// Description:       Voter module to allow for TMR representation of counter.
//
// Dependencies:      Basys2UserDemo.vhd (parent)
//
// Revision:
// Revision 1.00 - File Modified for Use in TMR Design
// Additional Comments: All switch and button lines voted on to allow for
//                      continued operation as per non-TMR design...
////////////////////////////////////
`timescale 1ns / 1ps
module voter(dp0,dp1,dp2,
            10,11,12,
            s0,s1,s2,
            a0,a1,a2,
            dp,led,seg,an);

    input dp0;
    input dp1;
    input dp2;

    input [7:0] 10;
    input [7:0] 11;
    input [7:0] 12;

    input [6:0] s0;
    input [6:0] s1;
    input [6:0] s2;

    input [3:0] a0;
    input [3:0] a1;
    input [3:0] a2;

    output dp;
    output [7:0] led;
    output [6:0] seg;
    output [3:0] an;

    assign dp = (dp0 & dp1) | (dp0 & dp2) | (dp1 & dp2);
    assign led = (10 & 11) | (10 & 12) | (11 & 12);
    assign seg = (s0 & s1) | (s0 & s2) | (s1 & s2);
    assign an = (a0 & a1) | (a0 & a2) | (a1 & a2);

endmodule
```

D.1.4 SEVEN-SEGMENT LED COUNTER (TMR SCHEMATIC)

The following schematic implements the seven-segment LED counter in TMR:

D.2 LAUNCH SEQUENCE GENERATOR (LAUNCH_SEQUENCER.VHD)

The following VHDL code provides the preliminary basis of the launch sequencer logic timing utilizing the FROM portion of the ProASIC3 to store timing constants:

```
