activities (29%), and motor vehicle crashes (24%). The case-fatality ratio was six deaths per 100 injured children. Of those children admitted to a hospital alive, 88% had a mild brain injury and 44% had no evidence of loss of consciousness. Two thirds of children with mild brain injuries and one third of those with serious brain injuries were transported to a hospital in private nonemergency vehicles.

2918. Kraus, J. F., et al. (1990). "Brain injuries among infants, children, adolescents, and young adults." American journal of diseases of children (1960) **144**(6): 684-691.

Blunt and penetrating force injuries to the brain constitute an enormous public health problem. If a child or young adult survives a moderate or severe brain injury, there is a strong likelihood of a lifetime of physical and mental impairment as well as tremendous economic and social impact on the family. The magnitude of this problem has only been recently appreciated, yet many questions on the causes and short- or long-term outcomes remain unanswered. One conclusion is clear: prevention is the best solution, but information on the nature of the brain injury, exposure factors, and effectiveness of countermeasures is incomplete. We sought to summarize certain basic epidemiological data on brain injuries in infants, children, adolescents, and young adults as well as findings on incidence of brain injury and current data on demographics and risk factors. We also estimated disability and person-years of life lost from brain injuries and highlight the value of helmets as a countermeasure for several exposures to head injury.

2920. Kretschmer, H. (1980). "[Cerebral missile injuries in civilian practice (author's transl)]." Hirnschussverletzungen in Friedenszeiten. **350**(3): 175-183.

Over a 10 year period we have treated 63 cases of cerebral gunshot injuries, most of them attempted suicides. Following the presentation of ballistic data, and the classification and pathophysiology of the clinical symptoms, early and late complications are reported in detail and recommendations for therapy given. The mortality rate of all admitted patients in our material was 60.9%; a direct relation between the severity of primary brain damage (recognizable in the degree of initial unconsciousness) and the chance of survival was found.

2921. Kriet, J. D., et al. (2005). "Self-inflicted submental and transoral gunshot wounds that produce nonfatal brain injuries: management and prognosis." Journal of neurosurgery **102**(6): 1029-1032.

OBJECT: Penetrating brain injuries caused by self-inflicted gunshot wounds are very often fatal and survivors suffer serious disabilities. Recognition of a possibly more favorable prognosis for a specific type of injury, the submental or transoral handgun or low-energy rifle wound, prompted the authors to review their experience with patients who had attempted suicide in this manner., METHODS: The records of 11 consecutive patients seen over a 10-year period (1992-2001) were retrospectively reviewed. Handguns were used by eight patients and .22 caliber rifles by the others. The patients presented with predominantly unilateral frontal brain injuries that required urgent attention. One elderly patient who had made an advance directive concerning care died. All other patients underwent craniotomy and repair of associated ophthalmological and maxillofacial injuries. Follow-up review ranged from 9 months to 3 years, during which time there were no repeated suicide attempts. All but one patient expressed satisfaction with their appearance and returned to a self-sufficient lifestyle., CONCLUSIONS: Self-inflicted submental and transoral handgun and low-energy rifle wounds may produce serious but survivable brain injuries if the path of the bullet is limited to the frontal area. Early aggressive management of brain, dural, and craniomaxillofacial injuries should return the patient to a highly functional neurological status and restore an acceptable outward appearance. Outcomes, therefore, appear to be much better for these patients than for most patients with a penetrating brain injury due to a self-inflicted gunshot wound.

2922. Kroehne, V., et al. (2011). "Regeneration of the adult zebrafish brain from neurogenic radial glia-type progenitors." Development (Cambridge, England) **138**(22): 4831-4841.

Severe traumatic injury to the adult mammalian CNS leads to life-long loss of function. By contrast, several non-mammalian vertebrate species, including adult zebrafish, have a remarkable ability to regenerate injured organs, including the CNS. However, the cellular and molecular mechanisms that enable or prevent CNS regeneration are largely

unknown. To study brain regeneration mechanisms in adult zebrafish, we developed a traumatic lesion assay, analyzed cellular reactions to injury and show that adult zebrafish can efficiently regenerate brain lesions and lack permanent glial scarring. Using Cre-loxP-based genetic lineage-tracing, we demonstrate that her4.1-positive ventricular radial glia progenitor cells react to injury, proliferate and generate neuroblasts that migrate to the lesion site. The newly generated neurons survive for more than 3 months, are decorated with synaptic contacts and express mature neuronal markers. Thus, regeneration after traumatic lesion of the adult zebrafish brain occurs efficiently from radial glia-type stem/progenitor cells.

2923. Kruchten, E. (2019). "Reevaluation of penetrating midface injury after removal of metallic foreign body." Folia neuropathologica **57**(3): 305.

Traumatic injuries of the midface can be life-threatening. Due to close anatomic proximity of vital structures and sensory systems, penetrating injuries of the skull base, the eye ball or the olfactory region can result in grave consequences. A timely diagnosis and treatment of such injuries is of the utmost importance. I report the case of a 64-year-old man presenting in the emergency room with a saucepan protruding from his right orbit. An initial CT-Scan was performed and showed multiple fractures of the midface. However, due to the presence of stainless steel and the resulting artefacts the assessability of soft tissues was greatly compromised and an intracranial bleeding or laceration of the ocular globe could not be confidently ruled out. After surgical removal of the saucepan a second CT-scan revealed neither apparent damage to the ocular globe nor intracranial bleeding. Three days after admission a surgical reconstruction of the orbital floor and a neurolysis of the infraorbital nerve were performed. The patient suffered no loss in eyesight or motility and was discharged on the 8th day.

2924. Krueger, E., et al. (2022). "SIMPLE WOUND CLOSURE COMPARED TO SURGERY FOR CIVILIAN CRANIAL GUNSHOT WOUNDS." Journal of neurotrauma **39**(11-12): A39.

The appropriate clinical scenario for utilizing simple wound closure (SWC) for civilian cranial gunshot wounds (CGSW) is not well described. We compared SWC and surgery patients in terms of their neurologic outcomes and incidence of infections, seizures, and additional operations. This was a single-center, retrospective review of adult patients. Excluded were patients with non-firearm penetrating injuries, initial Glasgow coma scale (GCS) 3, initial GCS 4 and nonreactive pupils, or mortality within 48 hours. Seventeen patients (25.4%) were treated with SWC and 50 (74.6%) were treated with surgery. The SWC group had a lower incidence of radiographic mass effect (3/17, 17.6% SWC versus 31/50, 62.0% surgery; p = .002) and lower incidence of involvement of the frontal sinus (0/0, 0.0% SWC versus 14/50, 28.0% surgery; p = .01). There were no differences in the frequency of Glasgow outcome scale extended scores ≥5 between the SWC and surgery groups at 30- (4/11, 36.4% SWC versus 12/35, 34.3% surgery), 60- (2/7, 28.6% SWC versus 8/26, 30.8% surgery), and 90-days (3/8, 37.5% SWC versus 12/26, 46.2% surgery). There were no differences in the incidence of infections (1/17, 5.9% SWC versus 6/50, 12.0% surgery; p = .67), cerebrospinal fluid fistulas (2/11, 11.6% SWC versus 3/50, 6.0% surgery; p = .60), seizures (3/17, 17.6% SWC versus 9/50, 18.0% surgery; p = 1), and reoperations (3/17, 17.6% SWC versus 4/50, 8.0% surgery; p = .36) between the SWC and surgery groups. There were clinically relevant differences between the two groups. SWC is a safe and efficacious alternative therapy in a carefully selected subset of civilian CGSW patients.

2925. Krueger, E. M., et al. (2022). "Simple Wound Closure for Civilian Cranial Gunshot Wounds: A Systematic Literature Review." Cureus **14**(5): e25187.

Civilian cranial gunshot wounds are common injuries associated with significant morbidity and mortality. Simple wound closure has been previously proposed as an alternative treatment option for a small subset of patients, but the exact outcomes of this strategy are not well-defined. The objective of this paper was to describe the scientific literature reporting simple wound closure of civilian cranial gunshot wounds, its effect on short-term and long-term neurologic outcomes, and rates of seizures and infections. A systematic literature review was performed in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) guidelines. The strength of evidence was assessed using the Grading of Recommendation, Assessment, Development, and Evaluation (GRADE) criteria. Seventeen studies were found that met inclusion criteria. There was very low strength of evidence that patients treated with simple wound closure can achieve good short and long-term neurologic outcomes. There was very low strength of evidence that simple wound closure has a higher incidence of mortality compared to operative intervention, especially in patients

with initial low Glasgow Coma Scale (GCS) scores. There was very low strength of evidence that patients treated with simple wound closure have a small risk of subsequently developing infections or seizures. In conclusion, under most circumstances, neurosurgical operative intervention should be viewed as the optimal treatment for salvageable civilian cranial gunshot wound patients. However, our literature review showed that simple wound closure is safe and viable. More data are needed to determine the appropriate clinical scenario for using this alternative option. 2926. Krueger, F., et al. (2009). "The neural bases of key competencies of emotional intelligence." Proceedings of the National Academy of Sciences of the United States of America **106**(52): 22486-22491.

Emotional intelligence (EI) refers to a set of competencies that are essential features of human social life. Although the neural substrates of EI are virtually unknown, it is well established that the prefrontal cortex (PFC) plays a crucial role in human social-emotional behavior. We studied a unique sample of combat veterans from the Vietnam Head Injury Study, which is a prospective, long-term follow-up study of veterans with focal penetrating head injuries. We administered the Mayer-Salovey-Caruso Emotional Intelligence Test as a valid standardized psychometric measure of EI behavior to examine two key competencies of EI: (i) Strategic EI as the competency to understand emotional information and to apply it for the management of the self and of others and (ii) Experiential EI as the competency to perceive emotional information and to apply it for the integration into thinking. The results revealed that key competencies underlying EI depend on distinct neural PFC substrates. First, ventromedial PFC damage diminishes Strategic EI, and therefore, hinders the understanding and managing of emotional information. Second, dorsolateral PFC damage diminishes Experiential EI, and therefore, hinders the perception and integration of emotional information. In conclusion, EI should be viewed as complementary to cognitive intelligence and, when considered together, provide a more complete understanding of human intelligence.

2927. Krueger, F., et al. (2011). "The role of the Met66 brain-derived neurotrophic factor allele in the recovery of executive functioning after combat-related traumatic brain injury." The Journal of neuroscience : the official journal of the Society for Neuroscience **31**(2): 598-606.

Brain-derived neurotrophic factor (BDNF), a member of the neurotrophin family, promotes survival and synaptic plasticity in the human brain. The Val66Met polymorphism of the BDNF gene interferes with intracellular trafficking, packaging, and regulated secretion of this neurotrophin. The human prefrontal cortex (PFC) shows lifelong neuroplastic adaption implicating the Val66Met BDNF polymorphism in the recovery of higher-order executive functions after traumatic brain injury (TBI). In this study, we examined the effect of this BDNF polymorphism on the recovery of executive functioning after TBI. We genotyped a sample of male Vietnam combat veterans consisting of a frontal lobe lesion group with focal penetrating head injuries and a non-head-injured control group for the Val66Met BDNF polymorphism. The Delis-Kaplan Executive Function System as a standardized psychometric battery was administrated to examine key domains of executive functions. The results revealed that the Met allele but not the hypothesized Val allele promotes recovery of executive functioning. Overall, the Met66 carriers in the lesion group performed as well as the Met66 carriers in the control group. The Met66 allele accounted for 6.2% of variance for executive functioning independently of other significant predictors including preinjury intelligence, left hemisphere volume loss, and dorsolateral PFC volume loss. The findings point to different mechanisms of the Val66Met BDNF gene in complex phenotypes under normal and pathological conditions. A better understanding of these mechanisms could be instrumental in the development and application of effective therapeutic strategies to facilitate recovery from TBI.

2928. Krukemeyer, M. G., et al. (2006). "Survived crossbow injuries." The American journal of forensic medicine and pathology **27**(3): 274-276.

The Hamburg University Institute of Legal Medicine presents 2 cases of injuries of crossbow arrows where the patients survived. Crossbows are used nowadays as sports and hunting weapons. They are freely obtainable, and since people without practice can shoot them, there are constant injuries and fatal cases. Crossbow arrows have a high penetration force and can even pierce bone. Depending on the tip of the arrow used, they bore or cut through tissue, here damage to the tissue being restricted to the direct surroundings. Due to the elasticity of the tissue, the arrow shaft in the wound track may have the effect of an incomplete tamponade so that major hemorrhaging is prevented. In this condition, the injured person may be conscious and capacitated. From the medical viewpoint, crossbow arrows should

therefore be invariably left in the wound, secured against displacement during transport, and only removed in the hospital.

2929. Krukemeyer, M. G. and K. Püschel (2008). "Transcranial crossbow injury - An unusual case of skull penetrating." Medizinische Welt **59**(9): 343-344.

We present the case of a man in whom a crossbow arrow penetrated through the right orbit into the brain and emerged again at the back of the head. Apart from the loss of the right eye, the patient survived without permanent damage. Crossbows are used nowadays as sports and hunting weapons. They are freely obtainable, and since people without practice can shoot them there are constantly injuries and fatal cases. Crossbow arrows have a high penetration force and can even pierce bone. Depending on the tip of the arrow used, they bore or cut through tissue, here damage to the tissue being restricted to the direct surroundings. Due to the elasticity of the tissue, the arrow shaft in the wound tract may have the effect of an incomplete tamponade, so that major haemorrhaging is prevented. From the medical viewpoint, crossbow arrows should therefore be invariably left in the wound, secured against displacement during transport and only removed in the hospital. © 2008 Schattauer GmbH.

The presented patient was injured while repairing a car. When the motor was running a metal blade of the fan broke off and struck him on the right side of his forehead. The blade sticking in the bone was removed surgically, and after 17 days he was discharged home without neurological deficit. After 60 days paresis of the left upper extremity and rhinorrhoea developed, and the patient had a second operation. Four months after the injury the first seizure appeared, provoked by discontinuation of anticonvulsants.

2931. Krum, J. M., et al. (1991). "Brain angiogenesis: variations in vascular basement membrane glycoprotein immunoreactivity." Experimental neurology **111**(2): 152-165.

Changes in the distribution and quantity of laminin and fibronectin within the basement membranes of developing or regenerating CNS blood vessels were investigated using two immunocytochemical techniques. Three models of angiogenesis were studied: normal pre- and postnatal development, wound healing, and vascularization of fetal neocortical transplants placed in the adult rat brain. Although all brain vessels were stained in enzymatically pretreated immunoreacted paraffin sections, those associated with wound and transplant sites were the most intensely reactive with both antisera during the first postoperative week. When 40-microns vibratome sections of normal adult brains were immunoprocessed, only the meninges and vessels of the circumventricular organs were stained. The remainder of the brain vasculature was immunoreactive only if sections were enzymatically treated prior to immunoprocessing. In contrast, the nascent vasculature in developing brain and the regenerating vessels at wound and transplant sites were reactive to both antisera without enzymatic pretreatment of the sections. This immunoreactivity decreased by 11 days postnatal in normal animals and 4 weeks postoperative in experimental animals, coinciding with the period of astrocytic contact and complete vascular basement membrane formation in both cases. The variations in staining pattern and intensity may be reflections of differences in the quantity of laminin and fibronectin within the basement membranes of proliferating and/or non-blood-brain barrier vasculature. However, the results of the different experimental protocols suggest that immature vascular basement membranes may have a molecular configuration that does not require an enzymatic unmasking step to react with the antisera. Alternatively, the looseness of the surrounding neuropil inherent in developing and injured CNS could allow the antisera greater access to basement membrane antigens.

2933. Krzych, L. J., et al. (2015). "Serum S100B protein concentration in brain-dead organ donors: a pilot study." Anaesthesiology intensive therapy **47**(4): 320-323.

BACKGROUND: Protein S100B is considered to be a marker of brain damage, but there is a paucity of data regarding the utility of its assessment in brain-dead organ donors. The aim of the study was to compare serum protein S100B concentrations between brain-dead organ donors and patients with a confirmed permanent neurological deficit but without signs of brain death., METHODS: The concentration of serum S100B protein was measured in 12 brain-dead organ donors (including 7 males with a median age of 40 years). All measurements were taken when brain death was confirmed by the commission. Twenty-nine patients (including 13 males with a median age of 63 years) who died in the medical ICU with confirmed permanent brain injury without signs of brain death acted as controls. In these patients, S-100B protein measurements were performed upon ICU admission., RESULTS: In brain-dead organ donors, the median values of serum S100B protein were much higher in comparison to the control group (median and IQR, respectively: 5.04 mug L-1; 1.775-6.765 vs 0.897 mug L-1; 0.324-1.880, P < 0.001). S100B serum values > 1.81 mug L-1 predicted brain death with the highest accuracy (AUROC = 0.83; 95% CI 0.68-0.93; P < 0.001)., CONCLUSION: Concentrations of serum S100B protein in brain-dead organ donors are extremely high and may support the diagnosis of brain death. This fact may be of value when the presence of reflex movements (frequently reported despite brain death) might delay determination of brain death and result in the failure of organ donation.

2934. Kuckelkorn, R., et al. (2001). "[Long-term results of large diameter keratoplasties in the treatment of severe chemical and thermal eye burns]." Langzeitergebnisse der Keratoplastik mit grossem Durchmesser von 11 - 12 mm bei schwerstveratzten und verbrannten Augen1. **218**(8): 542-552.

BACKGROUND: In severe chemical and thermal eye burns the limbal stem cells, which are important for the regeneration of the corneal epithelium, are lost. In our retrospective study two questions were investigated: 1) is it possible to restore the limbal region by transplantation of large diameter keratoplasties 2) has the time of transplantation an influence on the clinical outcome., PATIENTS AND METHOD: In a retrospective study the outcome of 48 eyes (43 patients) with severe chemical and thermal burns were analysed. Large diameter (11 - 12 mm) penetrating keratoplasties were performed between 1987 and 1996. Complete limbal deficiency was present in 17 eyes, while 31 eyes had developed sterile corneal ulceration. According to the time of transplantation three different groups were distinguished. Group I (early keratoplasty, n=24): transplantation within 3 months after the accident (mean: 26 days). Group II (intermediate keratoplasty, n=13): transplantation between 4 - 18 months after the burn (mean: 190 days). Group III (late keratoplasty, n=11): surgery more than 18 months after the injury (mean: 36.6 months)., RESULTS: Follow-up time was 28.4 months in early keratoplasty, 26.4 months after intermediate keratoplasty, and 34.3 months in late keratoplasty. Long-term results of the keratoplasties were poor. 60.4 % of the transplants failed due to surface problems, 18.8 % due to endothelial rejection episodes. Late keratoplasties were significantly more successful than intermediate keratoplasties. 25 % of the early keratoplasties and 36.4 % of the late keratoplasties showed an intact limbal region at the end of the follow-up time, but none of intermediate keratoplasties., CONCLUSION: The prognosis for large diameter keratoplasties depends on the time of transplantation. Late and early keratoplasties had the best results. However, survival of heterologous stem cells is limited.

2935. Küçük, E., et al. (2018). "A rare cause of foot drop: Tired bullet." World journal of emergency medicine **9**(4): 294-296.

2936. Kucuker, I., et al. (2016). "Our Treatment Approaches in Severe Maxillofacial Injuries Occurring After Failed Suicide Attempts Using Long-Barreled Guns." The Journal of craniofacial surgery **27**(2): e133-138.

Maxillofacial traumas with long-barreled guns may sometimes cause catastrophic results by means of smashing in facial structures. In these patients, reconstruction strategies of both fragmented/lost soft and hard tissues still remain controversial. In their clinic, the authors treated 5 patients with severely injured face after failed suicide attempt between 2008 and 2013. In this study, the authors aimed to present their clinical experiences on these severely injured maxillofacial gunshot traumas and offer a treatment algorithm to gain a result as possible as satisfactory in terms of functionality and appearance.

2937. Kugoeva, E. E., et al. (2002). "[Characteristics of the clinical picture of combined injuries of the organ of vision and eye appendages under conditions of peace-time and war injuries]." Osobennosti klinicheskoi kartiny sochetannykh povrezhdenii organa zreniia i pridatochnogo apparata glaza v usloviiakh mirnoi i boevoi travm. **118**(4): 11-13.

A total of 100 patients with combined injuries of the organ of vision and eye appendages, inflicted in peacetime and under war conditions, were examined. The clinical picture of combined injuries in the wounds inflicted at the battlefield (gunshot and resultant from mine explosions) and of traffic, communal, criminal, and occupational injuries was studied using traditional ophthalmological and common clinical instrumental methods of examination. Common regularities of the traumatic process were revealed in combined injuries: mutual aggravation of injuries to the eye and its appendages, a considerable incidence of bilateral injuries, and simultaneous impacts of several damaging factors. The most unfavorable prognosis as regards visual functions in the group observed was for patients with war injuries, particularly those caused by mine explosions.

2938. Kuhl, D. A., et al. (1990). "Prophylaxis of posttraumatic seizures." DICP : the annals of pharmacotherapy **24**(3): 277-285.

The issue of routine anticonvulsant prophylaxis for early and late posttraumatic epilepsy (PTE) has received much attention in the medical literature. Such problems as lack of standard definitions for early and late PTE, the retrospective design of most studies, the wide variability of inclusion and exclusion criteria, and the varied duration of follow-up make this body of literature extremely difficult to evaluate. Severe head trauma appears to cause injured neurons to become hyperexcitable; this in turn brings about the formation of an epileptogenic focus during the time between trauma and seizure occurrence. Both military and civilian head injury populations have been used to evaluate the incidence of PTE. Early seizures (i.e., less than 7 days) occur in approximately 3-5 percent of the head injury patients in both the military and civilian groups. Factors increasing this incidence include intracranial hematoma, focal neurologic deficits, posttraumatic amnesia (PTA) lasting greater than 24 hours, depressed skull fracture, and age less than 5 years. The incidence of late seizures is directly related to the extent of brain damage. The military population, composed primarily of cases with penetrating head injury, is associated with a late PTE incidence of approximately 30-50 percent. Closed head injuries in the military population involve a 5-15 percent seizure incidence. Late PTE incidence after head injuries in the civilian population is less than 5 percent. Risk factors associated with late PTE include loss of consciousness or PTA lasting greater than 24 hours, dural lacerations, depressed skull fractures, and various computerized tomography deficits. These factors vary slightly between the military and civilian populations.(ABSTRACT TRUNCATED AT 250 WORDS)

2939. Kuhne, C. A., et al. (2007). "[Penetrating gunshot injuries to the head and brain. Diagnosis, management and prognosis]." Penetrierende Schadel-Hirn-Verletzungen durch Schusswaffen. Diagnostik, Behandlungsmanagement und Prognose. **110**(4): 341-350.

Gunshot injuries to the head and brain are rare in Germany and the rest of western Europe. With the relatively low number of these injuries here, there are no standard methods of diagnosis and management, and there is some controversy over both. Quite a high proportion of such injuries result from suicide attempts and accidents. The main diagnostic procedure available is computed tomography of the head with contrast medium; in certain cases MRI is indicated. The operative management depends on the extent and prognosis of the injury; a ventricular drain is probably indicated in most cases. Debridement of the bullet's path and removal of the projectile are more controversial. Mortality is extremely high after such injuries; if the victim does survive the prognosis is comparable to that following closed cranial injuries.

2941. Kukner, A. S., et al. (2009). "Characteristics of pellet injuries to the orbit." Ophthalmologica. Journal international d'ophtalmologie. International journal of ophthalmology. Zeitschrift fur Augenheilkunde **223**(6): 390-395.

PURPOSE: To investigate the features of orbital injuries by pellets fired from the front., DESIGN: Retrospective, 4 cases of pellet injuries., METHODS: Five orbits of 4 patients who sustained pellet injuries received from the front were reviewed retrospectively. The course of injury and results were assessed. Radiological examinations were reviewed. The

patients were evaluated between December 1996 and June 2004., RESULTS: Five orbits of 4 patients sustained injuries caused by pellets fired from an anterior direction. The globe in the injured orbit was intact in 2 cases. Severe loss of vision was also present in these 2 globes due to optic nerve involvement. Final visual acuity was down to no light perception in 4 eyes and limited to light perception in 1 eye., CONCLUSIONS: The prognosis of orbital pellet injuries is, unfortunately, poor. A pellet passing through the floor of the orbit often causes double perforation of the globe and, once in the orbital aperture, it travels towards the apex as a result of the conical shape of the orbit and lodges in the optic canal or its entrance, severely damaging the optic nerve. Surgery or other treatments are usually unsuccessful. Even if the globe is intact, vision is usually severely impaired. Copyright 2009 S. Karger AG, Basel.

2943. Kulkarni, A. (2019). "Panga'ED: 10 year overview of maxillofacial trauma associated with witchcraft in east- central Africa." International journal of oral and maxillofacial surgery **48**: 37.

Background: The intriguing antiquarian belief in witchcraft is an accepted part of social reality and an established folk tradition, a component of indigenous belief systems and ritual practices that transcends in local and regional culture on continental Africa more so than other Low and Middle Income countries (LMIC). Objectives: To highlight the patterns of witchcraft related cranio-maxillofacial trauma and treatment strategies encountered over a 10 year period in East and Central Africa. Methods: Patients with assault related Cranio-Maxillofacial injuries inflicted by traditional weapons were identified out of the recorded cases of cranio-maxillofacial fractures consulted and treated in 3 tertiary referral hospitals in Tanzania and Rwanda. Inclusion: Withcraft related cranio-maxillofacial fractures Exclusion: Incomplete clinical data, other reasons of assaults, Gunshot wounds. Findings: Out of XXX cases of cranio-maxillofacial fractures associated with assault and interpersonal violence XXX cases were associated with witchcraft with XXX males and XXX females in the age group of XXX to XXX. Assaults involving elderly women were directly related to witch hunts and most of the fractures were compound - contaminated resultant from sharp machete wounds, though post-operative wound infection were not a common. Conclusion: Managing Cranio-maxillofacial trauma with ATLS protocol primarily and a multidisciplinary team in definitive management phase is recommended. Basic principles of fracture fixation with prompt resuscitation can result in good outcomes in these cases thus reducing the stress on the fragile medical system in rural settings in LMICs.

2944. Kulkarni, A., et al. (2016). "An interesting case of penetrating craniofacial trauma involving a wooden stick." Journal of Clinical and Diagnostic Research **10**(4): ZD01-ZD03.

Penetrating craniofacial trauma, although uncommon, has a high potential for death or catastrophic consequences from head injury or vital neurovascular injuries. The foreign body may cause significant challenge, especially when it is a large one. Airway obstruction, vascular injuries, intracranial communication, ocular injury and injuries to any other adjacent vital structures when involved may change the treatment objectives from simple foreign body retrieval to a comprehensive multidisciplinary approach to stabilize the patient. Retrieval of foreign bodies may be challenging because of many factors including the size of the object, its site, and the surrounding anatomical structures. Accurate localization of the foreign body before removal is essential in craniofacial region. We present a case of penetrating craniofacial trauma from a wooden stick, with an in situ foreign body, that was managed by emergency surgical exploration in general anaesthesia and retrieval of foreign body in Toto under antibiotic coverage and tetanus prophylaxis.

2945. Kulwin, C. G., et al. (2018). "Neurosurgical Management of Self-Inflicted Cranial Crossbow Injury." World neurosurgery **116**: 69-71.

BACKGROUND: Although gun-related penetrating traumatic brain injuries make up the majority of cranial missile injuries, low-velocity penetrating injuries present significant clinical difficulties that cannot necessarily be identically managed. Bow hunting is an increasingly popular pastime, and a crossbow allows a unique mechanism to cause a self-inflicted cranial injury with a large, low-velocity projectile. Historically, arrow removal is described in an operating room setting, which provides limited knowledge of the location of vascular injury in the setting of postremoval hemorrhage,

and may represent an inefficient use of operating room availability., CASE DESCRIPTION: Two patients presented after self-inflicted cranial crossbow injuries. Both were neurologically salvageable. Initial assessment with computed tomography angiography allowed triage into likely or unlikely vascular injury. Arrow removal was performed in a radiology setting rather than in the operating room to allow immediate postremoval imaging to localize hemorrhage. While an operating room was on standby, neither patient required neurosurgical operative intervention. Both patients made a good recovery with no further injury caused by arrow removal., CONCLUSIONS: We describe a novel approach to retained cranial arrow removal in a radiologic, rather than operative, setting and describe its relative benefits over traditional removal in the operating room.

2946. Kum, C., et al. (2018). "Nonsurgical Management of Retained Needlefish Jaw." Journal of neuro-ophthalmology : the official journal of the North American Neuro-Ophthalmology Society **38**(2): 190-191.

While scuba diving, the left medial canthus of a 53-year-old man was pierced by a needlefish. He immediately lost vision in his left eye. An orbital computed tomographic scan showed the needlefish jaw in the left optic canal. The left medial orbit was explored surgically but no foreign object was removed. One month later, MRI confirmed the presence of the retained needlefish jaw. A conservative approach was taken and the patient remained stable over 3 months of follow-up.

2947. Kumar, A., et al. (2010). "Effects of continuous sedation and, analgesia on cerebral metabolism using microdialysis monitoring." Neurocritical care **13**: S182.

Introduction Continuous sedation is frequently used in patients with severe traumatic brain injury and cessation of sedation for daily exams is often performed. There is concern that this may cause tissue distress or secondary injury due to increased metabolic demand in patients with severe traumatic brain injury. Cerebral microdialysis can demonstrate tissue injury or distress by low extracellular glucose (<2mmol/l) and elevated Lactate/Pyruvate ratios (L/P>40), which are biomarkers of cellular brain metabolism. Methods A retrospective chart review was performed on patients who were monitored with cerebral microdialysis, admitted to the neuroscience intensive care unit at Jackson Memorial Hospital with the diagnosis of traumatic brain injury. Hourly sampling of microdialysis fluid was performed and extracellular lactate, pyruvate (L/P) ratios, and glucose concentrations were recorded. Charts were then analyzed looking for changes of these biomarkers with cessation of continuous sedation and analgesia. Analyte measurements were compared for the hour of sedation/ analgesia change and the two subsequent hours. Results Four patient's data were reviewed. Three males (ages 21,57, 60) and one female age 21. One patient had a penetrating injury and three had blunt traumatic injury. Patient 1 glucose concentrations were .35 mmol/ L, .33 mmol/ L, .88 mmol/ L, L/P ratios were 44.7, 39, 42.6. Patient 2 glucose concentration was 2.03 mmol/ L, 1.94, mmol/ L and 2.06 mmol/ L L/P ratios were 20.2, 20.08, and 19.49. Patient 3 glucose concentration was 2.11 mmol/ L, 2.15 mmol/ L, and 1.7 mmol/ L and L/P ratios were 19.8, 22.2, and 20.65. Patient 4 glucose concentration was 1.9 mmol/ L, 0.41 mmol/ L, and 0.52 mmol/ L and L/P ratios were 18.2, 49. 9, 144.9 Conclusion We did not identify a significant decrease in extracellular glucose or elevation of L/P ratios with daily cessation of sedation in 3 patients. However, our last patient had markedly elevated L/P ratios and decreased glucose with cessation of sedation, indicating cellular distress and tissue vulnerability. This patient's brain neurochemistry appeared to be more volatile as there were also fluctuations in the glucose and L/P ratio with fever. More patients need to be studied to determine if there are specific patient characteristics which distinguish patients with volatile brain chemistry. These patients might have a higher risk for secondary injury and may benefit more from tissue monitoring.

2948. Kumar, A., et al. (2011). "Scissors in brain: an unusual presentation of tribal culture in India." Turkish neurosurgery **21**(3): 413-417.

AIM: To observe the neurological complications arising from various tribal practices and their management. Penetrating head injuries comprise only a small number of total head injuries. A penetrating head injury by deliberate attempt to treat an ailment is almost unheard of., MATERIAL AND METHODS: We present here a case of penetrating head injury caused by stabbing a scissor in head by a local witch doctor in order to treat a psychiatric ailment., RESULTS: The patient was taken up for for surgery and managed accordingly. Relevant literature was reviewed regarding various foreign bodies in traumatic missile and non missile brain injuries and their surgical management.

Traumatic intracranial aneurysms are rare lesions but should be considered in penetrating head injury, particularly in cases of low-velocity gunshot wounds or stab wounds to the head. Because most of these aneurysms are false aneurysms, treatment may require excision or trapping procedures.

2952. Kumar, M., et al. (2022). "Retrograde Intubation for Airway Management of Firearm Injury in the Maxillofacial Region." Journal of Clinical and Diagnostic Research **16**(3): UD04-UD05.

Endotracheal intubation is one of the most important anaesthetic skills. Trauma to the maxillofacial region is challenging in terms of airway management. Airway management in such patients is difficult and decides the survival of the patient. Endotracheal intubation in patients with difficult ventilation and difficult intubation always remains a challenge, especially in the absence of a flexible fibreoptic bronchoscope. The retrograde catheter technique is an acceptable option for airway management in cases where oral intubation is not possible because of difficult airway or is not recommended because of fear of dislodgement of fractured segments of facial bones. The author here reports a case of a 30-year-old male with firearm injury in maxillofacial region posted for emergency surgery with anticipated difficult airway. Emergency retrograde intubation was done for the management of airway with successful outcome.

2953. Kumar, P., et al. (2018). "Bull horn head injury with retained horn in brain: A rare case report." Journal of pediatric neurosciences **13**(2): 229-233.

Pediatric head injuries are a commonly seen emergency in trauma centers worldwide. There are various modes of injury such as fall from height, road traffic accidents, objects hitting the head, assault, and battered baby. We report here a child who presented to us with a history of sustaining head injury by a stray bull on the road and a retained broken bull horn inside the brain and its subsequent management.

2955. Kumar, V., et al. (2016). "Penetrating injury of orbital roof and brain sparing the eye ball in a pediatric patient: A rare occurrence." Journal of pediatric neurosciences **11**(2): 134-136.

Blowout fractures are a common occurrence in traumatic brain injury patients. In pediatric age group, orbital floor fracture is a common occurrence. We report a case of 2-year-old male admitted to trauma center, with penetrating injury to the left eye by the clutch of motorbike which fell on the child. Noncontrast computed tomography scan revealed fracture of the roof of left orbit with left frontal contusion sparing the left eyeball. There was also the

continuous leak of brain matter from the left eye which suggested tear of dura mater. Urgent left frontal craniotomy was done with the evacuation of contusion, reconstruction of orbital roof, and duroplasty under general anesthesia.

2957. Kummoona, R. (2008). "Posttraumatic missile injuries of the orofacial region." The Journal of craniofacial surgery **19**(2): 300-305.

Iraq became the world's battlefield for terrorist attack to the victims by different types of weapons of missile including explosive cars, explosive belt, fragments, rifle bullets, and handgun bullets. This situation in Iraq has been present for the last 3 years. As surgeons, we cannot influence the surge of this violence, but we are surely called upon to care for its victims. Missile injuries to the orofacial region have special features that provide the surgeon with multiple medical and surgical challenges when dealing with these injuries. This study include 140 patients who were treated in the maxillofacial unit, hospital of specialized surgery, in Medical City, Baghdad, during a period of 2 years; we had 28 women and 112 men, with ages ranging from 9 to 60 years (mean, 34.5 years), suffering from posttraumatic orofacial deformities. Deformities of the face as a complication of missile injuries were classified as bone loss, soft tissue loss, combined bone and soft tissue loss, and others (sinus tracts and poor scars); 62 patients (44%) had bone loss, 45 (32%) had soft tissue loss, 9 (6.4%) had combined bone and soft tissue loss, and 22 (15.7%) had other deformities.

2958. Kunjukunju, N., et al. (2010). "Bilateral macular hole formation secondary to sclopetaria caused by shockwaves transmitted by a posterior vector: case report." BMC ophthalmology **10**: 6.

BACKGROUND: Sclopetaria is a rare ophthalmic finding in trauma, CASE PRESENTATION: This is a report of a patient who developed macular holes from sclopetaria induced by indirect trauma. A 22-year-old male, suffered a gunshot wound that passed behind his eyes, resulting in bilateral macular hole formation, CONCLUSION: To our knowledge, this is the first reported case in which trauma posterior to the globes caused bilateral macular hole formation.

2959. Kunz, S. N. (2017). "An unusual exit wound as a result of a shotgun suicide to the head." Forensic science international **275**: e1-e5.

The location of a gunshot entrance wound as well as the wound path trajectory are the main findings that help to determine the position from which a weapon was fired and thus distinguish firearm suicides from homicides and accidents. We present a case of a 28-year old man, who was found dead in his car. Because of an unusual position of the firearm, which was clamped into the steering wheel, and an unclear entrance/exit wound, an autopsy was performed. The deceased showed typical signs of a contact shotgun wound to the head with an entrance wound in the right temporal region and an exit wound in the midface. With the help of gunpowder attachments and a muzzle imprint at the entrance site, a wound channel from the right lower posterior part of the temporal region to the left anterior part of the mid-facial region could be reconstructed. The stellate wound in the midface was assessed as an atypical exit wound. The cause of death was a contact shotgun shot to the right temple with a consequent central regulatory failure due to extensive brain injury. The manner of death was concluded to be a suicide.

2960. Kunz, S. N., et al. (2013). "Unusual blood spatter patterns on the firearm and hand: a backspatter analysis to reconstruct the position and orientation of a firearm." Forensic science international **228**(1-3): e54-57.

When it comes to firearm fatalities, the main goal of forensic analysis is to distinguish firearm suicides from homicides and accidents. Apart from the location of the entrance wound, wound path trajectory and gunshot residue, blood stain pattern analysis of gunshot-related backspatter on the hands of the victim can be an essential tool not only to determine which hand was holding the firearm, but also to reconstruct the position from which a weapon was fired. We present a case of a 90-year-old man, who was found dead in his house. Because of unclear circumstances and an unusual position of the deceased with a gunshot entrance wound to the right temporal region and a firearm found on the left side of his body, an autopsy was performed. Due to the unusual bloodspatter stains on the hands and the firearm, it was possible to deduce the position and orientation of the hands and the firearm of the deceased. We could reconstruct that the man held the weapon in his right hand, using the left hand to stabilise the firearm and the right thumb to pull the trigger. A contact shot to the right temple led to central regulatory failure due to extensive brain injury. The manner of death was concluded to be a suicide.

2961. Kunz, S. N., et al. (2020). "Beer stein blast to the head a rare case of combined blunt and sharp force trauma." International journal of legal medicine **134**(5): 1791-1796.

Cases of combined blunt and sharp force trauma to the head caused by one striking tool are rare. When beer steins are used as an assault weapon, they can cause blunt traumas upon initial contact phase. If the impact force exceeds the mechanical stability of the beer stein, it breaks into several sharp-edged pieces, which then can cause sharp force trauma injuries due to the interaction between the head and the stein fragments. We present a case of a 43-year old man, who suffered from blunt and sharp force head traumas due to one single blow with a 1-l beer stein. A forensic-biomechanical analysis of the event, together with witness testimony evaluation and experimental comparison helped to reconstruct the most probable chain of events. Based on these findings as well as on the medical diagnoses and treatment, the assault was assessed as a nonacute life-threatening, but potentially fatal offence. The case was indicted as grievous bodily harm.

2962. Kunz, U., et al. (1985). "[Gunshot wounds of the skull during peacetime]." Schussverletzungen des Schadels im Frieden. **28**(3): 134-142.

66 patients with gunshot wounds were treated at the Department of Neurosurgery of Hanover University up to May 1982. These included wounds inflicted by bolt guns of the type used in slaughter houses, and by bolt-setting or nail-setting tools used in building construction work. The total mortality was 50%. Seventeen patients died directly after admission or within the first 24 hours. Operation was not indicated in cases which appeared hopeless. In patients with mild neurological deficits, only the superficial skin wounds were treated to avoid additional damage to the brain. CT scans performed in approximately one-half of the patients yielded valuable information on the path of the bullet and on haematomas. Postoperatively, there were several complications, mainly pneumonia and cerebrospinal fluid fistulas; in fact, pneumonia was responsible for the death of some patients. The mortality is compared with the findings by other authors. No patients remained in need of care after rehabilitation.

2963. Kural, A., et al. (2020). "Evaluation of rat major celluler prion protein for early diagnosis in experimental rat brain trauma model." Deneysel beyin travmasi olusturulan sicanlarda erken tani icin selluler prion protein(PrPC)'nin degerlendirilmesi. **26**(1): 1-8.

BACKGROUND: Although traumatic brain injury (TBI) is an important problem, there has been no widespread utilization of neuro-biomarkers to aid the diagnosis of TBI. This study was conducted to evaluate serum S100B and prion protein (PrPC) levels in rats with TBI., METHODS: In this study, 15 albino rats were categorized into three groups as follows: sham-operated (1), control (6) and trauma (8) groups. The TBI model was based on the modified free falling model. S100B, PrPC levels were measured using ELISA. Brain specimens were obtained for the pathological examination., RESULTS: Serum S100B and PrPC levels were found to increase in T group at both 2h and 24h after trauma ($p<0.002$, $p<0.002$, respectively). We also found higher histopathological injury scores of brain tissues in the T group. Only a positive correlation was found between serum PrPC levels and the extent of brain injury ($p=0.039$, $r=0.731$). Using ROC analysis, among the two serum markers investigated, both of them revealed the same sensitivity and specificity for diagnosing TBI., CONCLUSION: The changes in serum S100B and PrPC levels showed good sensitivity in our experimental model. Therefore, PrPC could be helpful in the early prognostic prediction in patients with TBI. Further studies are

needed to test our findings in humans following TBI (penetrating bodies, blunt trauma) to definitively acknowledge it as a reliable biomarker and its subsequent diagnostic utility.

2964. Kurdi, S., et al. (2019). "Maxillofacial gunshot injuries management in tripoli from 2011–2018." International journal of oral and maxillofacial surgery **48**: 42.

Background: Management of facial gunshot wounds poses a challenge not only for the oral and maxillofacial surgeons but also for the reconstructive surgeons. Objectives: To determine pattern and presentation in terms of site of injury, airway, associated injuries; and early management of facial gunshot wounds occurred in Tripoli-Libya from 2011–2018. Methods: A total of 510 patients were treated during 1st January 2011 to 31st December 2018 have been included. Findings: Age ranged from 15 to 42 years with mean of 28 + 4.98 years. There were 695 bullet different calibers (7.62x39 mm, 9 mm, 12.5 mm, and 14.5 mm)& 20 land mine. All patients are males. 290 (56.8%)patients required airway management. The most frequent site involved was mandible in 335 (65.7%)patients while midface was involved in 175 (34.3%)patients. Open reduction and internal fixation (ORIF)was performed in 315 (61.7%). 75 (14.7%)patients had some complications; trismus, sinusitis and infection. Conclusion: All patient in this series required surgical intervention for treatment of their facial gunshot wounds. Primary treatment of soft and skeletal facial structures at the time of surgical debridement was possible in the majority of our patients. Early management and operative intervention for repair of the soft and skeletal facial structures leads to satisfactory results. Facial gunshot wounds frequently involve mandible with more likely requirement of establishment of emergency airway and (ORIF).

2965. Kureshi, N., et al. (2016). "Alcohol-related major traumatic brain injury: A province-wide retrospective analysis." Intensive Care Medicine Experimental **4**.

Introduction: Traumatic brain injury (TBI) is a leading cause of death and disability. In the Canadian province of Nova Scotia, TBI occurs in approximately 50 % of major trauma seen annually. Although alcohol use increases the risk of experiencing TBI, it remains unclear whether outcomes in alcohol-impaired TBI patients are different from those of unimpaired patients. Objectives: The objective of this study was to describe the characteristics and patterns of major TBI seen over a 14-year period at the provincial level in Canada. We evaluated the effect of alcohol on length of stay (LOS) and mortality in patients with major TBI. Methods: This was a retrospective case series. Data were obtained from the Nova Scotia Trauma Registry for all patients presenting with major TBI (abbreviated injury score [AIS] head α3) in Nova Scotia hospitals between 2002 and 2015. Injury rates were calculated on the basis of 100,000 population using population estimates from Statistics Canada. Patients were compared by blood alcohol concentration (BAC) at time of injury: Negative (0-1.9 mmol/L), low (2-21 mmol/L), and moderate/high (≥22 mmol/L). A logistic regression model was constructed to test for outcomes and adjusted for the effects of age, gender, location, injury severity score (ISS), maximum AIS head, and BAC level. Results: Overall, 4518 major TBI patients were seen in provincial hospitals during the study period. The mean age of TBI patients was 51 ± 25 years; 72 % were male. The majority of injuries were the result of blunt trauma (93 %), with relatively few major TBIs resulting from penetrating trauma (7 %). The most common mechanisms of injury were falls (46 %) and motor vehicle crashes (27 %). Analysis of census-based subpopulations demonstrated that injury rates varied significantly by geography (from 25 to 65 TBIs per 100,000 population). Testing for alcohol was performed in 43 % of cases. Patients who were tested for alcohol tended to be male (79 %) and middle-aged (mean age 44 ± 20 years). A positive BAC (i.e., ge;2 mmol/L) was found in 47 % of patients who were tested. Mean acute LOS was similar for all three BAC groups. Mortality was independently predicted by increasing age (odds ratio [OR] = 1.01; $p < 0.001$), male gender (OR = 1.30; $p = 0.049$), an ISS between 16 and 75 (OR = 2.67; $p < 0.001$), a maximum AIS head of 5 or 6 (OR = 3.21; $p < 0.001$), injuries occurring outside of the capital city of Halifax (OR = 1.70; $p < 0.001$), and having a lower BAC level (OR = 0.99; $p < 0.001$). Conclusions: The results of this study show significant regional variation in major TBI rates in the province of Nova Scotia. Our findings suggest that low BAC levels are associated with increased mortality in major TBI patients. There are ongoing needs for prevention and intervention efforts that focus on unintentional falls and motor vehicle crashes, especially in older adults. Further study is warranted to elucidate the mechanisms underlying the effects of alcohol on outcomes in patients with major TBI.

2966. Kurien, N., et al. (2020). "Spectrum of ocular injuries and visual outcome following firework injury to the eye." Journal of Emergencies, Trauma and Shock **13**(1): 39-44.

Background: Ocular injury due to fireworks requires urgent ophthalmic assessment and management to preserve vision. Methods: Spectrum of injury, type of intervention, visual outcome, and reasons for visual loss were assessed in consecutive patients presenting over 2 years with firework-related eye injury. The final visual outcome was recorded as best-corrected visual acuity. Results: In the 96 patients (75 males) enrolled, 122 eyes were involved. Twenty-six patients had bilateral eye injury. The median (interquartile) age was 14 (8, 28.5) years. Injuries occurred during Diwali festival (59.4%) and funeral processions (20.8%); over half (53.8%) were bystanders. Injury was due to negligence (78%), device malfunction (12.5%), and attempts to reignite (5.2%) or recover failed device (4.2%). Presenting symptoms were redness (100%), pain (97%), watering (86%), and reduced vision (77%). Facial laceration, contusion, or hematoma occurred in 13 patients. The most frequent adnexal and ocular surface injuries were lid burns (57.3%), edema (44.2%), charred eyelashes (24.6%), and laceration (13.9%). Open-globe injury occurred in 8 eyes. Common anterior segment injuries were corneal epithelial defect (51.6%) and hyphema (20.5%). Posterior segment injuries included commotio retinae (13.1%) and Berlin's edema (7.4%). Surgical treatment was required in 15 eyes; 107 (88%) were managed conservatively. At study completion, of the 99 eyes evaluated, 21 had reduced visual acuity (<6/6) including 7 with monocular blindness. Factors associated with poor vision were open-globe injury ($P < 0.001$) and poor initial visual acuity ($P = 0.05$). Conclusions: Open-globe injury and poor visual acuity at presentation predict the final visual outcome. Monocular blindness following firecracker injury is common.

2967. Kuroiwa, T., et al. (1994). "Traumatic intracranial foreign body embolization--case report." Neurologia medico-chirurgica **34**(12): 810-813.

A 27-year-old male presented with intracranial embolization due to accidental penetration of his neck by an iron fragment at work. Cerebral angiography revealed foreign body embolization of the left middle cerebral artery. The foreign body was successfully removed via craniotomy and arteriotomy. The extended period from onset to surgical treatment prevented acute hemodynamic reconstruction. However, he had good collateral circulation and was discharged with mild hemiparesis and moderate motor aphasia. The possibility of intracranial embolization should be considered in patients presenting with penetrating injury of the neck.

2968. Kurosaki, K., et al. (2005). "Identification of a bronze weapon based on an embedded fragment in a 3000-year-old skull." Forensic science international **151**(1): 105-108.

2969. Kurt, A., et al. (2006). "A challenging problem. Vertebral pseudoaneurysm and arteriovenous fistula involving vertebral artery and ipsilateral internal jugular vein due to craniocervical penetrating trauma." Interventional Neuroradiology **12**(2): 171-175.

Vertebral pseudoaneurysm and arteriovenous fistulas are very rare and are commonly due to penetrating trauma to craniocervical region. A 20-year-old man was presented with progressive swelling and pulsatile mass on the left side of his face. He had been stabbed two weeks ago on the left side of his face. Doppler Ultrasound revealed large left vertebral pseudoaneursym and arteriovenous fistulisation with the ipsilateral internal jugulat vein. MR Angiography and conventional angiography confirmed arteriovenous fistula between left vertebral artery and ipsilateral internal jugular vein and large pseudoaneurysm formation on vertebral artery. Arteriovenous fistula was closed surgically and embolized with surgicell. But the pseudoaneurysm was treated with endovascular covered stent placement.

2970. Kurt, G., et al. (2007). "Transcranial arrow injury: a case report." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES **13**(3): 241-243.

As demonstrated in various studies, with mortality and morbidity rates reaching 90%-100%, penetrating brain injuries are among the most devastating subjects of neurosurgery. Shell and sharapnell fragments are the most common cause of this type injuries; although rarely reported in "modern times", transcranial arrow injuries may also be the cause. In this report, a 37 year-old male patient, who was shot by an "arrow" accidentally, was evaluated regarding clinical presentation, treatment and clinical progress.

2971. Kusanagi, H., et al. (2000). "Pituitary insufficiency after penetrating injury to the sella turcica." Journal of Nippon Medical School = Nippon Ika Daigaku zasshi **67**(2): 130-133.

We report a 28-year-old male patient with a pituitary insufficiency after a simple fracture of the sella turcica. He was injured by a long nail that punctured the lower jaw. No fracture other than that of the sella turcica was detected. An endocrinological examination revealed both anterior and pituitary dysfunction and diabetes insipidus that continued for about two months.

2972. Kutcher, M. E., et al. (2013). "A principal component analysis of coagulation after trauma." The journal of trauma and acute care surgery **74**(5): 1223-1230.

BACKGROUND: Clotting factor abnormalities underlying acute traumatic coagulopathy are poorly understood, with application of traditional regression techniques confounded by colinearity. We hypothesized that principal components analysis (PCA), a pattern-finding and data reduction technique, would identify clinically predictive patterns in the complex clotting factor milieu after trauma., METHODS: Plasma was prospectively collected from 163 critically injured trauma patients. Prothrombin; factors V, VII, VIII, IX, X; D-dimer; activated and native protein C; and antithrombin III levels were assayed and subjected to nonlinear PCA to identify principal components (PCs)., RESULTS: Of 163 patients, 19.0% were coagulopathic on admission. PCA identified 3 significant PCs, accounting for 67.5% of overall variance. PC1 identified global clotting factor depletion; PC2 the activation of protein C and fibrinolysis; and PC3 factor VII elevation and VIII depletion. PC1 score correlated with penetrating injury and injury severity, predicting coagulopathy (odds ratio [OR], 4.67; $p < 0.001$) and mortality (OR, 1.47; $p = 0.032$). PC2 score correlated with injury severity, acidosis, and shock, and significantly predicted ventilator-associated pneumonia (OR, 1.59; $p = 0.008$), acute lung injury (OR, 2.24; $p < 0.001$), multiorgan failure (OR, 1.83; $p = 0.002$), and mortality (OR, 1.62; $p = 0.006$) but was not associated with international normalized ratio (INR)-based or partial thromboplastin time (PTT)-based coagulopathy ($p > 0.200$). PC3 did not significantly predict outcomes., CONCLUSION: PCA identifies distinct patterns of coagulopathy: depletion coagulopathy predicts mortality and INR/PTT elevation, while fibrinolytic coagulopathy predicts infection, end-organ failure, and mortality, without detectable differences in INR or PTT. While depletion coagulopathy is intuitive, fibrinolytic coagulopathy may be a distinct but often overlapping entity with differential effects on outcomes.

2973. Kute, V. B., et al. (2013). "Successful renal transplantation from a brain-dead deceased donor who died from snakebite: a case report." Transplantation proceedings **45**(7): 2801-2803.

Even though India is the country with the highest annual number of deaths (50,000) from snakebite, there is contradictory evidence regarding acceptance of deceased donors (DD) who died from this cause. We present 2 successful renal transplantations (RTx) from a brain-dead DD who died from a neurotoxic snakebite without manifestations of a viper bite. We accepted the donor as he exhibited no evidence of hematoxic snakebite. Rather the findings were consistent with a neurotoxic bite (probably krait), which can cause hypoxic brain injury. Both recipients established good diuresis intraoperatively and did not require hemodialysis. The patients were discharged with good diuresis and normal serum creatinines. After 3-month follow-up, both recipients show normal graft function. According to our experience of favorable RTx outcomes from a brain-dead DD who died from neurotoxic snakebite may expand the donor pool.

2974. Kutlay, M., et al. (2010). "A rare case of occipital neuralgia secondary to ball bullet gunshot wound." Central European neurosurgery **71**(4): 224-226.

2975. Kutlay, M., et al. (1997). "Intracranial sewing needle associated with epilepsy." Turkish neurosurgery **7**(3-4): 103-106.

A case of unusual intracranial foreign body associated with epilepsy is presented. A young man had been admitted to our unit for investigation of epileptic attacks. On radiological examination, a sewing needle in the left posterior frontal region was detected. There was no specific focal epileptogenic activity in the electroencephalogram, and it was surgically removed. Two years after operation, the patient was free of epileptic attacks. Review of the literature revealed only two reports of 4 similar cases. In this report, delayed onset of neurological symptoms is

emphasized, and removal of the retained intracranial foreign bodies in accessible areas by early surgical intervention is suggested.

2977. Kuvat, S. V., et al. (2011). "Our treatment approaches in head-neck injuries caused by animal bites." The Journal of craniofacial surgery **22**(4): 1507-1510.

Several approaches exist for the treatment of animal attacks targeting the head and neck region. The treatment options and timing vary depending on the animal species, the nature of the defect, and the experience of the surgeon. In this study, early surgical treatment options used in head-neck injuries caused by domesticated or wild animal attacks are presented. We consider 12 patients who were admitted to our clinic between June 2006 and May 2010 with head-neck injuries caused by animal attacks. Tissue defect had developed in 10 patients due to half-wild dog bite and in 2 patients due to wolf bite. The ages of the patients ranged from 3 to 45 years (mean, 21.3 years). Among the patients included in the study, 4 had facial injury, 3 had ear, 3 had scalp, 1 had eye, and 2 had nose injuries. In all patients, early surgical reconstruction was performed after irrigation, antisepsis, and debridement. Concurrent rabies and tetanus prophylactic antibiotherapy program was started. Infection or surgical complications were not observed in any of the patients. Rabies symptoms were determined in one of the quarantined dogs under surveillance. There were no positive findings in the patient bitten by the dog. The surgical treatment results from all patients were at satisfactory levels.As a result, it is observed that, in the treatment of head and neck injuries resulting from animal bites, early acute approach has replaced the traditional long-term treatment. We believe that debridement and early surgical reconstruction used in combination with medical support and prophylactic treatment are the best treatment method.

2978. Kuvat, S. V., et al. (2011). "Bimaxillary reconstruction with a single free fibular osteoseptocutaneous flap." The Journal of craniofacial surgery **22**(3): 1102-1104.

Flap combinations including free fibula have been commonly used to reconstruct composite maxillomandibular defects. On the other hand, a single free osteoseptocutaneous may be rarely used to reconstruct the bimaxilla. In this article, we report a bimaxillary reconstruction in a 63-year-old man with a single fibular osteoseptocutaneous free flap.

2979. Kuzeyli, K., et al. (2001). "Diabetes insipidus secondary to penetrating spinal cord trauma: case report and literature review." Spine **26**(21): E510-511.

STUDY DESIGN: Case report., OBJECTIVE: To present a case of central diabetes insipidus (CDI) that developed after a gunshot injury to the thorax and thoracic spinal cord and to discuss the disease process in light of the relevant literature., SUMMARY OF BACKGROUND DATA: Antidiuretic hormone (ADH) abnormalities may develop after spinal trauma and/or surgery. Although there are published reports of inappropriate ADH syndrome arising in this clinical picture, CDI is rare., METHODS: A 33-year-old woman with hemopneumothorax and a gunshot wound to her thoracic spine was treated with chest tube drainage. No surgery was performed for the spinal injury. The patient was paraplegic on admission and rapidly developed excessive urine output. Testing revealed that her serum ADH level was low, consistent with CDI. Desmopressin acetate nasal spray was the prescribed treatment., RESULTS: The patient responded well to the desmopressin acetate spray., CONCLUSIONS: CDI is a complicated hormonal disorder characterized by excessive urine output. It is typically linked to an abnormality in the hypothalamohypophyseal axis that markedly reduces ADH production. The most common inciting causes are craniocerebral trauma, brain tumor and/or surgery, and central nervous system infection. Although uncommon, CDI should be considered when a spinal trauma patient develops excessive urine output.

2980. Kuzon, W. M., Jr., et al. (1998). "Double free-flap reconstruction of massive defects involving the lip, chin, and mandible." Microsurgery **18**(6): 372-378.

Two patients with massive, composite defects of the total lower lip, chin, and anterior mandible underwent double free-flap reconstruction. A fibular osteoseptocutaneous flap was used to reconstruct the mandible and floor of

the mouth and a radial forearm fasciocutaneous composite flap, including the palmaris longus tendon, was used for total lower lip and chin reconstruction. Postoperatively, both patients had acceptable cosmesis, were orally competent, and recovered adequate mandibular function. Double free-flap reconstruction is indicated only in those circumstances in which composite tissue requirements or massive tissue defects preclude reconstruction with a single free-tissue transfer.

2981. Kveton, J. F. (1987). "Obliteration of mastoid and middle ear for severe trauma to the temporal bone." The Laryngoscope **97**(12): 1385-1387.

A review of four cases of severe trauma to the temporal bone involving fracture of the external auditory canal indicates that adipose obliteration of the mastoid and middle-ear cleft with closure of the external auditory canal is the optimal method of repair. In two of four patients, one-stage repair was successful using this technique, and in the other two patients, obliteration was required as a revision operation after cholesteatoma developed from previous procedures.

2982. Kwon, C.-S., et al. (2016). "Globus Pallidus Internus Deep Brain Stimulation for Traumatic Hemidystonia Following Penetrating Head Injury." World neurosurgery **92**: 586.e581-586.e584.

BACKGROUND: Deep brain stimulation (DBS) has been a major advance in the treatment of dystonias. Outcomes are, however, less predictable for secondary dystonias, predominantly due to progression of disease or specific brain lesions. There are few cases reported of globus pallidus internus (GPi)-DBS for posttraumatic dystonia. We describe the successful use of unilateral GPi-DBS in a patient with hemidystonia following penetrating head injury. To our knowledge, this is the first description of the use of DBS following penetrating head injury., CASE DESCRIPTION: We present the case of a 47-year-old man with phasic hemidystonia. At the age of 3 years he suffered a penetrating head injury from a welding needle. The patient developed dystonic and phasic right-sided movements. Preoperative Burke-Fahn-Marsden score was 26. Magnetic resonance imaging showed a linear encephalomalacic track extending from the cortex in the left parieto-occipital region, traversing just superolateral to the left trigone into the left thalamus and ending in the region of left cerebral peduncle and subthalamic nucleus. There was no left GPi lesion. A left GPi-DBS electrode was inserted. At 6 months' follow-up, the patient's arm was more relaxed and his spasms lessened in their severity and frequency. Although the Burke-Fahn-Marsden score of 21 had improved modestly by 20%, pain and comfort levels had significantly improved with 50% improvement in visual analog scale score, translating in better quality of life. There were no complications. The clinical benefit persists at 5 years post surgery., CONCLUSION: Selected patients with posttraumatic hemidystonia, including following penetrating head injury, represent one group of secondary dystonias that might benefit from DBS surgery.

2983. Kytta, J., et al. (1999). "Extracranial contribution to cerebral oximetry in brain dead patients: a report of six cases." Journal of neurosurgical anesthesiology **11**(4): 252-254.

The near infrared spectroscopy offers a noninvasive method to monitor regional brain oxygenation. The problem with the technique appears to be possible extacranial contribution to the measurements. As a part of another study, we monitored regional saturation (rSO2) in six brain dead patients either during the test for spontaneous respiration or in those not eligible for organ donation, after discontinuation of mechanical ventilation. Relatively normal rSO2 values were obtained after brain death, and the values decreased concomitantly with the hemoglobin saturation of oxygen (SpO2) after the discontinuation of mechanical ventilation. A corresponding decrease in SpO2 and rSO2 suggests extracranial contribution to the measured rSO2. The diagnosis of brain death cannot be made based on this technology; furthermore the presence of extracranial contribution may limit its potential value even in other applications.

2984. La Harpe, R., et al. (2013). "Gunshot deaths in Geneva, Switzerland: 2001 to 2010." The American journal of forensic medicine and pathology **34**(3): 248-252.

We have conducted a retrospective study of all gunshot deaths that occurred in Geneva, Switzerland, over a 10-year period (2001-2010). The 133 cases reviewed were classified according to the manner of death, that is, suicide (106 cases), homicide (25 cases), and accident (2 cases). Various data from police authorities and the medicolegal examinations of the bodies were studied, including the age and sex of the victims, location of the event, type of firearm

used, concomitant use or nonuse of alcohol and/or other drugs, seasonality, and entry site. These various elements were compared with data found in the literature.

2988. Labbe, D., et al. (2005). "Gunshot wounds: reconstruction of the lower face by osteogenic distraction." Plastic and reconstructive surgery **116**(6): 1596-1603.

BACKGROUND: Although osteogenic distraction is a well-established technique, the distraction device still needs to be improved, miniaturized, and made lighter, more flexible, and more adaptable for mandibular reconstruction in adults with gunshot wounds. The authors successively used unidirectional and bidirectional devices, followed by a bone transporter with a horseshoe-shaped trammel. The trammel system was then replaced by an endless screw, and finally by a customized endless screw., METHODS: Eleven adult patients with gunshot injuries underwent mandibular reconstruction using osteogenic distraction with an external device., RESULTS: An average bone gain of 79 mm was achieved. No infectious complications were observed. The authors encountered equipment problems during the study, requiring a change of material. The mean duration of mandibular distraction was 3.5 months., CONCLUSIONS: Distraction of bone fragments facilitates the simultaneous expansion of soft tissues, avoiding free or pedicled myocutaneous flaps, for soft-tissue reconstruction. The alveolar ridge with the attached gum is also recreated by distraction, allowing dental reconstruction by osseointegrated implants.

2989. L'Abbe, E. N. (2005). "A case of commingled remains from rural South Africa." Forensic science international **151**(2-3): 201-206.

In the spring of 2003, bush cutters discovered a large grain bag filled with human skeletal remains in a forest in South Africa. Differential taphonomic processes observed on the bones suggested that the individuals had not died at the same time or had decomposed under different circumstances. The remains were sorted using gross morphological techniques which included assessing the number of skeletal elements present, visual pair matching, articulation, process of elimination and taphonomy. Standard techniques were used to estimate age, sex, racial affinity and stature. A minimum number of individuals (MNI) of 10 was established, which included 7 adult males, 1 adult female and 2 juveniles. Trauma was observed on only one individual. Approximately, 80% of the skeletal remains were missing. These various skeletal elements may have been lost by accident, normal taphonomic processes or taken by scavengers. Possible origins for these skeletal remains include removal from a formal grave, found in the veldt or murdered.

2990. Lachard, J., et al. (1981). "[Intracranial penetration of the mandibular condyle: report on three cases (author's transl)]." Penetration intracranienne du condyle mandibulaire. A propos de trois cas. **98**(10-11): 543-546.

Three cases of intracranial penetrations of the mandibular condyle condyle are reported, the published literature reviewed, and therapy discussed. Often unrecognized during initial examinations, they are diagnosed when the patient is seen several months later with permanent constriction of the jaws. Frontal and sagittal tomographic examinations should therefore be performed in the articular region in all cases when it is involved in injuries. Orthopedic reduction gives good results in recent injuries, long-standing cases with temporomandibular ankylosis requiring sub-condylar resection by the pre-auricular approach.

2991. Lacqua, A. J., et al. (2021). "Diagnostic findings and successful management of central diabetes insipidus following a self-inflicted penetrating brain injury in a dog." Revista Brasileira de Medicina Veterinaria **43**(1).

A 6-year-old 12 kg male neutered mixed breed dog presented in lateral recumbency with dysphoria and vocalization following a self-inflicted fork impalement injury. Computed tomography (CT) was performed which showed a penetrating wound through the right orbit, into the calvarium, and through the brain parenchyma. The dog was hospitalized with supportive care, sedatives, analgesia, antiepileptics, anti-inflammatories, antibiotics, and desmopressin acetate (DDAVP) to control post-traumatic central diabetes insipidus (PTCDI) which developed during recovery. Magnetic resonance imaging (MRI) findings 16 days later revealed resolving ventricular hemorrhage and mild perilesional edema and inflammation. Normal mentation and ambulation slowly returned and 3 months later the dog was clinically normal. To the author's knowledge, this is the first report of a self-inflicted penetrating brain injury in a dog. This case demonstrates successful medical management of a dog with a traumatic brain injury (TBI) and PTCDI which is an uncommon occurrence in veterinary medicine.

2992. Lacqua, M. J. and P. Sahdev (1992). "Effective management of penetrating head injury." Hospital practice (Office ed.) **27**(9): 30-passim.

Although head injuries are usually easily recognized, other, less obvious lesions should also be promptly investigated. In either case, outcome is often determined in the first few minutes and hours of management.

2994. Laffers, Z. and H. Brehm (1980). "[Intraorbital extrabulbar gunshot wounds]." Intraorbitale, extrabulbar gelegene Projektilverletzungen. **176**(3): 413-417.

Report on two similar cases of intraorbital, extrabulbar injuries caused by lead bullets. Indication, risk, and final success of treatment after early surgery to remove the foreign bodies are discussed with reference to the literature.

2995. Lagalla, R., et al. (2000). "Plain film, CT and MRI sensibility in the evaluation of intraorbital foreign bodies in an in vitro model of the orbit and in pig eyes." European radiology **10**(8): 1338-1341.

Detection and characterization of intraorbital foreign bodies (IFB) is fundamental in acute trauma setting, preventing inflammatory sequelae or complications related to IFB movements when a MRI study is planned. Papers concerning plain film and CT sensibility in IFB detection show controversial results. For this reason we investigated plain film, CT and MRI sensibility in the evaluation of IFB. For an in vitro model, specimens of dry and fresh wood, glass, iron, plastic and graphite were immersed in animal lard and in a 0.9% sodium chloride plus 3.5 g/dl human serum albumin solution. Specimens of different size and nature where also implanted into enucleated pig eyes. Air bubbles were introduced also. Plain film, CT and MRI investigation were performed. Plain films underestimated intraocular IFB as plastic, fresh or dry wooden IFB were not demonstrated. The CT study was always able to depict and differentiate IFB according to the attenuation values. Severe artefacts prevented demonstration of iron, glass and graphite IFB on MRI, whereas plastic or wooden IFB were always detected. Despite radiographs have been suggested as a prerequisite for MR imaging, because our results showed plain film to underestimate radiolucent IFB, we suggest CT as the modality of choice when IFB has to be ruled out.

2996. Lahirish, I. A. M., et al. (2021). "Cerebellar mutism following head trauma: A case report and literature review." Surgical neurology international **12**: 446.

BACKGROUND: Cerebellar mutism (CM) is defined as the lack of speech production, despite an intact state of consciousness and cognitive function, that happens secondary to a cerebellar insult. To the best of our knowledge, only five cases have thus far been described in the English literature. In this paper, we report the sixth incidence overall, which is also the first case of a CM associated with penetrating head injury. The relevant literature is reviewed and analyzed, our current knowledge of the neuroanatomical and functional relations is summarized, and potential future research endeavors are indicated., CASE DESCRIPTION: An 8-year-old girl was transferred to our hospital having had

fallen on a rod that penetrated her neck behind the ear. An urgent computed tomography scan of the head revealed a right cerebellar contusion with surrounding edema. Three days later, she became mute but was still obeying commands. Repeat imaging showed a resolving cerebellar contusion with increased edema and mass effect. By day 9, she had uttered a few words. At 1-month follow-up, the child had regained normal speech., CONCLUSION: Posttraumatic CM is a rare and probably underreported condition with only six documented cases to date. Although it may well be on the same spectrum as postoperative CM, further understanding of the exact mechanism, clinical course, and prognosis of this entity is bound to significantly improve the recovery and quality of life of head trauma patients. 2998. Lakits, A., et al. (1999). "Orbital helical computed tomography in the diagnosis and management of eye trauma." Ophthalmology **106**(12): 2330-2335.

OBJECTIVE: To prospectively determine the accuracy of helical computed tomography (CT) and multiplanar reconstruction and its value in surgical planning for the management of ocular trauma with suspected intraocular and orbital foreign bodies using surgical and clinical follow-up findings as the gold standard., DESIGN: Prospective, observational case series., PARTICIPANTS: Thirty-six patients with ocular trauma and suspected foreign bodies were studied., INTERVENTION: All patients were examined using a standardized scanning protocol with helical CT direct scanning in the axial plane and multiplanar reconstruction of coronal and sagittal planes., MAIN OUTCOME MEASURES: The images were analyzed for the presence and number of intraocular and orbital foreign bodies, anatomic location, and foreign body size. The surgical and clinical follow-up findings (contact lens examination, gonioscopy, indirect ophthalmoscopy and scleral depression, perimetry, color testing, measurement of size) were used as the gold standard to which the image results were compared., RESULTS: Helical CT showed a single intraocular foreign body in 14 patients, a single orbital foreign body in 9 patients, and multiple orbital foreign bodies in 2 patients. Intraocular or orbital foreign bodies were excluded in 11 patients. Twenty foreign bodies were correlated with surgical results. Surgical and clinical follow-up findings were in agreement with helical CT results regarding the detection and determination of the number of presumed foreign bodies. Localization to intraocular versus orbital compartment and proximity to the optic nerve was accurate in all patients. Determination of size of the foreign bodies on the helical CT images was reliable and repeatable., CONCLUSIONS: Helical CT axial scanning with multiplanar reconstruction is accurate at detecting and localizing intraocular and orbital metallic, glass, and stone foreign bodies. This imaging method aids the surgeon in choosing the surgical approach to retained intraocular and orbital foreign bodies.

2999. Lakouichmi, M., et al. (2014). "An unusual intracranial metallic foreign bodies and panhypopituitarism." The Pan African medical journal **19**: 33.

A 49 years old man, with a history of aggression at the age of 18 years by a pair of scissors, who consulted for unilateral migraine headaches look straight. Paraclinical explorations concluded that trauma to anterior pituitary by a metallic foreign body from the right nostril to the sella, responsible for panhypopituitarism and sinusitis. The headaches are frequent causes of consultation, often treated symptomatically but rarely explored. The direct trauma to the pituitary gland, by a metallic foreign body, is exceptional. We report the case of neglected panhypopituitarism, discovered 31 years after injury with a pair of scissors.

3000. Lam, A. L. A., et al. (2022). "POS-982 A CASE REPORT OF THE FIRST DECEASED ORGAN DONOR IN THE PHILIPPINES DURING THE COVID-19 PANDEMIC." Kidney International Reports **7**(2): S430.

Introduction: The world was faced with a new pandemic that affected different societies, economies, normal work and daily living, and has significantly affected hospital functions and resources. It took an even bigger blow to the practice of organ donation and transplantation causing a decline in the pool of potential donors to meet the rising number of transplant candidates. We report a case of the first deceased organ donor reported in the Philippines during the COVID-19 pandemic. CASE A 19-year-old male was brought to our institution due to a self-inflicted gunshot wound to the head. A severe, irreversible, traumatic brain injury was documented. Maximal resuscitative efforts were done to keep his over-all neurovital status stable however the patient still remained unresponsive. A diagnosis of brain death

was done by two physicians with four hours interval. Knowing the patient's condition, the family's altruism led them to decide for the patient to become an organ donor. Written and informed consents were secured and the patient was then placed in a multidisciplinary team of medical and surgical intensivists for deceased donor management and organ procurement. The management was geared towards towards the preservation of the viable organs for donation. The transplant procurement teams and organizations were informed from local to national setting. Assessment of donor eligibility was done. After the patient was cleared as non-COVID, the organ procurement was facilitated at our institution. [Formula presented] Methods: DIAGNOSIS OF BRAIN DEATH An evaluation of brain death was considered in our patient who have suffered a massive, irreversible brain injury with an identifiable cause. Our patient was able to meet the 3 cardinal signs of brain death on top of the clinical prerequisites needed to consider brain death. A careful neurologic examination was performed. This was done by two physicians independent of the transplant team to make sure there is no conflict of interest. MANAGEMENT OF THE DECEASED ORGAN DONOR Optimum donor care was observed from the time of diagnosis of brain death up to the time of the organ procurement to avoid the inevitable changes that can result in graft dysfunction and increased chances of rejection. The organ donor management should be aggressive and requires an ICU setting. Anwar A et al, 2019 presented management protocol for brain-dead organ donors. The goal is to help other medical health facilities to prepare their own management protocols for proper management of potential organ donors and increased chances of successful transplantation in the future. Results: There is a rising number of FIlipinos nationwide who develop end-stage renal disease (ESRD) that need organ transplantation annually. In 2020 alone there are a total of 118 transplant candidates in the waiting list and only 18 eligible deceased donors, 11 from our local city, and of the 11, only 1 consented to be an actual donor - the case presented. [Formula presented] Conclusions: The practice of organ procurement and transplantation already faced a lot of challenges and was further aggravated by the pandemic. A thorough and precise diagnosis of brain death, aggressive deceased donor management with clear treatment goals, and adherence to protocols for organ procurement adjusted to the COVID-19 pandemic made this deceased organ procurement successful and possible despite this difficult time. No conflict of interest

3001. Lam, D. C., et al. (1999). "Intraorbital needle fragment: a rare complication of retrobulbar injection." Archives of ophthalmology (Chicago, Ill. : 1960) **117**(8): 1089-1090.

3002. Lam, D. S., et al. (2000). "Combined cataract extraction and submacular blood clot evacuation for globe perforation caused by retrobulbar injection." Journal of cataract and refractive surgery **26**(7): 1089-1091.

A 45-year-old woman, originally scheduled for cataract surgery in the left eye, was referred for management of a globe perforation noticed after the retrobulbar injection of an anesthetic solution. There was a moderate degree of vitreous hemorrhage, and initial visual acuity was hand movement. A submacular blood clot of about 4-disc diameter was detected when the vitreous hemorrhage gradually cleared. One week after the incident, combined phacoemulsification, intraocular lens implantation, pars plana vitrectomy, and submacular clot removal using tissue plasminogen activator (tPA) as an adjunct were performed. Recovery was uneventful. At the last follow-up 6 months after surgery, best corrected visual acuity was 20/30.

3003. Lam, L., et al. (2012). "The impact of early hormonal therapy in catastrophic brain-injured patients and its effect on organ procurement." The American surgeon **78**(3): 318-324.

The purpose of this study was to evaluate the impact of early hormonal therapy on organ procurement from catastrophic brain-injured patients. All catastrophic brain-injured patients admitted to a high-volume academic Level I trauma center who underwent successful organ procurement over a 3-year period (2006 to 2008) were reviewed. Patients were divided into two groups, those who received hormone therapy (HT) before brain death (BD) declaration and those who received HT after BD declaration. Thirty-two (60.4%) received HT before BD and 21 (39.6%) HT after BD. Trauma was the most common cause of brain injury in both groups (before BD 96.9 vs after BD 90.5%, P = 0.324). There were no significant differences in demographics and clinical data. Patients receiving HT before BD were more hypotensive on admission (28.2 vs 9.5%, P = 0.048); however, they required vasopressors less frequently (62.5 vs 100.0%, P = 0.001), for a shorter duration (17.2 +/- 16.3 hours vs 33.1 +/- 34.9 hours, P = 0.043), and at a lower dosage. Time from admission to procurement did not differ between the two groups (109.8 +/- 83.1 hours vs 125.0 +/- 79.9 hours, P = 0.505). Patients receiving HT before BD had significantly more organs procured (4.5 +/- 1.5 vs 3.5 +/- 1.3, P =

0.023). Although catastrophic brain-injured patients receiving early hormonal therapy were more hypotensive, they required less vasopressors and had higher procurement rates. The early use of hormonal therapy may decrease the need for vasopressors and increase the salvage of potentially transplantable organs.

3004. Lamb, T., et al. (2012). "Craniocerebral gunshot wounds: A current analysis armed with new technology." Emergency radiology **19**(5): 365-366.

Purpose: We analyzed multidetector head CT exams of civilian patients who suffered cranial gunshot wounds and correlated imaging findings with clinical outcome. Materials and Methods: Institutional review board approved, retrospective review of our database identified 34 patients who had intracranial gunshot injuries between January 2009 and March 2012 and had initial multidetector CT at our hospital. The patients' hospital course and operative history were reviewed; discharge condition was assigned a score based on the modified Rankin scale (MRS). Twenty of the 34 patients died (MRS of 6) and 1 was discharged in a vegetative state (MRS of 5). The remaining 13 patients were given MRS scores based on their level of disability (MRS of 0-4). Each patient's initial head CT was evaluated for entrance and exit wounds, ventricular involvement, and trajectory of the missile. Transcranial injury was defined by the presence of both entrance and exit wounds. Two and three dimensional reformatted images were utilized for precise identification of entrance and exit wounds and plotting missile trajectory. Fisher's exact test was applied to the data. Results: Twenty of 34 patients suffered bihemispheric injury, of which 17 patients had MRS >4 and 3 patients had MRS ≤4 confirming that multihemispheric involvement portends a poorer outcome (p-value = 0.001). 18/34 patients suffered transcranial injury, of which 15 patients had MRS >4 and 3 patients had MRS ≤4 confirming that transcranial injury correlates with a poorer outcome (p-value = 0.012). 14/34 patients suffered ventricular injury, of which 12 patients had MRS >4 and 2 patients had MRS ≤4 confirming that ventricular injury portends a poorer outcome (p-value = 0.030). 12/ 34 patients died within the first day of hospitalization. Among the 22 survivors, 12 patients underwent surgery, of which 2 had MRS >4 and 10 had an MRS ≤4 confirming that surgical intervention in patients that survive 24 hours correlates with improved outcome (p-value = 0.0274). We will illustrate several severe complications such as catastrophic delayed venous hemorrhage and venous sinus thrombosis. Conclusion: Our study identified several statistically significant predictors of poor clinical outcome (MRS >4) including bihemispheric involvement, ventricular injury, and transcranial missile injury.

3005. Lambert, A. O., et al. (2020). "Difficult Intubation due to Penetrating Trauma from a Crossbow Bolt." Air medical journal **39**(4): 300-302.

We present the case of a patient with penetrating neck and craniofacial trauma from a self-inflicted crossbow bolt injury. This case highlights the challenges involved in prehospital airway management related to an in situ foreign object penetrating the oral cavity. We review the complications associated with such injuries and considerations for effective prehospital airway management.

3006. Lambert, G. A., et al. (1999). "Effect of cortical spreading depression on activity of trigeminovascular sensory neurons." Cephalalgia : an international journal of headache **19**(7): 631-638.

The effect of cortical spreading depression, a proposed initiating event for migraine pain, on cortical blood flow (laser Doppler method) and on the spontaneous firing rate and stimulus-evoked responses of trigemino-cervical neurons with craniovascular input was studied in 17 neurons in 8 cats anesthetized with chloralose. Cortical spreading depression, induced via cortical pinprick injury, produced an initial wave of cortical hyperemia (243+/-57% of control) and a later and smaller phase of oligemia (96+/-4% of control). Neither the basal discharge rate (6.7+/-1.7 sec(-1)) nor the evoked responses to electrical stimulation of the superior sagittal sinus (4.1+/-0.8 discharges per stimulus) of upper cervical spinal cord neurons was altered over periods of up to 2 h following one, two, or three waves of spreading cortical depression. We conclude that a small number of episodes of cortical spreading depression is not capable of activating C2 cervical spinal cord craniovascular sensory neurons in the cat.

3007. Lamm, K., et al. (1986). "Long-term study after perforation of the round window. Animal experiments using electric response audiometry." Acta oto-laryngologica **102**(1-2): 27-30.

The round-window membrane of the inner ear of the guinea pig was perforated with a platinum wire under ketamine-xylazine anaesthesia. The latency times of waves I and V (Jewett) increased to 0.6 ms at 100 dB click HL stimulus loudness. The interpeak latencies did not change (4.0-4.2 ms). At 60 dB CHL stimulus loudness, no responses were discernible. Closure of the membrane damage by adhesive fibrin tissue had no effect on the auditory nerve potentials or the brain-stem responses. Normal latency times of waves I-V were seen 7 days after perforation. There was no difference between the animals with repaired and unrepaired membrane damage. We observed spontaneous healing of the round-window membrane 7 days after perforation, and a normal organ of Corti.

3008. Lamminmaki, S., et al. (2018). "Multiple cranial nerve injuries and neck abscesses caused by a transorally penetrating organic stick." BMJ case reports **2018**.

Foreign bodies cause a remarkable number of otolaryngological emergency visits and occasionally result in life-threatening conditions and later-emerging complications. Patient recovery depends on the detection and proper extraction of all foreign materials. Despite various obtainable diagnostic tools, adequate anamnesis forms the basis of clinical reasoning and should direct later examinations and radiological imaging. This case report describes a challenging patient with a unique trauma mechanism: many pieces of a fragmented organic foreign body emerged within 1 year of the initial injury, leading to repeated operations, a long period in an intensive care unit and a long-term swallowing and speech dysfunction.

3009. Lan, Z., et al. (2018). "Nonmissile Anterior Skull-Base Penetrating Brain Injury: Experience with 22 Patients." Asian journal of neurosurgery **13**(3): 742-748.

BACKGROUND: Nonmissile anterior skull-base penetrating brain injuries (NASBPBIs) have specific characteristic features that are different from missile injuries. Our study presents our experiences on the characteristic features as well as management of NASBPBI., MATERIALS AND METHODS: We retrospectively reviewed 22 consecutive patients with NASBPBI managed at our institute during a 13-year period. The mechanism of injury, clinical investigations, and complications were analyzed, with more emphasis on diagnostic and treatment regimen., RESULTS: The 22 cases included in our study comprise of 20 males and 2 females. Majority (72.7%) of the patients were adults with a mean age of 27.5 years. The mechanisms of injury often include accidental fall, either onto a small-diameter sharp object (10 cases) or while carrying such an object in the hand (4 cases). The other common mechanisms were stabbing, accident, or during an altercation (8 cases). Clinical manifestations included periorbital hematoma (10 cases, 45.5%) and cerebrospinal fluid rhinorrhea or orbitorrhea (4 cases, 18.2%) as well as signs of embedded foreign object (8 cases, 36.4%). We performed emergency craniotomy in 21 cases and skin debridement in one case. Postoperative complications were abscess (1 case), epilepsy (1 case), and traumatic carotid-cavernous fistula (1 case)., CONCLUSION: Nonmissile injuries are generally on the rise and therefore deserve more attention. We observed that clinical outcomes were excellent in 14 (Glasgow Outcome Scale [GOS] score of 5) and good in the remaining 8 patients (GOS of 4) during 6-month-10-year (mean 4.6 years) follow-ups.

3010. Lan, Z. G., et al. (2018). "Nonprojectile penetrating iron rod from the oral cavity to the posterior cranial fossa: a case report and review of literature." International medical case reports journal **11**: 41-45.

INTRODUCTION: Nonprojectile penetrating skull base injuries as a result of falls have rarely been confronted in normal neurosurgery although a few nonmissile injuries have been reported. These kinds of injuries represent a life-threatening emergency., CASE PRESENTATION: We present an unusual case of a 25-year-old male construction worker who suffered an accidental penetrating skull base injury when he fell on a metal rod while he was walking on a 2-meter-high platform. He was clinically stable at presentation. Skull radiograph showed a solid metallic bar, 30 cm long, that penetrated through the right anguli oris eminence and was lodged low in the right occipital bone., CONCLUSION: Penetrating injury to the head is considered a form of severe traumatic brain injury. Although case of penetrating head injuries as a result of fall from heights are very rare, we anticipate the construction works on high-rise buildings are at maximum risk. We advise that removal of this kind of foreign bodies be done in the theater and not outside because of risk of involvement of larger vessels leading to fatal hemorrhage. We further suggest that patients with nonprojectile injuries should undergo a preoperative computed tomography-angiography to rule out any vascular injury.

3011. Lancia, M., et al. (2014). "An unusual case of unintentional firearm death of a 3-year-old child." The American journal of forensic medicine and pathology **35**(3): 178-180.

The authors report the case of an accidental death of a 3-year-old child who unintentionally shot himself while he was handling his father's handgun. The peculiarity of the observed injury makes the case particularly interesting, along with the fact that, in Italy, unintentional firearm-related deaths are rather uncommon among children and adolescents.Because of the presence of only 1 bullet hole on the parietal-occipital region, radiological cranial examinations were performed before proceeding with the autopsy.Computed tomographic scans were useful to confirm the entrance site of the bullet and, especially, to establish the trajectory with the whole spectrum of fractures. The case shows that the unusual entrance site of the bullet through the nose led to a fatal cranial injury, as a result of curiosity of a 3-year-old child in the presence of an unsupervised handgun.

3012. Lane, P. L., et al. (2000). "Intracranial pressure monitoring and outcomes after traumatic brain injury." Canadian journal of surgery. Journal canadien de chirurgie **43**(6): 442-448.

OBJECTIVE: Uncontrolled intracranial hypertension after traumatic brain injury (TBI) contributes significantly to the death rate and to poor functional outcome. There is no evidence that intracranial pressure (ICP) monitoring alters the outcome of TBI. The objective of this study was to test the hypothesis that insertion of ICP monitors in patients who have TBI is not associated with a decrease in the death rate., DESIGN: Study of case records., METHODS: The data files from the Ontario Trauma Registry from 1989 to 1995 were examined. Included were all cases with an Injury Severity Score (ISS) greater than 12 from the 14 trauma centres in Ontario. Cases identifying a Maximum Abbreviated Injury Scale score in the head region (MAIS head) greater than 3 were selected for further analysis. Logistic regression analyses were conducted to investigate the relationship between ICP and death., RESULTS: Of 9001 registered cases of TBI, an MAIS head greater than 3 was recorded in 5507. Of these patients, 541 (66.8% male, mean age 34.1 years) had an ICP monitor inserted. Their average ISS was 33.4 and 71.7% survived. There was wide variation among the institutions in the rate of insertion of ICP monitors in these patients (ranging from 0.4% to over 20%). Univariate logistic regression indicated that increased MAIS head, ISS, penetrating trauma and the insertion of an ICP monitor were each associated with an increased death rate. However, multivariate analyses controlling for MAIS head, ISS and injury mechanism indicated that ICP monitoring was associated with significantly improved survival ($p < 0.015$)., CONCLUSIONS: ICP monitor insertion rates vary widely in Ontario's trauma hospitals. The insertion of an ICP monitor is associated with a statistically significant decrease in death rate among patients with severe TBI. This finding strongly supports the need for a prospective randomized trial of management protocols, including ICP monitoring, in patients with severe TBI.

3013. Lange, J., et al. (2012). "Maggots! An unusual complication of head trauma in the rockies." Journal of Hospital Medicine **7**: S210-S211.

Case Presentation: A 52-year-old female with end-stage liver disease and no recent travel history sustained head trauma 3 weeks prior to presentation that required laceration repair. She was transferred to our medicine service from an outside hospital Emergency Department after being found down with evident maggot infestation. Exam was significant for presence of larvae in her right ear canal and in her scalp wounds as well as grade I hepatic encephalopathy, ascites, and lower extremity edema. Her CBC displayed mild leukocytosis (11.2) and tissue culture grew MRSA and polymicrobial flora. Computed Tomography of the head demonstrated scalp wounds penetrating to bone, intact and thickened tympanic membranes, and no evidence of brain involvement. ENT and Plastic Surgery performed multiple procedures involving maggot removal and debridement of scalp wounds. The patient completed a 2- week course of antibiotics and was discharged. Discussion: Semi-specific myiasis results from deposition of fly eggs in decaying animal matter or in a living host if open wounds are present. Myiasis infestation occurs commonly in tropical areas but is rare in the US and rarer in arid climates, such as Colorado. Myiasis can no longer be considered a disease restricted to the tropics. Immigration, global commerce, eco-tourism, and global warming have contributed to an increased number of US cases involving these nonnative species. Larvae found in wounds should not be considered therapeutic. Therapeutic larvae spare vital tissue whereas acquired larvae invade necrotic and healthy tissue. Treatment for myiasis involves larvae removal, devitalized tissue debridement, and occasionally larvacides. Early treatment is curative and crucial to prevent invasion of healthy tissue. Conclusions: We present an unusual case of acquired cutaneous and cavitary myiasis following head trauma. Patients with poor personal hygiene and environmental exposure are at risk for developing myiasis, even in developed countries and arid climates.

3014. Lange, R., et al. (2017). "Factors affecting burden in family caregivers of military service members with traumatic brain injury." Brain injury **31**(6-7): 893-894.

Background: Family members often assume the role of 'caregiver' for a service member (SM) following a traumatic brain injury (TBI) to help with rehabilitation and community reintegration. Caregivers often experience significant burden from the demands placed on them. This study aimed to identify factors that increase caregiver burden. Methods: Participants were 214 caregivers [95.8% female; 92.5% Caucasian; Age: M = 38.6 years (SD = 10.4)] of US military SMs who sustained a penetrating, severe, moderate or mild TBI. The majority of the sample was caring for a spouse/ partner (86%) and had been caregiving for 4.1 years (SD = 2.9). Caregivers were recruited from medical treatment facilities nationwide and via community outreach. Participants completed the Caregiver Appraisal Scale (CAS), Mayo- Portland Adaptability Inventory (MPAI; significant other ratings), and a structured interviewed designed to evaluate a variety of caregiving issues (e.g. time spent caregiving, caregiving responsibilities). Only select variables were included that were hypothesized (a priori) to have an impact on caregiver burden. Using the CAS Caregiver Burden subscale, the sample was divided into two groups: High Burden (n = 138) and Low Burden (n = 76). Results: There were no significant group differences for age, gender, household income, number of dependents living in the household or the number of years caregiving (p >.05). However, there were significant group differences on the majority of remaining measures. High caregiver burden was significantly associated with a decrease in the SMs (i) sensorymotor and cognitive abilities; (ii) mood and interpersonal interactions; and (iii) initiation and social contact/activities [MPAI Ability, Adjustment, and Participation scales (all ps <.001; d=.77 to d = 1.30)]. In particular, high caregiver burden was associated with a SMs symptoms of anxiety, post-traumatic stress, depression, inappropriate behaviour in social situations, and verbal and physical expressions of irritability, anger, and aggression (all ps<.001; OR = 4.81 to 15.36). High caregiver burden was further associated with the caregiver's: [1] lack of mastery in their role (CAS Caregiver Mastery, p <.001; d=.77) and need for instruction/coaching to provide care (p <.001, OR = 3.79); [2] loss of income due to lack of employment or inability to work or find work (all ps <.006, OR = 2.78 to 14.57); [3] need for help managing medical appointments, navigating the medical health system, and finding information about available services/programmes (all ps<.001; OR = 3.70 to 10.32); and [4] providing care 7 days per week for more than 80 hours p/week; and a lack of time to devote to themselves (all ps<.001, OR = 3.74 to 10.36). Conclusion: These results suggest that caregiver burden among family caregivers providing care to SMs following TBI is very high. There is a significant need for increased focus on this population. In order to reduce burden, caregivers would benefit from (a) education programmes, (b) assistance with caregiving duties, (c) respite, (d) support groups, and (e) increased financial support.

3015. Lange, R. T., et al. (2015). "Clinical utility of the Neurobehavioral Symptom Inventory validity scales to screen for symptom exaggeration following traumatic brain injury." Journal of clinical and experimental neuropsychology **37**(8): 853-862.

The purpose of this study was to examine the clinical utility of three recently developed validity scales (Validity-10, NIM5, and LOW6) designed to screen for symptom exaggeration using the Neurobehavioral Symptom Inventory (NSI). Participants were 272 U.S. military service members who sustained a mild, moderate, severe, or penetrating traumatic brain injury (TBI) and who were evaluated by the neuropsychology service at Walter Reed Army Medical Center within 199 weeks post injury. Participants were divided into two groups based on the Negative Impression Management scale of the Personality Assessment Inventory: (a) those who failed symptom validity testing (SVT-fail; n = 27) and (b) those who passed symptom validity testing (SVT-pass; n = 245). Participants in the SVT-fail group had significantly higher scores (p<.001) on the Validity-10, NIM5, LOW6, NSI total, and Personality Assessment Inventory (PAI) clinical scales (range: d = 0.76 to 2.34). Similarly high sensitivity, specificity, positive predictive power (PPP), and negative predictive (NPP) values were found when using all three validity scales to differentiate SVT-fail versus SVT-pass groups. However, the Validity-10 scale consistently had the highest overall values. The optimal cutoff score for the Validity-10 scale to identify possible symptom exaggeration was >=19 (sensitivity = .59, specificity = .89, PPP = .74, NPP = .80). For the majority of people, these findings provide support for the use of the Validity-10 scale as a screening tool for possible symptom exaggeration. When scores on the Validity-10 exceed the cutoff score, it is recommended that (a) researchers and clinicians do not interpret responses on the NSI, and (b) clinicians follow up with a more detailed evaluation, using well-validated symptom validity measures (e.g., Minnesota Multiphasic Personality Inventory-2 Restructured Form, MMPI-2-RF, validity scales), to seek confirmatory evidence to support an hypothesis of symptom exaggeration.

3016. Langenegger, E. and C. Lanz (2005). "[Postmortem injury--an impressive postmortem phenomenon that can lead to diagnostic errors]." Treibverletzung--ein eindruckliches postmortales phanomen, das zu Fehldiagnosen fuhren kann. **63**(1): 103-106.

A single skull from a 6-year-old child was sent to the Anthropological Institute of the University of Zurich. It bore a considerable bone lesion in the frontal area. Closer inspection revealed that it was a postmortal lesion, resulting from the skull chafing on the river bottom whilst drifting in running water. The postmortal change, the so-called "Treibverletzung" (drift injury), is characteristic for bodies that are recovered from rivers or stillwater. A recent case from the Medical Examiners' Office from the same geographic area as the child, showed the same features of the "Treibverletzung". Since it is known from the recent case where it was found, it becomes clear that even small rivers can cause characteristic postmortal injuries.

3017. Langerman, A., et al. (2011). "Skull base approach to carotid artery lesions: Technique, indications, and outcomes." Skull Base **21**.

Operative approaches to lesions of the carotid artery at the skull base are challenging and place multiple cranial nerves at risk. Endovascular approaches have enhanced the accessibility of this area, but some lesions are not amenable to endovascular management. Herein we describe a preauricular approach utilizing anterior dislocation of the temporomandibular joint with microscopic drillout of the medial glenoid and eustachian tube to identify and skeletonize the carotid artery in the foramen lacerum. Reviewing our experience with a direct open approach to the distal carotid artery revealed 10 patients from our institution. Nine of the patients presented with aneurysm, six spontaneous and three following blunt trauma, and one patient presented with carotid artery rupture after penetrating trauma. Eight patients underwent reverse saphenous vein grafting and two had resection with primary reanastomosis. Two of the patients presented with cranial nerve (CN) X deficits, and these persisted following surgery. Three of the eight patients without CN deficits preoperatively experienced postoperative deficits. One patient also suffered a mild CVA but had no permanent sequelae. Thus overall 5 (50%) of the 10 patients suffered no neurologic deficits and 7 (70%) suffered no new neurologic deficits as a result of surgery. One patient had persistent temporomandibular joint dysfunction. All patients had long-term patency of the graft or anastomosis, and no new neurologic symptoms were reported with a mean follow-up of 55 months. Open approaches to the carotid artery at the skull base are feasible and with careful anatomic dissection can be carried out with minimal morbidity in most cases. We present full details and images of the operative approach.

3018. Langerman, A., et al. (2012). "Skull base approach to carotid artery lesions: Technique, indications, and outcomes." Journal of Neurological Surgery, Part B: Skull Base **73**(3): 163-167.

Operative approaches to lesions of the carotid artery at the skull base are challenging and place multiple cranial nerves at risk. Herein, we describe a preauricular approach utilizing anterior dislocation of the temporomandibular joint with microscopic drill-out of the medial glenoid and Eustachian tube to identify and skeletonize the carotid artery in the foramen lacerum. The facial nerve remains undissected during this approach. Nine of 10 patients presented with aneurysm, six spontaneous and three following blunt trauma, and one patient presented with carotid artery rupture after penetrating trauma. Three of the patients presented with cranial nerve (CN) deficits that persisted. One patient was unevaluable preoperatively due to trauma but awoke with multiple CN deficits. Only one of nine evaluable patients suffered a new long-term CN deficit (XI). One patient had persistent temporomandibular joint dysfunction. All patients had long-term patency of the graft or anastamosis and no new neurologic symptoms were reported with amean follow-up of 55months. Open approaches to the carotid artery at the skull base are feasible and with careful anatomic dissection can be performed with minimal morbidity in most cases. We present full details and images of the operative approach.

3019. Lanigan, A., et al. (2017). "The Joint Facial and Invasive Neck Trauma (J-FAINT) Project, Iraq and Afghanistan: 2011-2016." Otolaryngology--head and neck surgery : official journal of American Academy of Otolaryngology-Head and Neck Surgery **157**(4): 602-607.

Objective Define the number and type of facial and penetrating neck injuries sustained in combat operations in Iraq and Afghanistan from 2011 to 2016. Compare recent injury trends to prior years of modern conflict. Study Design Case series with chart review. Setting Tertiary care hospital. Methods The Joint Theater Trauma Registry (JTTR) was queried for facial and neck injuries from Iraq and Afghanistan from June 2011 to May 2016. Injury patterns, severity, and patient demographics were analyzed and compared to previously published data from combat operations during January 2003 to May 2011. Results A total of 5312 discrete facial and neck injuries among 922 service members were identified. There were 3842 soft tissue injuries (72.3%) of the head/neck and 1469 (27.7%) facial fractures. Soft tissue injuries of the face/cheek (31.4%) and neck/larynx/trachea (18.8%) were most common. The most common facial fractures were of the orbit (26.3%) and maxilla/zygoma (25.1%). Injuries per month were highest in 2011 to 2012 and steadily declined through 2016. The percentage of nonbattle injuries trended up over time, ranging from 14.7% to 65%. Concurrent facial/neck soft tissue trauma or fracture was associated with an overall mortality rate of 2.44%. Comparison of our data to that previously published revealed no statistical difference in concurrent mortality (3.5%-2.2%, P = .053); an increase in orbital fractures (P < .005), facial nerve injury (P < .0005), and ear/tympanic membrane perforations (P < .0005); and a decrease in mandible fractures (P < .005). Conclusion Penetrating neck and facial injuries remain common in modern warfare. Assessing injury characteristics and trends supports continued improvements in battlefield protection and identifies areas requiring further intervention.

3020. Lanner, G. (1974). "[Internal ricocheted gunshot]." Der innere Prellschuss **35**(2): 137-143.

3021. Lannon, M. M., et al. (2022). "Pediatric craniocerebral gunshot injuries: A National Trauma Database study." The journal of trauma and acute care surgery **92**(2): 428-435.

BACKGROUND: We aimed to determine the outcomes and prognostic factors in pediatric craniocerebral gunshot injury (CGI) patients. Pediatric patients may have significantly different physiology, neuroplasticity, and clinical outcomes in CGI than adults. There is limited literature on this topic, mainly case reports and small case series., METHODS: We queried the National Trauma Data Bank for all pediatric CGI between 2014 and 2017. Patients were identified using International Classification of Diseases, Ninth Revision, codes. Demographic, emergency department, and clinical data were analyzed. Subgroup analysis was attempted for groups with Glasgow Coma Scale (GCS) scores of 9 to 15 and ages 0 to 8 years., RESULTS: In a 3-year period, there were 209 pediatric patients (aged 0-18 years) presenting to American hospitals with signs of life. The overall mortality rate was 53.11%. A linear relationship was demonstrated showing a mortality rate of 79% by initial GCS in GCS score of 3, 56% in GCS scores of 4 to 8, 22% in GCS scores of 9 to 12, and 5% in GCS scores of 13 to 15. The youngest patients, aged 0 to 8 years, had dramatically better initial GCS and subsequently lower mortality rates. Regression analysis showed mortality benefit in the total population for intracranial pressure monitoring (odds ratio, 0.267) and craniotomy (odds ratio, 0.232)., CONCLUSION: This study uses the National Trauma Data Bank to quantify the prevalence of pediatric intracranial gunshot wounds, with the goal to determine risk factors for prognosis in this patient population. Significant effects on mortality for invasive interventions including intracranial pressure monitoring and craniotomy for all patients suggest low threshold for use of these procedures if there is any clinical concern. The presence of a 79% mortality rate in patients with GCS score of 3 on presentation suggests that as long as there is not a declared neurologic death, intracranial pressure monitoring and treatment measures including craniotomy should be considered by the consulting clinician., LEVEL OF EVIDENCE: Prognostic and epidemiological, level III.

3022. Lanoix, R., et al. (2000). "C-spine injury associated with gunshot wounds to the head: retrospective study and literature review." The Journal of trauma **49**(5): 860-863.

OBJECTIVE: To determine the incidence of C-spine injury (CSI) associated with gunshot wounds (GSWs) to the head., METHODS: A retrospective chart review including patients with GSWs to the head and excluding those with penetrating facial/neck trauma was performed. Cervical clearance was by clinical/radiologic criteria in survivors, and autopsy in nonsurvivors. A MEDLINE literature search was performed and relevant articles reviewed., RESULTS: One hundred seventy-four charts were available for review; 90 had C-spine radiographs (complete series [49], lateral [33], and computed tomographic scan [8]). Of 84 with no radiographs, 29 were clinically cleared, and 55 died (32 cleared at autopsy). Twenty-three died without evaluation. None of the remaining 151 (87%) had CSI. Literature search yielded only three relevant articles. Combining the data from these articles yielded 534 patients, and CSI was excluded in 507

(95%)., CONCLUSION: C-spine immobilization and diagnostic radiography are probably not necessary in patients with isolated GSWs to the head and may complicate and delay emergency airway management.

3023. Lanska, D. J. (2009). "Historical perspective: neurological advances from studies of war injuries and illnesses." Annals of neurology **66**(4): 444-459.

Early in the 20th century during the Russo-Japanese War and World War I (WWI), some of the most important, lasting contributions to clinical neurology were descriptive clinical studies, especially those concerning war-related peripheral nerve disorders (eg, Hoffmann-Tinel sign, Guillain-Barre-Strohl syndrome [GBS]) and occipital bullet wounds (eg, the retinal projection on the cortex by Inouye and later by Holmes and Lister, and the functional partitioning of visual processes in the occipital cortex by Riddoch), but there were also other important descriptive studies concerning war-related aphasia, cerebellar injuries, and spinal cord injuries (eg, cerebellar injuries by Holmes, and autonomic dysreflexia by Head and Riddoch). Later progress, during and shortly after World War II (WWII), included major progress in understanding the pathophysiology of traumatic brain injuries by Denny-Brown, Russell, and Holbourn, pioneering accident injury studies by Cairns and Holbourn, promulgation of helmets to prevent motorcycle injuries by Cairns, development of comprehensive multidisciplinary neurorehabilitation by Rusk, and development of spinal cord injury care by Munro, Guttman, and Bors. These studies and developments were possible only because of the large number of cases that allowed individual physicians the opportunity to collect, collate, and synthesize observations of numerous cases in a short span of time. Such studies also required dedicated, disciplined, and knowledgeable investigators who made the most out of their opportunities to systematically assess large numbers of seriously ill and injured soldiers under stressful and often overtly dangerous situations.

3024. Lanter, P., et al. (2019). "4 Minor Traumatic Head Bleeds, Emergency Department Observation Versus Inpatient Admission: Shorter Stays, Less Expensive, No Increased Risk." Annals of emergency medicine **74**(4): S2-S3.

Study Objectives: Patients with mild traumatic head injury with intracranial hemorrhage (mTBI) have low neurosurgical intervention rates. Inpatient admission for monitoring is common; this practice is costly and may be unnecessary. We developed and implemented a protocol to co-manage mTBI in our ED observation unit (OU) with Neurosurgery. The objective of this study is to review the safety and efficacy of an observation protocol for patients with mTBI Methods: This is a retrospective analysis of the mTBI protocol which was implemented on May 1, 2015. Admission criteria were: adult patients (> 17yo) with cerebral contusions < 1cm, convexity subarachnoid hemorrhage (SAH), or closed/nondisplaced skull fractures. Patients with epidural or subdural hematoma, open or displaced skull fractures, persistent neurological deficits, thrombocytopenia, coagulopathy, anticoagulant or antiplatelet use (except aspirin), or other trauma were not eligible for admission to the OU. After patients were scanned and evaluated by the Neurosurgical team, then were admitted to the OU with q 4 hour neuro checks and a scheduled interval head CT. If there was interval worsening in either exam or the CT, the patient was admitted to the inpatient ward. A sequential cohort of inpatient mTBI patients over the preceding three years was used as a control group. Categorical outcomes were analyzed with students T-test and Chi-square. A logistic regression was performed to identify possible risk factors for worsening and delayed subdural hematoma. Results: 60 mTBI patients were observed in the OU, and 85 were in the inpatient control cohort. Among co-morbidities, hypertension was the most common (36.67%). 20 patients (33.3%) used a daily aspirin. The most common mechanism of injury was a ground-level fall (53.3%), followed by fall from height (21.7%), motor vehicle collision (6.7%), altercation (5.0%), vehicle versus pedestrian (1.67%), and other/unspecified (11.7%). There was a lower incidence of fracture injury type in the OU group (3.33% vs 15.29%, p=.020); otherwise the groups were well matched. There were no differences in rates of radiographic progression, neurological deterioration, surgical intervention, delayed chronic subdural formation, or mortality. The OU group had significantly lower length of stay (1.0d vs. 1.59d, p=.001), shorter time to interval scanning (12.99h vs. 16.95h, p=.001) and lower encounter charges ($11,430 vs. $14,858, p=.008). Pooled univariate logistic regression analysis for age, sex, co-morbidities, mechanism of injury, aspirin usage, recent surgery, acute alcohol intoxication, and transient LOC did not identify any statistically significant predictor of either interval radiographic changes or delayed chronic subdural formation. [Figure presented] Conclusion: Admitting patients to an OU with mTBI is more efficient with shorter length of stays and charges. There was no statistical difference in adverse outcomes. Managing mTBI in the ED using a protocol can safely avoid inpatient admission, thereby improving resource allocation, alleviating capacity restraints, and lowering costs to the patient.

3026. Lantieri, L. A., et al. (2010). "Face transplantation outcomes: Feasibility reproducibility and efficacy." Transplantation **90**: 168.

Background While the conventional use of autologous transfer allows to reconstruct faces in most cases in some cases conventional surgery fails to restore normal appearance and function leading to indications for facial composite tissue allograft. We report here our series of patients showing the reproducibility, the difficulties, serious adverse events and the outcomes in term of quality of life. Patients and Methods Five patients were included in a registered clinical research protocol after a thorough clinical, and biological screening, assessed by an independant expert committee. Alternative procedures were discussed for each patient. One patient suffered from bilateral plexiform neurofibromas, two from extensive third degree burns and two from gunshot injuries. As any transplant they were included national waiting list with a dedicated face procurement procedure. All face transplants were harvested from heart beating brain-dead donors before other tissues and organs procurements after an alginate molding of the donor's face to allow reconstitution. The induction immunosuppressive regimens included anti-thymocyte globulins, steroids, mycophenolate mophetil and tacrolimus, the maintenance therapy was based on the last three ones. Extracorporeal photopheresis was used as adjuvant immunomodulatory therapy. Results Four patients were transplanted with a maximum follow up of 36 months and minimal of12 months. One patient which was on waiting list for 18 months could not be transplanted due to his panel reactive antibodies . Three patients experimented biopsy proven acute cellular rejection episodes easily controlled by conventional treatment. Voluntary facial activity appeared from 3 to 5 month. All patient experienced various infections which could be life threatening. These infections were either local or general One of our patient died two month after transplantation due to multi resistant bacterial infection. The dramatic changes obtained in the facial aesthetic and function and the improvement in patients quality of life had the same extent. Conclusion Face transplantation have been feasible, reproducible and has allowed major improvement. It represents a change in paradigm in facial reconstruction so as in transplantation.. Infections were always life threatening and were the main pitfall. The need for civilian and military reconstruction allowing social lives, might led the society to accept these new type of harvested organs and tissues.

3027. Lantz, E. J., et al. (1980). "Radiology of cerebrospinal fluid rhinorrhea." AJR. American journal of roentgenology **135**(5): 1023-1030.

Fifty-one patients with cerebrospinal fluid rhinorrhea were evaluated at the Mayo Clinic from 1974 to 1977. The causes of the leak were fairly even distributed among postoperative, traumatic unrelated to previous surgery, and nontraumatic. The slightly fewer patients with a traumatic cause compared with those reported in most series reflects the referral patterns and surgical nature of the practice at the institution. Three-fourths of the patients had plain films of the skull, although the site of the leak was identified in only 21% of them. Two-thirds of the patients had tomography, which was helpful in 53%, especially in 10 of the 13 patients with traumatic nonpostoperative cerebrospinal fluid rhinorrhea. Posteroanterior tomography generally was more helpful than lateral tomography, except in leaks around the frontal sinuses. Radioisotope cisternography with intranasal pledgets helped localize the site of leak in 50% of patients and suggested the site of the leak in 25%. Radioisotope cisternography with pledgets often gave helpful positive results when the plain films and tomography were not helpful.

3028. Lanzetta, M., et al. (2004). "Early use of artificial sensibility in hand transplantation." Scandinavian journal of plastic and reconstructive surgery and hand surgery **38**(2): 106-111.

Hands were transplanted from brain-dead donors for the treatment of two male unilateral amputees, aged 35 years and 32 years, involved in the Italian Hand Transplantation Programme. Each had lost his right dominant hand, in a farming accident and an explosion, respectively. In one case artificial sensibility was applied postoperatively using a Sensor Glove that transformed vibrotactile stimuli induced by touch, to stereophonic vibroacoustic stimuli perceived through earphones. The principle is based on the brain's capacity for multimodal plasticity, implying that deprivation of one sense (somatosensory) can be compensated for by another sense (auditory). Functional magnetic resonance images (fMRI) taken at regular intervals showed that cortical remodelling of the transplanted hand within the sensory-motor maps occurred early in the patient who used the artificial sensibility regimen compared with the one who did not. We

conclude that postoperative use of a device using hearing as a substitution for sensation in hand transplantation may have considerable potential value for speeding up cortical integration of a transplanted hand.

3029. Lapchenko, A. S., et al. (2018). "[Antimicrobial anti-inflammatory photodynamic and light-emitting-diode phototherapy of the consequences of the gunshot and mine-blast injury to the face, head, and neck including damage to the ENT organs]." Antimikrobnaia protivovospalitel'naia fotodinamicheskaia i svetodiodnaia fototerapiia posledstvii ognestrel'noi i minno-vzryvnoi travmy golovy i shei. **83**(1): 62-64.

The objective of the present study was the enhancement of the effectiveness of the treatment of the consequences of the gunshot wounds and mine-blast injuries inflicted to the face, head, and neck encountered in the otolaryngological practice as well as the prevention of the formation of the large demarcation areas in the injured tissues and the preparation of these tissues for the further restorative treatment. Anti-microbial and anti-inflammatory photodynamic therapy (PDT) as well as light-emitting-diode (LED) phototherapy were carried out in 20 patients who suffered gunshot wounds and mine-blast injuries to the face, head, and neck. The photodynamic therapy was performed with the use of an aqueous solution of methylene blue at a concentration of 0.1%, the 'Alod-1' infrared laser ('Granat' modification, Russia), and the 'AFS-Solaris' light-emitting diode-based phototherapeutic apparatus (Russia). The analysis of the results of the study has demonstrated the high efficiency of the proposed approach that made it possible to prevent the development of severe septic complications, reduce the amount of drug therapy, significantly shorten duration of the treatment, and create the conditions for the earlier rehabilitation and further plastic and cosmetic restoration of the tissue structures.

3030. Laraque, D., et al. (1995). "Children who are shot: a 30-year experience." Journal of pediatric surgery **30**(7): 1072-1076.

Three data sets describe the pattern of gunshot injuries to children from 1960 to 1993: The Harlem Hospital pediatric trauma registry (HHPTR), the northern Manhattan injury surveillance system (NMISS) a population-based study, and the National Pediatric Trauma Registry (NPTR). A small case-control study compares the characteristics of injured children with a control group. Before 1970 gunshot injuries to Harlem children were rare. In 1971 an initial rise in pediatric gunshot admissions occurred, and by 1988 pediatric gunshot injuries at Harlem Hospital had peaked at 33. Population-based data through NMISS showed that the gunshot rate for Central Harlem children 10 to 16 years of age rose from 64.6 per 100,000 in 1986 to 267.6 per 100,000 in 1987, a 400% increase. The case fatality for children admitted to Harlem Hospital (1960 to 1993) was 3%, usually because of brain injury, but the majority of deaths occurred before hospitalization. During the same period, felony drug arrests in Harlem increased by 163%. The neighboring South Bronx experienced the same increase in gunshot wound admissions and felony arrests from 1986 to 1993. The NPTR showed a similar injury pattern for other communities in the United States. In a case-control analysis. Harlem adolescents who had sustained gunshot wounds were more likely to have dropped out of school, to have lived in a household without a biological parent, to have experienced parental death, and to have known of a relative or friend who had been shot than community adolescents treated for other medical or surgical problems.(ABSTRACT TRUNCATED AT 250 WORDS)

3031. Large, M., et al. (2012). "Nails in the brain." The American journal of forensic medicine and pathology **33**(4): e16.

3032. Larkin, M. B., et al. (2018). "Two-year mortality and functional outcomes in combat-related penetrating brain injury: battlefield through rehabilitation." Neurosurgical focus **45**(6): E4.

OBJECTIVE There are limited data concerning the long-term functional outcomes of patients with penetrating brain injury. Reports from civilian cohorts are small because of the high reported mortality rates (as high as 90%). Data from military populations suggest a better prognosis for penetrating brain injury, but previous reports are hampered by analyses that exclude the point of injury. The purpose of this study was to provide a description of the long-term functional outcomes of those who sustain a combat-related penetrating brain injury (from the initial point of injury to 24 months afterward). METHODS This study is a retrospective review of cases of penetrating brain injury in patients who presented to the Role 3 Multinational Medical Unit at Kandahar Airfield, Afghanistan, from January 2010 to March 2013. The primary outcome of interest was Glasgow Outcome Scale (GOS) score at 6, 12, and 24 months from date of injury.

RESULTS A total of 908 cases required neurosurgical consultation during the study period, and 80 of these cases involved US service members with penetrating brain injury. The mean admission Glasgow Coma Scale (GCS) score was 8.5 (SD 5.56), and the mean admission Injury Severity Score (ISS) was 26.6 (SD 10.2). The GOS score for the cohort trended toward improvement at each time point (3.6 at 6 months, 3.96 at 24 months, p > 0.05). In subgroup analysis, admission GCS score <= 5, gunshot wound as the injury mechanism, admission ISS >= 26, and brain herniation on admission CT head were all associated with worse GOS scores at all time points. Excluding those who died, functional improvement occurred regardless of admission GCS score (p < 0.05). The overall mortality rate for the cohort was 21%. CONCLUSIONS Good functional outcomes were achieved in this population of severe penetrating brain injury in those who survived their initial resuscitation. The mortality rate was lower than observed in civilian cohorts.

3033. LaRoche, G. R., et al. (1988). "Epidemiology of severe eye injuries in childhood." Ophthalmology **95**(12): 1603-1607.

The authors conducted a cross-sectional study of all ocular injury cases admitted to a children's hospital between January 1978 and December 1984. Of 222 injuries reviewed, 77 (35%) resulted in some visual deficit. Males were significantly overrepresented in all age groups with an average male:female ratio of 3.5:1. The distribution of injuries was: contusions, 114 (51%); penetrating lacerations, 62 (28%); foreign bodies and burns, 11 (5%); and nonpenetrating lacerations, 35 (16%). Sixteen (7%) ocular injuries were associated with BB gun pellets and six of these children (42%) were blinded in the injured eye as a result. Two other cases of blindness resulted from ocular penetration by homemade "Jinsang Stars," underscoring the adverse influence of media on children's games. Adult supervision could have potentially prevented most cases of permanent visual deficit. The authors suggest that legislation restricting the use of BB guns be passed and that a program of adult and child eye safety education including "eye watch" warnings on potentially hazardous toys be developed.

3034. Larque-Daza, A. B., et al. (2010). "Epidemiology of open-globe trauma in the southeast of Spain." European journal of ophthalmology **20**(3): 578-583.

PURPOSE: To describe epidemiologic and clinical findings of open-globe trauma (OGT) in the southeast area of Spain., METHODS: A retrospective descriptive study of 94 eyes with OGT evaluated between 1999 and 2007, in a primary referral hospital., RESULTS: The incidence of OGT in our area was 6.76 per 100,000 inhabitants/year. The majority of patients were male (89%) and young (80% of patients < 50 years old), with an average age of 37 +/- 20 years (mean +/- SD). The most common causes and location of injury were wire-induced trauma (50%) and accidents at work (56%), respectively. The types of injury encountered were ruptures, intraocular foreign bodies, perforating injury, penetrating injury, and mixed injury. Sixty-six percent of these injuries were penetrating in zone I (55%). The injuries found were vitreous hemorrhage (33%), cataracts (47%), vitreous prolapse (30%), retinal detachment (8%), endophthalmitis (2%), and associated with a facial trauma (7%). Eighty percent of surgery was carried out under general anesthesia. Fifty-one percent of the eyes underwent one operation only (5% were enucleated). Sixty-one percent of the eyes resulted in visual acuity of less than 50%., CONCLUSIONS: The incidence of OGT in the southeast of Spain is very high, being in most cases produced by accidents while using wire in greenhouses. This provokes severe monocular visual loss among the young population.

3035. Larsen, A. R. and J. V. Lewis (1998). "BB gun injuries: two case reports." Tennessee medicine : journal of the Tennessee Medical Association **91**(11): 436-437.

3036. Larsen, D. W. (2002). "Traumatic vascular injuries and their management." Neuroimaging clinics of North America **12**(2): 249-269.

Traumatic vascular injury to the intracranial and extracranial circulation can be sequelae of blunt, penetrating, or iatrogenic insults to the head, face, or neck. Treatment options include conservative medical management, or more invasive surgical or endovascular therapy. The appropriate treatment depends on the risk-benefit ratio of each option considering the natural history of each. Injuries include mild intimal irregularities, intimal flaps, pseudoaneurysms, fistulas, and occlusions. Need for treatment is partly determined by the collateral circulation to the brain, and the degree to which the lesion is thrombogenic. Advances in endovascular devices and techniques provide us with less

invasive alternatives to surgery intervention or allow the interventionalist to treat lesions not treatable by any other modality.

3037. Larsen, E. A., et al. (2022). "Case report: Use of penicillin G potassium in poloxamer 407 gel to aid in healing of an equine sublingual abscess." Frontiers in Veterinary Science **9**.

The use of poloxamer 407 gels have been reported in several studies to prolong the release of drugs at the injection site. Oral lesions unrelated to dental disease are rare but may result in ulceration and sequestration of bone. To date, there have been no reports on the use of penicillin G potassium poloxamer 407 gel and its effect on wound healing. The present case report describes the use of a penicillin G potassium poloxamer 407 gel for the treatment of a sublingual abscess involving the mandible in a 20 year old Arabian mare who initially presented with acute onset of dysphagia, hypersalivation, and a mass under the tongue. A presumptive diagnosis of lingual cellulitis was made, and a sublingual abscess ruptured on day 7 of hospitalization. In this case, poloxamer 407 gel was used to decrease wound contamination, protect the exposed mandible, and potentially prolong the release of penicillin G potassium into the wound.

3038. Larson, O. and P. Heden (1988). "Tubed free flap combined with split-rib-graft for reconstruction of multiple oral cavity defects. A case report." Scandinavian journal of plastic and reconstructive surgery and hand surgery **22**(2): 187-191.

The successful use of a conventional bone graft for mandibular reconstruction in combination with a free forearm flap is described. Two separate intraoral mucosal defects, one in the mandible and one in the palate, were covered, using the same flap and partial tubing of the flap. Three weeks post-flap-transfer the flap was successfully divided. A safe reliable and versatile technique combining nonvascularized bone graft and free flap for simultaneous reconstruction of mandibular and intraoral mucosal defects is described. Simultaneous coverage of multiple intraoral defects with tubing of the flap is found to be possible.

3039. Larson, P. S., et al. (2000). "Traumatic intracranial aneurysms." Neurosurgical focus **8**(1): e4.

Traumatic intracranial aneurysms are rare, occurring in fewer than 1% of patients with cerebral aneurysms. They can occur following blunt or penetrating head trauma and are more common in the pediatric population. Traumatic aneurysms can be categorized histologically as true, false, or mixed, with false aneurysms being the most common. These aneurysms can present in a variety of ways, but are typically associated with an acute episode of delayed intracranial hemorrhage with an average time from initial trauma to aneurysm hemorrhage of approximately 21 days. The mortality rate for patients harboring these aneurysms may be as high as 50%. Prompt diagnosis based on arteriography and aggressive surgical management are associated with better outcome than conservative treatment. The authors describe a classification scheme for traumatic aneurysms based on their anatomical location and conclude that 1) posttraumatic aneurysm must be considered in patients with acute neurological deterioration following closed head injury; 2) they can occur following mild closed head injury; 3) they occur more commonly in children than in adults; and 4) surgical clipping and/or endovascular occlusion is the definitive treatment.

3040. Larson, S. J., et al. (1976). "Lateral extracavitary approach to traumatic lesions of the thoracic and lumbar spine." Journal of neurosurgery **45**(6): 628-637.

The lateral extracavitary approach to the spine was used for resection of displaced bpne and disc located anterior to the dura in 62 patients with traumatic lesions of the thoracic and lumbar spine. Fifty-two patients had closed vertebral fractures and 10 had gunshot wounds. The spinal cord was involved in 44 patients, and the cauda equina in 18. A spinal subarachnoid block was demonstrated in 17 of 57 preoperative gas myelograms. Evoked potential recordings, although related to preception of joint rotation, tended to reflect the overall neurological condition and had some prognostic value. Significant improvement followed surgery in 46 patients with incomplete neurological lesions, and one was transiently worse. Before operation 18 patients were able to walk; nine with assistance and nine without. After operation 47 patients were able to walk; 12 with assistance and 35 without. Adequate bladder function was present in 17 patients before surgery, and in 44 after surgery. A laminectomy had been done previously in 16 patients, 11 of whom improved significantly after anterior resection. Spine fusions were required in 26 patients, five of whom had a prior

laminectomy. The major factor in the pathogenesis of the incomplete neurological deficit appeared to be distortion of the cord and roots by displaced bone and disc. Consequently, the primary object of treatment was the restoration and maintenance of normal anatomical relationships between the spinal cord or cauda equina and the spinal canal.

3041. Lasisi, O. A., et al. (2006). "An unusual faciocerebellar arrow injury: successful surgical removal in a peasant Nigerian: a case report." The Nigerian postgraduate medical journal **13**(4): 370-372.

INTRODUCTION: Reports of penetrating injuries of the cranium have been mainly craniocerebral or faciocerebral, craniocerebellar projectiles are few., CASE: We present a case of a 23 year old Nigerian with a craniofacial penetrating injury by a hunting arrow. The trajectory of the arrow through the facial skeleton across the craniocervical junction into the posterior fossa makes this unique in the literature. Successful operative retrieval by a joint team of neurosurgeons and otorhinolaryngologists, problems of delayed presentation and inadequate diagnostic facilities are highlighted., CONCLUSION: The morbidity-free outcome of surgical removal despite the delay in presentation and management in our practice setting with limited facilities are the salient points of this presentation.

3042. Laske, A., et al. (1990). "[Injuries of the large brain-feeding arteries]." Verletzungen der grossen hirnversorgenden Arterien. **120**(29): 1050-1055.

Among 2923 severely injured patients in the period 1980-1988, 17 had injuries or large supraaortic arteries. The incidence was 0.58%, with an overall mortality of 53%. In 75% of survivors there was a persistent neurological deficit. We treated 5 penetrating (A. carotis 4, A. vertebralis 1) and 12 nonpenetrating (A. carotis 11, A. vertebralis 1) injuries. In all penetrating carotid injuries (4) repair was performed on admission and mortality was 50%; 1 of 2 survivors has postoperative hemiparesis. Localization of nonpenetrating carotid injuries (11) was intrathoracic (2), in the neck (7) and intracranial (2). Main complication of nonpenetrating extracranial carotid injuries is neurological deficit (7/9) due to thrombosis (3) or stenosis (4) with embolism (2). Surgery was performed in 3 cases comprising pseudoaneurysm in 2 and concomitant aortic rupture in 1. Mortality was 44%, and 80% of survivors had persistent neurological deficits. Extracranial carotid injuries (n = 13) carried a mortality rate of 83% in occluded and 29% in nonoccluded vessels (p less than 0.05). Location of carotid injury in the neck (n = 11) carried a mortality of 55%, and intracranial (n = 2) of 100% respectively. Duplex-Doppler scanning of carotid arteries is a safe, noninvasive method which is essential in blunt carotid artery trauma. Prognosis is dependent upon the size of cerebral infarction. Once neurologic deficit has been established for more than 24 hours, reconstruction of the artery should be postponed and performed only for complications (pseudoaneurysm or embolization). Clamping of arteries without hypothermic circulatory arrest or shunt should be avoided. The danger of rupture in dissection and pseudoaneurysm is slight.(ABSTRACT TRUNCATED AT 250 WORDS)

3043. Lasky, J. B., et al. (1997). "Household objects as a cause of self-inflicted orbital apex syndrome." The Journal of trauma **42**(3): 555-558.

This report describes two cases of self-inflicted penetrating nonprojectile orbitointracranial injury. Suicide attempts caused by these types of injuries are very rare. An understanding of the orbital and intracranial anatomy and the avoidance head turn help to predict potential injury sites. Computed tomography and cerebral angiography were helpful in the treatment of these two cases.

3044. Latronico, T., et al. (2013). "Assessment of cell toxicity and matrix metalloproteinase-9 expression by antiretroviral drugs in cultured primary astrocytes." Glia **61**: S81.

Background: The toxic effects of new antiretroviral drugs on the central nervous system (CNS) are unclear. Because these drugs penetrate the brain even at low concentrations, it becomes crucial to determine the doses which can be toxic for the CNS resident cells. Moreover, after the recent introduction into clinical practice, it is unclear whether the efficacy of the antiretroviral drugs of new generation may also derive from their ability to exert extravirological effects on factors responsible for the development of HIV brain injury, e.g. matrix metalloproteinases (MMPs). Objective: To investigate on the toxicity of four different antiretroviral drugs and their ability to modulate the expression of gelatinase B (MMP-9) in astrocyte cultures. Methods: Primary cultures of rat astrocytes were activated by exposure to 10 mg/ml lipopolysaccaride (LPS) (positive control) and simultaneously treated for 20 h with increasing doses (1-5-10-25. 50 mM) of: Efavirenz (EFV); Darunavir (DRV); Maraviroc (MVC) or Raltegravir (RAL). MMP-9 mRNA

expression was assessed by RT-PCR. Quantitative determination of MMP-9 expression was done by computerized scanning densitometry. Single drug toxicity was assessed by the MTT test. Each drug was considered toxic at the concentration able to induce a percentage of cell survival above 60%. Results: The treatment with antiretroviral drugs inhibited MMP-9 mRNA expression in LPS-activated astrocytes in a dose-dependent manner. In particular, a statistically significant inhibition of MMP-9 expression was observed when astrocytes were treated with 25mM EFV (54% of inhibition) or with 50 mM RAL (43% of inhibition). As assessed by the MTT test, the toxicity of the antiretrovirals ranges from 10 and 50 mM. In particular, EFV was toxic for astrocytes at the concentration of 25 mM, MVC at 10 mM, while DRV and RAL were toxic at the concentration of 50mM. Conclusions: The present results indicate that EFV and RAL directly inhibit MMP-9 expression in LPS-activated astrocytes with mechanisms that are independent from their antiviral activity. The toxic doses of antiretrovirals are much higher than those found in the CSF of HIV-positive patients. Our results highlight some beneficial/deleterious extra-viral effects of the antiretroviral drugs that may be useful to improve the development of new therapeutic strategies for the management of HIV infection.

3047. Lauer, S. A., et al. (1995). "Orbitocraniofacial gunshot wounds: craniofacial reconstruction and preparation of the anophthalmic socket." The Journal of cranio-maxillofacial trauma **1**(1): 21-27.

This article is a retrospective clinical and radiographic analysis of four patients who survived high caliber orbitocraniofacial gunshot injuries. Early multidisciplinary craniofacial reconstruction included repair of comminuted orbital fractures with multiple autogenous bone grafts and/or porous polyethylene implants, enucleation, and insertion of a hollow silicone sphere as an anophthalmic socket implant. Migration of the silicone implant occurred in one case, requiring replacement with an autogenous dermis fat graft. There were no cases of extrusion or infection. Socket motility remained limited in all cases, despite reapposition of the extraocular muscles. In two cases with autogenous bone grafts along the orbital roof, there was no radiographic evidence of graft resorption after three years. Soft tissue volume deficiency and superior sulcus deformity developed in the three cases which were followed for more than six months. Despite these limitations, all four patients are wearing comfortable ocular prostheses. The postoperative results support immediate preparation of the anophthalmic socket after craniofacial reconstruction of these injuries.

3048. Laure, B. (2008). "Re: Reconstruction of bony mandibular and maxillary defects with one single transfer of a free fibula osteocutaneous flap." Journal of Plastic, Reconstructive and Aesthetic Surgery **61**(11): 1386-1387.

3049. Laure, B., et al. (2007). "[Post-traumatic disinsertion of the superior oblique muscle trochlea]." Desinsertion post-traumatique de la poulie du muscle oblique superieur. **108**(6): 551-554.

INTRODUCTION: Ophthalmologic examination may rule out an ocular wound in the event of orbital traumatism. Some lesions are obvious but others may not be detected. We report a case of superior oblique muscle trochlea trauma. This infrequent pathology is illustrated with a scanned imagery and magnetic resonance imaging (MRI)., OBSERVATION: The initial penetrating trauma was caused by a hook in the medial canthus. The wound was sutured in the emergency unit. Three days later, oblique diplopia developed. Three weeks later, abnormal ocular movements appeared when contracting the frontal muscle. The patient then decided to consult. One month after the traumatism, the orthoptic assessment confirmed the presence of an acquired Brown syndrome suggesting a lesion of the superior oblique muscle. Orbital MRI could not find the trochlea and revealed a thickening by retraction of the posterior portion of the muscle and a hypotrophic aspect of the anterior portion. A fracture of the right orbital edge was revealed by the scanner. Surgical exploration was performed., DISCUSSION: The trochlea is located very anteriorly and likely to be affected in the event of an internal palpebral wound. A direct traumatism of the pulley and/or the superior oblique muscle leads to an acquired Brown syndrome. This observation stresses the importance of surgical wound exploration for the supero-medial palpebral area as well as using MRI which allows proving the diagnosis.

3050. Laure, B., et al. (2008). "Reconstruction of bony mandibular and maxillary defects with one single transfer of a free fibula osteocutaneous flap." Journal of plastic, reconstructive & aesthetic surgery : JPRAS **61**(2): 200-203.

One-stage bone reconstruction of both the maxilla and the mandible with a single bone transfer is unusual in microsurgery. The authors report and describe the surgical technique of an original one-stage bone reconstruction of the maxilla and the mandible in a defect caused by a gunshot injury. The reconstruction was performed with a free fibular osteocutaneous flap. A concomitant maxillo-mandibular defect is uncommon. Gunshot injuries and tumours are the two main causes of this defect. The reconstruction of maxillary and mandibular defects can be a surgical challenge. The reconstruction was performed in one stage with the free transfer of a fibular osteocutaneous flap.

3053. Lauterbach, A., et al. (2006). "Fatal impalement injury of the head due to a curtain rail." International journal of legal medicine **120**(6): 380-382.

During a dispute, a boy was injured by a curtain rail which penetrated the skull in the left frontal region and led to severe brain injury. Despite intensive medical care, death occurred 10 days later due to malignant cerebral edema. With regard to the question whether the trauma resulted from throwing or pushing, some biomechanical aspects are discussed including individual morphologic findings as well as the kinetic energy required for penetrating the skull. According to the calculated data, we conclude that the velocity necessary for penetrating could be reached by throwing the curtain rail.

3054. Lauzier, D. C., et al. (2022). "Neurointerventional management of cerebrovascular trauma." Journal of neurointerventional surgery **14**(7): 718-722.

Traumatic cerebrovascular injuries following blunt or penetrating trauma are common and carry a high risk of permanent disability or death. Proper screening, diagnosis, and treatment of these lesions is essential to improve patient outcomes. Advances in imaging continue to improve the accuracy of non-invasive diagnosis of these injuries while new clinical data provide better evidence for optimal management, whether medical or invasive. Here, we review screening, diagnosis, and treatment of traumatic cerebrovascular injuries.

3055. Lavergne, P., et al. (2016). "Penetrating brain injury, recent case series of a single institution and literature review." Canadian Journal of Neurological Sciences **43**: S39.

Background: Penetrating brain injury is a rare entity. Furthermore, clinical presentation can be highly variable and management difficult, especially when the foreign body is retain in the skull Methods: We present a serie of three recent cases of penetrating brain injury that happened at our institutionm including clinical and radiological data. We discuss management of those challenging cases and present a brief review of the literature. Results: Our cases (3) encompassed different mechanisms: bilateral nail gun injury, knife and aircraft propeller. All patients were male, with a median age of 37 years old. Work-up was negative for intracranial vascular injury. All patients were treated with initial craniectomy (bilateral in one case) and a course of antibiotics. Cranioplasty was later performed. All patients survived and evolved in favorable fashion. Conclusions: Penetrating brain injury is a rare injury, requiring individualized surgical and medical management. A few recommendations may be found in the literature but are often based on literature from blunt traumatic brain injury or war-related injuries.

3056. Lavin, J. P., Jr. and S. S. Polsky (1983). "Abdominal trauma during pregnancy." Clinics in perinatology **10**(2): 423-438.

In summary, trauma occurs relatively frequently among pregnant patients. Various anatomic and physiologic changes of pregnancy may alter the type of injury experienced by pregnant women. These changes may also alter the manifestations of given injuries and the treatment required to reestablish maternal-fetal hemostasis. Fortunately, most trauma experienced by pregnant individuals is minor and is associated with good prognosis for both the mother and her fetus. Blunt trauma as a result of automobile collision is the most frequent form of serious injury involving pregnant women. However, several cases of penetrating abdominal wounds have also been reported. Both blunt and penetrating trauma may frequently injure the uterus. Fetal intracranial injury and fracture, as well as abruption, often occur as a result of blunt trauma. Multiple direct fetal, placental, and cord injuries have been reported as a result of penetrating trauma. Both blunt and penetrating trauma frequently cause injury to other intraabdominal organs, and blunt trauma is associated with an especially high incidence of pelvic fracture and retroperitoneal hemorrhage. Laparotomy is often required to treat such injuries. At the time of the laparotomy, difficult decisions are required in determining whether the fetus is best delivered or left in utero. Recent technologic advances for assessing fetal status may be helpful in these decisions. Rarely, a mother may expire with her living fetus undelivered, and a rapid postmortem cesarean section may save the fetal life. During the last several years, the prognosis for both trauma victims and gravid women with complicated pregnancies and their fetuses has improved markedly. Hopefully, during the next several years, the knowledge and therapeutic modalities developed to treat each group will be combined to provide optimal care for the pregnant trauma victim and her fetus.

3057. Lavy, T. and S. A. Asleh (2003). "Ocular rubber bullet injuries." Eye (London, England) **17**(7): 821-824.

PURPOSE: To report the type and severity of ocular and orbital injuries caused by rubber bullets., METHODS: A total of 42 consecutive patients seen over a 3-month period with ocular and orbital rubber bullet injuries were assessed clinically and radiographically within 1 day of injury, and the findings were recorded. Clinical outcomes following treatment were also recorded up to 6 months postinjury., RESULTS: A total of 90% of the patients were male. The mean age of patients was 25.0 years (4-60). Of the patients, 54% had lid or skin lacerations, 40% hyphaema, 38% ruptured globe, 33% orbital fracture, 26% retinal damage, and 21% retained rubber bullet in or around the orbit. At follow-up, 53% of the patients had a visual acuity of less than 6/60, 7% less than 6/18 to 6/60, and 40% 6/18 or better., CONCLUSIONS: The term 'rubber bullet' is misleading. 'Rubber bullets' cause a wide variety of ocular and periocular injuries. Orbital fractures are common. The tissues of the orbit are easily penetrated. If the globe is hit, it is rarely salvageable.

3058. Lawan, A. and S. A. Danjuma (2012). "Arrow injuries to the eye." Annals of African medicine **11**(2): 116-118.

Two male siblings aged 10 and 17 years, respectively, presented to our hospital with two days history of being shot in the right eyes with arrows. The patients presented with severe pains, bleeding, swelling, discharge and loss of vision. There was positive history of application of traditional eye medicine and an unsuccessful attempt was made to remove the arrows. Both patients presented with panophthalmitis. X-rays of the orbits and para nasal sinuses indicated the tip of the arrow was lodged to the apex of the orbit in the younger patient, and the arrow vertically traverses the eye/ orbit and lodged in the roof of the maxillary sinus in the other patient with fluid level in the lower third of the sinus. The patients were placed on broad-spectrum systemic antibiotics, had base line investigations and prepared for exploration. The patients had evisceration with removal of the arrows.

3059. Lawless, M., et al. (1986). "Surfboard-related ocular injuries." Australian and New Zealand journal of ophthalmology **14**(1): 55-57.

Three cases of ocular trauma caused by surfboards are reported. The severe nature of the injuries is discussed and the prevalence of this type of injury is reviewed.

3060. Laws, E. R., et al. (2005). "Gunshot wounds to the head in the 16th century: Commentary." Neurosurgery **57**(6): 1314-1315.

3061. Lawson, D., et al. (1990). "An unusual intracerebral foreign body associated with eye trauma." Australian and New Zealand journal of ophthalmology **18**(2): 221-223.

A case report is presented of penetrating orbital trauma in the driver of a motor vehicle which collided with a kangaroo. A tooth fragment from the kangaroo traversed the orbit, lodging intracranially. Management of the case is described and appropriate choice of antibiotic regime discussed.

3062. Lawson-Smith, M. J., et al. (2006). "Lateral medullary syndrome caused by penetrating head injury." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **13**(7): 792-794.

Herein, we report a rare case of a patient surviving penetrating trauma to the brainstem. Low velocity penetrating head injuries may be occult and are associated with a high incidence of vascular injury.

3063. Layton, M. E., et al. (1997). "Cerebral penetration injury leads to H2O2 generation in microdialysis samples." Neuroscience letters **236**(2): 63-66.

Delayed tissue damage is proposed to be caused by reactive oxygen species. We investigated the effects of microdialysis probe penetration into rat piriform cortex on hydrogen peroxide (H2O2) in brain extracellular fluid (ECF). H2O2 decreased immediately after probe insertion into the brain, but increased over 300% in samples within minutes after collection. We assessed H2O2 changes in vitro in microdialysis perfusion media containing various ascorbic acid concentrations and confirmed ascorbic acid is a source of H2O2. We conclude that decreased H2O2 concentrations in perfusion media as it passes through the brain reflect an extracellular antioxidant effect, whereas the increase in H2O2 with time after sample collection indicates that H2O2 generating substances are present in ECF. Thus, the potential for producing reactive oxygen species in brain ECF exists following penetration injury, especially if transition metals are released into the neuronal microenvironment.

3064. Lazaridis, C., et al. (2021). "Civilian Firearm-Inflicted Brain Injury: Coagulopathy, Vascular Injuries, and Triage." Current neurology and neuroscience reports **21**(9): 47.

PURPOSE OF REVIEW: Civilian firearm-inflicted penetrating brain injury (PBI) carries high morbidity and mortality. Concurrently, the evidence base guiding management decisions remains limited. Faced with large volume of PBI patients, we have made observations in relation to coagulopathy and cerebrovascular injuries. We here review this literature in addition to the question about early prognostication as it may inform neurosurgical decision-making., RECENT FINDINGS: The triad of coagulopathy, low motor score, and radiographic compression of basal cisterns comprises a phenotype of injury with exceedingly high mortality. PBI leads to high rates of cerebral arterial and venous injuries, and projectile trajectory is emerging as an independent predictor of outcome. The combination of coagulopathy with cerebrovascular injury creates a specific endophenotype. The nature and role of coagulopathy remain to be deciphered, and consideration to the use of tranexamic acid should be given. Prospective controlled trials are needed to create clinical evidence free of patient selection bias.

3065. Lazarjan, M. S., et al. (2014). "Experimental investigation of the mechanical properties of brain simulants used for cranial gunshot simulation." Forensic science international **239**: 73-78.

The mechanical properties of the human brain at high strain rate were investigated to analyse the mechanisms that cause backspatter when a cranial gunshot wound occurs. Different concentrations of gelatine and a new material (M1) developed in this work were tested and compared to bovine brain samples. Kinetic energy absorption and expansion rate of the samples caused by the impact of a bullet from .22 air rifle (AR) (average velocity (uav) of 290m/s) and .22 long rifle (LR) (average velocity (uav) of 330m/s) were analysed using a high speed camera (24,000fps). The AR projectile had, in the region of interest, an average kinetic energy (Ek) of 42+/-1.3J. On average, the bovine brain absorbed 50+/-5% of Ek, and the simulants 46-58+/-5%. The Ek of the .22 LR was 141+/-3.7J. The bovine brain absorbed 27% of the .22LR Ek and the simulants 15-29%. The expansion of the sample, after penetration, was measured. The bovine brain experienced significant plastic deformation whereas the gelatine solution exhibited a principally elastic response. The permanent damage patterns in the M1 material were much closer to those in brain tissue, than were the

damage patterns in the gelatine. The results provide a first step to developing a realistic experimental simulant for the human brain which can produce the same blood backspatter patterns as a human brain during a cranial gunshot. These results can also be used to improve the 3D models of human heads used in car crash and blast trauma injury research.

3066. Lazarjan, M. S., et al. (2015). "Visualization of the air ejected from the temporary cavity in brain and tissue simulants during gunshot wounding." Forensic science international **246**: 104-109.

One hypothesis for the physical mechanism responsible for backspatter during cranial gunshot wounding is that air is ejected by the collapse of the temporary cavity formed around the bullet path. Using bovine and ovine heads and simulant materials, evidence of this ejection was sought by measuring the velocity of the air that was drawn in and ejected from the cavity in front of the wound channel after bullet impact. A laminar flow of fog-laden air was arranged in front of the wound channel and two high speed cameras recording at 30,000 frames/second captured the air motion. All samples were shot with standard 9 mm x 19 mm FMJ ammunition. Different concentrations of ballistic gelatine were used to characterize the effect of elasticity of the material on the velocity of the air. Fresh bovine and ovine heads were shot with the same experimental set up to investigate if there was induction of air into, and ejection of air from the entrance wounds. The results show, for the first time, that the temporary cavity does eject air in gelatine. The velocity of in-drawn air for 3, 5 and 10% concentration of gelatine was 81, 76 and 65 m/s respectively and the velocity of ejected air for 5 and 10% concentration of gelatine were 43 and 72 m/s respectively. The results show that when the concentration of gelatine is increased, the velocity of the air drawn into the cavity decreases and the velocity of the ejected air increases. However, no ejection was observed in 3% gelatine, ovine or bovine heads. Although ejection of air was not observed, ejection of brain from the wound channel was seen. Using the velocity of the ejected brain, the minimum intracranial pressure required to eject the brain tissue was estimated to be 712 kPa and 468 kPa for the sheep and bovine heads respectively.

3067. Lazic, T. and J. Strugar (2009). "Nail in the midbrain." Neurology **72**(17): 1531.

3068. Lazzeri, C., et al. (2020). "Comorbidities and Age in Brain-Dead Donors and Liver Transplantation: A 15-Year Retrospective Investigation." Experimental and clinical transplantation : official journal of the Middle East Society for Organ Transplantation **18**(1): 60-64.

OBJECTIVES: Although livers from older donors (> 70 y) have been shown to be increasingly more efficiently used for transplant, donor comorbidities are considered additional risk factors. This is quite intriguing as comorbidities are known to increase with advancing age in the donor population., MATERIALS AND METHODS: We assessed whether age and donor comorbidities influenced liver procurement over a 15-year period in a cohort of 1702 brain-dead donors in Tuscany, Italy., RESULTS: Over the study period, age of potential donors significantly increased (P = .02) as well as the proportion of patients who were > 55 years old. The incidence of hypertension, diabetes mellitus, and previously known coronary artery disease also significantly increased. We observed a progressive increase in the number of transplanted livers from donors with advancing age despite an increase in comorbidities. The highest incidences of traumatic brain injury and anoxic brain injury were observed in the youngest donors. Transaminase levels and use of vasoactive drugs were lower in donors who were >= 72 years old., CONCLUSIONS: According to our results, criteria for liver donors have already changed. Although age does not seem to be a limiting factor, older donors deserve a more accurate donor selection due to the higher incidence of risk factors (primarily diabetes mellitus).

3069. Le Blanc-Louvry, I., et al. (2012). "A brain penetration after Taser injury: controversies regarding Taser gun safety." Forensic science international **221**(1-3): e7-11.

We report the case of a 27 year old man who was injured by a Taser gun device which penetrated the frontal part of the skull and damaged the underlying frontal lobe. Cerebral penetration was revealed by a brain CT scan. A neurosurgical procedure was required to remove the dart from the skull and brain and the evolution was successful allowing discharge of the patient one week later. There were no additional lesions, particularly electrifying lesion, as only one probe had penetrated the skull. We also observed the length of a Taser dart is sufficient to allow brain penetration. Fortunately, no infection or neurological complication occurred following brain injury. This case study

underlines the potential risk induced by the use of Taser stun gun. Although generally regarded as a safe alternative, serious injuries have however been reported and questions regarding the safety of the device still remains unresolved.

3070. Le Feuvre, D. (2011). "Endovascular treatment of cranio-cervical vascular trauma." Journal of neurointerventional surgery **3**: A39.

Introduction Cranio-cervical trauma carries a high morbidity and mortality. Because of the vital structures and inaccessibility surgical treatment of these injuries is often high. Endovascular intervention lends itself to the treatment of vascular injuries. This in mind we reviewed our endovascular treatment of cranio-cervical injuries over a 1-year period. Methods Between September 15, 2008 and September 14, 2009 we reviewed the patients we had been asked to treat endovasculary by the trauma surgeons or who had been referred directly to our neurosurgical unit. The demographic profile and the mode of injury was reviewed and the vascular injury was anatomically and pathologically assessed using the DSA. Next the specific treatment for the different vascular injuries was reviewed. Results We identified 22 patients 64% sustaining penetrating injuries and 36% from blunt trauma. 50% of the injuries were false aneurysms, 36% CCFs, 9% were AVFs and 5% were dissections. Treatment used balloons, glue or coils depending on the injury. There was one asymptomatic complication. Conclusions Endovascular treatment offers a viable safe and often better alternative to surgical injuries to cranio-cervical injuries.

3071. Le Garff, E., et al. (2015). "Homemade Firearm Suicide With Dumbbell Pipe Triggering by an Air-Compressed Gun: Case Report and Review of Literature." The American journal of forensic medicine and pathology **36**(4): 257-261.

Firearm suicides are frequent and well described in the forensic literature, particularly in Europe and the United States. However, the use of homemade and improvised firearms is less well described. The present case reports a suicide with an original improvised gun created using an air-compressed pellet gun and a dumbbell pipe. The aims of this study were to describe the scene, the external examination of the corpse, the body scan, and the autopsy; to understand the mechanism of death; and to compare the results with a review of the forensic literature to highlight the epidemiology of homemade firearm use, the tools used for homemade and improvised firearms in suicides versus homicides, and the manners in which homemade firearms are used (homicide or suicide, particularly in complex suicide cases).

3072. Le, K., et al. (2014). "Does brain volume loss predict cognitive and narrative discourse performance following traumatic brain injury?" American journal of speech-language pathology **23**(2): S271-284.

PURPOSE: In this study, the authors investigated the relationship between brain volume loss and performance on cognitive measures, including working memory, immediate memory, executive functions, and intelligence, and a narrative discourse production task. An underlying goal was to examine the prognostic potential of a brain lesion metric for discourse outcomes. It was hypothesized that brain volume loss would correlate with and predict cognitive and narrative discourse measures and have prognostic value for discourse outcomes., METHOD: One hundred sixty-seven individuals with penetrating head injury participated. Correlational and regression analyses were performed for the percentages of total brain and hemispheric volume loss and scores on 4 cognitive measures (WMS-III Working Memory and Immediate Memory primary indexes, D-KEFS Sorting Test, and WAIS-III Full Scale IQ) and 7 narrative discourse measures (T-units, grammatical complexity, cohesion, local and global coherence, story completeness, and story grammar)., RESULTS: The volumetric measures had significant small-to-moderate correlations with all cognitive measures but only one significant correlation with the discourse measures. Findings from regression analyses were analogous but revealed several models that approached significance., CONCLUSION: Findings suggest that an overall measure of brain damage may be more predictive of general cognitive status than of narrative discourse ability. Atrophy measures in specific brain regions may be more informative.

3073. Le, T. D., et al. (2018). "Is the combat mortality index (CMI) applicable in prolonged field care for combat-related traumatic brain injury patients with polytrauma?" Shock **49**(6): 118.

Introduction: Traumatic brain injury (TBI) is the leading cause of death in combat casualties and is more lethal if hemorrhagic shock (HS) occurs. Early detection of HS has a discernible impact on timely interventions and can reduce

preventable death. The shock index (SI) and the new classification of HS (SI-4 Classification) lack reliable predictive capacity and have limited applicability in the forwarddeployed setting, especially in prolonged field care. As a solution to these limitations, we developed the CMI which reliably predicts early mortality in combat casualties. The purpose of this study was to determine if the CMI is applicable in prolonged field care for TBI patients and to assess its ability to identify early shock and risk of mortality. Methods: The Department of Defense Trauma Registry Data was used for this study. The study included US military patients injured in Iraq and Afghanistan from 2003 to 2014 with moderate and severe TBI (m/sTBI). m/sTBI was defined as an Abbreviated Injury Score (AIS) ≥2 for the head body region (BR) and was further stratified as isolated TBI (iTBI) or polytrauma TBI (pTBI). iTBI was defined as an AIS ≤2 for all other BRs and pTBI was defined as having an AIS >2 for one or more other BRs. The pre-hospital CMI (CMI-PH) was calculated as sum of scores of pre-hospital heart rate (HR) scaled 0 to 1 as 60-100 and < 60 or >100 bpm, systolic blood pressure (SBP) scaled 0 to 1 as ≥100 and < 100 mmHg and Glasgow Coma Scale total (GCS) scaled 0-2 as ≥14, 9-13 and 3-8. The CMI-PH scores ranged 0 to 4. The CMI-PH was compared to the SI, SI-4 classification as SI < 0.6 (I), 0.6≤SI < 1.0 (II), 1.0≤SI < 1.4 (III) and SI≥1.4 (IV), GCS and SBP with the primary outcome of mortality (died on arrival and inhospital). Area under the Receiver Operating Characteristic curve (AUROC), Hosmer-Lemeshow goodness of fit test, and sensitivity and specificity were used to discriminate and calibrate the CMI-PH from the existing indices. Logistic regression was used to calculate likelihood of mortality associated with the scores. Results: A total of 1398 patients met the inclusion criteria and 34.8% had polytrauma. Overall mortality was 4.2% (n = 59). Increasing CMI-PH scores were associated with increases in mortality (0.1%, 0.5%, 8.7%, 13.8%, and 57.5%). AUROC results showed the CMI-PH was a better predictor of mortality than GCS, SI, SI-4 Classification and SBP (0.89 vs 0.86, 0.55, 0.56, 0.53) in all m/sTBI and pTBI (0.84 vs 0.81, 0.68, 0.73, 0.56). Conclusion: The CMI-PH is a better predictor of mortality secondary to shock and can potentially facilitate timely life-saving interventions decreasing potentially preventable death from hemorrhage through early, accurate identification of trauma-related shock. The CMI-PH has potential applicability in prolonged field care and civilian trauma systems.

3074. Leach, P., et al. (2005). "An unusual cause of light headedness." Acta neurochirurgica **147**(12): 1301.

3075. Leach, P. and J. Thorne (2008). "Re: Unusual penetrating cranio-cerebral injuries in children from main plugs." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **24**(2): 163.

3076. Leake, D. (2012). "Transorbital intracranial penetrating injury: Evaluationofassociated vascular injury with cta and conventional angiography." Emergency radiology **19**(5): 377.

Purpose/Aim: 1. Recognize potential complications of transorbital intracranial penetrating injury including vascular injury. 2. Recognize the value of CTA (MIP's) and conventional angiography for initial and followup evaluation. Content Organization: 7 Y/O Boy found by parents. He had decrease level of consciousness and “not acting like himself”. A wicker basket with a exposed protruding metal structural support was noted by parents. There was blood on this structure. They also noted laceration of his upper eyelid. On admission to Emergency Room, patient was minimally responsive. Exam revealed a small 1.5 x 1.5 cm laceration of the lateral aspect of left upper eyelid. There was diffuse edema of left upper eyelid. Pupils were equally round and reactive to light. No ocular abnormality. Sclerae and conjunctivae are normal. CT Head exam demonstrated transorbital intracranial penetrating injury. CTA intracranial exam showed focal injury of anterior cerebral artery, confirmed by conventional angiography. Patient was treated conservatively. Initial followup (6 day) CTA exam showed apparent interval disappearance of vascular injury. Further followup imaging studies are scheduled. Summary/Conclusion: Transorbital intracranial penetrating injuries may have significant complications including vascular injury. Expeditious imaging with CT Face/ Brain and CTA Intracranial (MIP) is helpful in initial screening and followup of patients. In selected cases, further evaluation with MRI, MRA, and Conventional Angiography may sometimes be needed. Clinical evaluation may not disclose the intracranial penetrating injury. Imaging allows the classification of injury, so that appropriate clincial decisions can be made depending on the treatment algorithm. If vascular injuries are treated conservatively, then a followup CTA, MRA, or conventional angiogram is recommended in 1-3 months to rule out development of pseudoaneurysm.

3077. Leake, D. L. and M. B. Habal (1977). "Reconstitution of craniofacial osseous contour deformities, sequelae of trauma and post resection for tumors, with an alloplastic-autogenous graft." The Journal of trauma **17**(4): 299-303.

Our experience using a new technique for reconstructing contour defects of facial bones has been presented. It employs particulate, cancellous bone and an implantable prosthesis accurately fabricated of polyether urethane and polyethylene terephthalate cloth mesh which can be produced in a variety of configurations. A mannequin made of these materials displaying the various parts of the craniofacial complex that have been restored or are currently under investigation is shown in Figure 10. Large cranial vault defects, orbital floors, mandibles including chin augmentation, and nasal bone deformities have been successfully restored in man. Restoration of the pinna of the ear is currently being evaluated in laboratory animals.

3078. Leal, I., et al. (2015). "Exceptional penetrating orbital injury that spared the eye globe." BMJ case reports **2015**.

3079. Leary, J., et al. (2016). "Longitudinal changes in brain volume over the first year following traumatic brain injury." Brain injury **30**(5-6): 528-529.

Objectives: Studies in traumatic brain injury (TBI) have shown decreases in grey and white matter volumes following brain trauma. Despite continual volume loss, neuropsychological performance has been shown to improve over time. However, it is unclear whether volume loss is diffuse or regionally selective, if changes are related to TBI severity and if volumetric changes relate to changes in neuropsychological function. The present study sought to address these questions using a volumetric region of interest approach. We hypothesized that brain volumes would decrease in a regionally- specific manner and that volume loss would correspond with TBI severity. Additionally, we hypothesized that there may be an association between volume loss and neuropsychological performance. Methods: Twenty-seven patients (15 male) with non-penetrating TBI were classified by severity: mild, complicated mild or moderate/severe. Patients were assessed across three time points: sub-acute (less than 3 months), 6 months and an evaluation at 1 year following injury. The longitudinal pipeline within the Free Surfer software package (version 5.3) was used to quantify brain volumes. Neuropsychological assessments measured: attention, information processing speed, motor speed and fine motor dexterity, abstract reasoning and mental flexibility, whole-to-part construction and spatial reasoning, phases of memory including encoding, consolidation and recall and working memory. Statistical analyses were performed using SAS 9.3. Mixed effects models were used to detect brain volume changes over time, accounting for time since injury and total intracranial volume. Mixed effects models were also used to investigate changes in neuropsychological performance over time and to determine whether volumetric changes were associated with changes in neuropsychological performance. TBI severity was incorporated as a fixed effect variable. Results were corrected for multiple comparisons. The SAS Proc Mixed procedure was used to estimate correlations in the presence of repeated measures. Results: Volumetric analyses revealed significant decreases in the bilateral caudate (left: $p < 0.0001$; right: $p = 0.00014$), right putamen ($p = 0.0005$), right thalamus ($p = 0.0009$), right superior temporal gyrus ($p = 0.0005$) and left superior parietal lobule ($p = 0.0004$). Neuropsychological analyses revealed significant improvements in abstract reasoning ($p = 0.0024$) and processing speed ($p = 0.0018$). Volumetric changes and neuropsychological performance were not significantly related to TBI severity. No significant correlations were found between changes in brain volumes and neuropsychological performance. Conclusions: In line with our hypothesis, brain volumes appear to decline over the first year post-injury in a regionally- specific fashion. Volumetric reductions are independent of TBI severity, indicating that even mild injuries may result in chronic loss of brain tissue. However, neuropsychological performance does not appear to be associated with volume loss. Although neuropsychological performance in the first year post-injury appears to be unrelated to volumetric changes, there may be long-term implications for the development of co-morbid psychiatric and neurological disorders in patients who sustain TBI and subsequent volume loss.

3080. Leathers, R., et al. (2003). "Orofacial injury in underserved minority populations." Dental clinics of North America **47**(1): 127-139.

The translation of clinical and epidemiological research findings into cliniical practice in the management of orofacial injuries at an inner-city community promises a reduction in the incidence and severity of orofacial injuries. This article reports on the sociodemographic characteristics, economical impact, nature of injuries, and associated risk factors of mandible fractures sustained in the inner-city community treated at KDMC. An overwhelmingly high incidence of intentional/assaultive injuries were treated at KDMC that contribute to the escalating cost of medical care provided at the public county hospital. Knowledge of associated risk factors and nature of injuries is fundamental to the development of a sound screening and interventional program tailored to the high-risk minority groups, to reduce the

high burden of preventable orofacial injuries in this community. Multidisciplinary health professionals should recognize the relationship between alcohol and substance abuse and orofacial injuries and the subtle signs of domestic abuse. and should provide social support and counseling intervention to reduce risk of recurrent injuries in abused victims.

3081. Leaver, R. C. and J. D. Loeser (1971). "Lhermitte's phenomenon after high velocity missile injuries of the brain." Journal of neurosurgery **34**(2 Pt 1): 159-163.

High velocity wounds of the brain have been associated with the development of Lhermitte's phenomenon in 26 of 56 consecutive cases from Vietnam studied from 1 month to 1 year after injury. No antecedent factors could be identified. Civilian trauma and elective neurosurgical procedures have not, to our knowledge, been reported to cause this sign. Subarachnoid or subdural adhesions are suggested as the cause of Lhermitte's phenomenon in these patients.

3082. Lebedev, V. V., et al. (1996). "[Weapons-related craniocerebral wounds in peacetime (their classification and characteristics)]." Oruzheinye cherepno-mozgovye raneniia mirnogo vremeni (klassifikatsiia, kharakteristika).(3): 12-19.

3083. Lebedev, V. V., et al. (1996). "[The diagnosis of peacetime firearms craniocerebral wounds in the acute period]." Diagnosika oruzheinykh cherepno-mozgovykh ranenii mirnogo vremeni v ostrom periode.(4): 19-22.

The paper deals with the diagnostic potentialities of using various techniques in the wounded persons with arms-induced brain injuries. The diagnosis of arms-induced wounds of the skull and brain must be comprehensive and made concurrently with therapeutical measures. The instrumental methods must be applied to the extent accessible for the given wounded person and a study should be stopped immediately after a diagnosis is established.

3084. Lebl, D. R., et al. (2013). "Vertebral artery injury associated with blunt cervical spine trauma: a multivariate regression analysis." Spine **38**(16): 1352-1361.

STUDY DESIGN: Retrospective analysis of prospective registry data., OBJECTIVE: To determine the patient characteristics, risk factors, and fracture patterns associated with vertebral artery injury (VAI) in patients with blunt cervical spine injury., SUMMARY OF BACKGROUND DATA: VAI associated with cervical spine trauma has the potential for catastrophical clinical sequelae. The patterns of cervical spine injury and patient characteristics associated with VAI remain to be determined., METHODS: A retrospective review of prospectively collected data from the American College of Surgeons trauma registries at 3 level-1 trauma centers identified all patients with a cervical spine injury on multidetector computed tomographic scan during a 3-year period (January 1, 2007, to January 1, 2010). Fracture pattern and patient characteristics were recorded. Logistic multivariate regression analysis of independent predictors for VAI and subgroup analysis of neurological events related to VAI was performed., RESULTS: Twenty-one percent of 1204 patients with cervical injuries (n = 253) underwent screening for VAI by multidetector computed tomography angiogram. VAI was diagnosed in 17% (42 of 253), unilateral in 15% (38 of 253), and bilateral in 1.6% (4 of 253) and was associated with a lower Glasgow coma scale ($P < 0.001$), a higher injury severity score ($P < 0.01$), and a higher mortality ($P < 0.001$). VAI was associated with ankylosing spondylitis/diffuse idiopathic skeletal hyperosteosis (crude odds ratio [OR] = 8.04; 95% confidence interval [CI], 1.30-49.68; $P = 0.034$), and occipitocervical dissociation ($P < 0.001$) by univariate analysis and fracture displacement into the transverse foramen 1 mm or more (adjusted OR = 3.29; 95% CI, 1.15-9.41; $P = 0.026$), and basilar skull fracture (adjusted OR = 4.25; 95% CI, 1.25-14.47; $P= 0.021$), by multivariate regression model. Subgroup analyses of neurological events secondary to VAI occurred in 14% (6 of 42) and the stroke-related mortality rate was 4.8% (2 of 42). Neurological events were associated with male sex ($P = 0.024$), facet subluxation/dislocation (crude OR = 9.00; 95% CI, 1.51-53.74; $P = 0.004$) and the diagnosis of ankylosing spondylitis/diffuse idiopathic skeletal hyperosteosis (OR = 40.67; 95% CI, 5.27-313.96; $P < 0.001$)., CONCLUSION: VAI associated with blunt cervical spine injury is a marker for more severely injured patients. High-risk patients with basilar skull fractures, occipitocervical dissociation, fracture displacement into the transverse foramen more than 1 mm, ankylosing spondylitis/diffuse idiopathic skeletal hyperosteosis, and facet subluxation/dislocation deserve focused consideration for VAI screening.

3085. Lebos, M. R. and R. Saadia (1994). "The overlooked blunt component in penetrating neck injuries: three case reports." The Journal of trauma **36**(3): 410-411.

Three cases of penetrating neck injury associated with an unsuspected blunt carotid injury are reported. Attention is drawn to the possibility of this rare association, that can cause irreversible damage, if overlooked. Early angiogram and possibly duplex Doppler scanning are warranted to prevent neurologic sequelae.

3086. Lechner, R., et al. (2010). "[Patterns and causes of injuries in a contemporary combat environment]." Verletzungsmuster und -ursachen in modernen Kriegen. **113**(2): 106-113.

Epidemiological analyses of injury patterns and mechanisms help to identify the expertise military surgeons need in a combat setting and accordingly help to adjust infrastructure and training requirements. Therefore, a MEDLINE search (1949-2009), World Wide Web search (keywords "combat, casualties, war, military, wounded and neurosurgery") and an analysis of deaths among allied war casualties in Afghanistan and Iraq were performed. Up to 10th December 2009 there had been 4,688 allied military deaths in Iraq and 1,538 in Afghanistan. Of these 22% died in non-hostile action, 33% in direct combat situations and the majority of 45% in indirect combat actions. The leading causes of injury were explosive devices (70%) and gunshot wounds. Chest or abdominal injuries (40%) and traumatic brain injuries (35%) were the main causes of death for soldiers killed in action. The case fatality rate in Iraq is approximately half that of the Vietnam War, whereas the killed-in-action rate in Afghanistan (18.7%) is similar to the Vietnam War (20%); however, the amputation rate is twice as high in modern conflicts. Approximately 8-15% of the fatal injuries seem to be potentially survivable.Military surgeons must have an excellent expertise in a wide variety of surgical specialties. Life saving emergency care, especially in the fields of thoracic, visceral and vascular surgery as well as practical skills in the fields of neurosurgery and oral and maxillofacial surgery are required. Additionally, it is of vital importance to ensure the availability of sufficient tactical and strategic medical evacuation capabilities for the wounded.

3087. Lecklitner, M. L., et al. (1988). "Bone imaging in the assessment of en bloc osteocutaneous autotransplantation." Clinical nuclear medicine **13**(3): 186-187.

A patient is presented who sustained an avulsed portion of the mandible and all soft tissues of the floor of the oral cavity, requiring an autogenous en bloc transplant to replace the avulsed tissues. The clinical role of bone imaging in assessing the patency of the microvasculature and viability of the vascularized osteocutaneous graft is discussed, and the criticality of the time of image acquisition in prognosticating the success of the transplantation is emphasized.

3088. Ledgerwood, A. M., et al. (1980). "Primary repair vs ligation for carotid artery injuries." Archives of surgery (Chicago, Ill. : 1960) **115**(4): 488-493.

The morbidity and mortality of carotid arterial injuries in 36 patients were retrospectively reviewed. Primary repair was achieved in 31 patients; nine patients had a stroke postoperatively and five died. Five patients were treated with ligation; three had a stroke postoperatively, but all survived. Postoperative stroke and mortality correlated best with neurological deficit on administration. Patients in shock or with absent arterial flow were also more likely to have postoperative stroke. Twenty-two patients were normal neurologically on admission; all were normal postoperatively and all survived. Five patients were admitted unconscious in severe shock, precluding accurate neurological evaluation; two were normal following repair and three had stroke. Nine patients had a stroke or coma on admission; all nine had postoperative stroke and five died. Autopsy disclosed bilateral cerebral edema in two patients, cerebral edema and ipsilateral ischemic infarction in two patients, and cerebral edema with bilateral necrosis in one patient. No patient had hemorrhagic infarction. On the basis of these findings, carotid artery repair is recommended in all patients who are not comatose, have stable vital signs, and have technically reparable injuries.

3089. Lee, A. D. and Y. S. Oh (2007). "Unusual delayed presentation of a nail gun injury through the skull base." The Laryngoscope **117**(6): 977-980.

Published reports of nail gun injuries to the face are uncommon. We describe an unusual delayed presentation with injury through the infratemporal fossa and a literature review. A 55-year-old patient presented 2 weeks after an unrecognized injury with complaints of a headache. Imaging revealed a nail traversing the infratemporal fossa with intracranial extension. The nail was removed through a preauricular approach without sequelae. Nail gun missiles to the face are uncommon, dramatic, but often nonfatal because of their relative low velocity. Patients are usually diagnosed at the time of injury, evaluated with computed tomography and angiography, and treated with surgery.

3090. Lee, B. L. and P. Sternberg, Jr. (1996). "Ocular nail gun injuries." Ophthalmology **103**(9): 1453-1457.

PURPOSE: Penetrating ocular trauma resulting from nails can have disastrous visual consequences. Ocular nail gun injuries occur when a nail propelled at high velocity penetrates the globe. The authors report four consecutive patients with ocular injuries resulting from nail guns., METHODS: Four patients with ocular nail gun injuries are described: one with scleral penetrating injury, one with corneal penetrating injury, and two with perforating (through-and-through) injuries of the globe., RESULTS: Three of the four patients recovered good visual acuity after surgical intervention., CONCLUSION: Although dependent on the site of impact, the visual prognosis may be less severe than expected because the nail penetrates the eye at a high velocity such that there are less contusive forces. Adherence to safety precautions involving the use of nail guns as well as the obligatory use of safety glasses should reduce the incidence of these injuries.

3091. Lee, C., et al. (2017). "Patterns of trauma and violence among nomadic pastoralists at the nileke site (500-221 BCE), Northwestern Xinjiang Province, China." American journal of physical anthropology **162**: 259.

The Nileke cemetery site is located in the Junggar Basin between the Tianshan and Altai mountain ranges. This region connects the steppe grasslands of Kazakhstan and Mongolia with the oasis states of the Tarim Basin. They were nomadic pastoralists, possibly related to the Pazyryk culture. A total of 46 individuals were analyzed (18 females, 27 males, and 1 indeterminate) for cranial trauma. Twenty percent of the crania had some evidence of trauma (9/46). Seven males and two females had cranial trauma. One female had suffered a blow to the left eye orbit and one female had a broken right zygomatic bone. Both of these injuries are consistent with interpersonal violence. Two males also showed evidence of interpersonal fighting. Both males had broken noses. Five males showed injuries consistent with the use of weaponry. Two individuals had sword cuts to the left parietal and the nose. Two men had healed blunt force or low velocity projectile wounds to the frontal and parietals. One male had a keyhole shaped wound on the left parietal from being grazed by a high velocity projectile. One male had a penetrating wound from a metal weapon on the right parietal. This individual also had evidence of trepanation to treat the wound. The pattern and location of the majority of these injuries suggest that the attackers were on horseback while those injured were on the ground. The trauma pattern and frequencies at Nileke are similar to other regional nomadic pastoralist sites and different from agriculturalist sites.

3092. Lee, C. C., et al. (2021). "What Factors Are Associated With Open Treatment of Pediatric Mandibular Fractures?" Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **79**(6): 1292-1301.

PURPOSE: There is a paucity of data with respect to management of pediatric facial fractures. The purpose of this study was to describe the population of pediatric patients with mandibular fractures at our institution and to assess predictors of fractures requiring open reduction and internal fixation (ORIF)., PATIENTS AND METHODS: This was a retrospective cohort study of patients aged <=17 years presenting with mandibular fractures. The primary predictor variable was age >=13 years and <13 years. The primary outcome variable was ORIF (yes or no). Epidemiologic factors and complications were also assessed. Descriptive, bivariate, and multiple logistic regression statistics were computed to measure the association between predictor variables and ORIF., RESULTS: The study sample was composed of 84 subjects with 61 subjects aged >=13 years and 23 subjects aged <13 years. ORIF was used for 21.4% of subjects. Increased age was associated with ORIF (P = .009). After adjusting for the effects of concurrent variables, age (P = .047, OR = 2.30, 95% CI = 1.01 to 5.24), fracture displacement between 2 and 4 mm (P = .032, OR = 18.1, 95% CI = 1.29 to 254), fracture displacement >4 mm (P = .019, OR = 16.9, 95% CI = 1.60 to 179), and the presence of 3 fractures (P = .027, OR = 30.8, 95% CI = 0.001 to 0.641) were positive independent predictors of ORIF. Concomitant facial, skull, or skull base fractures (P = .039, OR = 0.027, 95% CI = 0.001 to 0.641) were a negative independent predictor of ORIF. Secondarily, both mechanism of injury and fracture location varied significantly by age and gender. Complication rate was 6.33%., CONCLUSIONS: Most pediatric mandibular fractures were managed nonoperatively. Increased age, fracture displacement, presence of 3 fractures, and concomitant craniofacial injuries were independent predictors of ORIF. Complication rates were low regardless of treatment modality.

3093. Lee, C. S. and K. H. Park (2010). "Six nails in the head: multiple pneumatic nail gun head injury." British journal of neurosurgery **24**(4): 493-494.

A 62-year-old man was admitted to our hospital after attempting to commit suicide with a pneumatic nail gun. Six nails were launched. Because the nail head acted as a brake, the launched nail could make a hole in the skull but could not entirely pass it.

3094. Lee, C. Y. and H. W. Kim (2018). "Angiographic change on time interval in traumatic-direct carotid cavernous fistula without venous reflux, and treatment with LVIS stent alone." Interdisciplinary Neurosurgery: Advanced Techniques and Case Management **14**: 5-8.

Traumatic carotid cavernous fistula (CCF) is usually high flow, direct type and typically manifested by venous hypertension and reflux, therefore it can lead to various neurologic deficit as well as severe ophthalmic symptoms including exophthalmos, congestion and visual disturbance. On the contrary, in traumatic-direct CCF without high flow that causes venous hypertension and/or reflux, the natural clinical course is obscure, and the diagnosis may be difficult. The treatment has not been well documented in detail. We are reporting on sequential angiographic change on time interval in traumatic-direct CCF without venous hypertension and/or reflux, and experience of treatment using LVIS stent.

3095. Lee, C. Y., et al. (1991). "Pediatric chin injury: occult condylar fractures of the mandible." Pediatric emergency care **7**(3): 160-162.

The diagnosis of occult mandibular condylar fractures in children is often missed or delayed on initial examination when children present with a laceration to the chin. A clue to the diagnosis of this type of skeletal injury to the mandible is the knowledge of a commonly occurring pattern of injury associated with chin trauma. Chin laceration, fracture of the parasymphyseal region near the chin, and fracture of the condyles are often concomitant injuries of the mandible. This article reviews three case reports of children who sustained a chin laceration, fracture in the region near the chin, and fracture to the mandibular condyles secondary to chin trauma that were not initially diagnosed on clinical examination.

3097. Lee, J. A. and H. Y. Lee (2002). "A case of retained wooden foreign body in orbit." Korean journal of ophthalmology : KJO **16**(2): 114-118.

A 41-year-old man visited our clinic complaining of esodeviation of the right eye. He had been operated on for corneal laceration 3 years before. One month later, exodeviation of the right eye had developed. The result of computed tomography (CT) was reported as orbital abscess and cellulitis. Although antibiotic treatment was administered for 2 weeks, the exodeviation didn't improve. On ocular examinations performed in our hospital in November-2001, his right eye was esotropic and had a relative afferent pupillary defect. Vision of the right eye was decreased to 0.02. Fundus examination showed optic atrophy. A new CT scan disclosed a foreign body introduced into the right medial orbital wall, nasal cavity and ethmoidal sinus. Although foreign body was surgically removed, vision and eye movement were not improved. In the case of a patient who has undergone orbital trauma, complete history taking and physical examinations must be performed. On suspicion of a foreign body, imaging study such as CT or MRI must be performed. However, because CT findings can be variable, careful follow-up is needed.

3098. Lee, J. H. and D. G. Kim (2000). "Brain abscess related to metal fragments 47 years after head injury. Case report." Journal of neurosurgery **93**(3): 477-479.

The authors report a case of symptomatic brain abscess in a 51-year-old man who presented with personality changes and generalized seizures. He had survived a grenade explosion injury during the Korean War 47 years previously. Computerized tomography scanning revealed multiple conglomerate rim-enhancing lesions and metallic foreign bodies in the right frontal lobe. The mass was totally removed and Pseudomonas aeruginosa was isolated from

microbial cultures. Retained foreign bodies in the brain, whether bone or metal, should be removed at the time of injury if at all possible. If this cannot be accomplished, patients with such retained foreign bodies should be carefully monitored for life.

3099. Lee, J. S., et al. (1999). "Orbitocranial injury caused by wood." Korean journal of ophthalmology : KJO **13**(2): 128-132.

A rare case of a patient with orbitocranial injury by a wooden foreign body is reported. Penetrating periorbital wound by a wooden stick with entry site at the right upper eyelid was related to the invasion into the temporal lobe. Fortunately, the anterior and posterior segments of eye were unharmed, but right ocular motility was markedly restricted mechanically in all directions. Forced duction test was strong positive, especially the dextroversion of the right eye. Computed tomography scan showed a well-delineated low density from the orbital wall into the temporal lobe. The wooden foreign body was subsequently removed from the orbit and the temporal lobe, through the neurosurgical frontotemporal approach. After the wooden foreign body was removed, the ocular movement of the right eye fully recovered without any intracranial or ocular complications.

3100. Lee, K. C., et al. (2021). "Are Facial Gunshot Wounds More Fatal When They Are Self-Inflicted or Other-Inflicted?" Craniomaxillofacial Trauma and Reconstruction.

Study Design: This was a retrospective cohort study of the 2014 Nationwide Emergency Department Sample (NEDS). Objective: Intraoral and submental projectile entry points may be less fatal than other facial entry points due to the indirect access to the intracranial structures and the protection offered by the intervening maxillofacial complex. Because intraoral and submental trajectories are almost always present in the setting of attempted suicide, this study sought to determine if intent (self-harm versus other-harm) influenced mortality in facial gunshot wound (GSW) patients. Methods: All patients with a diagnosis of a facial fracture secondary to firearm injury were included in the study sample. The primary predictor was self-harm. Secondary predictors were derived from patient, injury, and hospitalization characteristics. The study outcome was death. Univariate time to event analyses were conducted for all study predictors. A multivariate regression model for mortality was created using all relevant predictors. Results: The final sample included 668 facial GSW injuries, of which 19.3% were attributed to self-harm. Self-inflicted GSWs were more likely to involve the mandible (58.9 vs 46.0%, $P < 0.01$), ZMC/maxilla (47.3 vs 32.5%, $P < 0.01$), and intracranial cavity (48.1 vs 22.6%, $P < 0.01$). The overall mortality rate was 7.3%, and the mean time to death was 2.2 days. After controlling for pertinent covariates, the risk of mortality was independently decreased with mandibular injury (HR = 0.36, $P = 0.03$). However, mortality was increased by self-harm intent (HR = 3.94, $P < 0.01$) and intracranial involvement (HR = 11.24, $P < 0.01$). Conclusions: Consistent with a pattern of intraoral and submental entry points, self-inflicted facial GSWs demonstrated higher rates of mandibular injury. Despite this finding, self-harm injuries still carried a higher incidence of intracranial injury and a greater independent risk of mortality. Our results refute any notion that the mechanism and trajectory of self-inflicted GSWs is less fatal.

3101. Lee, K. H., et al. (2007). "An unusual case of penetrating injury to the spine resulting in cauda equina syndrome: case presentation and a review of the literature." Spine **32**(9): E290-293.

STUDY DESIGN: Case study., OBJECTIVE: We present an unusual case of cauda equina syndrome due to a penetrating injury in which the brake caliper of a motorcycle lodged in the lumbar canal of the operator of the vehicle after a road accident and provide a review of the literature on penetrating injury to the spine., SUMMARY OF BACKGROUND DATA: While the large majority of penetrating spinal injuries are due to gunshot wounds, penetrating injury to the spine causing cauda equina syndrome is rare., METHODS: We report the case of a 42-year-old man involved in a motorcycle accident in which the brake caliper penetrated the lumbar region and entered the lumbar canal through the interlaminar space between L2 and L3. He had a complete motor and sensory deficit in the lower extremities with absent rectal tone. The patient was taken urgently to the operating room and underwent removal of the foreign object and repair of a dural laceration. He was treated with a course of intravenous antibiotics., RESULTS: The wound healed without evidence for cerebrospinal fluid leakage or infection. The patient made a good neurologic recovery, becoming ambulatory with bowel and bladder continence at 5 months following the injury., CONCLUSIONS: Surgical removal of foreign object resulted in resolution of cauda equina syndrome injury.

3102. Lee, K. S. and B. L. Lee (2020). "Epilepsy caused by an unrecognized pencil lead misdiagnosed as intracerebral cavernous malformation." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **36**(3): 647-650.

Transorbital penetrating injury is relatively uncommon following head trauma, and delayed onset of neurological complications due to retained intracerebral foreign bodies has rarely been reported. We describe the first child case of late-onset epilepsy caused by an accidental transorbital penetrating injury, resulting in a retained pencil lead fragment that was mistaken for cavernous malformation. A 14-year-old girl presented with abrupt onset of nocturnal bilateral tonic seizures. The patient was previously healthy and denied any head trauma. The seizures were not well controlled by antiepileptic drugs. Right frontal lobe epilepsy due to a cavernous malformation was suspected on the basis of brain magnetic resonance imaging and electroencephalography findings. A planned operation unexpectedly revealed the intracerebral pencil lead. This foreign body had gone undetected for 11 years following a minor transorbital penetrating injury. The patient remained seizure-free during the 1-year post-operative follow-up period. Head trauma by a pencil can cause transorbital penetrating injury in children. It is difficult to detect retained small foreign body fragments and the clinical presentation can be delayed. It may be mistakenly diagnosed as other pathologies, especially when patients deny any history of head trauma.

3104. Lee, M., et al. (2018). "Traumatic brain injury induces calpain-2 mediated cleavage of HSP70.1, a lysosomal stabilisation protein." Journal of Investigative Medicine **66**(1): 120-121.

Purpose of study Recent studies suggest the role of heat-shock protein 70.1 (Hsp70.1) in maintaining lysosomal membrane integrity. Destabilisation of lysosomes promotes programmed cell death and is associated with progression of intracellular morphology relating to granulovacuolar degeneration, a pathological hallmark of Alzheimer's Disease (AD). Our laboratory previously identified a link between traumatic brain injury (TBI) and AD by showing that calpain-2 activation is involved in tau phosphorylation and oligomer accumulation. This study will investigate effects of TBI-induced calpain activation on Hsp70.1 and determine involvement of calpain-1 or calpain-2 in lysosomal stability. Methods used Controlled cortical impact model of TBI was used on wild-type (WT) and calpain-1 KO (C1KO) C57Bl/6 mice. A 5 mm craniotomy was performed with anaesthesia, and a penetrating injury was induced on cortex lateral to the sagittal suture. Single injection of a selective calpain-2 inhibitor (C2I, 0.3 mg/kg) was made intraperitoneally 1 hour after TBI. For sham surgery, mice were subjected to craniotomy only. Brains were isolated 24 hour after TBI and cortical tissue surrounding injury was homogenised in homogenization buffer containing a protease and phosphatase inhibitor cocktail. After two rounds of centrifugation, P2 membrane (pellet) fraction was resuspended in lysis buffer. Primary antibody for western blot (WB) was Hsp70.1 (1:3000). Summary of results WB showed breakdown products of Hsp70.1 after TBI with apparent Mw of 50, 37 and 25 kDa. Quantification of WB indicated that ratio of breakdown products to full-length Hsp70.1 was significantly higher in WT and C1KO mice after TBI, as compared to sham (n=3 animals. $p<0.05$ sham vs WT. $p<0.01$ sham vs C1KO). Post-TBI injection of C2I appeared to prevent Hsp70.1 truncation. Conclusions TBI resulted in rapid calpain-2-mediated Hsp70.1 truncation, as selective inhibition of calpain-2 decreased Hsp70.1 cleavage, which was evident in absence of calpain-1. Our results support the critical role of calpain-2 in neuronal death and provide an additional link between TBI and AD through calpain-2-mediated cleavage of Hsp70.1, and resulting lysosomal destabilisation.

3105. Lee, N., et al. (2005). "Penetrating brain injury leads to activation of ciliary neurotrophic factor receptors." Neuroscience letters **374**(3): 161-165.

Endogenous injury response mechanisms likely reduce secondary neuronal loss following CNS trauma by activating growth factor receptors. Therefore, it is important to determine which growth factor receptors are activated in vivo by CNS trauma and which signal transduction pathways are affected in which cell types. We present a model of penetrating brain injury utilizing stereotaxic insertion of a fine needle. This procedure can be used to anatomically characterize injury response mechanisms through immediate, local application of pharmacological agents. We find, through immunohistochemistry, that injury of the rat facial motor nucleus leads to activation of STAT3, a neuronal survival factor, in the dendrites, nuclei and cytoplasm of the motor neurons. A similar response was observed with the

trigeminal motor nucleus. Use of the ciliary neurotrophic factor (CNTF) receptor antagonist, AADH-CNTF, indicated that the STAT3 activation resulted largely, and perhaps entirely, from injury-induced activation of CNTF receptors.

3106. Lee, N., et al. (2013). "The contribution of ciliary neurotrophic factor receptors to adult motor neuron survival in vivo is specific to insult type and distinct from that for embryonic motor neurons." The Journal of comparative neurology **521**(14): 3217-3225.

Exogenous ciliary neurotrophic factor (CNTF) promotes motor neuron (MN) survival following trauma and in genetic models of MN disease. Unconditional disruption of the mouse CNTF receptor alpha (CNTFRalpha) gene leads to MN loss, demonstrating a developmental role for endogenous CNTF receptor signaling. These data also suggest that CNTF receptors may promote adult MN survival and that appropriately manipulating the receptors could effectively treat adult MN disorders. This effort would greatly benefit from a better understanding of the roles played by CNTF receptors in adult MNs. We have previously found that adult onset disruption of CNTFRalpha in facial MNs of "floxed CNTFRalpha" mice by AAV-Cre vector injection leads to significantly more MN loss than in identically treated controls. While indicating that CNTF receptors can promote adult MN survival, the data did not distinguish between potential roles in MN maintenance versus roles in protecting MNs from the injection associated trauma or the toxicity of the chronic Cre recombinase (Cre) produced by the AAV-Cre. Here we used an inducible Cre gene construct to produce adult-onset CNTFRalpha disruption in facial MNs without the traumatic and toxic effects of the AAV-Cre procedure. The MNs survive without CNTFRalpha, even when challenged by facial nerve crush or the injection-associated trauma, thereby suggesting, in conjunction with our previous study, that endogenous CNTF receptor signaling can protect MNs against toxic insult, such as that produced by chronic Cre. The data also indicate that in vivo CNTF receptors play very different roles in adult and embryonic MNs.

3107. Lee, P. K. H., et al. (2018). "Critical Consideration in Surgical Approach to the Neck in a Case of Absent Common Carotid with Concurrent Anomalous Vertebral Artery." The American surgeon **84**(12): e532-e534.

3108. Lee, R. K., et al. (1991). "Incidence rates of firearm injuries in Galveston, Texas, 1979-1981." American journal of epidemiology **134**(5): 511-521.

Firearm injury mortality rates have been characterized in various settings, but little is known of the total magnitude of firearm injury, including morbidity. The authors determined population-based incidence rates of firearm injury among residents of Galveston, Texas, from 1979-1981 by using police, emergency department, hospital, emergency medical services, medical examiner, and vital records to identify 239 firearm injury cases. Vital records, medical examiner, and police records each identified more than 95% of the fatalities, but police records (sensitivity = 98%) were better than emergency department or hospital records (sensitivity = 82% and 28%, respectively) for identifying all nonfatal cases. The annual age-adjusted incidence rate of firearm injury was 128 per 100,000 persons. Black males, with the highest firearm injury rate (459 per 100,000 persons), were injured at 46 times the rate of white females (10 per 100,000 persons). The overall case fatality rate was 30%, including 25% of the assaults/homicides, 81% of the parasuicides/suicides, and 0% of the unintentional injuries. On the basis of the case fatality rates, an estimated 140,000 firearm injuries occur in the United States annually. The case fatality rate for penetrating head injuries was 80% versus 48% for chest injuries and 6% for all other parts of the body. The results are discussed with respect to policy recommendations for reducing firearm injuries.

3109. Lee, S., et al. (2017). "Microglial inflammasome activation in penetrating ballistic-like brain injury." Journal of neurotrauma **34**(13): A4.

Penetrating traumatic brain injury (PTBI) remains a significant cause of death and disability in the United States without effective therapies. A rodent PTBI model, penetrating ballistic-like brain injury (PBBI) has uncovered several secondary pathophysiological mechanisms such as reduced glucose uptake, neurodegeneration, inflammation, and apoptosis that magnify the primary injury. Targeting components of these mechanisms may help improve PTBI outcomes. Activators of innate immunity contribute to secondary injury mechanisms following traumatic brain injury (TBI). Inflammasomes are the key regulators of Il-1b mediated inflammation after TBI and present as clinically relevant targets for therapy. The role of inflammasomes in PBBI pathophysiology has yet to be determined. Towards this, adult

male Sprague-Dawley rats were subjected to unilateral sham or PBBI surgery and sacrificed at various time points. Tissues were assessed for expression of cytokines IL-1b, IL-18 and components of the inflammasome, ASC (apoptosis-associated speck like protein containing a caspase activation and recruitment domain), caspase-1, NLRP3 (NOD-like receptor protein 3) and GSDMD (gasdermin-D) by immunoblot analysis and assessed for ASC cell-type expression by immunohistochemistry. Cortical IL-1b and IL-18 expression increased 4 h-48 h and 48 h-72 h, respectively after injury. PBBI also increased caspase-1, ASC, NLRP3, and GSDMD expression from 24 h-48 h. Compared to sham and contralateral cortex, microglial numbers significantly increased 48 h postinjury in the ipsilateral cortex. ASC expression was predominantly increased in activated microglia, permeating the enlarged cell bodies and into the processes. Taken together, this is the first report of inflammasome activation after PBBI and suggests that these activators of inflammation lead to an exacerbation of the pro-inflammatory state postinjury which could underlie the long-term sequlae of PBBI. Inhibition of the inflammasome in PBBI will evaluate its therapeutic potential for PTBI. Supported by NIH NINDS award R01NS089443.

3110. Lee, S. H., et al. (1991). "Diaphragmatic injury." Gaoxiong yi xue ke xue za zhi = The Kaohsiung journal of medical sciences **7**(12): 622-627.

From Feb. 1976 to Oct. 1990, 43 patients with diaphragmatic injuries were admitted to Kaohsiung Medical College Hospital. Blunt injuries occurred in 27 cases and penetrating injuries in 16 cases. The diagnosis is usually made by chest roentgenogram, chest CT, or during operations for other associated injuries. Delayed diagnoses were noted in 7 cases in blunt injury group and 2 cases in penetrating injury group. Isolated diaphragm injury was found in only 2 patients. The perforated diaphragm were almost repaired by two layers of continuous suture. None of them needed prosthetic mesh for reconstruction and no recurrence of hernia was found. In the blunt injury group, these patients usually combined with rib or long bone fractures, major intracranial injury, liver or spleen lacerations and intestinal perforations; while in the penetrating injury group, liver lacerations and stomach perforations were the most common associated injuries. Two deaths were noted in each group and the associated injury were accounted for these deaths.

3111. Lee, S. T. (1992). "A delayed unusual presentation of a penetrating foreign body." Singapore medical journal **33**(3): 304-305.

Complications resulting from the penetrating percutaneous foreign bodies almost always arise in the early post injury period. Delayed presentations of previous asymptomatic foreign bodies are rare. In this case report, symptoms of tracheal irritation arose seven years following the initial penetrating shrapnel injury to the neck. Computed tomography scans enabled localisation of the foreign body at the tracheal wall and carotid sheath interface. The usefulness of this radiologic modality in the evaluation of the penetrating soft tissue injury is highlighted. A review of the phenomenon of the migrating and asymptomatic foreign body follows.

3112. Lee, S. W., et al. (2019). "The role of microglial inflammasome activation in pyroptotic cell death following penetrating traumatic brain injury." Journal of neuroinflammation **16**(1): 27.

BACKGROUND: Traumatic brain injury remains a significant cause of death and disability in the USA. Currently, there are no effective therapies to mitigate disability except for surgical interventions necessitating a need for continued research into uncovering novel therapeutic targets. In a recent study, we used a rodent model of penetrating traumatic brain injury known as penetrating ballistic-like brain injury (PBBI) to examine the role of innate immunity in post-traumatic secondary injury mechanisms. We previously reported that the inflammasome, a multiprotein complex composed of apoptosis-associated speck-like protein containing card and caspase-1, plays a role in secondary cell death mechanisms after PBBI, including inflammatory cell death (pyroptosis)., METHODS: In the current study, we used flow cytometry analysis to evaluate activated microglia and CD11b-positive leukocytes after PBBI and assessed inflammasome activation and pyroptosis of specific cellular populations. Sprague-Dawley male rats underwent PBBI or sham-operated procedures and ipsilateral cortical regions processed for flow cytometry and cellular analysis. Flow cytometry results were compared using one-way ANOVA followed by Tukey's multiple comparisons., RESULTS: At 48 h following PBBI, there was an increase in activated microglia and infiltrating leukocytes compared to sham controls that were associated with increased caspase-1 activity. Using a florescent probe to identify caspase-1 activity and a fluorescent assay to determine cell viability, evidence for pyroptosis in CD11b+ cells was also determined. Finally, while post-traumatic treatment with an anti-ASC antibody had no effect on the number of activated microglia and infiltrating

leukocytes, antibody treatment decreased caspase-1 activity in both resident microglia and infiltrating leukocytes and reduced pyroptotic CD11b+ cell death., CONCLUSIONS: These results provide evidence for inflammasome activation in microglia and infiltrating leukocytes after penetrating traumatic brain injury and a role for pyroptotic cell death in the pathophysiology. In addition to inhibiting neuronal cell death, therapeutic treatments targeting inflammasome activation may also provide beneficial effects by reducing the potentially detrimental consequences of activated microglia and infiltrating CD11b+ leukocytes following penetrating traumatic brain injury.

3113. Lee, S. W., et al. (2018). "Microglial Inflammasome Activation in Penetrating Ballistic-Like Brain Injury." Journal of neurotrauma **35**(14): 1681-1693.

Penetrating traumatic brain injury (PTBI) is a significant cause of death and disability in the United States. Inflammasomes are one of the key regulators of the interleukin (IL)-1beta mediated inflammatory responses after traumatic brain injury. However, the contribution of inflammasome signaling after PTBI has not been determined. In this study, adult male Sprague-Dawley rats were subjected to sham procedures or penetrating ballistic-like brain injury (PBBI) and sacrificed at various time-points. Tissues were assessed by immunoblot analysis for expression of IL-1beta, IL-18, and components of the inflammasome: apoptosis-associated speck-like protein containing a caspase-activation and recruitment domain (ASC), caspase-1, X-linked inhibitor of apoptosis protein (XIAP), nucleotide-binding oligomerization domain (NOD)-like receptor protein 3 (NLRP3), and gasdermin-D (GSDMD). Specific cell types expressing inflammasome proteins also were evaluated immunohistochemically and assessed quantitatively. After PBBI, expression of IL-1beta, IL-18, caspase-1, ASC, XIAP, and NLRP3 peaked around 48 h. Brain protein lysates from PTBI animals showed pyroptosome formation evidenced by ASC laddering, and also contained increased expression of GSDMD at 48 h after injury. ASC-positive immunoreactive neurons within the perilesional cortex were observed at 24 h. At 48 h, ASC expression was concentrated in morphologically activated cortical microglia. This expression of ASC in activated microglia persisted until 12 weeks following PBBI. This is the first report of inflammasome activation after PBBI. Our results demonstrate cell-specific patterns of inflammasome activation and pyroptosis predominantly in microglia, suggesting a sustained pro-inflammatory state following PBBI, thus offering a therapeutic target for this type of brain injury.

3114. Lee, T. S., et al. (2014). "Management of carotid artery trauma." Craniomaxillofacial trauma & reconstruction **7**(3): 175-189.

With increased awareness and liberal screening of trauma patients with identified risk factors, recent case series demonstrate improved early diagnosis of carotid artery trauma before they become problematio. There remains a need for unified screening criteria for both intracranial and extracranial carotid trauma. In the absence of contraindications, antithrombotic agents should be considered in blunt carotid artery injuries, as there is a significant risk of progression of vessel injury with observation alone. Despite CTA being used as a common screening modality, it appears to lack sufficient sensitivity. DSA remains to be the gold standard in screening. Endovascular techniques are becoming more widely accepted as the primary surgical modality in the treatment of blunt extracranial carotid injuries and penetrating/blunt intracranial carotid lesions. Nonetheless, open surgical approaches are still needed for the treatment of penetrating extracranial carotid injuries and in patients with unfavorable lesions for endovascular intervention.

3115. Lee, Y. C., et al. (2017). "Self-inflicted transorbital brain injury by chopsticks in a patient with acute psychosis." Hong Kong medical journal = Xianggang yi xue za zhi **23**(3): 313-314.

3116. Lee, Y. H., et al. (1999). "Surgical reconstruction of the contracted orbit." Plastic and reconstructive surgery **103**(4): 1129-1128.

Anophthalmic patients and patients afflicted with retinoblastoma incur severe deformity of the orbit. Treatment of the severely contracted orbit is very difficult, and patient satisfaction is often poor. Since 1988, we have performed temporalis muscle transfer and surgical expansion of the contracted bony orbit in 26 patients. Satisfactory results were obtained. Gradual expansion of the orbit was performed in case of congenital anophthalmic patients. The treatment should be established in multiplicity, among many methods available for contracted eye sockets, according to the degree of orbital deformity and the amount of residual conjunctiva. In case of severe deformity, volume expansion surgery and temporalis muscle transfer are necessary. If augmentation is required in the periorbital region, rib bone

onlay graft must be performed. We were able to shorten the operative time by modifying the three-wall orbital expansion technique of Tessier and Wolfe to a more simplified method. Our observations show that our procedures achieved symmetry in both eyes in all patients, and there have been no remarkable complications.

3118. Legge, R. H., et al. (1992). "Hypertropia following trochlear trauma." Journal of pediatric ophthalmology and strabismus **29**(3): 163-166.

Hypertropia following trauma to the trochlea is rare. The more widely recognized response of the trochlea to trauma is hypotropia or acquired Brown syndrome. We observed three cases of hypertropia following penetrating trauma to the trochlea. Each had computerized tomography and/or magnetic resonance imaging to assist in the understanding of the mechanism of the observed superior oblique dysfunction. The clinical course of these cases was variable. Awareness of the damaged trochlea's capacity to respond as a hypertropic as well as a hypotropic syndrome will allow for improved management of these unusual patients.

3120. Lei, B., et al. (2011). "Xenon protects against brain injury in both ischemic and hemorrhagic stroke." Journal of neurosurgical anesthesiology **23**(4): 403.

Introduction: Low dose xenon (Xe, eg, 30% inhaled) offers rapid blood brain barrier (BBB) penetration, negligible effects on blood and intracranial pressure, and weak neuroprotective efficacy. Moderate therapeutic hypothermia (33 to 341C) has shown benefit against a variety of brain insults, but requires mechanical ventilation. Mild hypothermia (eg, 361C), while clinically feasible to achieve in awake patients, offers negligible neuroprotection.1 In this study, we hypothesized that combined post-ischemic administration of Xe and mild hypothermia would offer neuroprotection superior to either treatment alone in a rat transient middle cerebral artery occlusion (MCAO) model. This would allow simple therapeutic intervention to be available to a larger fraction of patients. Because Xe could be used as an emergency stroke treatment, it is important to determine whether it could exacerbate intracerebral hemorrhage (ICH), which could initially present as occlusive vascular stroke. Xe has no known effect on coagulation. Therefore we hypothesized that xenon would not worsen outcome from experimental ICH. Methods: Male Wistar rats (250 to 275 g) were subjected to 70 minutes MCAO with pericranial temperature held at 37.51C. At 90 minutes post- MCAO, rats (n=20 per group) were randomly assigned to experimental groups to breath 30% Xe in 30% O2/40% N2 or 30% O2/70% N2 for 20 hours while with pericranial temperature maintained at 37.51C or 361C. Neurological function and total cerebral infarct volumes were evaluated at 4 weeks post-ischemia. Male C57BL/6 J mice (10 to 12 wk) were used to study ICH. Type IV-S Clostridial collagenase (0.075U in 0.4 mL NS) was microinjected into the left striatum. At 2 hours after injection, mice were randomly treated with 30% Xe in 30% O2/40% N2 or 30%O2/70% N2 for 20 hours. Brain water content (n=4 to 5 per group) was assessed 24 hours after injury. Rotorod latencies (n=7 to 9 per group) were measured for 7 days after injury. Results: There was a main effect for treatment group for MCAO infarct size [(37.5/No Xe=224±51mm3, 36.0/No Xe=177±72mm3, 37.5+Xe=212±76mm3, 36.0+Xe=157±82mm3, P=0.015). Between group differences were present only for 37.5/No Xe vs. 36.0+Xe, P=0.04). An identical pattern was present for neurologic score (37.5/ No Xe vs. 36.0+Xe, P=0.005). In the ICH study, compared with air, Xe significantly decreased whole brain water content from 80.19%±0.14% to 79.3%±0.29% (P=0.038), and improved neurologic function (P<0.01, Fig. 1). Conclusion: Sub-anesthetic doses of post-ischemic Xe served as a therapeutic adjuvant to mild hypothermia in the context of focal cerebral ischemia with long-term efficacy. Xe did not worsen ICH. In fact, outcome was improved. This is consistent with prior demonstration of attenuated perivascular inflammation by Xe.2 Neuroprotective effects of Xe in both ischemic and hemorrhagic stroke provide evidence that Xe has therapeutic potential and could be started immediately before a computed tomography scan.

3122. Leite Cavalcanti, A., et al. (2012). "Injuries to the head and face in Brazilian adolescents and teenagers victims of non-natural deaths." The Journal of forensic odonto-stomatology **30**(1): 13-21.

This study aimed to evaluate the occurrence of injuries to the head and face in adolescent and teenager victims of non-natural deaths. A retrospective study was undertaken by the analysis of medical forensic reports obtained from medical forensic examinations performed at the Department of Forensic Medicine of the city of Campina Grande, PB, Brazil, between January 2003 and December 2007. From a total of 607 reports issued during this time span, the study sample consisted of 423 reports (69.6%) referring to adolescents and teenagers of both genders, aged 12 to 18 years, who were confirmed to have died from external causes. The causes of death were encoded according to the Chapter XX of the International Statistical Classification of Diseases and Related Health Problems (ICD-10). The majority of victims were 17 year old males (25.8%). Firearms (33.3%) and transport accidents (32.2%) were the most common causes of death, with boys showing a 3.7 times greater likelihood of getting killed by firearms than girls. There was statistically significant relationship between the occurrence of transport accidents and gender. The majority of victims (71.6%) presented with multiple injuries throughout the body. There was statistically significant relationship between the occurrence of transport accidents and the presence of multiple injuries. A high percentage of the victims presented with injuries to the head and face. There was statistically significant relationship between the occurrence of transport accidents and the presence of injury to the head. Fatal gunshot wounds and transport accidents were the main causes of death of male adolescents and teenagers. The victims presented with multiple injuries, especially to the head and face, and the mandible was the most frequently injured facial bone. .

3123. Leivo, T., et al. (2014). "Sports-related eye trauma." Acta ophthalmologica **92**: 15.

Purpose: To present the epidemiology, treatment and outcome of sports-related eye injuries. To give recommendations for the use of protective eye-wear. Methods: All new sports-related eye injury patients in Helsinki University Eye Hospital in one year (2011-2012). Epidemiological, clinical and resource use data from the hospital records, completed by a patient questionnaire. Follow-up 3 months. Statistical analysis of the data. Results: One hundred and forty-nine 149 sports injury patients. Floorball caused 47, football 19, tennis 15, ice-hockey 12, cycling 8, badminton 7, basketball, baseball and combat sports 6 eye traumas. Relative to sports participation rate, injuries were commonest in rink bandy, floorball and tennis. Contusion was the primary diagnosis in 114 cases, followed by lid trauma, orbital trauma and penetrating injury. 32% of contusion patients had severe secondary diagnoses. Number of outpatient visits was 459, inpatient days 25. 23 patients needed major, 12 minor surgery. Sick leave days were 1220, physical activity restriction 2982. Seventeen patients had permanent functional impairment. Relative to the number of injuries, a permanent impairment was significantly commonest in ice-hockey. 18 cases were in OTS classes 1-3. 7 patients used protective eye-wear, 4 in ice-hockey. Compared to previous data, the number of eye injuries had statistically significantly declined in floorball, badminton, rink bandy and squash, increased in tennis and ice-hockey. In floorball in under 14 years' age group, where protective eye-wear had meanwhile been made mandatory; 11 (2002-03) vs 1 (current) eye trauma was observed. Conclusions: Floorball is the leading eye injury causing sport in Finland. Protective eye- wear in junior floorball has been effective in preventing injuries and should be mandatory in all age groups. In icehockey eye injuries are in incline, relatively severe and a third of injuries incurred in spite of eye mask. The proper use of the mask should be emphasised and the masks further developed.

3124. Lekas, M. D. and P. T. Welch (1984). "Reconstruction of post-traumatic sinus osteomyelitis." The Laryngoscope **94**(10): 1277-1280.

Osteomyelitis with a fistulous tract of the left fronto-nasal area. The patient received an Anzio Beachhead WW II right fronto-nasal injury repaired with a lucite cranioplasty. A staphylococcal infection involved the remnant of the left frontal sinus with a fistula at the nasion near the orbital ridge. Bone scan revealed increased activity consistent with osteomyelitis. Patient was treated with intravenous oxacillin. The lucite skull prosthesis was removed 2 weeks after admission via the bilateral osteoplastic coronal flap approach with fat obliteration of the residual frontal sinus. The intravenous oxacillin was maintained for 48 days and the patient was discharged. The patient was later readmitted for a cranioplasty using a preformed tantalum plate. The nasal flange of the tantalum caused a deformity that did not allow

the patient to wear his glasses. His third admission was for reconstruction of the tantalum and nasal deformity via a W-shaped incision.

3125. Lekgwara, P., et al. (2019). "Predicting dural tear in patients will skull fractures secondary to assault." Interdisciplinary Neurosurgery: Advanced Techniques and Case Management **18**.

Aim: Skull fractures of the calvarium associated with a dural tear are regarded as neurosurgical emergencies to prevent potentially devastating infective complications. We aimed to determine the significance of pre-operative clinical and radiological variables in predicting dural tear in 135 patients admitted over a 2 year period with skull fractures secondary to assault whom went for operative intervention. Methods: Retrospective data analysis of 135 patients admitted with skull fractures secondary to assault from January 2015–December 2016 was performed. Medical records were analyzed for patient demographics, mechanism of injury, CT scan findings, pre-operative suspicion including evidence for this suspicion of a dural tear, operative confirmation of a dural tear, and Glasgow Outcome Score. Management involved surgery with antibiotic cover. Results: Considering the mechanism of injury being assaulted with a brick was significantly associated with the absence of a dural tear and being stabbed in the head with significantly associated with the presence of a dural tear ($p = 0.02$). On bivariate analysis having a depressed skull fracture ($p = 0.002$), pneumocephalus ($p = 0.02$) or an intracerebral hematoma ($p = 0.001$) were each statistically associated with the operative confirmation of a dural tear. Neither the combined presence of a skull fracture with an acute subdural hematoma or an intracerebral contusion was statistically associated with an intra-operative dural tear. Conclusion: In patients with a skull fracture secondary to assault considering the mechanism of injury being assaulted with a brick significantly excluded, and being stabbed in the head significantly predicted, the intra-operative finding of a dural tear. Considering pre-operative radiology having a depressed skull fracture, pneumocephalus, or intracerebral hematoma were each significant predictive variables of there being an intra-operative dural tear.

3126. Lelubre, C. and F. S. Taccone (2016). "Transfusion strategies in patients with traumatic brain injury: Which is the optimal hemoglobin target?" Minerva anestesiologica **82**(1): 112-126.

Robertson et al. (JAMA 2014; 312:36-47) investigated the effects of two different thresholds of hemoglobin (Hb) to guide red blood cells transfusions (RBCT; 7 g/dL vs. 10 g/dL) in patients suffering from traumatic brain injury (TBI). In a two-center, controlled, open-label trial (from May 2006 and August 2012), comatose patients with a closed TBI were randomized within 6 hours since initial resuscitation to one of the two RBCT strategies and, in a factorial design (2x2), to receive erythropoietin (EPO) or placebo. Patients were excluded if they had a Glasgow Coma Scale (GCS) score of 3 with fixed and dilated pupils, penetrating trauma, pregnancy, life-threatening systemic injuries and severe preexisting diseases. A total of 200 patients (7 g/dL with [N.=49] or without EPO [N. =50]; 10 g/dL with [N.=53] or without EPO [N.=48]) were enrolled among 598 who were screened. There was no interaction between EPO and Hb thresholds on the primary outcome, which was the occurrence of favorable neurological outcome, assessed using the Glasgow Outcome Scale (GOS) at 6 months after the injury (favorable=GOS 4-5). Favorable outcome was similar between patients included in the 7 g/dL (37/87-43%) and the 10 g/dL group (31/94-33%) as if receiving EPO or placebo, even after adjustment for several covariates. Thromboembolic events were significantly more frequent in the group transfused at 10 g/dL (22/101 [22%] vs. 8/99 [8%]; P=0.009). We discussed how theses results might influence the management of such patients as well as the methodological limitations that underline the need for further investigations.

3127. Lemke, S., et al. (2016). "Automated Perimetry and Visual Dysfunction in Blast-Related Traumatic Brain Injury." Ophthalmology **123**(2): 415-424.

PURPOSE: To evaluate feasibility and results of automated perimetry in veterans with combat blast neurotrauma., DESIGN: Prospective, longitudinal, observational case series., PARTICIPANTS: Sixty-one patients in a Veterans Affairs Polytrauma Center diagnosed with traumatic brain injury (TBI) from combat blast exposure., METHODS: Study participants underwent automated perimetry at baseline (median interval, 2 months after injury) (Humphrey Field Analyzer, Carl Zeiss Meditec, Dublin, CA, Swedish Interactive Threshold Algorithm 30-2 Standard or Fast), and 36 of them were followed up (median interval, 10 months after baseline). Presence of significant mean deviation and pattern standard deviation was determined for testing with reliability indices <=20% for fixation loss, 15% for false-positives, and 33% for false-negatives. Test-retest stability of global visual field indices was assessed for tests with these cutoffs or with elevated fixation loss. Associations between global visual field defects and predictors were examined., MAIN OUTCOME

MEASURES: Global visual field indices (mean deviation and pattern standard deviation)., RESULTS: Among 61 study participants (109 study eyes) with baseline testing, a field that met reliability cutoffs was obtained for 48 participants (79%) and 78 eyes (72%). Fixation loss was found in 29% of eyes in initial testing. Nine study participants (15%) demonstrated hemianopia or quadrantanopia, and an additional 36% had an abnormal global visual field index. Global indices were relatively stable at follow-up testing for tests meeting fixation-loss cutoffs and tests that did not. Visual scotomas due to post-chiasmal lesions were associated with moderate to severe TBI or penetrating head injury, but other visual field deficits were prevalent across the range of mild to severe TBI. Ocular injury to the retina or choroid, poorer visual acuity, and pupillary defect were associated with visual field defects. Participants with depressed visual field sensitivity reported lower visual quality of life., CONCLUSIONS: Reliable automated perimetry can be accomplished in most patients with TBI from combat blast exposure and reveals high rates of visual field deficits, indicating that blast forces may significantly affect the eye and visual pathways. 3128. Lengenfelder, J., et al. (2022). "Attention in Pediatric Traumatic Brain Injury and the Impact on Social Functioning." Brain injury **36**(SUPPL 1): 104.

Objective: Cognitive deficits following traumatic brain injury (TBI) in children often involve difficulties in attention. Studies report varying percentages of attentional impairments in pediatric TBI (pTBI) based on the severity of the injury. Additionally, some children receive a diagnosis of secondary attention deficit hyperactivity disorder (ADHD) when they have not had any attentional deficits prior to their brain injury. Because of the prevalence of attention problems following TBI and their impact on academic and functional outcomes, understanding the specific nature of attention problems is critical. The current study examines different aspects of attentional performance in pTBI and evaluates the impact of attentional deficits on social functioning. Participants/Methods: 21 children with TBI, (age: M = 11.71, SD = 3.72) and 22 typically developing children (TDC; age: M = 10.95, SD = 3.12) completed the TEA-ch subtests Creature Counting, Walk, Don't Walk, and Code Transmission. Parents completed the Social Responsiveness Scale (SRS) and the Social & Communication Disorders Checklist (SCDC) Results: Results indicate a significant difference between children with TBI and TDC on the scaled scores for Code Transmission (F[1,40] = 8.84,p = .005) but not for Walk, Don't Walk (F[1,40] = 1.56,p = .219) and Creature Counting (F[1,40] = 1.92,p = .173). Performance on Code Transmission is correlated with parental evaluations of social ability (SRS; r-.519, p = .001) and social communication traits (SCDC; r = -.446, p = .004). Conclusions: The results suggest that children with TBI differ from TDC in sustained attention on a task requiring the ability to continuously attend to a series of spoken numbers listening for a particular sequence. No differences were found on other attentional measures that require attention control/switching or a shorter sustained attention and task requiring response inhibition. Additionally, sustained attention performance was related to parental ratings of social functioning, indicating that attentional problems may have implications for a child's social success. Understanding the specific nature of attentional impairments can guide targeted interventions for pTBI and evaluating whether such interventions can also contribute to improvements in social functioning would also be important to evaluate.

3129. Lenz, J.-H., et al. (2003). "Reconstruction of the frontal calvarian continuity in a child using a freeze-preserved autogenous bone graft." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **31**(3): 154-158.

Today, extended craniofacial defects in childhood can be treated by using modern techniques of bone banking and osteosynthesis, of particular importance when the restoration needs to consider calvarial growth. This is a report of an 8-year-old boy whose right frontal bone was removed during primary multidisciplinary trauma care. The bone was stored at a tissue bank using sterilization and freeze-dried preservation. Nine months later the graft was replaced and fixed with resorbable miniplates. Postoperatively no complications were observed and the (auto)graft has taken well. There was symmetrical craniofacial growth as well as a good aesthetic result three years after reconstruction.

3131. Leone, A., et al. (2021). "Sinking bullet syndrome: A unique case of transhemispheric migration." Clinical neurology and neurosurgery **204**: 106607.

BACKGROUND: Spontaneous migration of retained intracranial bullet fragments is an increasingly recognized phenomenon. However, such migration is usually limited in extent, since it occurs along the bullet tract or cerebrospinal fluid (CSF) spaces. Transhemispheric migration through an intact cerebral hemisphere has not been previously reported., OBSERVATIONS: A 20-year old man sustained a gunshot wound (GSW) to the head with a left parieto-occipital entry point, resulting in retained bullet fragments within the anterior right frontal lobe. The patient developed medically refractory intracranial hypertension, necessitating a left decompressive hemicraniectomy. He exhibited a favorable postoperative course, with gradual neurologic recovery, and was ultimately discharged to a rehabilitation facility. Notwithstanding, serial head CT scans during the first 2 weeks revealed gradual transhemispheric migration of bullet fragments from the right frontal pole to the right occipital pole, traveling through largely intact, uninjured brain tissue., LESSONS: Transhemispheric migration of bullet fragments via intact brain tissue may rarely occur. While the exact mechanisms underlying this phenomenon remain unclear, potential factors may include: bullet weight, CSF pulsations, dissection through white matter tracts, and biomechanical effects of large skull defects. Bullet migration does not necessarily delay or prevent neurologic recovery.

3132. Leone, H. and B. W. Polsonetti (2005). "Amantadine for traumatic brain injury: does it improve cognition and reduce agitation?" Journal of clinical pharmacy and therapeutics **30**(2): 101-104.

OBJECTIVE: To review the available literature pertaining to amantadine as therapy for improving cognition and reducing agitation following a non-penetrating traumatic brain injury (TBI)., DATA SOURCES: Clinical literature was accessed through MEDLINE (from 1966 to February 2004) and bibliographic searches. Key search terms included 'amantadine', 'traumatic brain injury', 'cognition', and 'agitation'., DATA SYNTHESIS: Amantadine is primarily used for treatment and prophylaxis of influenza A. Its ability to improve mentation and motor function in patients with head injury remains questionable. An evaluation of five clinical trials, two case reports, and one case series is conducted focusing on the use of amantadine following TBI. Patients in clinical trials were assessed using a variety of neuropsychological tools aimed at, among other things, assessing cognition and agitation. Although individual patient results varied, the majority of patients studied showed improved neuropsychological test scores. Similar observations are noted in the case reports and case series. Improvement in cognition and reduced agitation seems to occur with post-injury amantadine therapy., CONCLUSIONS: Amantadine is a reasonable option for improving cognition and reducing agitation following a TBI but confirmatory evidence of the efficacy the drug is necessary.

3133. Leonessa, F., et al. (2011). "Identification of potential novel plasma biomarkers of closed head and penetrating ballistic traumatic brain injury by comparative count of unique peptides." Journal of neurotrauma **28**(6): A75.

OBJECTIVE: To identify novel potential candidate biomarkers of closed head and ballistic penetrating traumatic brain injury (TBI). METHODS: Plasma samples were collected transcardially at euthanasia from one hundred four Sprague-Dawley 15 min, and1, 6, 24 and 72 hours following lateral fluid percussion, penetrating ballistic brain injury or the respective control treatments (sham, anesthesia only and naïve). Each experimental group, as defined by injury/equivalent and survival time included 5-7 rats. Following abundant protein depletion, samples were digested with sequencing grade modified trypsin. Strong cation exchange fractions of the protein plasma digests were then analyzed by liquid chromatography-tandem mass spectrometry. Proteins were identified by at least two unique peptide sequences. Potential candidate biomarkers of TBI were identified by comparing the number of unique peptides per protein across different experimental groups. Potential candidates were prioritized by statistical significance of differences and biological significance. RESULTS: 10,217 proteins were identified by at least two unique sequences across 104 plasma samples; 1500-2500 proteins per sample. Based on the results, we have identified 24 nervous tissue proteins as potential novel candidate biomarkers of closed head and/or penetrating ballistic TBI. CONCLUSIONS: As an alternative for the preliminary identification of candidate biomarkers, a comparative count of unique peptide sequences detected per protein has the potential advantages of allowing for the comparative screen of a wider number of proteins, and of an intrinsic bias against more abundant proteins. Ongoing evaluations with antibody-based assays are aimed to obtain proof of concept for the validity of this identification approach, as well to verify some of the identified proteins as novel candidate biomarkers of TBI.

3134. Leonhard, M. J., et al. (2015). "Urban/Rural disparities in Oregon pediatric traumatic brain injury." Injury Epidemiology **2**(1): 1-10.

Background: Traumatic brain injury (TBI) greatly contributes to morbidity and mortality in the pediatric population. We examined potential urban/rural disparities in mortality amongst Oregon pediatric patients with TBI treated in trauma hospitals. Methods: We conducted a retrospective study of children ages 0–19 using the Oregon Trauma Registry for years 2009–2012. Geographic location of injury was classified using the National Center for Health Statistics Urban/Rural Classification Scheme. Incidence rates were calculated using Census data for denominators. Associations between urban/rural injury location and mortality were assessed using multivariable logistic regression, controlling for potential confounders. Generalized estimating equations were used to help account for clustering of data within hospitals. Results: Of 2794 pediatric patients with TBI, 46.6 % were injured in large metropolitan locations, 24.8 % in medium/small metropolitan locations, and 28.6 % in non-metropolitan (rural) locations. Children with rural locations of injury had a greater annualized TBI incidence rate, at 107/100,000 children per year, than those from large metropolitan areas (71/100,000 per year). Compared to children injured in urban locations, those in rural locations had more than twice the crude odds of mortality (odds ratio [OR], 2.5; 95 % CI, 1.6–4.0). This association remained significant (OR, 1.8; 95 % CI, 1.04–3.3) while adjusting for age, gender, race, insurance status, injury severity, and type of TBI (blunt vs. penetrating). Conclusion: We observed higher rates of TBI and greater proportions of severe injury in rural compared to urban areas in Oregon. Rural children treated in the trauma system for TBI were more likely to die than urban children after controlling for demographic and injury factors associated with urban/rural residence. Further research is needed to examine treatment disparities by urban/rural location. Future work should also identify interventions that can reduce risk of TBI and TBI-related mortality among children, particularly those who live in rural areas.

3135. León-Moreno, L. C., et al. (2020). "Kinematic Changes in a Mouse Model of Penetrating Hippocampal Injury and Their Recovery After Intranasal Administration of Endometrial Mesenchymal Stem Cell-Derived Extracellular Vesicles." Frontiers in Cellular Neuroscience **14**.

Locomotion speed changes appear following hippocampal injury. We used a hippocampal penetrating brain injury mouse model to analyze other kinematic changes. We found a significant decrease in locomotion speed in both open-field and tunnel walk tests. We described a new quantitative method that allows us to analyze and compare the displacement curves between mice steps. In the tunnel walk, we marked mice with indelible ink on the knee, ankle, and metatarsus of the left and right hindlimbs to evaluate both in every step. Animals with hippocampal damage exhibit slower locomotion speed in both hindlimbs. In contrast, in the cortical injured group, we observed significant speed decrease only in the right hindlimb. We found changes in the displacement patterns after hippocampal injury. Mesenchymal stem cell-derived extracellular vesicles had been used for the treatment of several diseases in animal models. Here, we evaluated the effects of intranasal administration of endometrial mesenchymal stem cell-derived extracellular vesicles on the outcome after the hippocampal injury. We report the presence of vascular endothelial growth factor, granulocyte–macrophage colony-stimulating factor, and interleukin 6 in these vesicles. We observed locomotion speed and displacement pattern preservation in mice after vesicle treatment. These mice had lower pyknotic cells percentage and a smaller damaged area in comparison with the nontreated group, probably due to angiogenesis, wound repair, and inflammation decrease. Our results build up on the evidence of the hippocampal role in walk control and suggest that the extracellular vesicles could confer neuroprotection to the damaged hippocampus.

3136. Lepić, M., et al. (2021). "Migration of the retained intracranial bullet to the spinal canal: A case report." Vojnosanitetski pregled **78**(10): 1103-1107.

Introduction. Retained intracranial missiles migration is rarely reported. Most of the time, the missile will migrate and remain intracranially, but in extremely rare cases, it may reach the spinal canal. The aim of the study was to present a patient with this rare clinical entity. Case report. The 29-years-old male suffered from the gunshot wound to the head through the left external auditory meatus. The bullet was located in the posterior fossa. Initial debridement without bullet removal was performed. Four months after the injury, the patient came back complaining of neck stiffness and progressive weakness of all extremities. Plain radiography revealed the bullet in the spinal canal at the level of C2 vertebra and computed tomography confirmed localization in the posterior aspect. An emergency procedure was performed for bullet removal and spinal cord decompression. Conclusion. The bullets tend to migrate. Migration to the spinal canal is rare, but takes a significant risk, due to the potential secondary injury. The removal of a bullet at-all-costs

may not be justified. However, the prediction of migration based on the predisposing factors would be of great value to treating these patients adequately.

Kaufmann). **89**(6-7): 811-818.

We performed 11 epikeratophakias with a congelated lenticule (H. Kaufmann and M. Mac Donald technique) for aphakic post-traumatic eyes. The results have been good for the cicatrisation, and the visual result.

3139. Leshko, N., et al. (2022). "Characterization of antibiotic prophylaxis in traumatic facial fractures at a level i trauma center." Critical care medicine **50**(1 SUPPL): 788.

INTRODUCTION/HYPOTHESIS: While prophylactic antibiotics may reduce the risk of infection and promote healing in select traumatic facial fractures, recent guidelines recommend against routine the use in non-operative management as well as continuation for beyond 24 hours in the operative setting. At our institution, a lack of standardization has been observed with antibiotic prophylaxis in traumatic facial fractures as it relates to fracture type and duration of therapy. The objective of this study was to characterize antibiotic prophylaxis use within this population. METHODS: This retrospective study included patients admitted between June 2018-2020 with traumatic facial fractures due to blunt or penetrating injury and receipt of prophylactic antibiotics. The primary objective assessed the use of antibiotic prophylaxis as it relates to type and duration in non-surgical and surgical management. Secondary outcomes evaluated the incidence of infection at the fracture site(s), infections attributed to antibiotic exposure, and the cost of total antibiotic use. Data was analyzed through descriptive statistics. RESULTS: Of 107 patients screened, 63 were included. Baseline characteristics consisted of a majority male (64%) population aged 45 ± 20 years with fractures due to blunt injury (89%). The median number of fractures per patient was 4 [2-8] commonly located in orbital (25%), maxillary (24%), and nasal (17%) areas and managed non-surgically (60%). Most patients (52%) received a median inpatient course of ≤ 5 days; of this cohort, 59% received an outpatient course for an additional ≥ 7 days. Patients undergoing surgical fixation received a longer median inpatient course compared to those treated non-surgically (10 vs 4 days). The average patient spent $224 for an antibiotic course. No documented infections were identified at the site(s) of injury. Two patients were diagnosed with Clostridioides difficile. CONCLUSION: Patients with traumatic facial fractures were likely to receive extended prophylaxis for approximately eleven days more than current recommendations. Following presentation of the project results, a stewardship guideline limiting prophylaxis to the peri-operative setting was implemented. Future steps include post-implementation assessment of the guideline.

3140. Lesieur, O., et al. (2006). "Retained knife blade: an unusual cause for headache following massive alcohol intake." Emergency medicine journal : EMJ **23**(2): e13.

Massive alcohol intake usually resolves in a banal headache. We report a case of a patient presenting with acute alcohol intoxication in which the ensuing "hangover" was due to a knife blade deeply retained in the brain parenchyma. This case underlines the unpredictability of retained foreign bodies without a high level of suspicion and a detailed description of the circumstances of admission.

3141. Lesperance, K., et al. (2008). "The significance of penetrating gluteal injuries: an analysis of the Operation Iraqi Freedom experience." Journal of surgical education **65**(1): 61-66.

BACKGROUND: Although penetrating gluteal injuries rarely are life-threatening, the risk for concomitant injury to regional anatomic structures warrants additional evaluation. We analyzed factors affecting the management and outcomes of these injuries., METHODS: Retrospective analysis of prospectively collected data from the 31st Combat Support Hospital during Operation Iraqi Freedom over a 16 month period., RESULTS: From 3442 patients, 115 patients

(3.3%) suffered penetrating gluteal injuries. They were predominately male (98%) with a mean injury severity score of 13. Mortality was 6% (n = 7). Primary mechanisms of injury were improvised explosive devices (41%) and gunshot wounds (59%). Associated injuries were present in 57% of patients [orthopedic (35%), abdominal (29%), rectal (25%), vascular (21%), genitourinary (14%), pulmonary (11%), sphincter (9%)]. Overall, 76% required surgical management, with 14% developing postoperative complications. In total, 27 patients (24%) required stoma placement. Gunshot wounds were associated with through and through injuries (43% vs 6%, $p < 0.01$), rectal injury (35% vs 11%, $p < 0.05$), and stoma placement (32% vs 11%, $p < 0.05$). Blast injuries were associated with a higher mean transfusion requirement (11 vs 6 units, $p < 0.05$), increased length of stay (14 vs 9 days, $p < 0.05$), and traumatic brain injury (24% vs 6%, $p < 0.05$). Independent predictors of a need for stoma placement were gunshot wounds (odds ratio = 10, $p < 0.05$) and injury severity score greater than 20 (odds ratio = 27, $p < 0.01$)., CONCLUSIONS: Penetrating gluteal injuries are associated with significant damage to local structures. Gunshot wounds carry a higher risk of injury to the rectum and stoma placement, whereas blast injuries are associated with less local injury and more multisystem trauma.

3142. Leung, A., et al. (2020). "Transcranial magnetic stimulation for persistent post-traumatic headache-an INS/NANS expert consensus panel review and recommendation." Neuromodulation **23**(3): e35.

Introduction: The US Center for Disease Control and Prevention (CDC) estimated the prevalence of new traumatic brain injury (TBI) cases in the United States at over 1.7 million every year1. Persistent Post-Traumatic Brain Injury (PTBI) Related Headache (PTBI-HA) is one of the most common debilitating chronic pain conditions in patients after a mild/moderate traumatic brain injury. This high prevalence (>60%) of persistent chronic headache is often associated with neuropsychological dysfunction in mood, attention, and memory, which casts a profound negative impact on patients' quality of life and increases stress in their caregivers. Unfortunately, conventional pharmacological treatments for PTBI-HA have not been shown to be effective 2-4. As part of the effort by the international non-invasive neuromodulation community to address the opioid epidemic and under the guidance of a steering committee composed of leadership from both the International Neuromodulation Society(INS) and the North American Neuromodulation Society(NANS), this multi-disciplinary expert panel aims to:1) assess and rate the existing outcome evidence of repetitive Transcranial Magnetic Stimulation (rTMS) in managing PTBI-HA; and 2) provide TMS treatment recommendation/guideline for the PTBI-HA. Methods: A five-member expert task group was established under the guidance of a five-member INS/NANS steering committee to assess the utilization of rTMS in the treatment of PTBI-HA. Individual studies were first rated by the guideline established by American Academy of Neurology Classification of Evidence for Therapeutic Studies. The overall clinical evidence was then rated based on Type of Study Design and Level of Certainty, and recommendation was provided based on the US Preventive Service Task Force (USPSTF) and Centers for Disease Control and Prevention (CDC) criteria. Results: Based on the existing clinical outcome evidence for the shortterm efficacy (1-2 month) in alleviating PTBI-HA symptoms, the majority of the task group members rated the Study Design as I (Randomized Controlled Trials) for TMS at M1 or left LDLPFC, Level of Certainty in Evidence as High for PTBI-HA. The task group also rated USPSTF recommendation as A (Extremely Recommendable) and CDC recommendation as IA (Strongly Recommended) for the clinical implementation of the rTMS at either M1 or left LDLPFC for mild PTBI-HA with the latter being considered as alternate treatment location for patients with PTBI-HA and co-morbid severe depression Conclusion: After reviewing the existing literature, the panel concluded that the level and scope of evidence for rTMS in managing PTBI-HA is High and the treatment is Strongly Recommendable for the condition. (Figure Presented).

3143. Leung, L. Y., et al. (2017). "Differential effects of resuscitation strategies on coagulopathy following traumatic brain injury and hemorrhagic shock." Journal of neurotrauma **34**(13): A21.

This study examined the changes in blood coagulation profiles in rats exposed to penetrating ballistic-like brain injury (PBBI) combined with hemorrhagic shock (HS), and compared the effect of resuscitation with Hextend, Lactated Ringer's solution (LR) or whole blood (WB) on post-injury coagulation. Rats were assigned into three groups: Hextend, LR, and WB. All animals received a frontal PBBI followed by a 35-minute of HS (mean arterial pressure < 45mmHg). In the Hextend and LR groups, resuscitation fluid was infused followed by shed blood reinfusion. In WB group, shed blood was re-infused 15 minutes after the hypotensive period. Blood samples were analyzed using thromboelastography (TEG) and blood gas analyzer at four time points: Pre-injury baseline, post-PBBI, post-HS, and after the infusion of Hextend, LR or WB. TEG parameters included Reaction Time (R), Kinetics Time (K), Angle (a) and Maximum Amplitude (MA). R was significantly reduced vs. baseline by both PBBI and HS. K was significantly shorter and a was significantly greater

immediately following PBBI and HS vs. baseline. MA was significantly greater following PBBI vs. either baseline or post-HS. Hextend, LR and WB produced different coagulation profiles after PBBI and HS insults. Hextend resulted in a significantly smaller a ($p < .05$ vs. WB) and MA ($p < .05$ vs. Baseline and WB), indicating that Hextend infusion leads to a slower coagulation rate and reduced clot strength. In contrast, the parameters in LR and WB groups were comparable to the baseline values. Blood gas analysis revealed a significant reduction in hemoglobin and hematocrit following HS and PBBI, which were restored to baseline levels by WB resuscitation. On the contrary, a significant decrease ($p < .05$ vs. baseline or WB) in ctHb and Hct as well as an increased lactate level were detected following LR or Hextend resuscitation. The current results show that PBBI altered the coagulation parameters, which returned to the baseline levels after LR or WB resuscitation whereas Hextend resuscitation after PBBI/HS resulted in hypocoagulation.

3144. Leung, L. Y., et al. (2016). "Cardiac baroreflex responses in a rat model of penetrating ballistic-like brain injury (PBBI) with hypoxemia and hemorrhagic shock." Journal of neurotrauma **33**: A133.

This study examined the temporal change in cardiac baroreflex response following severe traumatic brain injury (TBI) with or without additional hypotensive/hypoxemic insults. Rats were randomly assigned into three groups ± sham craniotomy only, 10% PBBI only, and PBBI combined with hypoxemia/hemorrhagic shock (PHH). The PHH group received 30-min hypoxemia (fraction of inspired oxygen = 0.1) and then 30-min hemorrhagic hypotension (mean arterial pressure = 40mmHg) following PBBI. To assess the baroreflex function, phenylephrine was injected via femoral vein catheter with a sequential dosing regimen of 2, 1, 0.5, 5, 10 lg/kg. Systolic blood pressure (SBP) and electrocardiogram were recorded. Twenty minutes after the last dose of phenylephrine, the dosing regimen was repeated. This phenylephrine pressor test was performed on the injury day (day 0), and again on 1 and 5 days postinjury. A linear regression line of heart period (R-R interval from the electrocardiogram) against SBP was plotted for each test, in which the slope of the line was taken as an index of baroreflex sensitivity (BRS). Additionally, heart rate was derived from the electrocardiogram recordings. In PBBI and PHH group, BRS was higher than that in the sham group at all time points. While BRS remained steady in the sham control group (ranged 0.26 ± 0.08 -0.36 ± 0.11 ms/mmHg) throughout the experiment, it exhibited a gradual increase in the PBBI group with the peak (0.65 ± 0.15 ms/ mmHg) occurring at day 5 post-injury. In contrast, a decreasing trend was observed in the PHH group, in which an acute increase in BRS (0.59 ± 0.1ms/mmHg) was detected on day 0. The differences in heart rate were not significant between groups, yet PHH trended lower acutely following injury and at 5 days post-injury, indicating bradycardia. Persistent disturbance of cardiovascular responses induced by TBI and the additional insults may potentially result in reduced perfusion of the vital organs and consequently worsen the clinical outcomes.

3145. Leung, L. Y., et al. (2016). "Neurochemical changes following combined hypoxemia and hemorrhagic shock in a rat model of penetrating ballistic-like brain injury: A microdialysis study." The journal of trauma and acute care surgery **81**(5): 860-867.

BACKGROUND: Energy metabolic dysfunction is a key determinant of cellular damage following traumatic brain injury and may be worsened by additional insults. This study evaluated the acute/subacute effects of combined hypoxemia (HX) and hemorrhagic shock (HS) on cerebral interstitial levels of glucose, lactate, and pyruvate in a rat model of penetrating ballistic-like brain injury (PBBI)., METHODS: Rats were randomly assigned into the sham control, PBBI, and combined injury (P + HH) groups. The P + HH group received PBBI followed by 30-minute HX and 30 minute HS. Samples were collected from striatum (perilesional region) using intracerebral microdialysis at 1 to 3 hours after injury and then at 1 to 3, 7, and 14 days after injury. Glucose, lactate, and pyruvate were measured in the dialysate samples., RESULTS: Glucose levels dropped significantly up to 24 hours following injury in both PBBI and P + HH groups ($p < 0.05$). A reduction in pyruvate was observed in the PBBI group from 24 to 72 hours after injury (vs. sham). In the P + HH group, the pyruvate was significantly reduced from 2 to 24 hours after injury ($p < 0.05$ vs. PBBI). This prominent reduction persisted for 14 days after injury. In contrast, lactate levels were significantly increased in the PBBI group during the first 24 hours after injury and remained elevated out to 7 days. The P + HH group exhibited a similar trend of lactate increase as did the PBBI group. Critically, P + HH further increased the lactate-to-pyruvate ratio by more than twofold (vs. PBBI) during the first 24 hours. The ratio reached a peak at 2 hours and then gradually decreased, but the level remained significantly higher than that in the sham control from 2 to 14 days after injury ($p < 0.05$)., CONCLUSION: This study identified the temporal profile of energy-related neurochemical dysregulation induced by PBBI and combined injury in the perilesional region. Furthermore, combined HX and HS further reduced the pyruvate level and increased the lactate-to-pyruvate ratio following PBBI, indicating the exacerbation of posttraumatic metabolic perturbation.

3146. Leung, L. Y., et al. (2015). "Combined hypoxemic and hypotensive insults altered physiological responses and neurofunction in a severity-dependent manner following penetrating ballistic-like brain injury in rats." The journal of trauma and acute care surgery **79**(4 Suppl 2): S130-138.

BACKGROUND: Traumatic brain injury often occurs with concomitant hypoxemia (HX) and hemorrhagic shock (HS), leading to poor outcomes. This study characterized the acute physiology and subacute behavioral consequences of these additional insults in a model of penetrating ballistic-like brain injury (PBBI)., METHODS: Rats were randomly assigned into sham control, HX + HS (HH), 5% PBBI alone, 5% PBBI + HH, 10% PBBI alone, and 10% PBBI + HH groups. Mean arterial pressure, heart rate, and breathing rate were monitored continuously. In the combined injury groups, animals were subjected to 30-minute HX (Pao2, 30-40 mm Hg) and then 30-min HS (mean arterial pressure, 40 mm Hg) followed by fluid resuscitation with lactated Ringer's solution after PBBI or sham PBBI. Motor function was assessed using the rotarod task at 7 days and 14 days after injury. Cognitive function was assessed in the Morris water maze task from 13 days to 17 days after injury., RESULTS: Combined HH caused acute bradycardia that was reversed by fluid resuscitation. During HX phase, tachypnea was observed in all HH groups. Persistent bradypnea was detected in 10% PBBI + HH group during the resuscitation phase. PBBI produced significant decrements in motor performance (vs. sham and HH groups). Additional insults significantly worsened motor deficits following 5% PBBI but not 10% PBBI. Both 5% PBBI and 10% PBBI produced significant cognitive deficits in the Morris water maze task with worsened deficits evident following the more severe injury (i.e., 10% PBBI). Alternatively, rats subjected to 5% PBBI + HH exhibited cognitive impairment that was significantly worse compared with 5% PBBI alone, whereas this worsening effect was not detected in the 10% PBBI groups., CONCLUSION: This study characterized the physiological responses and neurobehavioral profiles following combined PBBI and HH. Ten percent PBBI produces motor and cognitive deficits, which may exceed a sensitivity threshold capacity. In contrast, 5% PBBI produces a lower, albeit significant, magnitude of deficits and thus provides a more sensitive screen for evaluating the cumulative effects of additional insults, which were indeed demonstrated to significantly worsen outcome.

3147. Leung, L. Y., et al. (2012). "Temporal and spatial profile of histopathological changes caused by hemorrhagic shock after penetrating ballistic-like brain injury (PBBI)." Journal of neurotrauma **29**(10): A218.

Introduction Traumatic brain injury (TBI) is often accompanied with hemorrhagic shock (HS). Evidence suggests that HS may worsen the brain insult and corresponding outcome. However, the complex neuropathological cascade of the combined injuries(TBI + HS) is poorly understood. This study examined whether HS following PBBI exacerbated histopathological outcome in different brain regions. Methods Rats were randomly assigned into four groups: Sham control(craniotomy only); PBBI; HS; PBBI + HS (n = 6/group/time point). Unilateral frontal PBBI was produced in the right hemisphere of isoflurane anesthetized rats. HS was induced by drawing blood from the tail artery to reduce mean arterial pressure to 40-45 mmHg. This hypotensive state was maintained for 60min. Lactated Ringer's solution was given as fluid resuscitation after HS. In the PBBI + HS group, HS was initiated 5 minutes after PBBI. Rats were sacrificed by transcardial perfusion at 3 and 7 days post-injury. Brains were harvested, post-fixed in 4% paraformaldehyde and cryoprotected in 20% sucrose solution. The samples were processed for Hematoxylin-Eosin (HE) staining, silver staining and immunostaining for glial fibrillary acidic protein (GFAP) for astrocyte activation. Lesion volume was quantified on HE-stained slices. Positive stained areas in silver-stained and immunostained slices were quantified using threshold analysis in cortical and subcortical regions of interest. Results Lesion volume in the PBBI + HS group was comparable to the PBBI group at 3 and 7d post-injury. At 3d post-injury, upregulation of GFAP in the hippocampus was significantly (3-fold) higher in the PBBI + HS vs. PBBI group but no significant differences in GFAP expression were detected between these 2 groups in the ipsilateral cerebral cortex, corpus callosum, striatum and thalamus. At 7d postinjury, GFAP expression in these brain regions remained elevated (compared to sham and HS) but was more pronounced in the corpus callosum and thalamus of the PBBI + HS group (compared to PBBI alone; $p < .05$). At 3d post-injury, the PBBI + HS and PBBI groups showed similar profiles of neuronal degeneration (measured by silver staining). Particularly in the corpus callosum, significantly (2-fold) more degenerated axonal fibers was observed in the PBBI + HS vs. PBBI group at 7d post-injury ($p < .05$). Notably, neurodegeneration was also evident in the contralateral hemisphere of PBBI and PBBI + HS animals. Conclusions Overall, the differential profiles of astrocyte activation and neurodegeneration in the PBBI + HS vs. the PBBI alone groups indicates that HS exacerbates the effects of PBBI producing more severe neuropathological outcome. Critically, the combined effects of PBBI + HS increased over time and were more apparent at 7 days post-injury. It has been well-established that HS reduces cerebral blood flow, depriving tissue of oxygen and nutrients and

promoting further damage to already compromised neurons and glia. Based on the current results, lesion volume analysis alone may not be sensitive enough to capture this aggravated effect. On the contrary, GFAP expression and silver staining may provide sensitive measures to detect the pathological differences between PBBI and the combined injury. Chronic effects of combined HS and PBBI injuries as well as other neuroinflammatory responses involving microglia remain to be determined.

3148. Leung, L. Y., et al. (2013). "Polytrauma and penetrating ballistic-like brain injury (PBBI): Effects of multiple secondary insults and their sequence on acute physiology, neurological deficits and mortality." Journal of neurotrauma **30**(15): A95.

Introduction TBI accompanied by additional systemic insults e.g. hemorrhagic shock (HS) and respiratory distress-induced hypoxemia (HX), gives rise to aggravated deficits in surviving casualties. Here we examined the combined effects of penetrating ballistic-like brain injury (PBBI), HS and HX and how the sequence of these insults affects physiological and neurological outcomes. Methods Rats were randomly assigned into one of 4 groups (n = 10/group): (1) PBBI, (2) PBBI + HS +HX (PBBI animals exposed to HS and then HX), (3) PBBI +HX+ HS (PBBI animals exposed to HX and then HS) or (4) PBBI + HX/HS (PBBI animals exposed to HX and HS simultaneously). Unilateral frontal PBBI (10%) was produced in the right hemisphere under isoflurane anesthesia. HS was induced by withdrawing blood from tail artery until mean arterial pressure (MAP) reached 40 mmHg. The hypotensive state was maintained for 30min, followed by fluid resuscitation. HX was induced by reducing the fraction of inspired oxygen (FiO2) to 0.10 (balanced with nitrogen) and the hypoxemic state was maintained for 30 min MAP, brain tissue oxygen (PbtO2), cerebral blood flow (CBF) and direct-current (DC) shifts were monitored simultaneously prior to injury and continuously for 2.5h. A separate cohort of animals (n = 6-10/group) was used to evaluate the mortality rate and neuroscore (up to 7 d post-injury). Results PbtO2 decreased during both HS and HX. Following HS, PbtO2 further reduced to 42%baseline level during HX in PBBI + HS +HX group. Such changes were not detected when the sequence was reversed (PBBI +HX+ HS). PBBI reduced CBF significantly in lesion core (63%) and peri-lesion region (21%). Inducing HX prior to HS after PBBI significantly decreased CBF in peri-lesion region by an additional 29% vs. PBBI alone during hypotension. Notably, while HX itself only decreased PbtO2 level but not CBF, HS prior to HX appeared to amplify the effect of HX leading to 48% reduction in CBF in lesion core and 22% in peri-lesion region during HX. Prolonged DC shifts were observed during both HS and HX in PBBI + HS +HX group, whereas in PBBI +HX+ HS group, depolarization occurred only during HX. Simultaneous HX/HS following PBBI caused persistent decrease in CBF but PbtO2 recovered shortly after resuscitation. Mortality rate in PBBI +HS+HX and PBBI +HX+HS groups was 50% and 33%, respectively. In contrast, PBBI alone or PBBI +HX/HS groups had no mortality. Neuroscores of all polytrauma groups were higher than PBBI alone group on post-injury day1-4, with the most prominent deficit seen in PBBI +HS+HX group. All surviving animals recovered gradually and showed no difference vs. PBBI alone group by day 5. Conclusions HS prior to HX produced more severe injury in the PBBI model. Studies have shown that HS with aggressive fluid resuscitation causes hemodilution and decreases oxygen-carrying capacity. This may account for the HS-induced additive effect of HX as well as the ensuing high mortality rates and significant neurological deficits. In contrast, HX prior to HS produced more modest physiological changes, as the negative effects of HX were readily resolved by restoring normoxia, posing less threat to the injured brain during the later hypotensive state. Yet, mortality and deficits were detected in PBBI +HX+HS group. PBBI + HX/HS produced the least severe injury, as HX-induced hypotension lowered the volume of blood loss to achieve the HS state. In summary, the sequence of PBBI, HX and HS resulted in distinct patterns of injury outcomes. These data provide further guidance for designing experimental TBI/polytrauma models and insights into treatment of polytrauma casualties with different injury patterns.

3149. Levenson, J. L. and A. B. Hamric (1989). "Ethical dilemmas in the treatment of patients following traumatic brain injury." Psychiatric medicine **7**(1): 59-71.

3150. Levett, D., et al. (2006). "Resuscitation fluids in trauma 1: Why give fluid and how to give it." Trauma **8**(1): 47-53.

Fluid resuscitation following trauma is necessary to restore compromised organ perfusion and hypoxic tissue damage. The activation of the Systemic Inflammatory Response Syndrome in response to both traumatic and subsequent hypoxic insults has implications for what represents the optimal fluid resuscitation strategy. There is no single resuscitation strategy that can be applied to all patients with traumatic injury. This article reviews the evidence available to help guide fluid therapy. A number of studies have suggested that timing of fluid therapy with respect to

surgical intervention is crucial. Prior to definitive treatment of injury permissive hypotension confers advantage, particularly in the setting of penetrating trauma. The situation is less clear in cases of blunt trauma, where further studies comparing restrictive with liberal fluid regimes are required. The site of injury will also influence the strategy to be adopted. Following traumatic brain injury, maintenance of cerebral perfusion pressure is likely to be of overriding importance. Once definitive surgical control of haemorrhage has been achieved, fluid therapy to maximise stroke volume and cardiac output is advised. Following the development of established critical illness, goal-directed therapy may increase mortality. © 2006 Edward Arnold (Publishers) Ltd.

3151. Levi, L. (1992). "Intracranial infection after missile injuries to the brain: report of 30 cases from the Lebanese Conflict." Neurosurgery **31**(1): 162.

3152. Levi, L., et al. (1990). "Wartime neurosurgical experience in Lebanon, 1982-85. I: Penetrating craniocerebral injuries." Israel journal of medical sciences **26**(10): 548-554.

The present report analyzes 116 penetrating wounds of the brain sustained during warfare in Lebanon during 1982-85. Two basic mechanisms of injury were encountered: high-velocity bullets, and shrapnel and stones from explosive devices; and in one case a radio antenna penetrated the head through the orbit. The site of impact was at the convexity in 87% of cases and at the base of the skull in the remaining 13%. Surgery was performed in 83% of the patients: debridement-craniotomy in 73%, burr hole for intracranial pressure monitoring only in 6% and scalp closure only in 4%. The remaining 17% did not require surgery because of transbasal penetration without intracranial mass (10%) or due to moribundity. Indriven bone or foreign body fragments were removed only if readily accessible. The mortality rate was highest among patients with a Glasgow Coma Scale of less than or equal to 4 on arrival, after high-velocity bullet wounds, when the intracranial path was multilobar or transventricular, and when associated lesions were accompanied by shock. A follow-up study of the 49 Israeli survivors for almost 6 years revealed intracerebral-retained bone fragments in 48%, but these did not result in increased immediate or late complications (e.g., infection, epilepsy). These results support our conservative approach. Since all victims of penetrating head injuries were evacuated from Lebanon to Rambam Medical Center, Haifa, our report can serve as an estimation of the incidence of penetrating brain wounds and their burden on a front-line hospital.

3153. Levi, L., et al. (1991). "Penetrating craniocerebral injuries in civilians." British journal of neurosurgery **5**(3): 241-247.

During a 6-year period (1984-89), 31 patients were treated at Rambam Medical Center with penetrating craniocerebral injuries (PCCI) not associated with military action. Eighteen (58%) patients died during their initial hospitalization; only two of them had admission Glasgow Coma Scale (GCS) above five. The admission GCS coupled with the mode of injury (type of missile and motivation of shooting) were valuable for early accurate prognosis assessment. Patients with admission GCS of 3 and 4 invariably died despite rapid treatment and attempted haematoma evacuation. The neurological status, CT appearance, as well as the motivation of shooting should be considered in order to assess accurately the possible outcome. Compared with our military series of 113 patients with PCCI, there were more extensive injuries, although the mean period until neurosurgical treatment was the same. Long-term complications connected to dural tears remote from the entrance wound occurred in three of the survivors.

3154. Levin, H. S. (2003). "Neuroplasticity following non-penetrating traumatic brain injury." Brain injury **17**(8): 665-674.

The primary objective of this review is to examine the methodology and evidence for neuroplasticity operating in recovery from traumatic brain injury (TBI), as compared with previous findings in patients sustaining perinatal and infantile focal vascular lesions. The evidence to date indicates that the traditional view of enhanced reorganization of function after early focal brain lesions might apply to early focal brain lesions, but does not conform with studies of early severe diffuse brain injury. In contrast to early focal vascular lesions, young age confers no advantage in the outcome of severe diffuse brain injury. Disruption of myelination could potentially alter connectivity, a suggestion which could be confirmed through diffusion tensor imaging (DTI). Initial reports of DTI in TBI patients support the possibility that this technique can demonstrate alterations in white matter connections which are not seen on conventional magnetic resonance imaging (MRI) and might change over time or with interventions. Preliminary functional MRI studies of TBI

patients indicate alterations in the pattern of brain activation, suggesting recruitment of more extensive cortical regions to perform tasks which stress computational resources. Functional MRI, coupled with DTI and possibly other imaging modalities holds the promise of elucidating mechanisms of neuroplasticity and repair following TBI.

3156. Levine, S. B., et al. (1986). "Evaluation and treatment of frontal sinus fractures." Otolaryngology--head and neck surgery : official journal of American Academy of Otolaryngology-Head and Neck Surgery **95**(1): 19-22.

We treated twenty-three patients with blunt or penetrating wounds of the frontal sinus from 1978 through 1983. Nondisplaced anterior wall fractures were observed or explored. Posterior table fractures--with displacement confirmed by computed tomography or polycycloidal tomography--were explored. Either obliteration of the sinus or nasofrontal duct reconstruction with a Sewall-Boyden-McKnaught flap was selected, depending on the magnitude of duct injury. In all cases, the anterior wall was primarily reconstructed. All penetrating wounds with posterior table involvement were treated by cranialization of the frontal sinus and temporalis muscle obliteration of the nasofrontal ducts. Only one case of meningitis occurred, resulting in prolonged hospitalization.

3157. Levkovitch-Verbin, H., et al. (2006). "Minocycline delays death of retinal ganglion cells in experimental glaucoma and after optic nerve transection." Archives of ophthalmology (Chicago, Ill. : 1960) **124**(4): 520-526.

OBJECTIVE: To evaluate the effect of minocycline hydrochloride on the survival of retinal ganglion cells (RGCs) in glaucomatous rat eyes and rat eyes after optic nerve transection (ONT)., METHODS: The effect of intraperitoneal injections of minocycline at dosages of 15 mg/kg per day, 22 mg/kg per day, and 45 mg/kg per day was evaluated and compared with saline in ONT (n = 174) and experimental glaucoma (n = 51)., RESULTS: The mean +/- SEM survival rate of RGCs 1 week after ONT was significantly higher with minocycline at dosages of 15 mg/kg per day (36% +/- 3%; n = 9; P = .04), 22 mg/kg per day (44% +/- 2%; n = 15; P = .001), and 45 mg/kg per day (39% +/- 3%; n = 10; P = .008) compared with saline (29% +/- 2%; n = 28). Minocycline at a dosage of 22 mg/kg per day was also significantly neuroprotective compared with saline 2 weeks after ONT (mean +/- SEM survival rate, 5% +/- 1% vs 3% +/- 0.4%, respectively; n = 20 [10 rats in each group]; P = .03). In experimental glaucoma, the mean +/- SEM percentage of RGCs after 4 weeks was 84% +/- 4% in the minocycline group (n = 15) compared with 65% +/- 4% in the saline group (n = 18) (P = .003). Apoptosis of RGCs was significantly delayed by minocycline 4 days and 1 week after ONT., CONCLUSION: Minocycline significantly enhances the survival of RGCs after ONT and in experimental glaucoma by delaying the apoptosis pathway., CLINICAL RELEVANCE: The safety record of minocycline and its ability to penetrate the blood-brain barrier suggest that this drug is a promising neuroprotective drug for optic nerve injuries.

3158. Levy, A. D., et al. (2006). "Virtual autopsy: preliminary experience in high-velocity gunshot wound victims." Radiology **240**(2): 522-528.

PURPOSE: To retrospectively assess virtual autopsy performed with multidetector computed tomography (CT) for the forensic evaluation of gunshot wound victims., MATERIALS AND METHODS: The institutional review board approved this HIPAA-compliant study and did not require informed consent of the next of kin. Thirteen consecutive male gunshot wound victims (mean age, 27 years) were scanned with 16-section multidetector CT prior to routine autopsy. Retrospectively, the total-body nonenhanced scans were interpreted at a three-dimensional workstation by radiologists blinded to autopsy findings. Images were evaluated for lethal wound, number and location of wound tracks, injured structures, and metal fragment location. After image review, autopsy reports and photographs were compared with the images and interpretations to validate the multidetector CT determinations., RESULTS: Multidetector CT aided in correct identification of all lethal wounds, and metallic fragment location was always precise. In four cases, multidetector CT aided in accurate assessment of organ injuries and lethal wounds but led to underestimation of the number of wounds if comingling paths occurred. In two cases of a chest wound, multidetector CT aided in accurate assessment of the chest as having the lethal wound but failed to help identify specific sites of hemorrhage. In two cases of craniofacial injury, the path of the wound was not clear. Autopsy revealed a total of 78 wound tracks (mean, 6; range, 1-24). Ten (13%) wound tracks were not identified at multidetector CT (six upper extremity wounds and four thigh wounds). In two cases, findings missed at autopsy (fracture of the cervical spine, bullet fragments in the posterior area of the neck) were

identified at multidetector CT., CONCLUSION: Multidetector CT can aid prediction of lethal wounds and location of metallic fragments.

3159. Levy, J. and T. Lifshitz (2001). "Eyelid fish-hook injury." International ophthalmology **24**(5): 297-298.

OBJECTIVE: To report a rare case of fish-hook eyelid injury., METHODS: Interventional case-report. A 25-year-old man presented with an upper eyelid fish-hook wound., RESULTS: The hook was extracted under local anaesthesia using the back-out method. Postoperatively, no complications were observed., CONCLUSIONS: In the absence of serious ocular damage, the back-out method seems to be the best option for the removal of the hook in eyelid injuries.

3161. Levy, M. L. (2000). "Outcome prediction following penetrating craniocerebral injury in a civilian population: aggressive surgical management in patients with admission Glasgow Coma Scale scores of 6 to 15." Neurosurgical focus **8**(1): e2.

In an attempt to assess admission Glasgow Coma Scale (GCS) scores and other radiographic variables after penetrating craniocerebral injury in relationship to outcome, the author evaluated a series of 294 patients with penetrating injuries who presented with a GCS score of 6 to 15 over a 6-year period. Entrance criteria required a replicable neurological examination that was not altered by the presence of hypotension, drugs/toxins, or systemic injury. All patients underwent surgical intervention and aggressive perioperative management, including resuscitative protocols, in the neurosurgical intensive care unit. The author previously devised prospective models of outcome remained unchanged in this series. The variables most predictive of death include admission GCS score and subarachnoid hemorrhage in one model and admission GCS score and pupillary changes in a second when pupillary response was definitive at admission ($p < or = 0.00005$). Other important variables related to morbidity include admission GCS, bihemispheric injury when associated with intraventricular hemorrhage, and diffuse fragmentation ($p < or = 0.001$). In this study a significant relationship between operative intervention and survival ($p < or = 0.01$) was found in patients with an admission GCS scores of 6 to 8. No significant relationships between operative intervention and survival were found in patients with admission GCS scores of 9 to 12 and 13 to 15. A significant relationship between operative intervention and morbidity ($p < or = 0.01$) was also demonstrated in patients with an admission GCS score of 12 to 15. No significant relationships between operative intervention and morbidity were found in patients with an admission GCS score of 6 to 8 and 9 to 12.

3162. Levy, M. L., et al. (1996). "Economic, ethical, and outcome-based decisions regarding aggressive surgical management in patients with penetrating craniocerebral injury." Journal of health communication **1**(3): 301-308.

Each year fatalities in the United States increase as a result of gunshot wounds to the head. This increase, coupled with the progressive limitation of medical and economic resources available at major trauma centers, has brought into question the concept that everything possible should be done to save the lives of victims, who have only a minimal and nonpredictable chance of having a good outcome. Thus, consideration must be given to the economics of treating cranial gunshot wounds and the relationship of this treatment to outcome. When a good outcome can be predicted, treatment should be aggressive. However, when a good outcome cannot be predicted, surgical intervention will have no effect and the potential costs of aggressive treatment must also be considered. Clearly, there are ethical dilemmas involved in withholding operative treatment from any individual, even if there is only a minimal chance of a reasonable neurologic recovery. A negotiation-based approach should be used in determining the medical and ethical benefits of aggressive management strategies. Unfortunately, the care of critically ill patients is inconsistent with this approach. In order to insure that the best decision is made, guidelines dictating when to surgically intervene must be made an essential part of the patient/health care provider negotiation--even in worst case scenarios. The combination of an extremely poor prognosis for these injuries, and economic constraints faced by government-run facilities today could suggest that some patients should be allowed to die. Thus, the physician must be a source of information for the families, providing support and becoming a decision-making partner regarding potential intervention. In each situation, a strict set of guidelines must be formulated to establish a moral foundation for the ultimate mutual decision.

3163. Levy, M. L., et al. (1994). "Outcome prediction after penetrating craniocerebral injury in a civilian population: aggressive surgical management in patients with admission Glasgow Coma Scale scores of 3, 4, or 5." Neurosurgery **35**(1): 77-75.

In an attempt to evaluate the response of patients who have low admission Glasgow Coma Scale scores (GCS) after a penetrating craniocerebral injury to aggressive management, we evaluated a series of 190 patients with penetrating injuries who presented with a GCS score of 3, 4, or 5 during a 6-year period. Entrance criteria required replicable neurological examinations that were not altered by the presence of hypotension, drugs/toxins, or systemic injury. The surgical patients included 21 patients with an admission GCS score of 3, 24 with an admission GCS score of 4, and 15 with an admission GCS score of 5. All patients underwent surgical intervention and aggressive perioperative management in the neurosurgical intensive care, including resuscitative protocols. Five of the patients with a GCS score of 3 survived, all with poor outcomes. Seven of the patients with a GCS score of 4 survived, although only one had a good outcome. Eleven of the patients with a GCS score of 5 survived. Five had a Glasgow Outcome Score of 2, five had a Glasgow Outcome Score of 3, and one had a Glasgow Outcome Score of 4. We have devised a prospective model of outcome based on our series in an attempt to predict nonsurvivors at admission (while overpredicting for survivors). The variables most predictive of mortality include admission GCS score and subarachnoid hemorrhage in one model and admission GCS score and pupillary changes in a second, when pupillary response was definitive at admission ($P < \text{or} = 0.00005$). 3164. Levy, M. L., et al. (1993). "Penetrating craniocerebral injury resultant from gunshot wounds: gang-related injury in children and adolescents." Neurosurgery **33**(6): 1018-1015.

We prospectively and retrospectively reviewed a series of 780 patients who presented to the University of Southern California/Los Angeles County Medical Center with a diagnosis of gunshot wound to the brain during an 8-year period. Of these, 105 were children ranging in age from 6 months to 17 years. Injuries were gang related in 76 (72%) children and adolescents. Stepwise linear regression analysis was used to formulate a predictive model of outcome in this population. Patient age ($F = 10.92$), sex ($F = 9.32$), occipital entry site ($F = 8.17$), bihemispheric injury ($F = 8.50$), and admission Glasgow Coma Scale ($F = 69.91$) were all found to correlate with outcome ($P < 0.05$). Significant differences between pediatric and adult populations were noted in transit time, entrance site, and age-related outcome. Occipital or assassination-type wounds were most common in children. In addition, a younger age was associated with poor outcome ($P < 0.0001$). We describe both the economic and racial trends in our population of patients in addition to weapon type and toxicological evaluation. The Department of Neurological Surgery is becoming directly involved in providing information to children at the junior high school level regarding gang activity and brain and spinal cord injury. In conjunction with the Community Youth Gang Services Organization and Think First Organization, we are attempting to integrate prevention through education and community mobilization. This is a plan aimed at informing and recovering the youth affected by gangs.

3165. Levy, M. L., et al. (1993). "The significance of subarachnoid hemorrhage after penetrating craniocerebral injury: correlations with angiography and outcome in a civilian population." Neurosurgery **32**(4): 532-540.

Certain clinical factors are considered to have an effect on patient outcome after penetrating missile injury. These include bilateral hemispheric injury, ventricular hemorrhage, intracerebral hemorrhage, mass effect, and missile or bony fragmentation. The relationship of subarachnoid hemorrhage (SAH) after penetrating craniocerebral injury and outcome is unknown. In addition, controversy exists regarding the role of angiography and the incidence of traumatic intracranial aneurysm in this population. Finally, can we assume that the incidence of traumatic intracranial aneurysm is equal in military and civilian populations, given the absence of penetrating shrapnel injury in civilian populations? Now that computed tomography has supplanted angiography as the primary diagnostic modality, increasing vigilance on the part of the physician and examination of angiography in high-risk patients should allow for enhanced outcome. We evaluated 100 patients with a diagnosis of cerebral gunshot wound over a 12-month period. All patients were evaluated neurologically at the time of admission and had imaging studies. Thirty-one patients with radiological evidence of SAH on computed tomography underwent angiography. Angiograms were limited to the side of the injury in patients with single-lobe or unilateral multilobe injuries and were bilateral in patients with bilateral hemispheric involvement. One intracranial aneurysm (3.2%) was documented and treated surgically. In those patients who died within 48 hours of

admission, 68% had SAH as compared with only 17% of those surviving. Outcome was based upon neurological evaluation at the time of discharge and at the time of clinical follow-up at 3 and 6 months.(ABSTRACT TRUNCATED AT 250 WORDS)

3166. Levy, M. L., et al. (2004). "A neuroforensic analysis of the wounds of President John F. Kennedy: Part 2--A study of the available evidence, eyewitness correlations, analysis, and conclusions." Neurosurgery **54**(6): 1298-1292.

A substantial body of literature exists surrounding the assassination and subsequent pathological examination of President John F. Kennedy. In the first part of this series, we provided a previously undocumented eyewitness account by a neurosurgeon of what transpired in Trauma Room 1 of Parkland Memorial Hospital on November 22, 1963. The current article reviews the copious literature and extensive controversy regarding President Kennedy's wounds. The autopsy report, ballistics data, official reviews of the autopsy data, and Dr. Grossman's observations are correlated in an effort to provide a neuroforensic analysis of the nature of the wounds that President Kennedy sustained. The final article of the series will relate the wounds to the timing of the shots and the location of the President as his limousine traversed Dealey Plaza and will discuss the sites from which the bullets could have been fired.

3167. Levy, Y. E., et al. (2014). "Surgical resections for posttraumatic epilepsy following gsws to the brain." Epilepsy Currents **14**: 361.

Rationale: Penetrating craniocerebral gunshot wounds (GSWs) have a high mortality, leaving survivors with devastating neurological deficits in the majority of cases. Posttraumatic intractable epilepsy is a major health problem in these patients and significantly impacts quality of life and leads to high rates of morbidity. While the surgical management of posttraumatic epilepsy following head trauma has previously been described, epilepsy surgery in patients following GSWs to the head has never before been reported. In this study, we aim to report the evaluation, and surgical treatment strategies used in patients who underwent successful epilepsy resections for medically refractory epilepsy following GSWs to the brain. Methods: A prospectively compiled database of epilepsy patients was used to identify patients that underwent epilepsy surgery for medically refractory epilepsy as a consequence of a prior GSW to the brain. Data regarding the seizure frequency, type of surgical resection and seizure outcomes were compiled. Results: From an epilepsy surgery database of 235 patients, three patients with a prior history of posttraumatic epilepsy following cranio-cerebral GSWs to the head were identified. Ages at surgery were 21, 25, and 27 years old and their GSWs to the head occurred at 18, 13 and 5 years respectively. Seizures began soon after the injury in all patients and became refractory to medications thereafter. All patients had shrapnel fragments intra-cranially and one patient had a prior VNS placed with no improvement in seizure frequency. In two patients, intracranial electrodes were placed for prolonged monitoring. In these patients a partial frontal lobectomy in one and a frontal-parietal resection in the other were performed. One of them underwent an awake craniotomy with language mapping due to the proximity of the seizure foci to language areas. The third patient underwent an orbitofrontal resection. All three patients became seizure free (Engel class Ia) following surgery. Conclusions: Post-traumatic epilepsy is a common sequel of penetrating head injuries. These cases might seem daunting and complex, but intracranial monitoring and surgical resections in these patients can be safely performed and may lead to favorable seizure outcomes. To our knowledge the surgical management of epilepsy following GSWs to the head has never described.

3168. Lew, J. F., et al. (1990). "Aerotolerant Clostridium tertium brain abscess following a lawn dart injury." Journal of clinical microbiology **28**(9): 2127-2129.

A young girl developed an intracranial abscess and necrotizing cellulitis following penetrating injury from a lawn dart. Initial identification of a gram-positive rod growing aerobically from clinical specimens was as a Bacillus organism, but the observation that the isolate grew poorly in subcultures for susceptibility testing but quite well under standard anaerobic culture techniques led to the identification of the organism as an aerotolerant Clostridium tertium. Early management of penetrating head trauma should include cranial imaging studies to detect fractures and intracranial pathology. Clinical microbiologists and clinicians should be aware of the phenomenon of aerotolerance in anaerobic bacteria to avoid errors in choice of antibiotic therapy.

3169. Lewis, A., et al. (2016). "Pregnancy and Brain Death: Lack of Guidance in U.S. Hospital Policies." American journal of perinatology **33**(14): 1382-1387.

Objective The death of Marlise Munoz, a pregnant woman who suffered an anoxic brain injury in November 2013, highlights the social, ethical, legal, and medical controversies associated with brain death in pregnancy. We sought to evaluate whether institutions in the United States have policies in place for situations in which a pregnant woman is declared brain dead. Study Design Institutional brain-death protocols from hospitals in the United States were obtained in cooperation with local and regional organ procurement agencies. Each protocol was reviewed to determine if and how it addressed brain death in pregnancy. Results We reviewed 317 unique brain-death protocols. In eight protocols (2.5%), it was noted that a pregnant patient could not be evaluated for brain death if the fetus could be preserved. Of the protocols that permitted brain-death evaluation, 289 (93.8%) did not include guidance about fetal management after maternal brain death and 305 (99%) did not indicate who was responsible for making decisions for the fetus. Conclusion Very few institutional brain-death policies address the issue of pregnancy. The creation of guidelines on management of the social and ethical challenges associated with brain death in pregnancy may be helpful. 3170. Lewis, D. D., et al. (1996). "Thirty hours from referral to cross-clamp: a case study in organ procurement." Journal of transplant coordination : official publication of the North American Transplant Coordinators Organization (NATCO) **6**(2): 75-77.

Families of potential organ donors might have requests that prolong the donation process. Organ procurement organizations therefore should be sensitive to these issues, or risk losing potential donors. This study focused on a case that in duration surpassed 30 hours from initial referral to cross-clamp in the operating room. This article examines the legal, family, and management issues involved in such a case.

3171. Lewis, D. D. and R. R. Vidovich (1997). "Organ recovery following childbirth by a brain-dead mother: a case report." Journal of transplant coordination : official publication of the North American Transplant Coordinators Organization (NATCO) **7**(3): 103-105.

Little information is available in the medical and nursing literature concerning organ recovery from brain-dead, pregnant individuals. Many healthcare professionals might rule out such patients as potential donors, especially if childbirth is a possibility. This article presents an actual case study in which the birth of a healthy infant and recovery of organs from the mother were successful. It also reviews the available literature and discusses factors related to organ placement.

3172. Lewis, J. D., et al. (2015). "Anhedonia in combat veterans with penetrating head injury." Brain imaging and behavior **9**(3): 456-460.

Anhedonia is a common symptom following traumatic brain injury. The neural basis of anhedonia is poorly understood, but believed to involve disturbed reward processing, rather than the loss of sense of pleasure. This analysis was undertaken to determine if injury to specific regions of prefrontal cortex (PFC) result in anhedonia. A CT-based lesion analysis was undertaken in 192 participants of the Vietnam Head Injury Study, most with penetrating head injury. Participants were divided into left and right ventrolateral prefrontal, bilateral ventromedial prefrontal, and other injury locations. Anhedonia was measured by self-report in each group using the four-item anhedonia subscale score of the Beck Depression Inventory-II. Individuals with right ventrolateral injury reported greater severity of anhedonia compared to those with injury in the left ventrolateral region. These findings support an association between injury in the right ventrolateral PFC and anhedonia.

3173. Lewis, J. R., et al. (2008). "Mandibular reconstruction after gunshot trauma in a dog by use of recombinant human bone morphogenetic protein-2." Journal of the American Veterinary Medical Association **233**(10): 1598-1604.

CASE DESCRIPTION: A 6-year-old German Shorthaired Pointer was evaluated for possible reconstruction of a mandibular defect resulting from gunshot trauma., CLINICAL FINDINGS: A 5-cm defect of the right mandibular body was evident. A segment of the mandibular body was removed 9 weeks earlier because of severe contamination and comminution associated with gunshot trauma. Subsequent right-sided mandibular drift resulted in malocclusion in

which the left mandibular canine tooth caused trauma to mucosa of the hard palate medial to the left maxillary canine tooth. The right maxillary canine tooth caused trauma to gingiva lingual to the right mandibular canine tooth., TREATMENT AND OUTCOME: The right mandible was stabilized with a 2.0-mm maxillofacial miniplate positioned along the lateral alveolar margin and a 2.4-mm locking mandibular reconstruction plate placed along the ventrolateral mandible. An absorbable compression-resistant matrix containing collagen, hydroxyapatite, and tricalcium phosphate was soaked in recombinant human bone morphogenetic protein-2 (rhBMP-2; 7.2 mL of a 0.5 mg/mL solution for a dose of 3.6 mg) and placed in the defect. By 4 weeks after surgery, an exuberant callus was evident at the site of the defect. By 7 months after surgery, the callus had remodeled, resulting in normal appearance, normal occlusion, and excellent function of the jaw., CLINICAL RELEVANCE: Mandibular defects resulting from gunshot trauma can be treated by removal of contaminated tissue and comminuted bone fragments, followed by staged reconstruction. The combination of rhBMP-2 and compression-resistant matrix was effective in a staged mandibular reconstruction in a dog with a severe traumatic mandibular defect.

3175. Lewis, S. R., et al. "Interventions to reduce body temperature to 35 [SUPERSCRIPT ZERO]C to 37 [SUPERSCRIPT ZERO]C in adults and children with traumatic brain injury." (10).

Background, Traumatic brain injury (TBI) is a major cause of death and disability, with an estimated 5.5 million people experiencing severe TBI worldwide every year. Observational clinical studies of people with TBI suggest an association between raised body temperature and unfavourable outcome, although this relationship is inconsistent. Additionally, preclinical models suggest that reducing temperature to 35 [degrees]C to 37.5 [degrees]C improves biochemical and histopathological outcomes compared to reducing temperature to a lower threshold of 33 [degrees]C to 35 [degrees]C. It is unknown whether reducing body temperature to 35 [degrees]C to 37.5 [degrees]C in people admitted to hospital with TBI is beneficial, has no effect, or causes harm. This is an update of a review last published in 2014., Objectives, To assess the effects of pharmacological interventions or physical interventions given with the intention of reducing body temperature to 35 [degrees]C to 37.5 [degrees]C in adults and children admitted to hospital after TBI., Search methods, We searched the Cochrane Central Register of Controlled Trials (CENTRAL), MEDLINE, Embase, Web of Science, and PubMed on 28 November 2019. We searched clinical trials registers, grey literature and references lists of reviews, and we carried out forward citation searches of included studies., Selection criteria, We included randomised controlled trials (RCTs) with participants of any age admitted to hospital following TBI. We included interventions that aimed to reduce body temperature to 35 [degrees]C to 37.5 [degrees]C: these included pharmacological interventions (such as paracetamol, or non-steroidal anti-inflammatory drugs), or physical interventions (such as surface cooling devices, bedside fans, or cooled intravenous fluids). Eligible comparators were placebo or usual care., Data collection and analysis, Two review authors independently assessed studies for inclusion, extracted data, and assessed risks of bias. We assessed the certainty of the evidence with GRADE., Main results, We included one RCT with 41 participants. This study recruited adult participants admitted to two intensive care units in Australia, and evaluated a pharmacological intervention. Researchers gave participants 1 g paracetamol or a placebo intravenously at four-hourly intervals for 72 hours., We could not be certain whether intravenous paracetamol influenced mortality at 28 days (risk ratio 2.86, 95% confidence interval 0.32 to 25.24). We judged the evidence for this outcome to be very low certainty, meaning we have very little confidence in this effect estimate, and the true result may be substantially different to this effect. We downgraded the certainty for imprecision (because the evidence was from a single study with very few participants), and study limitations (because we noted a high risk of selective reporting bias). This study was otherwise at low risk of bias., The included study did not report the primary outcome for this review, which was the number of people with a poor outcome at the end of follow-up (defined as death or dependency, as measured on a scale such as the Glasgow Outcome Score), or any of our secondary outcomes, which included the number of people with further intracranial haemorrhage, extracranial haemorrhage, abnormal intracranial pressure, or pneumonia or other serious infections., The only other completed trial that we found was of a physical intervention that compared advanced fever control (using a surface cooling device) versus conventional fever control in 12 participants. The trial was published as an abstract only, with insufficient details to allow inclusion, so we have added this to the 'studies awaiting classification' section, pending further information from the study authors or publication of the full study report., We identified four ongoing studies that will contribute evidence to future updates of the review if they measure relevant outcomes and, in

studies with a mixed population, report data separately for participants with TBI., Authors' concl sions, One small study contributed very low-certainty evidence for mortality to this review. The uncertainty is largely driven by limited research into reduction of body temperature to 35 [degrees]C to 37.5 [degrees]C in people with TBI. Further research that evaluates pharmacological or physical interventions, or both, may increase certainty in this field. We propose that future updates of the review, and ongoing and future research in this field, incorporate outcomes that are important to the people receiving the interventions, including side effects of any pharmacological agent (e.g. nausea or vomiting), and discomfort caused by physical therapies.

3177. Li, D.-R., et al. (2006). "Postmortem serum protein S100B levels with regard to the cause of death involving brain damage in medicolegal autopsy cases." Legal medicine (Tokyo, Japan) **8**(2): 71-77.

The protein S100 is an acidic calcium-binding protein, and the subunit S100B is the most abundantly found in the brain. The aim of the present study was a comprehensive analysis of serum S100B levels in medicolegal autopsy cases (within 48 h postmortem, n = 283) including victims with head and non-head injuries and also non-injury fatalities with regard to the cause of death involving brain damage. The serum level was usually higher in the subclavian vein than in the right heart and external iliac vein, and the lowest in the left heart blood, showing no significant postmortem influence. The serum level in the right heart and subclavian vein was markedly higher for acute deaths from head injury and asphyxiation due to neck compression (strangulation and hanging), and moderately and mildly elevated for other blunt and sharp instrument injury cases, respectively. For head injury, the serum levels were lower for subacute deaths than for acute deaths. These observations suggest that the elevation of serum S100B may mainly be caused by leakage following massive brain damage due to injury and cerebral hypoxia/ischemia, and in part by systemic hypoxic/traumatic tissue damage, depending on the survival time.

3178. Li, L., et al. (2016). "Multidisciplinary Team Treatment of Penetrating Head and Neck Trauma." The Journal of craniofacial surgery **27**(6): e534-536.

Penetrating head and neck trauma could cause significant mortality because of many important structures located in the brain and neck. Although high-velocity penetrating brain injury is often reported, reports of low-velocity, combined head and neck penetrating injury are rare. Hereby, the authors present a case of an old man who had encountered a serious accident, a 29-cm iron fork penetrated into his neck, through the skull base and into brain. After treatment by multidisciplinary team, the patient was in rehabilitation. The multidisciplinary team assists rapid diagnosis and treatment of penetrating neck and head injury is the key to ensure a good outcome. Therefore, as the authors face such patients again, a multidisciplinary team is needed.

3179. Li, M., et al. (2013). "Bridging gaps between the recurrent laryngeal nerve and ansa cervicalis using autologous nerve grafts." Journal of voice : official journal of the Voice Foundation **27**(3): 381-387.

OBJECTIVES/HYPOTHESIS: We investigated the clinical efficacy of free nerve grafts in bridging gaps between the recurrent laryngeal nerve (RLN) and ansa cervicalis in patients with unilateral RLN injury., STUDY DESIGN: We retrospectively reviewed the charts of 14 patients who underwent relevant free nerve grafting and assessed the clinical outcomes of this procedure., METHODS: Between January 2000 and January 2010, 14 patients with unilateral vocal fold paralysis were enrolled in this study. In all patients, the RLN was resected and free nerve grafts were applied to bridge the gap between the distal stump of the RLN and the anterior root of ansa cervicalis during surgery. Videostroboscopy, acoustic analysis, perceptual evaluation, maximum phonation time (MPT), and laryngeal electromyography (EMG) were performed both preoperatively and postoperatively to assess the clinical outcomes., RESULTS: Videostroboscopic findings showed that glottic closure, vocal fold edge, vocal fold position, phase symmetry, and phase regularity were significantly improved postoperatively (P<0.05), and no paradoxical movements of vocal folds were observed. Perceptual evaluation showed that overall grade, roughness, breathiness, asthenia, and strain were also significantly decreased postoperatively (P<0.05). The acoustic parameters jitter (local) and shimmer (local) and the mean noise-to-harmonics ratio were significantly lower than the corresponding preoperative values (P<0.05). The postoperative MPT

values were also significantly longer than the preoperative values. Laryngeal EMG revealed significant improvement in voluntary motor unit recruitment during phonation postoperatively (P<0.05)., CONCLUSIONS: Free nerve grafting is an effective procedure in bridging the gap between the RLN and ansa cervicalis in patients with unilateral RLN injury, as well as a safe procedure without obvious morbidity. A satisfactory vocal outcome can be obtained.

3180. Li, M. S. and S. David (1996). "Topical glucocorticoids modulate the lesion interface after cerebral cortical stab wounds in adult rats." Glia **18**(4): 306-318.

A lesion interface, consisting of a glia limitans lined by a laminin-rich basal lamina and leptomeningeal cells, forms within 2-3 weeks after penetrating wounds to the adult mammalian central nervous system (CNS). This interface prevents the growth of axons across the lesion. We have examined the effects of topically applied steroids on the formation of such an interface after stab wounds to the adult rat cerebral cortex. Immediately after lesioning, the surface of cortex in the region of the wound was treated with a topical application of either 0.1% halcinonide or 0.05% betamethasone dipropionate or their respective placebos. Cryostat sections through the lesioned area were obtained 3 weeks later and assessed by immunofluorescence. Steroid treatment attenuated all components of the lesion. The continuous anti-laminin labeling along the lesion in untreated rats became patchy after steroid treatment. The number of leptomeningeal cells that infiltrated into the wound was reduced in the laminin-negative regions in steroid-treated rats. In addition, astrocytic processes in the laminin-negative regions after steroid treatment were loosely arranged, compared with the tightly packed parallel processes forming the glia limitans in laminin-positive regions in controls. The mechanism of steroid-mediated attenuation of the lesion interface was examined in vitro. Betamethasone but not halcinonide reduced laminin secretion slightly in leptomeningeal cell cultures, but both steroids reduced cell proliferation. These results suggest that steroids modulate the formation of the lesion interface after CNS injury, at least in part by decreasing leptomeningeal cell proliferation. Such modulation of the lesion interface by steroids or other agents may permit the growth of axons across the lesion site and thus could enhance the overall degree of axon regeneration if other factors such as neurotrophic support and neutralization of axon growth inhibitory molecules are optimized.

3181. Li, S.-X., et al. (2011). "[Advance in animal models of traumatic brain injury]." Fa yi xue za zhi **27**(4): 286-294.

Traumatic brain injury (TBI) is a highly complex multi-factorial disorder. Animal models of TBI are used to elucidate primary and secondary injury mechanisms and pathophysiological changes and to provide the diagnostic and therapeutical basis for TBI. The choices of animal models depend upon the research objectives. However, various animal models have limitations. The models only can duplicate the pivotal injury mechanisms or a certain important pathophysiological course. The characteristics of human TBI can not fully be reflected by using these models. In the review, animal models of traumatic brain injury are classified as dynamic direct brain injury, indirect dynamic brain injury and combined neuro-traumatic models. Several common models are described for consideration.

3182. Li, X., et al. (2012). "Intraspinal penetrating stab injury to the middle thoracic spinal cord with no neurologic deficit." Orthopedics **35**(5): e770-773.

The annual incidence of traumatic spinal cord injury worldwide is estimated to be 35 patients per million. Nonmissile penetrating spinal injuries most commonly occur in the thoracic region, and the majority has neurologic deficits on admission. The management of patients who lack neurologic deficits is controversial due to the risk of neurologic status alteration intraoperatively. However, failure to intervene increases the risk of infection, delayed onset of neurologic deficits, and worsening functional outcome.A 17-year-old boy presented with an intradural T7-T8 knife penetration injury to the spinal cord with no neurologic deficit. Rapid surgical intervention was critical because the knife was lodged between the 2 hemispheres of the spinal cord. The patient was intubated in the lateral position, transferred to the prone position on a Jackson table, and underwent surgical decompression with laminectomy 1 level above and below the injury site, removal of the knife blade in the original path of trajectory, and repair of the dural tear with a collagen matrix. The patient sustained no neurologic sequelae from the penetrating knife injury. He was able to ambulate at discharge and had no complications. To our knowledge, this is the only report of a patient with intradural spinal cord penetration by a foreign object (knife blade) presenting with a normal neurologic preoperative examination that persisted throughout the course of postoperative care.

3183. Li, X., et al. (2021). "Blood-Based Brain and Global Biomarker Changes after Combined Hypoxemia and Hemorrhagic Shock in a Rat Model of Penetrating Ballistic-Like Brain Injury." Neurotrauma reports **2**(1): 370-380.

Penetrating traumatic brain injury (pTBI) often occurs with systemic insults such as hemorrhagic shock (HS) and hypoxemic (HX). This study examines rat models of penetrating ballistic-like brain injury (PBBI) and HX+HS to assess whether the blood levels of brain and systemic response biomarkers phosphorylated neurofilament-heavy protein (pNF-H), neurofilament-light protein (NF-L), alphaII-spectrin, heat shock protein (HSP70), and high mobility group box 1 protein (HMGB1) can distinguish pTBI from systemic insults and guide in pTBI diagnosis, prognosis, and monitoring. Thirty rats were randomly assigned to sham, PBBI, HS+HX, and PBBI+HS+HX groups. PBBI and sham groups underwent craniotomy with and without probe insertion and balloon expansion, respectively. HX and HS was then simulated by blood withdrawal and fraction of inspired oxygen (FIO2) reduction. Biomarker serum concentrations were determined at one (D1) and two (D2) days post-injury with enzyme-linked immunosorbent assay (ELISA) methods. Axonal injury-linked biomarkers pNF-H and NF-L serum levels in PBBI groups were higher than those in sham and HX+HS groups at D1 and D2 post-injury. The same was true for PBBI+HX+HS compared with sham (D2 only for pNF-H) and HX+HS groups. However, pNF-H and NF-L levels in PBBI+HX+HS groups were not different than their PBBI counterparts. At D1, alphaII-spectrin levels in the HX+HS and PBBI+HS+HX groups were higher than the sham groups. alphaII-spectrin levels in the HX+HS group were higher than the PBBI group. This suggests HX+HS as the common insult driving alphaII-spectrin elevations. In conclusion, pNF-H and NF-L may serve as specific serum biomarkers of pTBI in the presence or absence of systemic insults. alphaII-spectrin may be a sensitive acute biomarker in detecting systemic insults occurring alone or with pTBI.

3184. Li, X. S., et al. (1998). "Induction of IGF-1 mRNA expression following traumatic injury to the postnatal brain." Brain research. Molecular brain research **57**(1): 92-96.

A variety of adult, non-neural tissues respond to injury by increasing expression of the gene which encodes for insulin-like growth factor-1 (IGF-1). This response is thought to be a key component in the regenerative capacity of these tissues. In contrast, the central nervous system (CNS) has relatively little regenerative capacity following injury. Interestingly, compared to many non-neuronal tissues, little IGF-1 mRNA can be detected in the adult CNS, raising the possibility that its lack of regenerative capacity is related its relative lack of IGF-1 expression. However, in the 2-week-old adolescent CNS IGF-1 mRNA can be detected in numerous brain regions. Therefore, the purpose of this study was to determine the responsiveness of the IGF-1 gene to injury in adolescent CNS tissue, a period in which expression of this gene is relatively abundant. Expression of IGF-1 mRNA was measured by means of a sensitive solution hybridization/RNase protection assay in the parieto-occipital lobes of 2-week-old and adult mice following penetrating injury. Levels of IGF-1 transcript in the injured brains were significantly increased above those of controls in both 2-week-old and adult brains 3-day post injury and remained elevated for 1 week after injury. These observations demonstrate that the adult CNS, like other tissues, can respond to injury by increasing expression of IGF-1 mRNA.

3185. Li, X.-S., et al. (2017). "Nonmissile Penetrating Head Injuries: Surgical Management and Review of the Literature." World neurosurgery **98**: 873.e879-873.e825.

BACKGROUND: Nonmissile penetrating head injuries (NPHIs) in the civilian population are rare but potentially fatal. Although numerous cases have been reported in the literature, the surgical management of such injuries is still ambiguous, especially with development of surgical techniques. Here, we report 5 cases of NPHIs managed with different surgical techniques and review the literature on surgical treatment of these injuries to outline the appropriate management for these patients from a neurosurgical perspective., METHODS: We retrospectively reviewed 5 cases of NPHIs managed surgically in our department. The clinical data were collected, including cause, type of objects, way of penetration, initial clinical evaluation, imaging, surgical intervention, postoperative care, complication, follow-up, and outcome. In addition, a systematic review of the literature was performed in the PubMed database to search for articles on surgical treatment of these injuries., RESULTS: These 5 cases were caused by twisted steel bar, electric welding rod, and sewing needle, respectively. Preoperative imaging, including computed tomography, magnetic resonance imaging, and digital subtraction angiography, was selectively performed to assist the operative plan. Foreign objects were removed surgically in all cases. Postoperative prophylactic administration of antibiotics and anticonvulsants was used to

prevent infectious and epileptic complications. Most of the patients achieved a better outcome except for one., CONCLUSIONS: NPHIs can be fatal but they can be managed with satisfactory results by proper preoperative imaging evaluation, rapid appropriate surgical management, and accurate postoperative care. Personalized surgical intervention should be undertaken depending on the mechanism and extent of the NPHI.

3186. Li, Y., et al. (2021). "Wearable Mixed-Reality Holographic Navigation Guiding the Management of Penetrating Intracranial Injury Caused by a Nail." Journal of digital imaging **34**(2): 362-366.

Penetrating brain injury caused by a nail is an extremely rare neurosurgical emergency that poses a challenge for neurosurgeons. Nail entering the brain from the orbit and lodging within the cranial cavity is even more unusual. A 53-year-old male was found unconscious at a construction site, and brain CT revealed not only the presence of a nail beneath the inner table of the parietal bone, but also traumatic intracerebral hematoma. Consequently, accurate localization of the nail and hematoma was mandatory for surgical plan. During surgical planning, computational model reconstruction and trajectory calculation were completed using preoperative CT in 3D Slicer. Under the guidance of a head-mounted mixed-reality holographic computer, the neurosurgeon was able to visualize and interact with the hologram of the surgical plan, and intraoperative findings demonstrated that our low-cost portable wearable mixed-reality holographic navigation assisted precise localization of the nail and intracerebral hematoma, assuring less injury to the already compromised brain. After the surgery, the patient could obey commands, and postoperative imaging ruled out the possibility of brain abscess during follow-up. To the best of our knowledge, this is the first report on using a low-cost wearable mixed-reality holographic navigation to guide the management of penetrating intracranial injury caused by a nail.

3187. Li, Y., et al. (2011). "Clinical research on surgery of inferior orbital wall fracture caused by gun or ammunition explosion." International Journal of Ophthalmology **11**(3): 498-499.

AIM: To investigate an effective treatment of craniofacial fracture patients in modern warfare for rapid recovery in normal face and physiological function. METHODS: Different parts of different pathological fractures were submitted to different treatment options: minimally invasive surgery, cosmetic incision and fixing method such as titanium mesh and plate were taken to different parts of the craniofacial fracture under the guidance of nasal endoscope; medical Earbrain cements (EC) was applied for reposition and fixation of craniofacial bone fragments. RESULTS: The patients could quickly return to normal face and physiological function after craniofacial fracture surgery. CONCLUSION: Different minimally invasive surgery, cosmetic incision and fixing method such as titanium mesh and plate endoscope-guidedly is a very effective method; application of EC for fracture reduction and fixation of craniofacial bone fragments can accelerate healing.

3188. Li, Y.-q., et al. (2003). "[Repair of facial defect with expanded skin flap from medial upper arm]." Zhonghua shao shang za zhi = Zhonghua shaoshang zazhi = Chinese journal of burns **19**(4): 223-225.

OBJECTIVE: To investigate the blood supply of the expanded skin flap from medial upper arm and its application on the reparation of facial defect due to scar resection., METHODS: The operation was carried out for three steps: 1) The expander was embed under the superior proper fascia. 2) The skin flap from medial upper arm was created with superior ulnar collateral artery as blood supply and attributive branches of basilic and axillary veins as blood collection and was grafted onto the facial defect. 3). After being separated from donor site, the skin flap was employed to cover the facial defect with maximal area of 15 x 10 cm(2)., RESULTS: Seven patients in all with facial scar and defects were managed with the skin flap. All the grafted skin flaps survived at last with nearly normal skin color, texture and contour. And the scar in donor sites seemed to be neglectable., CONCLUSION: Reparation of facial defects with medial upper arm skin flap after expanding could be recommended. But longer treatment time and some obsessive action of upper limbs and head might be disadvantages.

3189. Li, Z., et al. (2019). "Management of a Steel Bar Injury Penetrating the Head and Neck: A Case Report and Review of the Literature." World neurosurgery **123**: 168-173.

BACKGROUND: Nonmissile penetrating injuries to the head and neck caused by a steel bar are rare, and a standard management strategy is lacking., CASE DESCRIPTION: A 42-year-old woman sustained a steel bar injury with penetration of the head and neck. Computed tomography and three-dimensional reconstruction were performed for preoperative evaluation. Digital subtraction angiography was performed to confirm potential vascular injury. The steel bar was successfully removed through an open surgical procedure by a multidisciplinary team., CONCLUSIONS: Relevant literature regarding nonmissile penetrating injuries involving a steel bar was reviewed to propose appropriate management strategies. Comprehensive imaging evaluation and prompt surgery by a multidisciplinary team contributed to the successful removal of the steel bar.

3190. Li, Z., et al. (2001). "Gut barrier function damage following multiple firearm injuries in a porcine model." Chinese medical sciences journal = Chung-kuo i hsueh k'o hsueh tsa chih **16**(4): 209-213.

OBJECTIVE: To study the characteristics and pathogenesis of gut barrier damage following multiple firearm injuries in a porcine model., METHODS: Twenty-four small pigs were divided into 4 groups: control group (n = 6, group C), group H (n = 6, gunshot-induced tangential fracture of parietal bone), group L (n = 6, gunshot-induced comminuted fracture of bilateral femora) and group M (n = 6, combined group H + L). Gastric intramucosal pH (pHi), plasma endotoxin levels in portal vein, and plasma D-lactate levels were measured and blood samples were cultured at different intervals after trauma. The animals were sacrificed at 72 h following trauma and intestinal tissues were harvested for pathological examination and diamine oxidase (DAO) activity measurement., RESULTS: In group M at 72 h, pHi was significantly lower than that of group H and L ($P < 0.01$), and plasma endotoxin level was significantly higher than that of group H ($P < 0.01$) and group L ($P < 0.05$). Simultaneously, in group M, D-lactate level was markedly higher than that of group H ($P < 0.01$), and incidence of positive blood culture was much higher than that of group H and L ($P < 0.05$). Necrosis and exfoliation were revealed at ileum villus top in all trauma groups, especially in group M, in which ileum DAO activity declined most significantly as well., CONCLUSION: Multiple trauma is prone to cause gastrointestinal ischemia even without hemorrhagic shock. The damage of gut barrier in multiple trauma appears to be more severe than that in one-site trauma, thereby promoting gut-derived endotoxemia and bacterial translocation and contributing to the development of endogenous infection.

3191. Liang, B. (2000). "[Radiological study of orbital foreign body]." Yan ke xue bao = Eye science **16**(2): 116-117.

OBJECTIVE: To study the factors influencing of foreign body., METHODS: 527 cases of orbital foreign body was analysed and the relationship between foreign body and projection position or projection angle was retrospectively reviewed., RESULTS: Foreign body in 13 cases was found in the lateral radiogram(No foreign body in the posteroanterior radiogram). In 12 cases foreign body was found in the Belot's radiogram(No foreign body in P. A. and lateral radiognam). In ten cases foreign body was found in the Vogts radiogram (No foreign body in P. A., lateral, Belot's radiogram). In the first radiogram, one case was found to have foreign body in the Lateral but P. A. In the second radiogram, just the reverse of above., CONCLUSION: The image of foreign body was influenced by projection position and projection angle between foreign body and X-ray. The patients must take Belot's or Vogt's radiogram except routine P. A. and Lateral radiogram. Sometimes the patients should be taken more radiogram after moving the eye ball direction in order to find the small and flact foreign body.

3192. Liang, C., et al. (2016). "RNAi-mediated silencing of HLA A2 suppressed acute rejection against human fibroblast xenografts in the striatum of 6-OHDA lesioned rats." Journal of neuroimmunology **297**: 28-37.

Major histocompatibility complex class l (MHC I) molecules play a role in determining whether transplanted cells will be accepted or rejected, and masking of MHC I on donor cells has been found useful for immunoprotection of neural xenografts. In the present study, primary human embryonic lung fibroblasts (HELF), HELF treated with lentivirus-mediated small interfering RNAs (siRNAs) targeting human leukocyte antigen A2 (HLA A2, MHC I in humans) (siHELF), and rat embryonic lung fibroblasts (RELF) were stereotaxically grafted into the striatum of 6-hydroxydopamine lesioned rats to explore whether knockdown of HLA A2 could reduce host immune responses against xenografts. Before lentiviral infection, the cells were transduced with retroviruses harboring tyrosine hydroxylase cDNA. Knockdown of HLA A2 protein was examined by Western blotting. The immune responses (the number of CD4 and CD8 T-cells in the brain and peripheral blood), glial reaction, and survival of human fibroblasts were quantitatively evaluated by flow cytometry and immunohistochemistry at 4d, 2w, and 6w post-graft. Animal behaviors were assessed by counting apomorphine-induced

rotations pre- and post-grafts. It was shown that a lower level of HLA A2 was observed in siHELF grafts than in HELF grafts, and knockdown of HLA A2 decreased rat immune responses, as indicated by less remarkable increases in the number of CD8 and CD4 T-cells in the brain and the ratio of CD4:CD8 T-cells in the peripheral blood in rats grafted with siHELF. Rats grafted with siHELF exhibited a significant improvement in motor asymmetry post-transplantation and a better survival of human fibroblasts at 2w. The increasing number of activated microglia and the decreasing number of astrocytes were found in three groups of rats post-implantation. These data suggested that RNAi-mediated knockdown of HLA A2 could suppress acute rejection against xenogeneic human cell transplants in the rat brain.

3193. Liang, C.-C., et al. (2004). "Reconstruction of traumatic Stensen duct defect using a vein graft as a conduit: two case reports." Annals of plastic surgery **52**(1): 102-104.

Treatment of Stensen duct defect is still controversial. The authors describe the successful use of a retrograde vein graft as a conduit for traumatic segmental Stensen duct defect reconstruction. One patient sustained facial trauma with severe duct crushing and severance, the other had multiple cutting injuries with segmental duct defect. However, primary repair was impossible. A retrograde vein graft harvested from forearm for Stensen duct defect reconstruction was performed using microsurgical technique. A silicon stent was retained for 8 weeks. The sialographic examination showed good functional results without stricture postoperatively. This could be an option for treating such a complicated defect.

3194. Liao, Y., et al. (2013). "Rescuing the neonatal brain from hypoxic injury with autologous cord blood." Bone marrow transplantation **48**(7): 890-900.

Brain injury resulting from perinatal hypoxic-ischemic encephalopathy (HIE) is a major cause of acute mortality in infants and chronic neurologic disability in surviving children. Recent multicenter clinical trials demonstrated the effectiveness of hypothermia initiated within the first 6 postnatal hours to reduce the risk of death or major neurological disabilities among neonates with HIE. However, in these trials, approximately 40% of cooled infants died or survived with significant impairments. Therefore, adjunct therapies are required to improve the outcome in neonates with HIE. Cord blood (CB) is a rich source of stem cells. Administration of human CB cells in animal models of HIE has generally resulted in improved outcomes and multiple mechanisms have been suggested including anti-inflammation, release of neurotrophic factors and stimulation of endogenous neurogenesis. Investigators at Duke are conducting studies of autologous CB infusion in neonates with HIE and in children with cerebral palsy. These pilot studies indicate no added risk from the regimens used, but results of ongoing placebo-controlled trials are needed to assess efficacy. Meanwhile, further investigations are warranted to determine the best strategies, that is, timing, dosing, route of delivery, choice of stem cells and ex vivo modulations, to attain long-term benefits of CB stem cell therapy.

3195. Lichte, P., et al. (2010). "A civilian perspective on ballistic trauma and gunshot injuries." Scandinavian journal of trauma, resuscitation and emergency medicine **18**: 35.

BACKGROUND: Gun violence is on the rise in some European countries, however most of the literature on gunshot injuries pertains to military weaponry and is difficult to apply to civilians, due to dissimilarities in wound contamination and wounding potential of firearms and ammunition. Gunshot injuries in civilians have more focal injury patterns and should be considered distinct entities., METHODS: A search of the National Library of Medicine and the National Institutes of Health MEDLINE database was performed using PubMed., RESULTS: Craniocerebral gunshot injuries are often lethal, especially after suicide attempts. The treatment of non space consuming haematomas and the indications for invasive pressure measurement are controversial. Civilian gunshot injuries to the torso mostly intend to kill; however for those patients who do not die at the scene and are hemodynamically stable, insertion of a chest tube is usually the only required procedure for the majority of penetrating chest injuries. In penetrating abdominal injuries there is a trend towards non-operative care, provided that the patient is hemodynamically stable. Spinal gunshots can also often be treated without operation. Gunshot injuries of the extremities are rarely life-threatening but can be associated with severe morbidity.With the exception of craniocerebral, bowel, articular, or severe soft tissue injury, the use of antibiotics is controversial and may depend on the surgeon's preference., CONCLUSION: The treatment strategy for patients with gunshot injuries to the torso mostly depends on the hemodynamic status of the patient. Whereas hemodynamically unstable patients require immediate operative measures like thoracotomy or laparotomy,

hemodynamically stable patients might be treated with minor surgical procedures (e.g. chest tube) or even conservatively.

3196. Lichter, H., et al. (1999). "Penetrating orbitocranial knife injury." Journal of pediatric ophthalmology and strabismus **36**(1): 44-46.

3197. Lidin, E., et al. (2022). "Hippocampal Expression of Cytochrome P450 1B1 in Penetrating Traumatic Brain Injury." International journal of molecular sciences **23**(2).

Hippocampal dysfunction contributes to multiple traumatic brain injury sequala. Female rodents' outcome is superior to male which has been ascribed the neuroprotective sex hormones 17beta-estradiol and progesterone. Cytochrome P450 1B1 (CYP1B1) is an oxidative enzyme influencing the neuroinflammatory response by creating inflammatory mediators and metabolizing neuroprotective 17beta-estradiol and progesterone. In this study, we aimed to describe hippocampal CYP1B1 mRNA expression, protein presence of CYP1B1 and its key redox partner Cytochrome P450 reductase (CPR) in both sexes, as well as the effect of penetrating traumatic brain injury (pTBI). A total 64 adult Sprague Dawley rats divided by sex received pTBI or sham-surgery and were assigned survival times of 1-, 3-, 5- or 7 days. CYP1B1 mRNA was quantified using in-situ hybridization and immunohistochemistry performed to verify protein colocalization. CYP1B1 mRNA expression was present in all subregions but greatest in CA2 irrespective of sex, survival time or intervention. At 3-, 5- and 7 days post-injury, expression in CA2 was reduced in male rats subjected to pTBI compared to sham-surgery. Females subjected to pTBI instead exhibited increased expression in all CA subregions 3 days post-injury, the only time point expression in CA2 was greater in females than in males. Immunohistochemical analysis confirmed neuronal CYP1B1 protein in all hippocampal subregions, while CPR was limited to CA1 and CA2. CYP1B1 mRNA is constitutively expressed in both sexes. In response to pTBI, females displayed a more urgent but brief regulatory response than males. This indicates there may be sex-dependent differences in CYP1B1 activity, possibly influencing inflammation and neuroprotection in pTBI.

3198. Lieb, A. S., et al. (1997). "Tetraparesis due to vertebral physeal fracture in an adult dog with congenital hypothyroidism." The Journal of small animal practice **38**(8): 364-367.

A four-year-old male affenpinscher was referred for evaluation of hindlimb weakness that had progressed to tetraparesis over a period of four weeks. Neurological examination was suggestive of a cervical spinal cord lesion. Radiographic examination revealed diffuse skeletal immaturity with open physes and epiphyseal dysplasia in long bones and vertebrae, consistent with a diagnosis of congenital hypothyroidism. Total and free serum T4 concentrations were very low, indicative of hypothyroidism. Survey radiographs of the cervical spine revealed a dorsally displaced Salter-Harris type I fracture of the cranial portion of the fourth cervical vertebra with the endplate present in the vertebral canal. Although signs of transverse myelopathy are uncommon in dogs with congenital hypothyroidism, they may be associated with either intervertebral disc protrusion or endplate displacement into the vertebral canal secondary to the epiphyseal abnormalities associated with congenital hypothyroidism.

3199. Liebenberg, W. A., et al. (2005). "Penetrating civilian craniocerebral gunshot wounds: a protocol of delayed surgery." Neurosurgery **57**(2): 293-299.

OBJECTIVE: Several factors have led to our unique approach of delayed definitive debridement. We wanted to evaluate the effectiveness of our management and compare it with the existing data in the literature., METHODS: We retrospectively reviewed the records of 194 patients presenting between January 1996 and October 2003 with penetrating craniocerebral gunshot wounds. After exclusion criteria, 125 patients qualified., RESULTS: Of the patients, 88.8% were male. The mean age was 24.9 +/- 10.9 years. In 70.4% of patients, the presenting Glasgow Coma Scale (GCS) score was 3 to 8. Only 38 (30.4%) of the 125 patients survived, with poor outcome in 2 and good outcome in 36. Bilaterally fixed and dilated pupils and bihemispheric tract on computed tomographic scan were significantly related to poor outcome. There were 49 surgical procedures performed on 27 of the patients, with a mortality rate of 7.4%. Of the 38 survivors, 13 underwent no surgery. Average time to surgery was 11.04 days. Total rate of infection was 8%, and it did not influence outcome. No patient presenting with a GCS score of 3 or 4 survived. Seventeen patients attended follow-up, for a total of 3609 days (average, 212 d) and very few late complications., CONCLUSION: Our supportive care

of patients is not optimal. We should have saved more of our patients who presented with GCS scores of 14 and 15 who subsequently died. We have been able to report unconventionally late surgical management of two-thirds of survivors, with no surgery in one-third of survivors. Despite a high rate of infectious complications, infection did not lead to death or disability. Our protocol rarely leads to patients surviving in a permanently vegetative state. In the future, we would perform early surgery for patients who present awake and continue our current management for poor-grade patients. In this way, we will improve the number of good outcomes without increasing the population of severely damaged and dependent survivors.

3201. Liebman, K. M., et al. (1996). "Endovascular management of aneurysm and carotid-cavernous fistulae from gunshot wounds to the skull base and oropharynx." The Journal of cranio-maxillofacial trauma **2**(2): 10-16.

The clinician must be aware of the potential for vascular injury that can result from gunshot wounds to the skull base and oropharynx. These lesions can be life-threatening or can result in irreversible neurologic defects. The goal is early diagnosis and efficient appropriate treatment. Endovascular therapy has been proven to be of great benefit for the treatment of traumatic aneurysms and carotid-cavernous fistulae. Utilizing either a reconstructive or a deconstructive approach, the traumatic lesions can be treated without the morbidity inherent to surgery of the skull base or cavernous sinus. This article discusses the authors' experience with endovascular treatment, explaining in detail the reconstructive and deconstructive approaches and providing clinical examples of the treatment of pseudoaneurysms and carotid-cavernous fistulae.

3202. Lignitz, E. and B. Madea (1994). "[Gunshot injuries in the orbital area]." Einschussverletzungen im Bereich der Orbita. **193**(5-6): 139-146.

Report on 4 cases with gunshot entrance wounds of the orbit or of periorbital regions. Among these cases is a certain suicide as well as a homicide where the physicians misdiagnosed the real cause of the perforating injury of the bulbus. In cases with single gunshot wounds and entrance in the orbit the diagnostic decision suicide or homicide may be impossible based alone on the anatomic findings.

3204. Liliav, B. and R. Kalimuthu (2012). "Mantle design: a composite construct for orbital floor reconstruction." The Journal of craniofacial surgery **23**(4): 1125-1126.

We present a unique case of orbital floor and wall reconstruction after complete destruction by a self-inflicted gunshot wound. The complex comminuted fracture was repaired using a composite construct design (the mantle design) that was fixed in place using mini plates and screws. The designed composite graft was shaped exactly to fit the area of the orbital floor and maxilla to create stability and support for the globe. The orbital floor and maxilla were repaired using this special design, which was created based on the basic physical principles of mantle constructs that have been known for many years to be strong, durable, and stable. After surgery, radiologic evaluation revealed excellent placement of our construct. This particular reconstruction method may be used in patients with severe orbital bony destruction with no surrounding stable bony support elements, which are required to reconstruct the orbital floor in patients with trauma using either an autologous or a biologic implant.

3205. Lillard, P. L. (1978). "Five years experience with penetrating craniocerebral gunshot wounds." Surgical neurology **9**(2): 79-83.

This report reviews the clinical course and treatment of 83 cases of civilian penetrating craniocerebral gunshot wounds seen over a five-year period. The factors that determine mortality and morbidity are discussed. A conservative surgical approach in neurologically intact or less severely injured patients is re-emphasized. Increased intracranial

pressure appears to be a significant factor in more severely injured patients, and should be monitored and treated vigorously.

3206. Lim, B. X., et al. (2018). "Microbial characteristics of post-traumatic infective keratitis." European journal of ophthalmology **28**(1): 13-18.

PURPOSE: To determine the demographics, risk factors, clinical and microbiological characteristics, and treatment outcome of post-traumatic infective keratitis., METHODS: Consecutive patients with post-traumatic infective keratitis presenting to the Ophthalmology Department of a tertiary referral hospital in Singapore between March 2012 and March 2016 were prospectively identified. A standardized data collection form was used to document patient demographics, microbiological diagnosis, antibiotic sensitivity, and pretreatment and posttreatment ocular characteristics. Any contact lens-induced keratitis was excluded from the study., RESULTS: In total, 26 patients were included for analysis. The mean age was 40.0 years (SD +/- 19.4) and 84.6% of the patients were male. The majority of the patients (69.2%, n = 18) had sustained work-related injury in their eyes. Gram-negative organisms were predominant isolates (75.0%, n = 12) in culture-positive corneal scrapings (n = 16). Pan-sensitive Pseudomonas aeruginosa was the commonest organism isolated among the culture-positive cases (56.2%, n = 9). Three patients (18.7%) had developed fungal keratitis and Acanthamoeba was isolated in 1 patient (6.2%) with polymicrobial keratitis. Infections resolved with medical treatment in 22 eyes (84.6%) and 4 eyes (15.3%) required therapeutic corneal transplantation., CONCLUSIONS: A shift of practice in post-traumatic infective keratitis should be considered in tropical countries to include Gram-negative cover. Work safety practices with vigilance in initiating treatment and education by front-line physicians such as ophthalmology and general practitioners should be reinforced.

3207. Lim, J., et al. (2017). "Use of patient specific hardware in panfacial gun shot wound trauma." Journal of oral and maxillofacial surgery **75**(10): e410-e411.

Panfacial injuries from gunshot wounds present a challenge to even the most seasoned facial trauma surgeons. Military surgeons documented experience comprise conventional treatment of pan facial injury from gunshot wound. The civilian/ noncombat experience has roots in military medicine. Additionally, evolving technology, virtual surgical planning (VSP), selective laser melting (SLM) custom plates are now available at our disposal. Our case report describes pre-surgical planning with VSP and fabrication of predetermined dimensions and contoured custom SLM plate. With such preparation we were able to lessen the intraoperative burden with a shortened general anesthesia time and provided predictable surgical outcomes. Patient was arrived to level 1 trauma center as level 1 trauma alert. Patient was triaged via standard ATLS protocol. Initial treatment of irrigation and debridement, and application of external fixation (Ex-Fix) was performed. CT face of post debridement and Ex-Fix was obtained with 1mm cuts. This imaging information was electronically transferred to 3D Systems Healthcare (3D Systems Healthcare, Littleton, Colorado). All reduction was planned virtually. Reduced dimensions were then utilized to fabricate SLM custom plates (KLS Martin, Jacksonville, FL). Custom plate system included surgical guides for predrilling, zygomaticofrontal suture plate, anterior maxilla plate, mandible recon plate. Post-operative CT scan shows reduction of fracture identical to VSP as planned. 6 month follow-up reveals stable facial dimensions and reconstruction. The patient has returned to normal activities of daily living. Intraoperatively, considerable time was spent to negotiate fibrotic scar tissue to develop soft tissue envelope for the hardware, as well as mobilizing fractured segments. A limitation of VSP lies in the prediction of the soft tissue envelope. However, this surgical obstacle was expected with re-entering at 2 weeks post injury. VSP and SLM custom platting system may provide a superior treatment option to conventional techniques. The biggest challenge of VSP and SLM plating system in this particular application is that current manufacturing turnaround time is approximately 2 weeks, from planning to operating theater. The 2- week delay of treatment can result in additional operative time spent to negotiate fibrotic tissue. This challenges the goal of shortening general anesthesia time. However, there are still benefits of virtual preplanning, including less intraoperative decision making and high precision reduction of fractures. As with any commercial product and services, we expect to see shorter turnaround time of these resources as VSP and SLM custom plating system is more widely utilized and as the market matures. By streamlining the process such as organizing VSP, manufacture of SLM plates and surgical guides (possible domestic or local manufacture), and transportation, these resources may become available with lower turnaround time. Then VSP and SLM plating system may be more feasible and universally embraced for cases such as ours. Currently, VSP and SLM plating system may be reserved for patients with extensive facial fractures and comorbidities that preclude immediate definitive surgical intervention.

3208. Lim, L. W., et al. (2007). "Iatrogenic traumatic brain injury: penetration of Kirschner's knitting needle into the middle cranial cavity." The Journal of craniofacial surgery **18**(3): 674-679.

Traumatic penetrations of foreign objects into the craniocerebral cavity are often encountered in the department of emergency and traumatology. A 5-year-old child was brought to the department of pediatric neurosurgery with a severe headache and fatigue. On admission, the patient had initial neurologic examinations and radiologic scans. The consciousness assessment by Glasgow Coma Scale was 13. Neuroradiologic studies revealed a long hyperdense object extending from the extracranial cavity into the middle cranial fossa. A thorough history was obtained with attention to how and when the injury was sustained. Two weeks before the incident, the child had a blunt trauma of mandibular fractures with dislocation of the temporomandibular joint. Maxillomandibular surgery was performed with a Kirschner's knitting needle to fixate the temporomandibular articulation and simple interdental ligatures for mandibular fracture stabilization. The present radiologic film suggested that the mandibular fracture was not properly fixated allowing the mobilization of Kirschner's needle moving either externally or internally. A standard pterional access with frontotemporosphenoidal approach was performed according to the method of Yasargil and Oikawa-Miyazawa followed by an extradural approach method of Dolenc to the middle cranial structure at the skull base. Several stages of hemostasis were carried out with electrohemocoagulation on the penetrated Kirschner's needle during the needle extracting process at the extradural space of the middle cranial fossa. Two weeks postoperatively, computed tomography scan revealed the supratentorial and middle craniocerebral structures were in symmetric localization. The patient was free of neurologic deficits with no signs of excessive cerebrospinal fluid volume formation. In conclusion, the method of fixation requires appropriate application techniques to ensure adequate fracture fixation during the healing cascade. The neurosurgical approach also requires a specific measure on its management and rehabilitation for the maintenance of such a patient.

3209. Lim, M., et al. (2001). "An unusual case of ocular self-injury." Eye (London, England) **15**(Pt 5): 660-661.

3211. Limaiem, R., et al. (2013). "An unusual clinical presentation of ocular trauma in a child." International ophthalmology **33**(1): 87-89.

To report an unusual clinical presentation of ocular trauma in a child. Observational case report used in this study. A 12 year-old previously healthy boy presented with decreased vision and corneal opacity in the right eye following a punch in the face three years earlier. At presentation, his vision in the right eye was counting fingers. Ophthalmologic examination of the right eye revealed paracentral Descemet's membrane detachment and slit-lamp examination showed corneal opacity occupying almost 80 % of the corneal surface. In addition, there was a corneal white liquid collection communicating with the anterior chamber. The contralateral eye was within normal limits. The patient underwent penetrating keratoplasty. Bacteriological cultures of the corneal liquid did not reveal the presence of germs. The post-operative course was uneventful, the graft was clear and there was no evidence of graft rejection or failure. Visual acuity in the operated eye was 5/10. At present, the patient is still being followed up. The authors believe that this case is unique since Descemet's membrane detachment with liquid collection and corneal opacification has never been reported in literature to date.

3212. Limb, R. and M. Hunn (2020). "Management of penetrating anterior skull base injury from transnasal foreign body." Journal of Neurological Surgery, Part B Skull Base **81**.

We report the unusual case of a 35-year-old man who presented post self-insertion of a foreign body (a toothbrush with the bristled end snapped off) transnasally while suffering from a drug-induced psychosis. The tip of the retained object extended intracranially as far as the right foramen of Munro and caused unilateral obstructive hydrocephalus requiring emergency external ventricular drain insertion. There was no evidence of significant intracranial hemorrhage on initial imaging but the postcommunicating segments of both anterior cerebral arteries were significantly displaced by the object. After deliberating the safest surgical approach, we elected to perform a bifrontal craniotomy to

approach the anterior fossa floor inter-hemispherically, to gain proximal control of the anterior cerebral arteries and protect them from laceration. Once this was achieved, the foreign body was removed transnasally by the ENT surgeon, who had performed prior ligation of the ipsilateral anterior ethmoidal artery to prevent catastrophic nasal hemorrhage. Nasoendoscopy revealed surprisingly little damage to the nasal cavity. The skull base defect was repaired utilizing split calvarial bone graft obtained during the craniotomy, and a vascularized pericranial flap. Postoperatively the patient did not develop a CSF leak and displayed no signs of meningitis. His psychosis self-resolved within two weeks postoperatively and he was discharged home after a 2- week course of intravenous antibiotics and with psychiatry input. A delayed postoperative MRI demonstrated no obvious abscess, empyema or cerebral infarction. On review of the literature, such extreme cases of skull base penetrating injury appear to be rare and there is little technical advice available on optimal surgical strategies. This case provides an opportunity to discuss the management of such injuries and adds to a currently scarce body of knowledge on the topic. (Figure Presented) .

3213. Lin, C. and M. Lind (2017). "Pediatric intraoral trauma and neurologic sequela." Otolaryngology - Head and Neck Surgery (United States) **157**(1): P278.

Objectives: To describe a case of penetrating intraoral injury resulting in internal carotid artery (ICA) thrombosis and neurologic sequela in a pediatric patient. To recognize appropriate management and intervention for intraoral trauma. Methods: A 3-year-old boy presented to our pediatric tertiary medical center with a penetrating intraoral injury sustained when he fell off of a bed with a pencil in his mouth. This resulted in penetration of the pencil lateral to the right maxillary molars. Initial imaging revealed the foreign body within the masticator space and abutting the ICA at the level of the jugular foramen. On initial evaluation, he was neurologically intact. Additional radiologic evaluation with a computed tomography angiogram revealed thrombosis of the ICA from just distal to the carotid bifurcation to the level of the skull base. Results: After consultation with neurosurgery and interventional radiology, the foreign body was removed in the operating room without significant bleeding. The child was started on anticoagulation and antibiotics. Subsequent magnetic resonance angiography revealed thrombosis in the right middle cerebral artery. The patient developed left hemiplegia on postoperative day (POD) 1. The child regained left-sided strength over the next week and was discharged on POD8 with physical therapy. Conclusions: While pediatric intraoral trauma rarely results in vascular injury and neurologic sequelae, imaging is needed in cases of penetrating trauma for timely diagnosis of thrombosis and medical and surgical intervention. Patients with internal carotid thrombosis can initially present in the “lucid interval” without neurologic symptoms and become symptomatic several hours to days later.

3214. Lin, C. H., et al. (2001). "Microsurgical tissue transplantation or replantation in patients with psychoneurological impairment." Plastic and reconstructive surgery **108**(5): 1211-1217.

Sometimes patients with a psychoneurological impairment present with a traumatic injury that requires either microsurgical replantation or free-tissue transfer. We reviewed 38 patients undergoing 40 microvascular operations; the patients included 26 patients with psychological impairment (group 1), 3 with mental disability (group 2), and 9 with an acquired head injury and consciousness disturbance (Glasgow Coma Scale score < or =14) (group 3). Patients with a psychological impairment, especially those with a self-inflicted injury, are often uncooperative and do not recognize the necessity of restorative procedures. A multidisciplinary approach by the trauma surgeon, plastic surgeon, psychiatrist, and neurosurgeon, with coordinated assistance from the physician, nurse, therapist, and family, is required for treatment. In our study the success rate of replantation was 77.8 percent (14 of 18); for free tissue transfer the success rate was 95.5 percent (21 of 22). The overall success rate of microsurgical procedures (87.5 percent, 35 of 40) was similar to that in the population at large. Patients with psychological impairment tend to be lost during follow-up; therefore, their functional results may be poorer than expected. Nonetheless, patients with psychological impairment should not be deprived of the benefits of restorative surgery.

3215. Lin, H.-L., et al. (2007). "Management of transorbital brain injury." Journal of the Chinese Medical Association : JCMA **70**(1): 36-38.

Transorbital brain injuries caused by metal bar penetration are uncommon and often cause serious damage without prompt treatment. Artifacts caused by the penetrating metal bar on computed tomography (CT) often obscure the actual brain damage along the path of penetration, and delayed treatment for the brain insult may result. We present 2 cases of transorbital brain injury following penetration by a metal bar. CT scans were initially performed on

both patients. However, image resolution was poor and the extent of brain damage could not be ascertained due to severe artifacts associated with the metal bars. Both patients deteriorated in the emergency room and subsequently received surgical intervention. One patient recovered uneventfully. Unfortunately, the other patient died following surgery due to an unrecognized intracranial hemorrhage with brain herniation. Based on this experience, we recommend prompt surgical decompression with early CT follow-up to determine the true extent of brain damage and assess for possible delayed events inpatients with extended transorbital brain injuries caused by metal bars.

3216. Lin, N., et al. (2016). "Treatment of distal anterior circulation aneurysms with the pipeline embolization device: A US multicenter experience." Clinical neurosurgery **79**(1): 14-22.

Background: Utilization of the Pipeline embolization device (PED) to treat distal carotid circulation aneurysms has not been well studied. OBJECTIVE: To report the collective experience of using PED to treat distal anterior circulation aneurysms. METHODS: We retrospectively reviewed clinical and radiographic records of all patients who underwent Pipeline embolization of distal anterior circulation aneurysms at 10 US neurosurgical centers between 2011 and 2013. RESULTS: Twenty-eight patients (mean age 51.7 years; 18 women) with 28 aneurysms were included in the analyses. Fifteen aneurysms were fusiform, 5 dissecting, and 8 saccular. Average aneurysm size was 12.3 mm; 7 were giant. Twenty aneurysms were located along the middle cerebral artery, 6 along the anterior cerebral artery, and 2 along the anterior communicating artery. PED deployment was successful in 27 patients, with coils utilized in 6 cases. Clinical follow-up was available for an average of 10.7 months (range 3-26). Twenty-seven patients had follow-up neurovascular imaging: 21 aneurysms had complete occlusion, 4 had residual neck filling, and 2 had residual dome filling. Periprocedural complications (<30 days) occurred in 3 patients (10.7%), including 1 case of device failure resulting in stroke. Outcomes were good (modified Rankin Scale score 0 to 2) in 27 patients (96.4%) and fair (modified Rankin Scale 3) in 1. CONCLUSION: PED can be utilized in the treatment of distal anterior circulation aneurysms with difficult anatomy for conventional surgical or endovascular techniques. Larger-scale studies with long-term follow-up are needed to further elucidate the durability of PED treatment and its effect on perforator-rich vascular segments.

3217. Lin, V. W., et al. (2010). "Rehabilitation for a facial transplant patient: A case report." PM and R **2**(9): S36-S37.

Patients or Programs: A 46-year-old woman who sustained a gunshot wound to the face in 2004. Program Description: The patient had 23 reconstructive surgeries before near-total face transplant surgery in December 2008. Before the transplant, she required assistance for activities of daily living (ADL), community mobility, ate a pureed diet, had no sense of smell, and had a tracheotomy. Social interaction was nearly impossible, due to devastating facial disfigurement, including a lack of a nose and maxilla. Setting: Tertiary care hospital. Results: PM&R, physical, occupational, and speech therapy consults were initiated 7 days after surgery. Baseline deficits included no right eye, legal blindness in left eye, tracheostomy and gastrostomy tubes. She used written word, head nods/shakes, and hand gestures for expressive communication. She had no deficits in receptive communication or cognition. Her ICU goals included functional mobility and ADLs to minimal assist in 2 weeks, nutrition with PEG feeding, the use of a beside commode, functional transfers, performance of all light ADLs and retraining in basic facial expressions such as smiling, frowning, and opening/closing eyes. She was discharged to a surgical unit 22 days after surgery. She accomplished mastery of her ADL, including dressing and toileting in the bathroom. She resumed grooming, including brushing and braiding her long hair. Bathing, facial grooming, and feeding were initially restricted due to concern for infection in a host under immunosuppressive therapy. She vocalized after capping the tracheostomy but continued to use the white board for complex communication. With a screen reader, she read books and handouts. After surgical placement of an obturator prosthesis, her speech improved. She began olfactory reeducation and feeding training. Within 2 weeks, she could identify smells of coffee and perfume, and began to drink coffee and eat full pureed meals with set up. Conclusions: 10 weeks after facial transplant, the patient made significant improvement in mobility, ADLs and communication skills, and was discharged from the hospital.

3218. Lindeman, R. C. (1979). "Temporal bone trauma and facial paralysis." Otolaryngologic clinics of North America **12**(2): 403-413.

Temporal bone trauma includes a wide range of injuries of greater and lesser severity, most of which require the immediate attention of an otolaryngologist. The most common temporal bone injuries encountered in an emergency room setting include longitudinal and transverse fractures of the temporal bone with and without facial paralysis,

labyrinthine concussion, foreign bodies in the external canal, penetrating injuries via the external auditory canal, and pressure injuries, including otitic barotrauma, water skiing accidents, blows or slaps to the ear or side of the head, and severe impact noise. A brief but inclusive examination can be performed within the limitations necessarily imposed by an emergency room setting. Cranial nerve screening, balance testing, hearing, and vestibular evaluation can be accomplished with a considerable degree of accuracy. To a large extent, the long term result reflects the quality of the initial examination.

3219. Linden, J. A. and G. S. Renner (1995). "Trauma to the globe." Emergency medicine clinics of North America **13**(3): 581-605.

Trauma to the globe is a common problem seen in the emergency department that may lead to significant permanent visual disability. Common causes of globe trauma include motor vehicle crashes, assaults, falls, and sports-related and occupational injuries. Rapid collection of accurate historical data, expedient physical examination, evaluation, and treatment are of paramount importance in preserving visual capacity. This article summarizes the initial diagnostic and therapeutic approach, important prognostic indicators, and delayed complications of the traumatized globe. Accurate diagnosis and proper disposition are vital in salvaging visual capacity.

3220. Lindfors, M., et al. (2019). "Prognostic performance of computerized tomography scoring systems in civilian penetrating traumatic brain injury: an observational study." Acta neurochirurgica **161**(12): 2467-2478.

BACKGROUND: The prognosis of penetrating traumatic brain injury (pTBI) is poor yet highly variable. Current computerized tomography (CT) severity scores are commonly not used for pTBI prognostication but may provide important clinical information in these cohorts., METHODS: All consecutive pTBI patients from two large neurotrauma databases (Helsinki 1999-2015, Stockholm 2005-2014) were included. Outcome measures were 6-month mortality and unfavorable outcome (Glasgow Outcome Scale 1-3). Admission head CT scans were assessed according to the following: Marshall CT classification, Rotterdam CT score, Stockholm CT score, and Helsinki CT score. The discrimination (area under the receiver operating curve, AUC) and explanatory variance (pseudo-R2) of the CT scores were assessed individually and in addition to a base model including age, motor response, and pupil responsiveness., RESULTS: Altogether, 75 patients were included. Overall 6-month mortality and unfavorable outcome were 45% and 61% for all patients, and 31% and 51% for actively treated patients. The CT scores' AUCs and pseudo-R2s varied between 0.77-0.90 and 0.35-0.60 for mortality prediction and between 0.85-0.89 and 0.50-0.57 for unfavorable outcome prediction. The base model showed excellent performance for mortality (AUC 0.94, pseudo-R2 0.71) and unfavorable outcome (AUC 0.89, pseudo-R2 0.53) prediction. None of the CT scores increased the base model's AUC ($p > 0.05$) yet increased its pseudo-R2 (0.09-0.15) for unfavorable outcome prediction., CONCLUSION: Existing head CT scores demonstrate good-to-excellent performance in 6-month outcome prediction in pTBI patients. However, they do not add independent information to known outcome predictors, indicating that a unique score capturing the intracranial severity in pTBI may be warranted.

3221. Lindner, D., et al. (2004). "Unusual penetrating cranio-orbital injury by a cut-off wheel." The Journal of craniofacial surgery **15**(2): 226-228.

The rare case of a penetrating cranio-orbital injury and the surgical treatment is presented. A 38-year-old woman was brought to the Emergency Unit of the University of Leipzig Hospital after suffering a severe craniocerebral injury from a broken cut-off wheel. A computed tomography (CT) scan demonstrated the entrance of the cut-off wheel with extension from the left sinus maxillaris and frontalis through the median part of the left-sided orbit to the anterior skull base. After removing the cut-off wheel and metal splinters, the neurosurgeon performed an osteoplastic bifrontobasal trepanation with revision of the wound channel. Three years later, the patient has no neurological deficit and the CT scan shows a small hypodensity behind the sinus frontalis on the left side.

3223. Ling, E. A. (1979). "Electron microscopic study of macrophages appearing in a stab wound of the brain of rats following intravenous injection of carbon particles." Archivum histologicum Japonicum = Nihon soshikigaku kiroku **42**(1): 41-50.

Colloidal carbon was introduced intravenously into young rats to label circulating monocytes before the stabbing of the brain. The rats were sacrificed 1 to 14 days after the stab wound. In the rats sacrificed between 3 to 7 days after the stabbing, numerous phagocytic cells were present in the needle wound. Electron microscope study showed that some of these phagocytic cells carried intracytoplasmic carbon particles. These carbon-labelled cells showed features either of a monocyte, full-blown macrophages, or typical microglia. It is believed that they are all derived from circulating monocytes which have ingested carbon particles in circulation and thereafter invaded the stab wound.

3224. Ling, S., et al. (2009). "Crucial role of corneal lymphangiogenesis for allograft rejection in alkali-burned cornea bed." Clinical & experimental ophthalmology **37**(9): 874-883.

BACKGROUND: To examine the time course of hemangiogenesis, lymphangiogenesis, inflammation after corneal alkaline burns and compare with the importance of corneal hemangiogenesis, lymphangiogenesis and inflammation in allograft rejection on alkali-burned cornea bed, respectively., METHODS: Rat corneal hemangiogenesis and lymphangiogenesis were examined by whole mount immunofluorescence and double enzyme-histochemistry, and the state of corneal inflammation was evaluated by inflammation index scoring and histopathology. Then, corneal transplantations were divided into six groups and performed before the burn (group A) and on day 3 (group B), 2 weeks (group C), 5 weeks (group D), 6 weeks (group E) and 8 weeks (group F) after alkaline burns, respectively. The immune rejection of grafts was evaluated by interferon-gamma, interleukin-2 enzyme-linked immunosorbent assay and slit-lamp examination., RESULTS: Both corneal lymphatic and blood vessels reached the top 2 weeks after the burn. Corneal lymphangiogenesis disappeared 5 weeks after the burn, and corneal hemangiogenesis regressed completely 3 weeks later. Corneal inflammation was strong on day 3, but resolved 6 weeks after the burn. Compared with other groups, the mean survival time of groups B (4.67 +/- 1.03 days) and C (5.00 +/- 0.63 days) was significantly shorter ($P < 0.05$). The difference of mean survival time of grafts between group D (9.50 +/- 1.05 days) and group E (9.83 +/- 0.75 days), between group D and group F (10.00 +/- 0.89 days) was not significant ($P > 0.05$)., CONCLUSIONS: Corneal lymphangiogenesis presents for a shorter duration than corneal hemangiogenesis or corneal inflammation but plays a crucial role in allograft rejection on alkali-burned cornea bed.

3225. Link, M. J., et al. (2010). "Vagoglossopharyngeal-associated syncope due to a retained bullet in the jugular foramen." Skull Base **20**(2): 105-109.

Gunshot wounds (GSWs) to the head are frequently fatal. Rarely, the bullet may lodge in the skull base and not cause significant brain injury. Typically, the bullet fragments are felt to be inert and do not require operative extirpation if they are within the bony confines of the skull base. We report the case of a bullet in the jugular foramen causing recurrent syncope that resolved after surgical removal of the bullet. The medical records from a patient who suffered a GSW to the head were retrospectively reviewed and the treatment and outcome documented. In 2000, a 20-year-old man suffered a GSW to the head. Immediate evaluation revealed the bullet in the right skull base at the jugular foramen, but no parenchymal brain injury. One year after the GSW, he began to experience stereotypical spells resulting in loss of consciousness. Extensive cardiovascular workup was normal. In 2002, the patient underwent removal of the bullet. He has been syncope-free since the operation and returned to his career in the military. We believe the retained bullet in this patient was irritating the IXX cranial nerves, resulting in syncope, similar to the mechanism in vagoglossopharyngeal neuralgia. Removing the bullet relieved the irritation and stopped the syncopal spells.

3226. Linskey, M. E., et al. (1994). "Stereotactic localization and removal of a bullet in the third ventricle causing obstructive hydrocephalus after a cerebral gunshot wound: case report." The Journal of trauma **36**(6): 881-884.

A bullet, lodged in the pineal-posterior region of the third ventricle and causing obstructive hydrocephalus, was removed without damage to critical adjacent vascular structures using stereotactic localization followed by laser-guided stereotactic craniotomy. Stereotactic techniques provided precise target localization and allowed dissection to be restricted to the previously injured missile track, thus avoiding any additional morbidity from the surgical procedure.

3227. Lipke, K. J. and H. O. C. Gumbel (2013). "Management of injuries of the eye and its adnexa." Facial plastic surgery : FPS **29**(4): 310-315.

The face plays the main role in interpersonal communication and in aesthetic perception. What is more, on account of the complex eyelid anatomy required to ensure the functioning of the eye, the treatment of periocular injuries requires a profound knowledge of anatomy and plastic reconstructive surgery, even if a loss of soft tissue is involved. Many methods for the reconstruction of eyelid defects have been described in the current literature. These methods must be guided by the site and extent of the defect on the one hand and by cosmetic requirements on the other to produce best results in terms of form and function. The treatment of injuries in the area of the eyelid involves some peculiarities that must be considered. The management of large defects in particular requires the cooperation of all head surgery disciplines. Copyright Thieme Medical Publishers 333 Seventh Avenue, New York, NY 10001, USA.

3228. Lippa, S. M., et al. (2020). "United States Military Service Members Demonstrate Substantial and Heterogeneous Long-Term Neuropsychological Dysfunction after Moderate, Severe, and Penetrating Traumatic Brain Injury." Journal of neurotrauma **37**(4): 608-617.

The objective of the study was to examine long-term neuropsychological outcome after moderate, severe, and penetrating traumatic brain injury (TBI) in U.S. military service members and veterans (SMVs). Eighty-five SMVs with a history of moderate (n = 18), severe (n = 17), or penetrating (n = 26) TBI, or an injury without TBI (i.e., trauma control [TC], n = 24) were assessed five or more years (mean = 69.4 months; standard deviation = 35.6) post-injury. All passed performance validity tests. Participants completed a battery of neurocognitive tests and a personality inventory. Five cognitive domain composites, each composed of four test scores, and an overall test battery mean (OTBM) were computed. The penetrating TBI group performed worse than the TC group and/or the moderate TBI group on most cognitive domains and the OTBM. The severe TBI group also performed worse than the TC group and moderate TBI group on processing speed and the OTBM, and worse than the TC group on attention/working memory. Just more than half of participants with severe (56%) or penetrating (64%) TBI met criteria for mild neurocognitive disorder, with processing speed the most commonly impaired domain. In addition, 80% of TBI participants had one or more clinically elevated scales on the Minnesota Multiphasic Personality Inventory-2-Restructured Form R (MMPI-2-RF), with somatic complaints the most common elevation. In conclusion, there was significantly reduced cognitive and psychological functioning many years after severe and penetrating TBI in SMVs. Cognitive and psychological dysfunction, however, were highly variable, with a substantial minority of SMVs having good outcome. Long-term individualized support is necessary for individuals after moderate, severe, and penetrating TBI.

3229. Lippa, S. M., et al. (2021). "Blood Biomarkers Relate to Cognitive Performance Years after Traumatic Brain Injury in Service Members and Veterans." Journal of the International Neuropsychological Society : JINS **27**(5): 508-514.

OBJECTIVE: This study examines the relationship of serum total tau, neurofilament light (NFL), ubiquitin carboxyl-terminal hydrolase L1 (UCH-L1), and glial fibrillary acidic protein (GFAP) with neurocognitive performance in service members and veterans with a history of traumatic brain injury (TBI)., METHOD: Service members (n = 488) with a history of uncomplicated mild (n = 172), complicated mild, moderate, severe, or penetrating TBI (sTBI; n = 126), injured controls (n = 116), and non-injured controls (n = 74) prospectively enrolled from Military Treatment Facilities. Participants completed a blood draw and neuropsychological assessment a year or more post-injury. Six neuropsychological composite scores and presence/absence of mild neurocognitive disorder (MNCD) were evaluated. Within each group, stepwise hierarchical regression models were conducted., RESULTS: Within the sTBI group, increased serum UCH-L1 was related to worse immediate memory and delayed memory (R2DELTA = .065-.084, ps < .05) performance, while increased GFAP was related to worse perceptual reasoning (R2DELTA = .030, p = .036). Unexpectedly, within injured controls, UCH-L1 and GFAP were inversely related to working memory (R2DELTA = .052-.071, ps < .05), and NFL was related to executive functioning (R2DELTA = .039, p = .021) and MNCD (Exp(B) = 1.119, p = .029)., CONCLUSIONS: Results suggest GFAP and UCH-L1 could play a role in predicting poor cognitive outcome following complicated mild and more severe TBI. Further investigation of blood biomarkers and cognition is warranted.

3230. Lippa, S. M., et al. (2022). "APOE Is Associated With Serum Tau Following Uncomplicated Mild Traumatic Brain Injury." Frontiers in neurology **13**.

Background and Objectives: APOE e4 has been linked to poor outcome following traumatic brain injury (TBI); however, the mechanisms behind this relationship are unclear. Few studies have investigated the relationship between the APOE genotype and established brain related protein biomarkers following TBI. The purpose of this study was to examine this relationship in service members and veterans (SMVs) following TBI. Methods: Participants were 209 SMVs [124 uncomplicated mild TBI (mTBI); 85 complicated mild, moderate, severe, or penetrating TBI (mod-sev TBI)] prospectively enrolled in the DVBIC-TBICoE 15-Year Longitudinal TBI Study. APOE genotyping was undertaken using non-fasting blood serum samples. Participants were divided into three groups: APOE e2+, APOE e3/e3, and APOE e4+. Results: In participants with mTBI, those with the APOE e2 allele had significantly lower levels of tau than those with APOE e4 ($p = 0.005$, $r = 0.43$, medium-large effect size). Those with APOE e3/e3 trended toward having higher tau than those APOE e2+ ($p = 0.076$, $r = 0.20$, small-medium effect size) and lower tau than those with APOE e4+ ($p = 0.062$, $r = 0.21$, small-medium effect size). There were no significant differences in biomarkers based on APOE in the mod-sev TBI group. Discussion: This study is the first to demonstrate APOE genotype is related to serum tau levels following a mTBI, extending prior findings to human serum following mTBI. In addition to higher serum tau levels in APOE e4 carriers, lower tau levels were observed in APOE e2 carriers, suggesting a possible protective effect.

3231. Lippa, S. M., et al. (2019). "Plasma Tau and Amyloid Are Not Reliably Related to Injury Characteristics, Neuropsychological Performance, or White Matter Integrity in Service Members with a History of Traumatic Brain Injury." Journal of neurotrauma **36**(14): 2190-2199.

The aim of this study was to examine the relationship between plasma tau and amyloid beta-42 (Abeta42), neuropsychological functioning, and white matter integrity in U.S. military service members with (n = 155) and without (n = 42) a history of uncomplicated mild (n = 83), complicated mild (n = 26), or moderate, severe, or penetrating (n = 46) traumatic brain injury (TBI). We hypothesized that higher levels of tau and Abeta42 would be related to reduced neurocognitive performance and white matter integrity. Participants were enrolled prospectively from Walter Reed National Military Medical Center. Participants completed a blood draw, neuropsychological assessment, and diffusion tensor imaging (General Electric 3T) of the whole brain. From 20 neuropsychological test scores, five cognitive domain scores were computed. Measures of fractional anisotropy (FA), mean diffusivity (MD), axial diffusivity (AD), and radial diffusivity (RD) were generated for 18 regions of interest (ROIs). There was no relationship found between the plasma biomarkers and neurocognitive performance in any of the three TBI groups (all ps >0.05; all R2 changes <0.146). Although not reaching statistical significance after correction for multiple comparisons, higher tau and Abeta42 tended to be related to higher FA and lower MD, RD, and AD in patients with a history of moderate, severe, or penetrating TBI. There was no consistent relationship between either of the biomarkers and white matter integrity in the complicated and uncomplicated mild TBI groups. In addition, there was no significant relationship between the biomarkers and age, education, sex, race, bodily injury severity, time since injury, TBI severity, or number of TBIs (all ps >0.15). Future investigation in larger samples of moderate, severe, and penetrating TBI are needed. Other plasma biomarkers, including phosphorylated tau, exosomal tau, and interleukin-10, may be more promising measures to use in the diagnosis, management, and treatment of TBI.

3232. Lipponen, A., et al. (2019). "In Vitro and In Vivo Pipeline for Validation of Disease-Modifying Effects of Systems Biology-Derived Network Treatments for Traumatic Brain Injury-Lessons Learned." International journal of molecular sciences **20**(21).

We developed a pipeline for the discovery of transcriptomics-derived disease-modifying therapies and used it to validate treatments in vitro and in vivo that could be repurposed for TBI treatment. Desmethylclomipramine, ionomycin, sirolimus and trimipramine, identified by in silico LINCS analysis as candidate treatments modulating the TBI-induced transcriptomics networks, were tested in neuron-BV2 microglial co-cultures, using tumour necrosis factor alpha as a monitoring biomarker for neuroinflammation, nitrite for nitric oxide-mediated neurotoxicity and microtubule associated protein 2-based immunostaining for neuronal survival. Based on (a) therapeutic time window in silico, (b) blood-brain barrier penetration and water solubility, (c) anti-inflammatory and neuroprotective effects in vitro ($p < 0.05$) and (d) target engagement of Nrf2 target genes ($p < 0.05$), desmethylclomipramine was validated in a lateral fluid-percussion model of TBI in rats. Despite the favourable in silico and in vitro outcomes, in vivo assessment of clomipramine, which metabolizes to desmethylclomipramine, failed to demonstrate favourable effects on motor and memory tests. In fact, clomipramine treatment worsened the composite neuroscore ($p < 0.05$). Weight loss ($p < 0.05$) and prolonged upregulation of plasma cytokines ($p < 0.05$) may have contributed to the worsened somatomotor outcome. Our pipeline

provides a rational stepwise procedure for evaluating favourable and unfavourable effects of systems-biology discovered compounds that modulate post-TBI transcriptomics.

3233. Liška, M., et al. (2017). "Traumatic aneurysms of middle cerebral artery after a penetrating craniocerebral trauma." Ceska Radiologie **71**(1): 41-46.

I.iika M, Vulev I, Llikovi Z, Kozik J, StcAo A, Stcno |. Traumatic aneurysms of middle cerebral artery after a penetrating craniocerebral trauma Traumatic aneurysms of cerebral arteries (TCA) are rare ami therefore their pathophysiology and morfology is not so thoroughly known. The goal of this paper is to present a case report of a TCA after a penetrating craniocerebral trauma in a 17-ycars old adolescent. The patient was admitted to hospital after a stab injury with an iron pole. Initial CT of the head showed an intracerebral hematoma, traumatic subarachnoidal hemorrhage and intraventricular hematoma, without hydrocephalus. Patients clinical status was improving on conservative therapy, however on 18th day following trauma a sudden clinical deterioration oc- cured. Control CT scan showed rebleeding and CT angiography showed two aneurysms of the left middle cerebral artery, that were according to localisation and history considered as traumatic. The patient underwent a successful endovascular treatment of both aneurysms and was dismissed from the hostpital with a minor neurologic deficit with a tendency to improve. Given the high risk of vascular injury after penetrating head trauma the authors suggest to perform cerebral angiography in these patients. Prove of a traumatic aneurysm may lead to prompt treatment with better prognosis.

3234. Little, J. M., et al. (1986). "Liver trauma." The Australian and New Zealand journal of surgery **56**(8): 613-619.

A series of 97 patients has been studied who were treated for liver injury at Westmead Hospital between January 1979 and January 1985. Patients were noted to be younger than those reported in previous series from Sydney, and to have suffered more frequent, significant, head injuries. Paramedical roadside intervention probably allowed more patients to reach hospital alive than was the case before the advent of the Intensive Care Ambulance system. Improved organ imaging has allowed more confident non-operative management of 13% of patients. Hepatic resection has been used infrequently (10%). Packing has been used in six patients as part of the definitive treatment of severe injuries and coagulopathy, and to allow the transfer of a further seven patients from peripheral hospitals. Ten of these 13 patients survived. Head injury continues to be a major cause of death in these patients. Death from the liver injury itself is usually associated with high grade damage to the liver and the associated hepatic veins and vena cava. It is speculated that improvement in the management of these lethal injuries will come about only from the early identification of patients likely to have suffered such trauma, and the pre-operative control of bleeding. Balloon catheter placement under radiological control, to tamponade the inferior vena cava and abdominal aorta, is suggested as one means by which this goal might be achieved.

3235. Littleton, T., et al. (2011). "Comparison of selected outcomes for traumatic brain injury with intracranial hemorrhage resulting from falls." Journal of Head Trauma Rehabilitation **26**(5): 423-424.

Introduction/Rationale Falls are the second leading cause of trauma activations and often result in traumatic brain injury (TBI), a leading cause of morbidity and mortality. Guidelines for the diagnosis and management of TBI vary, but the literature is scant regarding the management of intracranial hemorrhages (ICH) <1 centimeter(cm). Current protocol at a Level I trauma center allows trauma surgeons to manage ICH <1 cm, but no evidence exists regarding the frequency of ICH management by trauma surgeons versus neurosurgeons or differences in patient outcome. We hypothesize no difference in outcomes for patients managed by a trauma surgeon compared with a neurosurgeon. Method/Approach This is a retrospective chart review of data collected in the trauma registry of JPS Health Network (JPS) from 2006 to 2011. Patients included in the study presented to JPS with fall as the primary mechanism of injury and TBI with an ICH <1 cm. Patients sustaining penetrating wounds and patients transferred to other acute care facilities were excluded from analysis. Results/Effects Between 2006 and 2011, 343 patients presented with a TBI resulting from a fall. Patients ranged in age from 13 to 100 years, with a mean age of 58.05 (SD = 21.48). Sixty-six percent were male (n = 225), 70% were white (n = 239), 88% (n = 302) received neurosurgical consultation, and 13% (n = 44) died.With respect to between neurosurgical management and trauma surgeon management, no significant differences were found between patients' condition on discharge, $\chi 2(2) = 1.28$, ns, destination at discharge, $\chi 2(4) = 1.47$, ns, and length of stay, $F(1, 341) = 2.46$, ns. Conclusions/Limitations Although not all TBIs are a result of falls, this homogenous sample of patients enables us to draw conclusions regarding patient outcomes based on management services in the absence of

co-morbidities. With the expected increase of the aging population, we predict an increase in the number of trauma activations resulting from falls. Due to the demand placed on neurosurgeons for more severe brain injuries, these data suggest patients managed by trauma surgeons could have comparable outcomes to those managed by neurosurgeons when ICH <1 cm.

3236. Litvack, Z. N., et al. (2006). "Self-inflicted nail-gun injury with 12 cranial penetrations and associated cerebral trauma. Case report and review of the literature." Journal of neurosurgery **104**(5): 828-834.

In this case report, the authors describe a 33-year-old man who presented with headache due to the presence of 12 nail-gun nails impacted in his cranium and cerebral parenchyma. The authors also review the relevant literature regarding penetrating brain injury. The patient's physical examination revealed a Glasgow Coma Scale score of 15 and impairment of abduction of the right eye and abduction of the jaw producing dysarthria; the remaining results of the neurological examination were normal. Both x-ray films and computerized tomography (CT) scans of the head revealed the presence of 12 nails, the majority of which were located intracranially. A scattering artifact limited the ability of CT scanning to demonstrate any intracranial hemorrhage. Angiography did not demonstrate any evidence of traumatic vascular injury. After general anesthesia had been induced in the patient, the nails were removed in the operating room. Following removal of the final nail, a small left temporal craniotomy was performed to control hemorrhage from a tear in the left middle meningeal artery. Despite the development of a postoperative insular hematoma, the patient was discharged home with minimal deficits. This patient is the only known survivor of the largest number of foreign objects (12) to penetrate the skull intentionally. Overall, self-inflicted nail-gun injuries are less common than accidental discharges. A review of the literature, however, suggests that for penetrating brain injury, self-infliction is the more common mechanism. For those patients who survive such an injury, clinical decision making must focus on preventing further cortical or vascular damage. A rational management strategy should permit these patients to be discharged with no additional injury.

3237. Litvinenko, A. D., et al. (1964). "[METHOD OF INTERNAL COMPRESSION METALLO-OSTEOSYNTHESIS WITH OSTEOPLASTY]." METOD VNUTRENNEGO KOMPRESSIONNOGO METALLOOSTEOSINTEZA S KOSTNO I PLASTIKO I. **25**: 34-38.

3238. Liu, D. (2010). "Common denominators in retained orbital wooden foreign body." Ophthalmic plastic and reconstructive surgery **26**(6): 454-458.

PURPOSE: To identify some of the common denominators in the diverse presentation of retained orbital wooden foreign bodies., METHODS: A review of 9 cases of previously unrecognized retained orbital wooden foreign bodies. Intervention included surgical removal of the foreign bodies in 8 cases and fistula repair in 1 case after spontaneous foreign body extrusion. Outcome measures included return of normal vision, absence of motility disturbance, and resolution of pain, inflammation, eyelid abnormalities, and other symptoms., RESULTS: Presenting symptoms were diverse and included motility disturbance (5 of 9 patients), conjunctival injection with or without discharge (5 of 9 patients), decreased vision (4 of 9 patients), draining fistula (4 of 9 patients), and localized pain or sensation of tightness in the eyelid (4 of 9 patients). Uncommon symptoms included proptosis (2 of 9 patients), ptosis (2 of 9 patients), lower eyelid retraction (2 of 9 patients), and pain on ocular movement (1 of 9 patients). The interval between the injury and the diagnosis of retained wooden foreign body ranged from 10 days to 42 weeks., CONCLUSION: Occasionally, not all of the wooden pieces are removed at the time of initial orbital exploration, despite best efforts. Signs and symptoms of retained orbital wooden foreign body vary greatly. There is no single specific diagnostic or pathognomonic finding. Heightened awareness and a high index of suspicion are keys to proper diagnosis. It is important to have a properly worded consent that includes the possibility of residual wooden foreign bodies and the need for subsequent surgical exploration.

3239. Liu, D. and E. Al Shail (2002). "Retained orbital wooden foreign body: a surgical technique and rationale." Ophthalmology **109**(2): 393-399.

OBJECTIVE: To emphasize the potential complications of a retained orbital wooden foreign body (WFB) and the rationale of a surgical technique., DESIGN: Two interventional case reports., PARTICIPANTS: Two patients sustained an

orbital WFB injury. Both patients had ocular complications despite repeated attempts to remove the suspected residues., INTERVENTION: Computed tomography and magnetic resonance imaging of both patients at different intervals revealed evidence of orbital foreign body migration toward the cranium. A surgical technique combing transcranial and orbital approaches was used to remove the residues., MAIN OUTCOME MEASURES: Preoperative and postoperative vision, proptosis, ocular motility, and various ocular symptoms and signs., RESULTS: In both patients, no postoperative complications were seen, and all preoperative symptoms and signs were resolved at 9- and 19-month follow-ups, respectively., CONCLUSIONS: A retained orbital WFB can cause early or late complications and is known to have the potential to migrate intracranially. In selected patients, a team approach may be the best technique to ensure complete removal.

3240. Liu, H.-C., et al. (2008). "[Neurosurgical therapy of transorbital intracranial foreign bodies: review of 28 cases]." Zhonghua yi xue za zhi **88**(25): 1737-1741.

OBJECTIVE: To discuss the benefits and complications of the neurosurgical therapy in transorbital intracranial foreign bodies., METHODS: The clinical data of 28 cases of transorbital intracranial foreign bodies, metallic in 13 cases, vegetal 5 cases, and vitreous, plastic and other kinds in 10 cases, were analyzed retrospectively. Optic nerve injury was found in 13 cases, orbital apex syndrome in 11 cases; CSF rhinorrhea in 13 cases, CSF orbital leak in 3 cases, and hemiplegia in 2 cases. All the patients underwent head CT scan, and orbital horizontal and coronal CT scan. The patients with metallic foreign bodies had DSA exams, and the non-metallic cases had MRA scans. 22 cases had orbital-frontal craniotomy and foreign body resection, and 6 cases had direct foreign body extraction. All the cases received antibiotic and nerve nutritional therapy postoperatively., RESULT: The cases in which the foreign bodies came from the orbital roof into the skull recovered well postoperatively; and the cases in which the foreign bodies came from the superior orbital fissure into the skull showed hemiplegia (n = 2) or orbital apex syndrome (n = 6) postoperatively., CONCLUSION: Transorbital intracranial foreign body should be diagnosed in early stage to avoid missed diagnosis. Omission should be avoided during resection of the foreign body. The relationship between the foreign body and internal carotid artery should be examined carefully before the extraction. Direct extraction of foreign body causes less injury, and patients' condition should be followed up.

3242. Liu, N., et al. (2011). "A novel model of traumatic brain injury that shows graded brain damage and behavioral deficits." Journal of neurotrauma **28**(5): A18.

Background: Animal models of traumatic brain injury (TBI) are essential for testing novel hypotheses and therapeutic interventions. Unfortunately, no single model has been able to reproduce the entire spectrum of these injuries. Dominant models currently used by investigators to examine focal injuries include the closed head injury (CHI), fluid percussion injury (FPI), and controlled cortical impact (CCI) injury models. CHI is produced by weight-dropping, and induces obvious brain damage and functional deficits. However, the force used may cause skull fracture and high mortality. The CCI model utilizes a rigid, piston-like impactor to produce a graded TBI. Because of the softness of the brain tissue, tip plunge imitates a penetration brain injury, and does not cause diffuse brain deformation and distinct functional deficits. In this study, we combined advantages of both the CHI and CCI models, and developed a new model of TBI that produces graded brain injury and functional deficits in mice. Methods: C57BL/6 mice (age 10 weeks, weight 20 g) were divided into four groups based on impact depth: sham, 0.5 mm, 1.0 mm, and 1.5mm from the surface of the skull. A midline craniotomy (5-mm diameter) was performed extending 2mm anteriorly and 3mm posteriorly from the bregma, centered over the sagittal suture. The skull flap was left in place and stabilized with adhesive, allowing for direct impact of the exposed skull without producing fractures. A bilateral cortical impact on the surface of the skull flap was performed using an electromagnetic impactor (tip diameter 3 mm, speed 3m/sec, and dwell time 50 msec). Following injury, the mice were subjected to a variety of cognitive and behavioral tests, and 4 weeks later they were sacrificed for histopathological examination. Results: Our results showed that the injury significantly decreased the neuroscore and increased foot drops in a severity-dependent manner, suggesting that our TBI model can produce graded motor deficits. In addition, Morris water maze testing showed increased latency to locate the hidden platform in a severity-dependent manner, suggesting that our model can produce graded memory deficits. Furthermore, adhesive removal testing

showed significant increases in time-tocontact and time-to-remove the adhesive tape from the paw in a severity-dependent manner, indicating graded somatosensory and motor deficits. Histological analysis showed a clear gradation in brain tissue damage following graded brain injuries. Conclusion: These findings collectively suggest that the current model may offer a sensitive, reliable, and clinically relevant model for the assessment of therapeutic strategies for TBI.

3243. Liu, P., et al. (2016). "Treatment of Pediatric Traumatic Intracranial Pseudoaneurysm Using Endovascular Covered Stent: Three Case Reports." World neurosurgery **88**: 693.e691-693.e696.

BACKGROUND: Pediatric traumatic intracranial pseudoaneurysm (TIPA) is a relatively rare clinical entity resulting from blunt, penetrating, or iatrogenic head trauma. The diagnosis, management, and prognosis of patients with pediatric TIPA is not well understood. Surgical craniotomy for TIPA is a high-risk operation. Advancements in minimally invasive technology have allowed for endovascular reconstruction of TIPA., CASE DESCRIPTION: We present our experience with use of endovascular covered stents for treatment of 3 pediatric patients with TIPA. The clinical and radiologic characteristics are presented. No procedure-related complications or deaths occurred during follow-up., CONCLUSIONS: In this study, the use of the Willis covered stent was associated with favorable prognoses in 3 patients with TIPA. No major complications were encountered during follow-up. The Willis covered stent appears to be a viable therapeutic modality in these patients. A definitive prognosis assessment will necessitate prospective clinical trials with longer duration of follow-up.

3244. Liu, Q., et al. (2002). "Up-regulation of cadherin-2 and cadherin-4 in regenerating visual structures of adult zebrafish." Experimental neurology **177**(2): 396-406.

Cadherins are homophilic cell adhesion molecules that control development of a variety of tissues and maintenance of adult structures. In this study, we examined expression of zebrafish cadherin-2 (Cdh2, N-cadherin) and cadherin-4 (Cdh4, R-cadherin) in the visual system of adult zebrafish after eye or optic nerve lesions using immunocytochemistry and immunoblotting. Both Cdh2 and Cdh4 immunoreactivities were specifically up-regulated in regenerating retina and/or the optic pathway. Furthermore, temporal expression patterns of these two cadherins were distinct during the regeneration of the injured tissues. Cadherins have been shown to regulate axonal outgrowth in the developing nervous system, but this is the first report, to our knowledge, of increased cadherin expression associated with axonal regeneration in the vertebrate central nervous system. Our results suggest that both Cdh2 and Cdh4 may be important for regeneration of injured retinal ganglion cell axons.

3245. Liu, R., et al. (2018). "Gunshot penetrating brain injury in children: report of three cases with review of the literature." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **34**(8): 1459-1463.

INTRODUCTION: Gunshot penetrating brain injury is common in military conflict area and in urban violence area, but similar incident in pediatric population is rarely reported., CASE REPORT: We reported three cases of gunshot penetrating brain injury in children. Two patients had a good recovery after surgery and no significant deficit on his neurologic function, the other patient was not having surgery due to the severity of the condition., CONCLUSIONS: We suggest surgery should be performed immediately to prevent further injury and refractory brain edema due to the injury, in any case of penetrating brain injury; a good prognosis can be achieved from early surgery and with appropriate post-operative treatment.

3246. Liu, S., et al. (2018). "Ileocecal junction perforation caused by a sewing needle in incarcerated inguinal hernia: An unusual case report." Medicine **97**(22): e10787.

INTRODUCTION: This case study is concerning the meticulous observation of the moving process and track of 2 ingested needles using interval x-ray radiography, trying to localize the foreign bodies and reduce unnecessary exploration of digestive tract., CASE PRESENTATION: An unusual case of a 1-year, 9-month-old female baby, with incarcerated hernia perforation caused by sewing needles with sharp ends, was reported herein. The patient had swallowed 2 sewing needles. One needle was excreted uneventfully after 8 days. On the contrary, the other needle stabbed the ileocecal junction wall into the right side of inguinal hernia sac after 9 days, and the patient received successful operation management. Interval x-ray confirmed that 1 needle-like foreign body moving down in 8 days until

excretion along with feces. However, the other pierced into the incarcerated hernia. Preoperative x-ray radiography successfully monitored the moving process and tract of the sewing needles. Considering the penetrating-migrating nature of the foreign bodies, once the sharp-pointed objects were located, they should be removed as the mortality and risk of related complications may be increased., CONCLUSION: Interval x-ray radiography represents a meticulous preoperative monitoring method of the moving process and tract of needle-like foreign bodies. Interval x-ray with real-time images accurately detecting the moving foreign bodies could be help to reduce the unnecessary exploration of digestive tract and subsequently prevent possible complications. Based on the basic findings from the interval x-ray, treatment choices of endoscopic removal and surgical intervention may be attempted.

3247. Liu, S.-Y., et al. (2008). "Endonasal transsphenoidal endoscopy-assisted removal of a shotgun pellet in the sphenoid sinus: a case report." Surgical neurology **70 Suppl 1**: S1-9.

BACKGROUND: Gunshot accidents are not uncommon in Taiwan, but involvement limited to the ocular region and sphenoid sinus is rare. Minimal invasive treatment by endonasal transsphenoidal endoscopy-assisted procedure should be considered if there are no additional injuries in the craniocerebral region., CASE DESCRIPTION: A 39-year-old man had severe pain in the left eye with resulting blindness after being accidentally hit in the left eye by a gunshot pellet while walking in a wooded area. He was referred from another hospital with the impression of left eyeball rupture. There was no severe neurologic deficit except for blindness of the left eye when he arrived at the emergency department of our hospital. Brain and orbits CT scans showed a round metallic foreign body at the right sphenoid sinus without predominant damages of brain parenchyma. Endonasal transsphenoidal endoscopy-assisted procedure was used to remove the shotgun pellet, and the patient had good clinical outcomes., CONCLUSION: Herein we present this rare case to show the possibility of a shotgun pellet injury remaining in the sphenoid sinus. The role of radiological studies such as CT scans and intraoperative C-arm fluoroscope plain films in diagnosis and management of this case is affirmed. The strategy of minimally invasive treatment by endonasal transsphenoidal endoscopy-assisted procedure for those limited injuries is a good choice for treatment.

3248. Liu, W., et al. (2019). "Role of Exosomes in Central Nervous System Diseases." Frontiers in Molecular Neuroscience **12**.

There are many types of intercellular communication, and extracellular vesicles are one of the important forms of this. They are released by a variety of cell types, are heterogeneous, and can roughly be divided into microvesicles and exosomes according to their occurrence and function. Of course, exosomes do not just play a role in cell-to-cell communication. In the nervous system, exosomes can participate in intercellular communication, maintain the myelin sheath, and eliminate waste. Similarly, exosomes in the brain can play a role in central nervous system diseases, such as stroke, Alzheimer's disease (AD), Parkinson's disease (PD), prion disease, and traumatic encephalopathy (CTE), with both positive and negative effects (such as the transfer of misfolded proteins). Exosomes contain a variety of key bioactive substances and can therefore be considered as a snapshot of the intracellular environment. Studies have shown that exosomes from the central nervous system can be found in cerebrospinal fluid and peripheral body fluids, and that their contents will change with disease occurrence. Because exosomes can penetrate the blood brain barrier (BBB) and are highly stable in peripheral circulation, they can protect disease-related molecules well and therefore, using exosomes as a biomarker of central nervous system diseases is an attractive prospect as they can be used to monitor disease development and enable early diagnosis and treatment optimization. In this review, we discuss the current state of knowledge of exosomes, and introduce their pathophysiological roles in different diseases of the central nervous system as well as their roles and applications as a viable pathological biomarker.

3249. Liu, W.-H., et al. (2011). "Transorbital penetrating brain injury by branchlet: a rare case." The Journal of emergency medicine **41**(5): 482-485.

Penetrating injury of the brain and skull is uncommon, representing about 0.4% of head injuries. With advances in radiological techniques such as high-resolution and reconstruction computed tomography (CT), assessment of injuries is more accurate and easier. In this article, we report the case of a 46-year-old man presenting with head injury after a branchlet had penetrated through the right orbit into the brain. CT scan of the brain revealed diffuse subarachnoid hemorrhage, intraventricular hemorrhage, and mild obstructive hydrocephalus. CT scan of the brain with reconstruction revealed that the branchlet tip penetrated through the medial aspect of the right orbit to the parasellar region. CT scan

of the brain with contrast showed gradual tapering of the right proximal internal carotid artery with total occlusion after the carotid bulb. Advance radiological examinations, such as three-dimensional CT, are required to obtain the correct emergent diagnosis and treatment of such injuries. Copyright A© 2011 Elsevier Inc. All rights reserved.

3250. Liu, W.-K., et al. (2009). "A delayed frontorbital abscess caused by a penetrating nonmissile foreign body (a bamboo stick)." Neurology India **57**(2): 208-210.

We report an interesting case of delayed frontal abscess caused by a penetrating nonmissile foreign body, a bamboo stick in a 1.5-year-old male child. A parietal craniotomy was performed, and the brain abscess was resected along with the foreign body without any damage to the surrounding brain tissue. He also received the appropriate antibiotics. The child made a good recovery.

3251. Liu, Y., et al. (2010). "Fabrication and surface characterization of single crystal PtBi and PtPb (100) and (001) surfaces." Physical chemistry chemical physics : PCCP **12**(40): 12978-12986.

High quality single crystal PtM (M = Bi or Pb) (100) and (001) surfaces have been generated from solid state bulk materials. The specific orientation was determined via X-ray Laue back-reflection and the miscut angles of the single crystal surfaces were ~0.3degree which was limited by instrumental resolution. The PtM (001) electrode had a Pt termination based on cyclic voltammetric (CV) profiles. The surface structure and composition of single crystal PtM surfaces have been studied by synchrotron-based in situ X-ray grazing incidence diffraction (GID) under active electrochemical control. Cycling of the potential to increasingly high values resulted in dramatic changes to the surface crystalline structure and composition of these single crystal electrodes. Well-defined Pt nano-domains in a hexagonal pattern with a 23degree offset angle to the substrate were formed on the PtM (001) surface after electrochemical pretreatment in supporting electrolyte (0.1M H(2)SO(4)), especially for E(ulp) (E(ulp) = upper limit potential) of +0.80 V or beyond. From an analysis of the diffraction peaks, the size of the Pt domains was estimated to be ~15 nm. The Pt domain formation on the single crystal surfaces, similar to results on polycrystalline intermetallic phases, was due to leaching of the less-noble elements (Bi or Pb) from the intermetallic matrix and sintering of the Pt atoms on the surfaces. On the other hand, Pt domains with a preferential direction but no offset angle to the substrate were formed on PtM (100) surface after similar electrochemical pretreatment. PtBi and PtPb single crystal surfaces exhibited different anisotropic electrocatalytic activities towards the electrooxidation of formic acid and other potential fuels for fuel cell applications. The reactivities of these single crystal electrodes towards the oxidation of small organic molecules were a function of E(ulp) values and maximal activities were around +0.60 V for PtBi(001) surface which might be due to formation of partially oxidized surfaces but around +1.20 V for PtPb(100) and (001) surfaces which might be due to the increasing boundary lines of Pt and PtPb grains.

3252. Liu, Y., et al. (2017). "Comparison of efficacy and safety of different chemotherapy regimens for progressive patients with brain metastasis of small cell lung cancer after radiotherapy." Cancer Research and Clinic **29**(3): 172-175 and 179.

Objective To analyze the efficacy and safety of different chemotherapy regimens for treatment of progressive patients with small cell lung cancer (SCLC) brain metastasis after radiotherapy. Methods 96 SCLC brain metastasis patients with progressive intracranial lesions after radiotherapy were divided into four groups: carmustine group (Group A, 28 cases), temozolomide group (Group B, 19 cases), topotecan group (Group C, 24 cases) and no chemotherapy group (Group D, 25 cases). Results In terms of brain metastases, there were no complete response cases in the whole groups. The rates of partial remission (PR), stable disease (SD) and progression of disease (PD) in Group A were 17.8 % (5/28), 53.6 % (15/28) and 28.6 % (8/28), respectively, the response rate (RR) of intracranial lesions was 17.9 % (5/28), and disease control (CR + PR + SD) rate was 71.4 % (20/28). The rates of PR, SD and PD in Group B were 15.8 % (3/19), 63.2 % (12/19) and 21.1 % (4/19), respectively, the RR of intracranial lesions was 15.8 % (3/19), and disease control rate was 78.9 % (15/19). The rates of PR, SD and PD in Group D were 8.3 % (2/24), 54.2 % (13/24) and 37.5 % (9/24), respectively, the RR rate of intracranial lesions was 8.3 % (2/24), and disease control rate was 62.5 % (15/24). In Group D, there was no response case, and 20 patients with PD (80.0 %) were found. The median progression-free survivals (PFSs) were (3.64±0.43) months, (4.68 ±0.49) months, (3.58 ±0.50) months, (2.60 ±0.31) months in Group A, B, C and D, respectively, and the median overall survivals (OSs) were (18.80±1.74) months, (18.76±1.85) months, (19.10±1.64) months and (9.64±0.84) months, respectively. The median OS of Group A, B or C was longer than that of Group D (P = 0.002). The

differences of grade HI - IV hematologic toxicities among the four subgroups were not statistically different. Patients in Group B had better tolerance to nausea and vomit. In Group D, the central nervous system symptoms such as fatigue and headache occurred frequently. Conclusions The response rate and OS of SCLC brain metastasis patients with progressive intracranial lesions after radiotherapy are improved after chemotherapy, however, PFS is not significantly prolonged. The efficacies of carmustine, temozolomide and topotecan are similar in short and long term, besides, temozolomide shows less adverse events and a higher disease control rate. The application of chemotherapy that could penetrate the blood-brain barrier can improve the efficacy on SCLC brain metastasis patients with progressive intracranial lesions after radiotherapy with well tolerance.

3253. Liuzzi, G. M., et al. (2011). "In vitro cell toxicity and matrix metalloproteinase-9 inhibition by antiretroviral drugs in cultured primary astrocytes." Infection **39**: S66.

Background: The toxic effects of new antiretroviral drugs on the central nervous system (CNS) are unclear. Because these drugs penetrate the brain even at low concentrations, it becomes crucial to determine the doses which can be toxic for the CNS resident cells. Moreover, after the recent introduction into clinical practice, it is unclear whether the efficacy of the antiretroviral drugs of new generation may also derive from their ability to exert extravirological effects on factors responsible for the development of HIV brain injury, e.g. matrix metalloproteinases (MMPs). Objective: To investigate on the toxicity of four different antiretroviral drugs and their ability to modulate the activity of MMPs in astrocyte cultures. Methods: Primary cultures of rat astrocytes were activated by exposure to 10 ?g/ml lipopolysaccaride (LPS) (positive control) and simultaneously treated for 20 h with increasing doses (1-5-10-25. 50 ?M) of: Efavirenz (EFV); Darunavir (DRV); Maraviroc (MVC) or Raltegravir (RAL). Culture supernatants were subjected to gelatin zymography for the assessment of MMP-2 and MMP-9 protein levels. Quantitative determination of MMP-9 and MMP-2 was done by computerized scanning densitometry. Single drug toxicity was assessed by the MTT test. Each drug was considered toxic at the concentration able to induce a percentage of cell survival above 60%. Results: The treatment with antiretroviral drugs inhibited MMP-9 levels in LPS-activated astrocytes in a dose-dependent manner, while no statistically significant changes of MMP-2 levels were observed. In particular, a statistically significant inhibition of MMP-9 was observed when astrocytes were treated with 25?M EFV (60% of inhibition) or with 50 ?M RAL (40% of inhibition). As assessed by the MTT test, the toxicity of the antiretrovirals ranges from 10 and 50 ?M. In particular, EFV was toxic for astrocytes at the concentration of 25 ?M, MVC at 10 ?M, while DRV and RAL were toxic at the concentration of 50?M. Conclusions: The present results indicate that EFV and RAL directly inhibit MMP-9 levels in LPS-activated astrocytes with mechanisms that are independent from their antiviral activity. The toxic doses of antiretrovirals are much higher than those found in the CSF of HIVpositive patients. Our results highlight some beneficial/deleterious extra-viral effects of the antiretroviral drugs that may be useful to improve the development of new therapeutic strategies for the management of HIV infection.

3254. Lively, S. and L. C. Schlichter (2012). "SC1/hevin identifies early white matter injury after ischemia and intracerebral hemorrhage in young and aged rats." Journal of neuropathology and experimental neurology **71**(6): 480-493.

The progression of white matter damage after ischemic and hemorrhagic strokes can exacerbate the initial injury, but little is known about the processes involved. We show that the antiadhesive matricellular glycoprotein SC1 is a novel early marker of white matter damage in 3 models of acute injury in the rat striatum: transient focal ischemia, intracerebral hemorrhage, and a needle penetration wound. SC1 was restricted to the damaged portions of axon bundles that bordered stroke lesions in young-adult and aged rats. SC1 peaked at 1 and 3 days after intracerebral hemorrhage and at 7 days after ischemia. The SC1-positive bundles usually expressed degraded myelin basic protein and amyloid precursor protein, a marker of axonal injury. At the hematoma edge, SC1 was seen in a few axon bundles that retained myelin basic protein staining. In these bundles, punctate SC1 staining filled individual axons, extended beyond a core of pan-axonal neurofilament and NF200 and was inside or overlapped with myelin basic protein staining when it was present. Aged rats had less SC1 (and amyloid precursor protein) after both types of stroke, suggesting a reduced axonal response. SC1 also labeled amyloid precursor protein-positive axon bundles along the needle penetration tract of saline-injected rats; thus, SC1 appears to characterize damaged striatal white matter damage after multiple types of injury.

3256. Llompart-Pou, J. A., et al. (2009). "Contrast-enhanced transcranial color sonography in the diagnosis of cerebral circulatory arrest." Transplantation proceedings **41**(5): 1466-1468.

OBJECTIVE: We sought to determine the utility of constrat-enhanced transcranial color sonography (TCCS) in the diagnosis of cerebral circulatory arrest in cases of difficult acoustic window., MATERIALS AND METHODS: From January 2007 to July 2008, we prospectively studied 50 patients who fulfilled clinical criteria of brain death. In all cases, we performed TCCS aiming to insonate both middle cerebral arteries (MCA) and the basilar artery (BA). In those case in which insonation of any vessel was not possible, we repeated the exploration after injecting a 2.5-mL bolus of sulphurhexafluoridedispersion. Afterward, we compared the rate of insonation of the vessels and the number of conclusive studies., RESULTS: The mean patient age was 53.2 +/- 15.9 years. Thirty-two were men (64%). The most frequent neurologic injury was hemorrhagic stroke and traumatic brain injury. Contrast-enhanced TCCS resulted in an increased rate of insonation in both MCA and in BA, and in the number of conclusive studies., CONCLUSIONS: Contrast-enhanced TCCS increased the number of conclusive studies with cerebral circulatory arrest, which minimized the importance of a previous study in cases with a poor acoustic window.

3260. Loggini, A., et al. (2022). "Case Report: Management of Traumatic Carotid-Cavernous Fistulas in the Acute Setting of Penetrating Brain Injury." Frontiers in neurology **12**.

Traumatic carotid-cavernous fistulas (tCCFs) after penetrating brain injury (PBI) have been uncommonly described in the literature with little guidance on optimal treatment. In this case series, we present two patients with PBI secondary to gunshot wounds to the head who acutely developed tCCFs, and we review the lead-up to diagnosis in addition to the treatment of this condition. We highlight the importance of early cerebrovascular imaging as the clinical manifestations may be limited by poor neurological status and possibly concomitant injury. Definitive treatment should be attempted as soon as possible with embolization of the fistula, flow diversion via stenting of the fistula site, and, finally, vessel sacrifice as possible therapeutic options.

3261. Loggini, A., et al. (2021). "Neuroendocrine Dysfunction in the Acute Setting of Penetrating Brain Injury: A Systematic Review." World neurosurgery **147**: 172-180.e171.

BACKGROUND: Data on neuroendocrine dysfunction (NED) in the acute setting of penetrating brain injury (PBI) are scarce, and the clinical approach to diagnosis and treatment remains extrapolated from the literature on blunt head trauma., METHODS: Three databases were searched (PubMed, Scopus, and Cochrane). Risk of bias was computed using the Newcastle-Ottawa Scale, or the methodological quality of case series and case reports, as indicated. This systematic review was registered in PROSPERO (42020172163)., RESULTS: Six relevant studies involving 58 patients with PBI were included. Two studies were prospective cohort analyses, whereas 4 were case reports. The onset of NED was acute in all studies, by the first postinjury day. Risk factors for NED included worse injury severity and the presence of cerebral edema on imaging. Dysfunction of the anterior hypophysis involved the hypothalamic-pituitary-thyroid axis, treated with

hormonal replacement, and hypocortisolism, treated with hydrocortisone. The prevalence of central diabetes insipidus was up to 41%. Most patients showed persistent NED months after injury. In separate reports, diabetes insipidus and hypocortisolism showed an association with higher mortality. The available literature for this review is poor, and the studies included had overall low quality with high risk of bias., CONCLUSIONS: NED seems to be prevalent in the acute phase of PBI, equally involving both anterior and posterior hypophysis. Despite a potential association between NED and mortality, data on the optimal management of NED are limited. This situation defines the need for prospective studies to better characterize the clinical features and optimal therapeutic interventions for NED in PBI.

3262. Loggini, A., et al. (2020). "Management of civilians with penetrating brain injury: A systematic review." Journal of critical care **56**: 159-166.

PURPOSE: There has been a dramatic increase in penetrating gunshot-inflicted civilian penetrating brain injuries (cvPBI). We undertook a systematic review with exclusive focus on the management of cvPBI., METHODS: We explored: (1) cervical spine immobilization, (2) seizure incidence and prophylaxis, (3) infection incidence and antibiotic prophylaxis, (4) coagulopathy (5) vascular complications, and (6) surgical management. We searched PubMed, EMBASE, and Cochrane (1985-2019). The PRISMA guidelines were followed. The Newcastle-Ottawa Scale was employed for qualitative assessment; risk of bias was evaluated based upon the RTI item bank. The full protocol was registered to PROSPERO (CRD42019118877)., RESULTS: The literature is scant, and of overall low quality and high risk of bias. Incidence of c-spine injury with no direct trauma is low; incidence of seizures does not appear to be different from non-penetrating mechanisms; there is no robust data for prophylactic antibiotics; coagulopathy is prevalent and has been independently associated with outcome; there is a high incidence of vascular injuries with traumatic intracranial aneurysms the most common sequelae; neurosurgical decision-making appears largely influenced by operator's assessment of salvageability. Surgery has been associated with decreased mortality., CONCLUSIONS: Limited amount of published work is clinically meaningful; this systematic review identified key knowledge gaps.

3263. Logvinov, I. O., et al. (2014). "GSB-106, a low molecular weight dipeptide analogue of BDNF, protected cells via the TrkB, Akt, Erk 1/2 activation." European Neuropsychopharmacology **24**: S221-S222.

Purpose of study: In the pathogenesis most of neurodegenerative diseases and depression revealed reduction of brain-derived neurotrophic factor (BDNF) as endogenous neuroprotector. It has been shown that BDNF rescues different types of neurons from ischemic, traumatic and toxic brain injury. The particular interest in BDNF is due to its involvement in the pathogenesis of depressions and possible antidepressant activity. The cellular actions of BDNF are mediated through the activation of the TrkB neurotrophin receptors. Pathways activated by BDNF include the Ras/Erk mitogen activated protein kinase (MAPK) pathway, the phosphatidylinositol-3-kinase [PI(3)K]/Akt pathway and PLCg pathway. MAPK pathway implicates in differentiation, neuroprotection, synaptic plasticity and antidepressant effect. Phosphatidylinositol-3-kinase [PI(3)K]/Akt pathway leads to neuroprotection, neuritogenesis, synaptic plasticity, angiogenesis. Unfortunately, the pharmacological application of BDNF is limited because of its rapid degradation in the organism, low ability to penetrate the blood-brain barrier, and undesirable side effects. Therefore, in order to develop neuroprotective and antidepressant drugs, it seems urgent to synthesize low-molecular mimetics of BDNF, which are capable of activating the TrkB receptor signaling pathways and have no disadvantages of fulllength BDNF protein. In Zakusov Institute of Pharmacology Russian Academy of Medical Sciences was synthesized lowmolecular dipeptide analogue of BDNF - GSB-106 [bis(Nmonosuccinyl- L-seryl-L-lysine)hexamethylenediamide]. We have previously shown that GSB-106 had neuroprotective effects in different models of cell damages: oxidative stress, glutamate toxicity or 6-hydroxydopamine-induced toxicity. Also GSB-106 showed the typical for BDNF antidepressant activity in several rodent tests. The objective of this study was to investigate the involvement of TrkB and two signaling pathways: MAPK/ERK1/2 and PI3K/Akt in neuroprotective and antidepressant effects. Methods: Experiments were carried out on hippocampal cell line HT-22. Cells were maintained at 37°C, 5% CO2 in DMEM (Dulbecco's modified Eagle's medium) containing 5% FBS (fetal bovine serum). For experiments cells were passaged into 6-well plates. For this assay, cells were plated at 250×103 cells per well in complete medium. Cultured HT-22 hippocampal neurons were incubated with GSB-106 (10-8M) and BDNF (10-9M) at the 30 s, 5 min, 15 min, 30 min and 60 min time points. For detection phosphorylated TrkB, Akt and Erk 1/2 levels was used Western blot analysis by using specific antibodies against these proteins. Results: BDNF binds to the TrkB receptor, which leads to its dimerization, autophosphorylation, and activation of a number of signal pathways. TrkB activation promotes neuronal survival, differentiation, and synaptic function. We have shown that GSB-

106 caused a significant increase in phosphorylation of TrkB at 30 s and 15 min of exposition HT-22 cells. Two major signaling pathways have been implicated in responses underlying antidepressant effects; the phosphatidylinositol- 3-kinase [PI(3)K]/Akt signaling pathway and the MAPK/ERK signaling pathway. Numerous studies have implicated these two pathways in etiology and treatment of mood disorders. In our experiments GSB-106 indused the activation of Akt and Erk 1/2 signal pathways at the 15 and 60-minute time points in hippocampal neurons line HT-22. Conclusions: Activation of TrkB, Akt, Erk 1/2 may be involved in neuroprotective and antidepressant effects of GSB-106.

3265. London, S. D., et al. (1993). "Rigid internal fixation techniques for mandibular fractures." Journal of Long-Term Effects of Medical Implants **3**(4): 295-304.

Rigid internal fixation techniques are indicated in all mandibular fractures in which stability is required for healing to occur. Advances in current biotechnology have led to development of biocompatible bone plates and screws that provide a reliable method of producing rigid internal fixation. The benefits of rigid internal fixation are a decrease in maxillomandibular fixation time, improved oral hygiene and nutrition, and maintenance of a patent airway. With adherence to technical details (such as atraumatic screw insertion and the fixation of a well-contoured plate), rigid fixation techniques provide a reliable method for the treatment of mandibular fractures. The use of plates and screws in the management of mandible fractures can be associated with infections and neurosensory disturbances.

3266. Long, G., et al. (2011). "Cranial impalement in a child driving an all-terrain vehicle." Pediatric emergency care **27**(5): 409-410.

BACKGROUND: All-terrain vehicle (ATV) injury is a serious problem in children and adolescents. We report an unusual case of a child with cranial impalement in a rollover ATV crash., CASE: An 8-year-old, reportedly helmeted, was driving an ATV uphill when it rolled over causing cranial impalement of the brake handle just above the left ear. The child was awake and alert at the scene and on arrival in the pediatric emergency department. The child was taken to the operating room where he underwent fiber-optic intubation followed by removal of the brake handle. He was discharged home after 3 days with a normal neurological examination., CONCLUSIONS: All-terrain vehicle injury is an increasing problem in children. This case demonstrates that serious injury can occur even while wearing a helmet. The case demonstrates the dangers associated with children driving or riding ATVs.

3267. Long, T., et al. (2006). "Information sharing: its impact on donor and nondonor families' experiences in the hospital." Progress in transplantation (Aliso Viejo, Calif.) **16**(2): 144-149.

OBJECTIVE: To illustrate the methods used to convey complicated information regarding the critical injury, and death diagnosed by means of brainstem testing, to the next of kin of potential organ donors., DESIGN: 3-year, prospective, longitudinal study., PARTICIPANTS AND SETTING: Forty-three family members who chose to donate their deceased relatives' organs were recruited via 4 transplant coordinating centers, and 3 family members who chose not to donate were recruited via 1 intensive care unit., METHOD: Face-to-face qualitative interviews were carried out with 46 family members of 43 individuals who died between June and December 2000. Family members who agreed to donation were interviewed during and after their next of kin's admission to hospital and 3 to 5 months, 13 to 15 months, and 18 to 26 months after bereavement. Three participants who chose not to donate were interviewed on 1 occasion only. Interviews were audio-recorded, and the transcribed reports were analyzed using a comparative, thematic approach focusing on the detection of similarities and differences between cases., RESULTS: Participants who were offered verbal information supported by complementary methods of communication had (1) a greater understanding of the critical injury sustained by their next of kin, and (2) fewer questions over time regarding brainstem testing., CONCLUSION: Better methods of communicating complicated information are needed, as the sheer load of information shared makes demands of next of kin at a time when they are cognitively and emotionally poorly equipped to respond.

3269. Lopez, F., et al. (2000). "Penetrating craniocerebral injury from an underwater fishing harpoon." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **16**(2): 117-119.

Weapon injuries other than gunshot wounds or low-velocity stab wounds to the head are extremely rare. We report the case of a 6-year-old girl who sustained a penetrating craniocerebral injury after being accidentally shot with an underwater fishing harpoon. This mechanism of injury seems to share characteristics of both high- and low-velocity projectiles. We discuss the management of this unusual injury in a child, remarking that foreign body removal in these cases must be carried out following the original direction of the projectile trajectory. We review the current literature on craniocerebral injuries caused by similar objects, especially those occurring in children.

INTRODUCTION: Penetrating head injuries are rare especially in the paediatric age group. Relatively minor falls over common household objects can cause potentially life-threatening brain injuries., CASE REPORT: We describe a penetrating head injury caused by a household electrical plug in a 6-month-old child. The two rounded pins of the plug were embedded in the posterior parietal area of her head, very close to the cranial midline. There was no neurological deterioration or bleeding. Radiological investigation showed a depressed skull fracture underneath the two pins. One of them came very close to the superior sagittal sinus but there was no evidence of intracranial bleeding. The electrical plug was extracted under general anaesthesia in the operating theatre. The penetrating fracture segments were removed. The sagittal venous sinus was fortunately undamaged., CONCLUSIONS: Household objects like electrical plugs may constitute a risk for children. It may be worthwhile to reconsider the design of electrical plugs.

3271. Lorenz, K. J., et al. (2011). "[Diagnosis and treatment of injuries to the frontal skull base]." Diagnostik und Therapie von Verletzungen der Frontobasis. **59**(8): 791-799.

The role of ENT surgery in the management of anterior skull base defects has become increasingly important in recent years. Transnasal endoscopic surgical techniques and intraoperative navigation enable a minimally invasive approach in a large proportion of patients, thus helping to avoid morbidity typically associated with neurosurgical subfrontal approaches. Whereas traffic accidents and sport injuries are the main causes of anterior skull base trauma in the civilian setting, penetrating injuries caused by gunshots and improvised explosive devices (IEDs) play an increasing role in the military arena and terroristic attacks. Minor injuries to the anterior skull base are usually managed by ENT surgeons. Major injuries, involving the midface or neurocranium, require an interdisciplinary approach including maxillofacial surgeons and neurosurgeons. A centre for head and neck medicine and surgery is an ideal setting for such interdisciplinary teams to provide appropriate care for patients with complex skull base trauma in cooperation with ophthalmologists and interventional neuoradiologists. The present article describes concepts for the treatment of anterior skull base trauma established at the head, neck and skull base center at the Ulm military hospital in Germany.

3272. Lorenzini, M., et al. (1998). "Successful reconstruction of refractory posttraumatic skull base defects with free radial forearm flap." Plastic and reconstructive surgery **102**(6): 2097-2099.

After our experience with two patients who had persistent posttraumatic defects of the anterior skull base, we recommend using a deepithelialized free radial forearm flap for one-stage reconstruction. The flap provides a thin, water-tight barrier between the cranial cavity and the subcranial spaces for effective prevention of cerebrospinal fluid leakage and ascending infection. It is particularly useful when local flap options are not available.

3273. Lorger, M. and B. Felding-Habermann (2011). "Interactions between breast cancer brain metastases and their microenvironment." Clinical and Experimental Metastasis **28**(2): 236.

Twenty to 35% of breast cancer patients present with brain metastases. These patients have an extremely poor prognosis since no efficient therapies are available. Brain lesions are often shielded by the blood- brain barrier which hinders drug penetration. They mostly develop late during a progressive metastatic disease after administration of systemic therapies and clinical data suggest that they are resistant against standard systemic treatments. Furthermore,

the presence of multifocal brain lesions often hinders their complete removal by surgery due to neurotoxicities. Thus, novel therapeutic concepts tailored to overcome these current limitations in the treatment of brain lesions are urgently required. We therefore seek to understand interactions between the brain microenvironment and cancer cells upon their entry into the brain from the blood stream in order to develop therapeutic concepts that might target brain metastases by targeting the supportive tumor microenvironment. Our particular focus is on reactive microglia/macrophages, because we were able to show that these cells accumulate around malignant brain lesions in our models of breast cancer brain metastasis. Reactive microglia/macrophages can be observed around individual cancer cells immediately after their extravasation into the brain parenchyma and remain associated with developing brain lesions. The majority of these cells stain positive for F4/80, a marker of microglia/macrophages, and Gr1, a marker of inflammatory monocytes. This latter observation suggests that brain lesions-associated microglia/macrophages originate from the bone marrow-derived hematopoietic stem cells. We are currently exploring the role of these cells in the initiation and growth of metastatic brain lesions in our animal models of brain metastasis.

3275. Lorincz, D. and M. Kalman (2020). "No rapid and demarcating astroglial reaction to stab wounds in Agama and Gecko lizards and the caiman Paleosuchus - it is confined to birds and mammals." Histology and histopathology **35**(12): 1455-1471.

The present study proves that rapid and demarcating astroglial reactions are confined to birds and mammals. To understand the function of post-lesion astroglial reaction, the phylogenetical aspects are also to be investigated. Considering the regenerative capabilities, reptiles represent an intermediate position between the brain regeneration-permissive fishes and amphibians and the almost non-permissive birds and mammals. Damage is followed by a rapid astroglial reaction in the mammalian and avian brain, which is held as an impediment of regeneration. In other vertebrates the reactions were usually observed following long survival periods together with signs of regeneration, therefore they can be regarded as concomitant phenomena of regeneration. The present study applies short post-lesion periods comparable to those seen in mammals and birds for astroglial reactions. Two species of lizards were used: gecko (leopard gecko, Eublepharis macularius, Blyth, 1854) and agama (bearded dragon, Pogona vitticeps, Ahl, 1926). The gecko brain is rich in GFAP whereas the agama brain is quite poor in this. Crocodilia, the closest extant relatives of birds were represented in this study by Cuvier's dwarf caiman (Paleosuchus palpebrosus, Cuvier, 1807). The post-lesion astroglial reactions of crocodilians have never been investigated. The injuries were stab wounds in the telencephalon. The survival periods lasted 3, 7, 10 or 14 days. Immunoperoxidase reactions were performed applying anti-GFAP, anti-vimentin and anti-nestin reagents. No rapid and demarcating astroglial reaction resembling that of mammalian or avian brains was found. Alterations of the perivascular immunoreactivities of laminin and beta-dystroglycan as indicators of glio-vascular decoupling proved that the lesions were effective on astroglia. The capability of rapid and demarcating astroglial reaction seems to be confined to mammals and birds and to appear by separate, parallel evolution in them.

3276. Lorkiewicz, W., et al. (2011). "[A murder case from 900 years ago? Analysis of extensive cranial trauma observed in a historical skeleton recovered in central Poland]." Morderstwo sprzed 900 lat? Analiza rozleglych urazow czaszki zaobserwowanych na szkielecie historycznym odkrytym w centralnej Polsce. **57**(3): 101-106.

This work presents the results of study of a human skeleton from the early Middle Ages recovered in Peclawice (province of Lodz), presenting signs of extensive cranial trauma suffered perimortem. The skeleton belonged to a 20-30 year-old male of sturdy build, with prominent bone processes, marked right-side asymmetry of the bones and joints of the upper extremities, and tallness (stature well above average for early medieval times). Except for the skull, the skeleton lacks any pathologic or traumatic lesions. The right side of the skull bears signs of three extensive injuries involving the frontal and parietal bones and the temporomandibular joint. Two of them penetrated deeply into the cranial cavity. The nature and location of the lesions suggests that the axe was used and that the victim was not confronted face-to-face. None of the lesions show any signs of healing. Fragmentation of the facial bones, which were mostly incomplete except for the well-preserved mandible, suggests additional blows to the face. These massive injuries must have been fatal due to damage to the brain and main blood vessels of the neck and thus they were recognized as the cause of death of the individual.

3277. Lough, E. G., et al. (2013). "An unusual case of air rifle pellet migration from the brain to the thoracic spine." The American surgeon **79**(1): E33-34.

3278. Lovrencic-Huzjan, A., et al. (2011). "Transcranial Doppler in brain death confirmation in clinical practice." Ultraschall in der Medizin (Stuttgart, Germany : 1980) **32**(1): 62-66.

PURPOSE: Transcranial Doppler (TCD) can be used as a confirmatory test in brain death. The aim was to present the usefulness of TCD in brain death confirmation., MATERIALS AND METHODS: Forty-four patients with severe brain lesions leading to brain death were treated over a 4-year period. After the clinical diagnosis of brain death was made, the appropriate confirmatory test was chosen according to patient condition, taking into consideration the restrictions of the test protocol. Due to the inconclusive test results, some patients underwent repeat testing., RESULTS: Among 44 patients, 19 had neurotrauma, 11 massive aneurysmal subarachnoidal hemorrhages, 1 arteriovenous subarachnoidal and parenchymal hemorrhage, 12 hypertensive parenchymal hemorrhages, and 1 ischemic stroke. As a primary test, TCD was used in 30, brain scintigraphy in 2, multislice CT angiography (CTA) in 10, and cerebral angiography in 2 patients, and the diagnosis was confirmed in 26, 3, 9 and 2 patients, respectively. Due to inconclusive results CTA was repeated in five patients. In patients in whom TCD was applied, the time to confirm the diagnosis was the shortest, and in most (61 %) cerebral circulatory arrest was confirmed within 2 hours of clinical diagnosis., CONCLUSION: TCD is a favorable confirmatory test for cerebral circulatory arrest in brain death diagnosis.

3279. Lowe, M., et al. (2019). "Monthly variance in UK renal transplantation activity: a national retrospective cohort study." BMJ open **9**(9): e028786.

OBJECTIVE: To identify whether renal transplant activity varies in a reproducible manner across the year., DESIGN: Retrospective cohort study using NHS Blood and Transplant data., SETTING: All renal transplant centres in the UK., PARTICIPANTS: A total of 24 270 patients who underwent renal transplantation between 2005 and 2014., PRIMARY OUTCOME: Monthly transplant activity was analysed to see if transplant activity showed variation during the year., SECONDARY OUTCOME: The number of organs rejected due to healthcare capacity was analysed to see if this affected transplantation rates., RESULTS: Analysis of national transplant data revealed a reproducible yearly variance in transplant activity. This activity increased in late autumn and early winter (p=0.05) and could be attributed to increased rates of living (October and November) and deceased organ donation (November and December). An increase in deceased donation was attributed to a rise in donors following cerebrovascular accidents and hypoxic brain injury. Other causes of death (infections and road traffic accidents) were more seasonal in nature peaking in the winter or summer, respectively. Only 1.4% of transplants to intended recipients were redirected due to a lack of healthcare capacity, suggesting that capacity pressures in the National Health Service did not significantly affect transplant activity., CONCLUSION: UK renal transplant activity peaks in late autumn/winter in contrast to other countries. Currently, healthcare capacity, though under strain, does not affect transplant activity; however, this may change if transplantation activity increases in line with national strategies as the spike in transplant activity coincides with peak activity in the national healthcare system.

3280. Lu, M., et al. (2011). "Dose response effects of phenytoin on attenuation of nonconvulsive seizures caused by penetrating ballistic-like brain injury in rats." Journal of neurotrauma **28**(6): A121.

Acute post-traumatic nonconvulsive seizures (NCS) require prompt intervention. As NCS, they are more difficult to diagnose and more refractory to antiepileptic drug treatments. Phenytoin (PHT) is widely considered as the first choice for seizure treatment in the neurointensive care unit. In this study we evaluated the dose-response effects of PHT to attenuate acute nonconvulsive seizures caused by a penetrating ballistic-like brain injury (PBBI) in rats. Continuous EEG recordings were collected for 72h following PBBI from awake animals. Four doses of PHT (PHT-10/5, PHT-20/10, PHT-40/20, and PHT-60/30, N=15/dose) were tested. Each dose consisted of a loading dose (10, 20, 40, 60 mg/kg i.v. injection) initiated at 30 min after injury followed by a maintenance dose (5, 10, 20, 30 mg/kg, respectively) given at 8h after the loading dose on Day 1 and then twice per day (at 8h intervals) on days 2-3. Overall, 73% of vehicletreated

animals exhibited an average of 7.4 NCS episodes/rat yielding a total NCS duration of 303 ± xx sec/rat during the 72h post-injury period. The onset latency was @27h post-injury. PHT treatments, except for the lowest dose, significantly reduced NCS incidence to 33- 40%. In all PHT treated groups, the NCS episodes and durations were also dose-dependently mitigated, resulting in an average of 6.2-1.8 episodes/rat (267-66 sec/rat) measured from the highest to the lowest doses, with the significant reductions being afforded by the two highest dose regimens. Transient (5-30 min) sedation was also correlated to the escalating doses of PHT, i.e. the higher the dose, the longer the sedation. Since PHT treatment was initiated before NCS occurred, these results indicate that PHT is effective in ameliorating post-traumatic NCS as prophylactic treatment and the PHT-40/20 dose has a better therapeutic index than PHT-60/30 dose because of its similar efficacy but lesser degree of sedation.

3281. Lu, X. C., et al. (2017). "Combination therapy of anti-epileptic drugs against post-traumatic nonconvulsive seizures in rats." Journal of neurotrauma **34**(13): A50.

We previously demonstrated synergistic effects of combination therapy using phenytoin paired with levetiracetam (PHT+LEV) or ethosuximide (PHT+EXM) for mitigating acute post-traumatic nonconvulsive seizures (NCS) induced by penetrating ballistic like brain injury (PBBI) in rats. We also observed sub-additive effects of LEV paired with gabapentin (LEV+GBP). In this study we evaluated two different pairs of combinations of these drugs: EXM+LEV and PHT+GBP, in the PBBI model. All rats received a frontal PBBI and skull EEG electrodes implantation. EXM+LEV were tested at four dose ratios: EXM/LEV: 5.6/6.3, 11.1/12.7, 22.2/25.4, or 44.5/ 50.7 mg/kg. PHT+GBP were tested at five dose ratios: PHT/GBP: 1.8/0.6, 3.6/1.3, 7.2/2.5, 14.5/5.0, or 28.9/10.0mg/kg. Treatments were given intravenously twice/day for three days following the injury. The NCS were detected by continuous EEG recording for 72 h. Similar to previous studies, approximately 65% of PBBIvehicle treated animals showed evidence of post-traumatic NCS within the first 72h following injury. PBBI animals treated with EXM+LEV showed reduced NCS incidence to 33-44% across all dose ratios tested and dose-dependently decreased NCS frequency and duration by 10-84% ($p < 0.05$ at 2 highest dose ratios) and 2- 88% ($p < 0.05$ at 2 highest dose ratios), respectively. However, for PHT+GBP treatments, only the highest dose ratio reduced NCS incidence to 41% and significantly reduced seizure frequency by 78% ($p < 0.05$) and seizure duration by 82% ($p < 0.05$). Isobolographic analysis further indicated that EXM+LEV combination therapy achieved synergism because the observed effects exceeded the expected additive effects, whereas PHT+GBP had sub-additive effects. These results extended our previous findings on AED combinations involving PHT, EXM, and LEV and indicated their favourable interactions when any two pairs were combined at lower dose constituents than their monotherapy doses. On the other hand, similar to the lack of beneficial effects of LEV+GBP combination therapy, PHT+GBP also failed to improve their anti-seizure activities, suggesting that GBP may not be a good candidate for combination therapy against post-traumatic NCS.

3282. Lu, X. C. M., et al. (2018). "Ethosuximide and gabapentin combination failed to achieve synergism against seizures induced by penetrating brain injury." Journal of neurotrauma **35**(16): A85-A86.

Early post-traumatic seizures are one of the major complications of traumatic brain injury. These seizures may lead to elevated intracranial pressure and cerebral metabolic distress, worsening the patients' outcomes. In this study we evaluated combination therapy of ethosuximide (EXM) paired with gabapentin (GBP) to ameliorate posttraumatic non-convulsive seizures induced by a penetrating-ballistic like brain injury (PBBI) in rats. Adult male rats were prepared with skull EEG electrodes 4 days prior to receiving the right frontal PBBI. EEG recording started immediately after the injury and continued for 72 h to detect non-convulsive seizures. EXM+GBP combinations were tested at four dose ratios (EXM/GBP: 5.6/0.6, 11.1/1.3, 22.2/2.5, 44.5/ 5.0) derived from their monotherapy dose-response profiles according to the isobolographic analysis. The individual dose constituents of these two drugs were 2-5 folds lower than their monotherapy effective doses. Treatments were given intravenously twice per day for three days following the PBBI. Compared to vehicle treated control rats, the two high dose ratios of EXM+GBP combination therapy significantly reduced seizure frequency by 46-53% and seizure duration by 58- 61%. They also moderately reduced seizure incidence from 63% in the vehicle treatment group to 56-39%. In these two high dose ratios, the EXM doses were 4-5 folds lower than its monotherapy effective doses. However, isobolographic analysis indicated that the combined treatments of EXM+GBP failed to achieve additivity in 3 of the 4 dose ratios tested, including the two highest dose ratios, because the magnitude of the observed effects failed to reach the expected additive effects. The results of this study confirmed our previous findings in the same PBBI-induced NCS model, which showed that addition of GBP to phenytoin or Levetiracetam as combination therapy also failed to achieve additive effects when the dose constituents were reduced

in the combination In fact, a combination of GBP with these antiepileptic drugs, including EXM, produced potential sub-additive (antagonistic) effects, e.g. the observed effects were lower than the expected additive effects. Thus, these results collectively indicated that simultaneous usage of GBP with other anti-epileptic drugs should be avoided in managing post-traumatic seizures following TBI.

3283. Lu, X. C. M., et al. (2016). "Dose response effects of simvastatin on attenuation of nonconvulsive seizures induced by penetrating ballistic-like brain injury." Journal of neurotrauma **33**: A43.

Simvastatin (SIM) is a 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor commonly used to reduce serum cholesterol. Recently the neuroprotective and anti-seizure effects of SIM have emerged from animals studies. For example, we have demonstrated that intravenous treatment of SIM mitigated cognitive deficits following penetrating ballistic-like brain injury (PBBI). Preclinical studies by others have shown that SIM reduced kainic acid or picrotoxin-induced seizures. A clinical study has also shown that patients treated with statins, including simvastatin, within 3 days after a stroke had a reduced risk of developing post-stroke seizures. In this study, we evaluated the anti-seizure effects of SIM against PBBI induced nonconvulsive seizures (NCS), which were detected by 72 h continuous EEG recordings immediately following the injury. Four doses of SIM (0.001, 0.01, 0.1, or 1.0 mg/kg) were tested intravenously, twice/day for three days, initiated 30min post-injury. Control animals received matching vehicle treatments. The results showed that 73% of vehicle-treated animals exhibited an average of 14.5 NCS episodes/rat, yielding an average accumulative duration of 386.6 sec/rat during the 72 h post-injury period. The onset latency was 26 h post-injury. Compared to the vehicle treatment, SIM manifested anti-seizure activities in a dose-dependent fashion by significantly decreasing NCS frequency to 6.0 ± 9.7 NCS/rat (59%-33% reduction) and shortening total NCS duration to 173-282 sec/rat (55%-27% reduction) at the two does tested. However, the effects of SIM treatment on NCS incidence and onset latency were non-significant. In summary, the findings of this study provide further support on the anti-seizure properties of SIM in a clinically relevant animal model of post-traumatic seizures. Considering the clinical evidence of beneficial effects of SIM on post-stroke seizures, our results are highly encouraging, warranting further support for more advanced preclinical and clinical evaluations of SIM as a potential seizure prophylaxis in patients having suffered severe brain trauma.

3284. Lu, X. C. M., et al. (2012). "Similarities and differences of acute epileptic activities following penetrating ballisticlike brain injury and focal brain ischemia in rats." Journal of neurotrauma **29**(10): A172.

Introduction In this study, we characterized the similarities and differences of nonconvulsive seizures (NCS) and other epileptic events, such as periodic epileptic discharges (PED) and intermittent rhythmic delta activities (IRDA) in rat models of penetrating ballistic-like brain injury (PBBI) and permanent middle cerebral artery occlusion (pMCAO). Methods Rats received either unilateral frontal PBBI (n = 43) or pMCAO (n = 28). Brain activity was monitored continuously by EEG recordings for 72h (PBBI) or 24h (pMCAO). Epileptic activities examined included: NCS, PED, and IRDA. The NCS profile was characterized based on EEG waveform patterns, seizure incidence frequency, duration, and time distribution. The PED and IRDA activities were also characterized based on EEG waveform patterns, but the severity of these activities was rated based on the abundance of their occurrence and their associations with NCS. Results NCS occurred in 70% PBBI rats and 79% pMCAO rats, manifested in three EEG waveforms: Type I-rhythmic high frequency (> 2Hz) spikes, Type II-rhythmic low frequency (∗1Hz) sharp waves, and Type III-arrhythmic (0.5-2 Hz) spikes. Type I seizures resembled clinical EEG patterns of generalized/partial complex seizures and were predominant following both injuries. Types II/III seizures appeared to reflect inter-ictal activities. Overall, NCS occurred more acutely and intensely after pMCAO (latency = 0.6h, frequency = 25 episodes/rat) compared to post- PBBI NCS (latency = 26h, frequency = 10 episodes/rat). The most salient feature that differentiated post-traumatic and postischemic NCS was their time distribution. After pMCAO, > 50% seizures occurred within the first 3h of injury, whereas after PBBI NCS occurred sporadically (0-5% per hour) throughout the 72h recording period. In both models, severity of PEDs was positively correlated to the severity of Type I seizures. But IRDA appeared to be an independent index, not predictive of other epileptic events. Conclusions This study provided comprehensive comparisons of post-traumatic and post-ischemic epileptic profiles. The identification of the similarities and differences across a broad spectrum of epileptic events may lead to differential strategies for post-traumatic/stroke seizure interventions, e.g. treating post-ischemic seizures more aggressively during the acute phase of injury, and treating post-traumatic seizures more selectively when time allows for referencing other epileptic activities.

3285. Lu, X. C. M., et al. (2016). "Synergistic effects of phenytoin and levetiracetam combination therapy on attenuation post-traumatic nonconvulsive seizures." Journal of neurotrauma **33**: A105-A106.

Post-traumatic seizures during the emergent state of traumatic brain injury (TBI) are deemed detrimental to the recovery of TBI patients. Phenytoin (PHT) and levetiracetam (LEV) are the commonly prescribed drugs as prophylaxis. Although LEV has become more favorable than PHT owing to its improved safety profile, many patients are still intractable to the monotherapy of either drug. In this study we applied the isobolographic approach to evaluate PHT + LEV combination therapy against penetrating ballistic-like brain injury (PBBI) induced nonconvulsive seizures (NCS) in rats, aimed at achieving synergism with properly paired dose ratios of the two drugs. NCS were induced by PBBI and detected by EEG recording for 72 h. PHT and LEV were tested at the following dose ratios (PHT/LEV): 1.8/6.3, 3.6/12.7, 7.2/25.4, or 14.5/50.7 mg/kg, which were derived from previous monotherapy results of each drug. Treatments were given intravenously twice/day for three days. Control animals received matching vehicle treatments. The results showed that except for the lowest dose ratio, PHT + LEV combination therapy significantly reduced NCS frequency and total seizure duration by 61%-84% across the three high dose ratios (as compared to vehicle treatments). The highest dose ratio also significantly reduced NCS incidence from 65% (Vehicle) to 25% and delayed NCS latency from 39 h (vehicle) to 57 h post-injury. The dose equivalent analysis of the isobolographic design indicated an achievement of synergism because the observed effects across all dose ratios exceeded the expected additive effects. Compared to our previous results of a PHT or LEV monotherapy derived from the identical TBI, the combined treatments of PHT + LEV outperformed the monotherapy of each individual drug by achieving statistically defined synergism. Critically, the doses of each drug used in combination were 2-3 fold lower than the monotherapy doses required of each drug, which may alleviate the safety concerns of these drugs used in TBI patients.

3286. Lu, X.-C. M., et al. (2020). "Post-Traumatic Epilepsy and Seizure Susceptibility in Rat Models of Penetrating and Closed-Head Brain Injury." Journal of neurotrauma **37**(2): 236-247.

Traumatic brain injury (TBI) carries a risk of developing post-traumatic epilepsy (PTE). Currently, animal models that replicate clinical PTE (delayed spontaneous and recurrent seizures) are limited, which hinders pre-clinical research. In this study, we used two rat models of penetrating ballistic-like brain injury (PBBI) and closed-head injury (CHI) to induce spontaneous seizures and also measure changes in seizure susceptibility. In the PBBI model, two trajectories (frontal and lateral) and two injury severities for each trajectory, were evaluated. In the CHI model, a single projectile impact to the dorsal/lateral region of the head was tested. Continuous video-electroencephalographic (EEG) recordings were collected for 10 days at 1 or 6 month(s) post-injury. After EEG recording, all rats were given a sub-convulsant dose of pentylenetetrazole (PTZ) to challenge the seizure susceptibility. The video-EEG recording did not detect PTE following the PBBI. Only one CHI rat demonstrated persistent and recurrent non-convulsive seizures detected at 6 months post-injury. However, after PTZ challenge, 50-100% of the animals across different TBI groups experienced seizures. Seizure susceptibility increased over time from 1 to 6 months post-injury across the majority of TBI groups. Injury severity effects were not apparent within the PBBI model, but were evident between PBBI and CHI models. These results demonstrated the difficulties in detecting delayed spontaneous post-traumatic seizures even in a high-risk model of penetrating brain injury. The PTZ-induced increase in seizure susceptibility indicated the existence of vulnerable risk of epileptogenesis following TBI, which may be considered as an alternative research tool for pre-clinical studies of PTE.

3287. Lu, X.-C. M., et al. (2017). "Combination therapy of levetiracetam and gabapentin against nonconvulsive seizures induced by penetrating traumatic brain injury." The journal of trauma and acute care surgery **83**(1 Suppl 1): S25-S34.

BACKGROUND: Posttraumatic seizures are a medical problem affecting patients with traumatic brain injury. Yet effective treatment is lacking owing to the limitations of antiepileptic drugs (AEDs) applicable to these patients., METHODS: In this study, we evaluated the dose-response efficacy of levetiracetam (12.5-100.0 mg/kg) and gabapentin (1.25-25.0 mg/kg) administered either individually or in pairs at fixed-dose ratios as a combination in mitigating posttraumatic nonconvulsive seizures induced by severe penetrating ballistic-like brain injury (PBBI) in rats. Seizures were detected by continuous electroencephalogram (EEG) monitoring for 72 hours postinjury. Animals were treated twice per day for 3 days by intravenous injections., RESULTS: Both levetiracetam (25-100 mg/kg) and gabapentin (6.25-25 mg/kg) significantly reduced PBBI-induced seizure frequency by 44% to 73% and 61% to 69%, and seizure duration by 45% to 64% and 70% to 78%, respectively. However, the two drugs manifested different dose-response profiles. Levetiracetam attenuated seizure activity in a dose-dependent fashion, whereas the beneficial effects of gabapentin plateaued across the three highest doses tested. Combined administration of levetiracetam and gabapentin mirrored

the more classic dose-response profile of levetiracetam monotherapy. However, no additional benefit was derived from the addition of gabapentin. Furthermore, isobolographic analysis of the combination dose-response profile of levetiracetam and gabapentin failed to reach the expected level of additivity, suggesting an unlikelihood of favorable interactions between these two drugs against spontaneously occurring posttraumatic seizure activities at the particular set of dose ratios tested., CONCLUSION: This study was the first attempt to apply isobolographic approach to studying AED combination therapy in the context of spontaneously occurring posttraumatic seizures. Despite the failure to achieve additivity from levetiracetam and gabapentin combination, it is important to recognize the objectivity of the isobolographic approach in the evaluation of AED combination therapy against seizures directly associated with brain injuries.

3288. Lu, X.-C. M., et al. (2009). "NNZ-2566, a glypromate analog, improves functional recovery and attenuates apoptosis and inflammation in a rat model of penetrating ballistic-type brain injury." Journal of neurotrauma **26**(1): 141-154.

Glycine-proline-glutamate (GPE) is an N-terminal tripeptide endogenously cleaved from insulin-like growth factor-1 in the brain and is neuroprotective against hypoxic-ischemic brain injury and neurodegeneration. NNZ-2566 is an analog of GPE designed to have improved bioavailability. In this study, we tested NNZ-2566 in a rat model of penetrating ballistic-type brain injury (PBBI) and assessed its effects on injury-induced histopathology, behavioral deficits, and molecular and cellular events associated with inflammation and apoptosis. In the initial dose-response experiments, NNZ-2566 (0.01-3 mg/kg/h x 12 h intravenous infusion) was given at 30 min post-injury and the therapeutic time window was established by delaying treatments 2-4 h post-injury, but with the addition of a 10- or 30-mg/kg bolus dose. All animals survived 72 h. Neuroprotection was evaluated by balance beam testing and histopathology. The effects of NNZ-2566 on injury-induced changes in Bax and Bcl-2 proteins, activated microgliosis, neutrophil infiltration, and astrocyte reactivity were also examined. Behavioral results demonstrated that NNZ-2566 dose-dependently reduced foot faults by 19-66% after acute treatments, and 35-55% after delayed treatments. Although gross lesion volume was not affected, NNZ-2566 treatment significantly attenuated neutrophil infiltration and reduced the number of activated microglial cells in the peri-lesion regions of the PBBI. PBBI induced a significant upregulation in Bax expression (36%) and a concomitant downregulation in Bcl-2 expression (33%), both of which were significantly reversed by NNZ-2566. Collectively, these results demonstrated that NNZ-2566 treatment promoted functional recovery following PBBI, an effect related to the modulation of injury-induced neural inflammatory and apoptotic mechanisms.

3289. Lu, X.-C. M., et al. (2011). "Electrocortical pathology in a rat model of penetrating ballistic-like brain injury." Journal of neurotrauma **28**(1): 71-83.

Traumatic brain injury (TBI) causes severe disruption of cerebral electrical activity and electroencephalography (EEG) is emerging as a standard tool to monitor TBI patients in the acute period of risk for secondary injuries. However, animal studies of EEG pathology in the context of TBI are surprisingly sparse, largely because of the lack of real-time continuous EEG (cEEG) monitoring in animal TBI models. Here, we performed long-term EEG monitoring to study nonconvulsive seizures (NCS), periodic epileptiform discharges (PED), and EEG power spectra following three injury severity levels in a rat model of penetrating ballistic-like brain injury (PBBI). EEG signals were recorded continuously from bilateral hemispheres of freely behaving rats for 72 h and for 2 h on days 7 and 14 after the injury. We report that the incidence of NCS and PED positively correlated with the injury severity, where 13%, 39%, and 59% of the animals exhibited NCS, and 0%, 30%, and 65% of the animals exhibited PED following 5%, 10% and 12.5% PBBI, respectively. Similar correlations existed for the number of NCS and PED events and their duration. NCS and PED occurred either independently or in tandem. Longer NCS durations were associated with larger lesion volumes. Significant EEG slowing evidenced by the EEG power shift toward the delta frequency band (0.5-4 Hz) occurred within 2 h after PBBI, which resolved over time but persisted longer after greater injury severity. In contrast, decreases in higher frequency power (i.e., 30-35 Hz) remained depressed throughout 14 days. This is the first long-term cEEG study of the acute injury phase in a rat model of severe TBI, demonstrating common occurrences of clinically observed electrocortical pathology, such as NCS, PED, and cortical slowing. These EEG pathologies may serve as critical care biomarkers of brain injury, and offer clinically relevant metrics for studying acute therapeutic interventions.

3290. Lu, X.-C. M., et al. (2013). "Similarities and differences of acute nonconvulsive seizures and other epileptic activities following penetrating and ischemic brain injuries in rats." Journal of neurotrauma **30**(7): 580-590.

The similarities and differences between acute nonconvulsive seizures (NCS) and other epileptic events, for example, periodic epileptiform discharges (PED) and intermittent rhythmic delta activities (IRDA), were characterized in rat models of penetrating and ischemic brain injuries. The NCS were spontaneously induced by either unilateral frontal penetrating ballistic-like brain injury (PBBI) or permanent middle cerebral artery occlusion (pMCAO), and were detected by continuous electroencephalogram (EEG) monitoring begun immediately after the injury and continued for 72 h or 24 h, respectively. Analysis of NCS profiles (incidence, frequency, duration, and time distribution) revealed a high NCS incidence in both injury models. The EEG waveform expressions of NCS and PED exhibited intrinsic variations that resembled human electrographic manifestations of post-traumatic and post-ischemic ictal and inter-ictal events, but these waveform variations were not distinguishable between the two types of brain injury. However, the NCS after pMCAO occurred more acutely and intensely (latency=0.6 h, frequency=25 episodes/rat) compared with the PBBI-induced NCS (latency=24 h, frequency=10 episodes/rat), such that the most salient features differentiating post-traumatic and post-ischemic NCS were the intensity and time distribution of the NCS profiles. After pMCAO, nearly 50% of the seizures occurred within the first 2 h of injury, whereas after PBBI, NCS occurred sporadically (0-5%/h) throughout the 72 h recording period. The PED were episodically associated with NCS. By contrast, the IRDA appeared to be independent of other epileptic events. This study provided comprehensive comparisons of post-traumatic and post-ischemic epileptic profiles. The identification of the similarities and differences across a broad spectrum of epileptic events may lead to differential strategies for post-traumatic and post-stroke seizure interventions.

3291. Lu, X.-C. M., et al. (2016). "Comprehensive Evaluation of Neuroprotection Achieved by Extended Selective Brain Cooling Therapy in a Rat Model of Penetrating Ballistic-Like Brain Injury." Therapeutic hypothermia and temperature management **6**(1): 30-39.

Brain hypothermia has been considered as a promising alternative to whole-body hypothermia in treating acute neurological disease, for example, traumatic brain injury. Previously, we demonstrated that 2-hours selective brain cooling (SBC) effectively mitigated acute (<=24 hours postinjury) neurophysiological dysfunction induced by a penetrating ballistic-like brain injury (PBBI) in rats. This study evaluated neuroprotective effects of extended SBC (4 or 8 hours in duration) on sub-acute secondary injuries between 3 and 21 days postinjury (DPI). SBC (34degreeC) was achieved via extraluminal cooling of rats' bilateral common carotid arteries (CCA). Depending on the experimental design, SBC was introduced either immediately or with a 2- or 4-hour delay after PBBI and maintained for 4 or 8 hours. Neuroprotective effects of SBC were evaluated by measuring brain lesion volume, axonal injury, neuroinflammation, motor and cognitive functions, and post-traumatic seizures. Compared to untreated PBBI animals, 4 or 8 hours SBC treatment initiated immediately following PBBI produced comparable neuroprotective benefits against PBBI-induced early histopathology at 3 DPI as evidenced by significant reductions in brain lesion volume, axonal pathology (beta-amyloid precursor protein staining), neuroinflammation (glial fibrillary acetic protein stained-activated astrocytes and rat major histocompatibility complex class I stained activated microglial cell), and post-traumatic nonconvulsive seizures. In the later phase of the injury (7-21 DPI), significant improvement on motor function (rotarod test) was observed under most SBC protocols, including the 2-hour delay in SBC initiation. However, SBC treatment failed to improve cognitive performance (Morris water maze test) measured 13-17 DPI. The protective effects of SBC on delayed axonal injury (silver staining) were evident out to 14 DPI. In conclusion, the CCA cooling method of SBC produced neuroprotection measured across multiple domains that were evident days/weeks beyond the cooling duration and in the absence of overt adverse effects. These "proof-of-concept" results suggest that SBC may provide an attractive neuroprotective approach for clinical considerations.

3292. Lu, X.-C. M., et al. (2015). "Dual Therapeutic Effects of C-10068, a Dextromethorphan Derivative, Against Post-Traumatic Nonconvulsive Seizures and Neuroinflammation in a Rat Model of Penetrating Ballistic-Like Brain Injury." Journal of neurotrauma **32**(20): 1621-1632.

Post-traumatic seizures can exacerbate injurious outcomes of severe brain trauma, yet effective treatments are limited owing to the complexity of the pathology underlying the concomitant occurrence of both events. In this study, we tested C-10068, a novel deuterium-containing analog of (+)-N-methyl-3-ethoxymorphinan, in a rat model of penetrating ballistic-like brain injury (PBBI) and evaluated the effects of C-10068 on PBBI-induced nonconvulsive seizures (NCS), acute neuroinflammation, and neurofunctional outcomes. NCS were detected by electroencephalographic

monitoring. Neuroinflammation was evaluated by immunohistochemical markers, for example, glial fibrillary acidic protein and major histocompatibility complex class I, for activation of astrocytes and microglia, respectively. Neurofunction was tested using rotarod and Morris water maze tasks. Three infusion doses of C-10068 (1.0, 2.5, and 5.0 mg/kg/h x 72 h) were tested in the antiseizure study. Neuroinflammation and neurofunction were evaluated in animals treated with 5.0 mg/kg/h x 72 h C-10068. Compared to vehicle treatment, C-10068 dose dependently reduced PBBI-induced NCS incidence (40-50%), frequency (20-70%), and duration (30-82%). The most effective antiseizure dose of C-10068 (5.0 mg/kg/h x 72 h) also significantly attenuated hippocampal astrocyte activation and perilesional microglial reactivity post-PBBI. Within C-10068-treated animals, a positive correlation was observed in reduction in NCS frequency and reduction in hippocampal astrocyte activation. Further, C-10068 treatment significantly attenuated astrocyte activation in seizure-free animals. However, C-10068 failed to improve PBBI-induced motor and cognitive functions with the dosing regimen used in this study. Overall, the results indicating that C-10068 exerts both potent antiseizure and antiinflammatory effects are promising and warrant further investigation.

3293. Lu, X. M., et al. (2014). "A combination therapy of phenytoin and ethosuximide improved therapeutic benefits against post-traumatic nonconvulsive seizures." Journal of neurotrauma **31**(12): A77-A78.

Previously we reported that treatment with phenytoin (PHT) or ethosuximide (EXM) dose-dependently attenuated post-traumatic nonconvulsive seizures (NCS) induced in rats by penetrating ballistic-like brain injury (PBBI). The efficacious monotherapy dose ranges of the two drugs were identified to be 20-30 mg/kg (PHT) and 125-187.5 mg/kg (EXM), but moderate-severe sedation resulted. In this study isobolographic analysis was used to construct fixed dose ratios for the combination of PHT and EXM to determine if combined treatments could improve anti-seizure efficacy. All rats received frontal PBBI and were immediately subjected to postinjury EEG/video monitoring for 72 h for seizure detection. PHT and EXM were tested in pairs at the following fixed dose ratios: 1.8/ 5.5, 3.6/11.1, 7.2/22.2, or 14.4/44.4 mg/kg (PHT/EXM) and the treatments were given intravenously twice/day for three consecutive days, initiated 30 min post-injury. Control animals received matching vehicle treatments. Outcome measures included NCS incidence, frequency, duration, and onset latency. The results showed that among the four dose ratios tested, the highest dose ratio (14.4/44.4 mg/kg) significantly reduced the overall incidence of NCS from 69% (vehicle group) to 29% (PHT +EXM group), decreased NCS frequency by 80% (Vehicle: 14.3±5.5 NCS episodes/rat vs. PHT + EXM: 2.8±1.3 episodes/rat), and shortened NCS cumulative duration by 84% (Vehicle: 502.8±277 sec/rat vs. PHT/EXM: 82.5±38.1 sec/rat). The PHT +EXM combination treatment also significantly delayed onset latency of NCS from 20±4.4 h post PBBI (vehicle) to 53±7.9 h (PHT + EXM). More importantly, compared to the effective monotherapy doses of PHT and EXM as mentioned above, the PHT +EXM combination therapy proved to be equally efficacious without overt sedation using 28% less PHT and 64% less EXM, which resulted in an additive effect as defined by the isobolographic analysis. This study supports the idea that combination therapy enhances the effectiveness of the drug constituents and provides improved therapeutic benefits by limiting potential side effects of individual drugs.

3297. Lucas, J. W., et al. (1975). "Management of shotgun wound of the symphysis." Journal of oral surgery (American Dental Association : 1965) **33**(8): 622-628.

3298. Lucas, R. M. and D. Mitterer (1990). "Pneumatic firearm injuries: trivial trauma or perilous pitfalls?" The Journal of emergency medicine **8**(4): 433-435.

This report describes an injury due to a pneumatic firearm. Though powder firearm injuries are generally considered serious, pneumatic weapon injuries are often viewed as minor or insignificant trauma. Children and adolescents primarily wield these weapons contributing to their "harmless" aura. However, dramatic increases in muzzle and impact velocities have transformed the newer generation of pneumatic firearms into formidable weapons. Consequently, the literature is replete with increasing incidences of serious injury due to pneumatic weapons.

3299. Luderwald, S., et al. (2008). "[Suicidal gunshot to the nape from a small-bore rifle]." Suizid durch Gewehrschuss in den Nacken. **221**(1-2): 36-42.

A 55-year-old man was found dead on the bed lying on his side in a pool of blood with a bullet entrance hole in the nape. Behind his body, a semi-automatic rifle Remington Nylon, cal. .22 LR, was detected. As the gunshot entrance site was rather unusual for suicide, a forensic autopsy was performed, which showed a contact shot to the nape with the bullet path running upward to the left frontal area. The man had been treated with citalopram for delusional depression, so that a suicidal act seemed plausible, and the autopsy and criminalistic findings were also compatible with this assumption. A remarkable fact of the present case is that a long firearm had been used. Reports on suicidal shots to the nape are comparatively rare in the medicolegal literature and usually refer to pistols or revolvers.

3300. Ludlow, C. L., et al. (1986). "Brain lesions associated with nonfluent aphasia fifteen years following penetrating head injury." Brain : a journal of neurology **109 (Pt 1)**: 55-80.

Men who sustained penetrating head injuries resulting in nonfluent aphasia within six months following injury, were examined fifteen years later and classified into two groups, 13 with persistent nonfluent aphasia, and 26 without symptoms of aphasia. Relative to a normal control group on a comprehensive battery of speech and language tests, the chronic nonfluent aphasics demonstrated syntactic processing deficits in all language modalities, with only mild or no impairment in other language faculties. The recovered group demonstrated deficits only in written expressive syntax. The CT lesions of the two groups differed in the extent of left hemisphere lesion volume and the degree of posterior and deep lesion extension within the left hemisphere. The nonrecovered group did not have greater right hemisphere damage. Broca's area was equally involved in 77 per cent of patients in both groups. All patients in the nonrecovered group had posterior extension of their lesions in Wernicke's area with some involvement of the underlying white matter and basal ganglia in the left hemisphere.

3301. Ludlow, C. L., et al. (1987). "Site of penetrating brain lesions causing chronic acquired stuttering." Annals of neurology **22**(1): 60-66.

Ten subjects exhibited acquired stuttering that had persisted for 10 to 15 years following penetrating missile wounds sustained during the Vietnam War. None had a history of developmental or chronic adult stuttering. In comparison with other head-injured subjects and normal control subjects, the subjects with acquired stuttering had significant deficits in skilled rapid hand movements and oral and speech movements, suggesting a motor control disorder. The identified brain lesions of the acquired stuttering group were on the right in 5 subjects, on the left in 4, and bilateral in 1. The internal and external capsules, the frontal white matter, and the striatum were more frequently involved in the acquired stuttering group than in other head-injured subjects (p less than or equal to 0.05). This speech rhythm and rate disorder was not associated with evident cortical lesions in either hemisphere but with predominantly unilateral lesions of the subcortical pyramidal and extrapyramidal systems.

3302. Ludwig, C. A., et al. (2019). "Traumatic chorioretinitis sclopetaria: Risk factors, management, and prognosis." American Journal of Ophthalmology Case Reports **14**: 39-46.

Purpose: To describe new cases of sclopetaria and evaluate the risk factors, management, and visual prognosis of all reported cases in the literature. Observations: We performed a retrospective, observational case series. This study included six cases (median age 23, interquartile range 33) of sclopetaria. Additionally, literature searches were conducted in the PubMed and Cochrane Library databases to uncover risk factors associated with all published cases of sclopetaria. Main outcome measure was best corrected visual acuity (BCVA) worse than 20/20. Sixty-seven cases (71 eyes) of sclopetaria have been reported, of which 59 cases (61 eyes) met inclusion criteria in this study. Most were young (median age 19.5 years) men (51/59, 88.1%). Thirty-seven eyes were observed while 24 underwent immediate surgery including six pars plana vitrectomies and three scleral buckles. Compared to initial presentation, BCVA improved in 31/48 (64.6%) eyes, remained stable in 12/48 eyes (25.0%), and worsened in 5/48 eyes (10.4%). Ten patients (16.4%) achieved a final BCVA of 20/20 with median follow up time of seven months. In a multivariate model, location of sclopetaria in the macula, temporal retina, or immediate orbital foreign body removal predicted poor final BCVA with an area under receiver operating characteristic curve of 0.767. Conclusions and importance: Traumatic chorioretinitis sclopetaria is rare, but reports have increased dramatically over the past two decades. While pars plana vitrectomy may be required for the management of retinal detachments and non-clearing vitreous hemorrhage, close observation is appropriate in most cases. Visual prognosis is poor with most patients attaining 20/200 vision or worse.

3303. Luef, S. M., et al. (2016). "Trends in weapon-related injuries from violence in Odense Municipality, Denmark 1991-2009." Danish medical journal **63**(11).

INTRODUCTION: The aim of this study was to examine the development in incidence rates and the severity of weapon-related physical interpersonal violence in Odense Municipality, Denmark from 1991 to 2009., METHODS: All victims of physical interpersonal violence with weapon-related injuries treated at the Emergency Department in the 1991-2009 period at Odense University Hospital, Denmark, and/or subjected to medico-legal autopsy at the Institute of Forensic Medicine in the 1991-2009 period at the University of Southern Denmark were included. Incidence rates were estimated following stratification by gender and age. The development in the incident rates was examined., RESULTS: Overall, 2,957 victims were included. The overall incidence rate was 8.5 per 10,000 population/year (14.6 and 2.7 for males and females, respectively). The rates did not change significantly in the study period. Most victims were injured with bottles/glass and blunt weapons (44.8% versus 28.2%), whereas 24% were injured with sharp weapons and 3% with firearms. Most lesions were sustained to the head/neck (56.1%) and to the upper limbs (26.2%). A total of 182 (6.1%) victims had lesions that were considered severe. The mortality rate was 4.8 per 1,000 victims in males and 29.1 per 1,000 victims in females. More than half (57%) of the homicides were caused by lesions due to sharp weapons., CONCLUSION: Weapon-related injuries are rare in the Odense Municipality. The incidence rate of weapon-related violence did not increase in the study period. Additionally, no evidence of an increased proportion of severe injuries was found. Women had a seven-fold higher mortality than males., FUNDING: none., TRIAL REGISTRATION: not relevant.

3304. Lujan, M., et al. (2019). "Neural stem cell transplantation mitigates penetrating ballistic-like brain injury (PBBI) induced motor deficit." Journal of neurotrauma **36**(13): A77.

Penetrating traumatic brain injury (PTBI) is associated with poor neurological outcomes. No restorative treatments are currently available. Cell replacement via neural stem cell transplantation is a putative therapeutic approach based on preclinical studies. Previous studies from our group established (i) durable engraftment of human fetal NSC (hNSC; Neuralstem Inc.), FDA approved for use in clinical trials, (ii) optimal location and injury-transplant interval. This study tests the hypothesis that engraftment and PTBI deficit amelioration will be cell dose dependent. Fifty adult male Sprague Dawley rats were randomized to five groups (10 per group). Unilateral PTBI was induced by rapid inflation of a balloon on a perforated probe stereotactically inserted through the right frontal lobe in 30 rats. Pair of injured and uninjured (Sham) to receive either 160,000 cells/rat (0.16M)- low dose or 1,600,000 cells/rat (1.6M) - high dose of hNSCs intracerebrally in PTBI perilesion. The injured group with vehicle injection served as negative control. Animals were immunosuppressed and assessed on 'GridWalk' for motor ability pre transplantation and 12 weeks post transplantation. The mean left front foot faults pre transplant were 23.2±3.34 (n= 30). At 12 weeks post transplantation, vehicle, low and high cell dose group LFF were 25.6±2.386 (n= 10), 13±0.948 (n= 5) and 21.2±3.917 (n= 5) respectively. One-way ANOVA revealed statistical significant differences only between pre transplant and 12 week low dose group (PTBI +0.16M 12wk) with a mean difference of 10.2 and p value 0.0016. GFP cell count based engraftment was not significantly different for a given cell doses between groups. Thus a cell dose dependent therapeutic effect in conjunction with previous data collectively support the notion that hNSC transplants preserve motor function. Follow up

studies in gyrencephalic TBI models with appropriate cell dose would help arrive at appropriate cell dose for a human application.

3305. Lund, J. R., et al. (2021). "Computed tomographic assessment of brain tissue disruption and skull damage in equine cadaveric heads caused by various firearm-ammunition combinations applied as potential gunshot methods for euthanasia of horses." American journal of veterinary research **82**(1): 28-38.

OBJECTIVE: To evaluate with CT the characteristics of brain tissue disruption and skull damage in cadaveric heads of adult horses caused by each of 6 firearm-ammunition combinations applied at a novel anatomic aiming point., SAMPLE: 53 equine cadaveric heads., PROCEDURES: Heads placed to simulate that of a standing horse were shot with 1 of 6 firearm-ammunition combinations applied at an aiming point along the external sagittal crest of the head where the 2 temporalis muscles form an inverted V. Firearm-ammunition combinations investigated included a .22-caliber long rifle pistol firing a 40-grain, plated lead, solid-core or hollow-point bullet (HPB); a semiautomatic 9-mm pistol firing a 115-grain, jacketed HPB; a semiautomatic .223-caliber carbine firing a 55-grain, jacketed HPB; a semiautomatic .45-caliber automatic Colt pistol firing a 230-grain, jacketed HPB; and a 12-gauge shotgun firing a 1-oz rifled slug. Additional heads placed in a simulated laterally recumbent position were shot with the semiautomatic 9-mm pistol-HPB combination. All heads underwent CT before and after being shot, and images were evaluated for projectile fragmentation, skull fracture, and cerebrum, cerebellum, and brainstem disruption., RESULTS: Computed tomography revealed that all firearm-ammunition combinations caused disruption of the cerebrum, cerebellum, and brainstem that appeared sufficient to result in instantaneous death of a live horse. Hollow-point ammunition was as effective as solid-core ammunition with regard to brain tissue disruption. Brain tissue disruption was not affected by head positioning., CONCLUSIONS AND CLINICAL RELEVANCE: Results indicated that the examined firearm-ammunition combinations, when applied at a novel aiming point, appear to be reasonable options for euthanasia of horses.

3306. Lundstrom, M. and L. Frisen (1975). "Evolution of descending optic atrophy. A case report." Acta ophthalmologica **53**(5): 738-746.

Fundus changes following severe trauma to the intracranial optic nerve were followed by means of serial fundus photography. The eye was completely blind. Little change was seen during the first 4 weeks. The retinal nerve fibre layer disappeared gradually during weeks 4 to 8. At the same time the retinal vessels turned narrow, and vascular pseudo-sheathing appeared close to the optic disc. Disc pallor was not maximal until the 12th week, when the peripapillary retina also had acquired a mottled appearance.

3307. Lundy, C. T., et al. (2010). "Outcome and cost of childhood brain injury following assault by young people." Emergency medicine journal : EMJ **27**(9): 659-662.

INTRODUCTION: Media interest in inter-juvenile violence in the UK has emphasised to clinicians the lack of data on medical outcomes following injury. A study was undertaken to examine the incidence of childhood head injury in a large trauma centre serving an inner city multiethnic community. The aim was to establish the physical and financial cost of survival with a head injury following inter-juvenile assault., METHODS: All children aged 8-16 years attending King's College Hospital, London (KCH) because of a head injury were identified restrospectively. The case notes of those admitted to the neurosurgical and neurorehabilitation service with a head injury between 1 August 2006 and 30 September 2008 were reviewed., RESULTS: A total of 1126 children attended KCH with a head injury. Eight boys required admission for treatment of a head injury following alleged inter-juvenile assault. The mechanisms of brain injury included a penetrating knife wound, assault with a bottle and physical assault. One child died following admission as a result of his brain injury. Complete neurological outcome data were available on six cases. Three had a hemiplegia, four had speech and language difficulties, two had visual impairment, five had behavioural changes and five had cognitive difficulties., CONCLUSIONS: This study demonstrates the serious consequences of inter-juvenile assault. Survival can be associated with neurological and psychological deficits. The cost to the health service is substantial. Further work is required to establish the long-term needs of these children.

3308. Lunetta, P., et al. (2002). "Suicide by intracerebellar ballpoint pen." The American journal of forensic medicine and pathology **23**(4): 334-337.

Self-inflicted eye injuries among psychiatric patients are relatively common. Transorbital penetrating traumas are more rare but if undiagnosed may cause lethal intracranial lesions. We report a fatal case of a 25-year-old schizophrenic man who introduced a plastic ballpoint pen through his right orbit up to the cerebellum. The computed tomography findings were misinterpreted as a penetrating track from a bullet. The patient died 4 days after the trauma, and the causative object was identified only at autopsy. When no precise information about an apparently trivial ocular trauma is available, clinicians and investigators must adequately consider, especially in psychiatric patients, the possibility of an intracranial penetrating lesion.

3309. Lunsford, L. D., et al. (1977). "Cranial computed tomographic demonstration of intracranial penetration by an orbital foreign body." Neurosurgery **1**(1): 57-59.

A 9-year-old boy suffered intracerebral penetration by a stick driven into his right orbit. Diagnosis was obtained by cranial computed tomography (CT), and this test directed appropriate immediate surgical intervention. Combined orbital exploration and craniotomy was followed by a gratifying recovery. The importance of CT in orbital and possible intracranial trauma is stressed.

3310. Luo, D., et al. (2021). "Lincs dataset-based repositioning of dutasteride as an anti-neuroinflammation agent." Brain Sciences **11**(11).

Neuroinflammation is often accompanied by central nervous system (CNS) injury seen in various CNS diseases, with no specific treatment. Drug repurposing is a strategy of finding new uses for approved or investigational drugs, and can be enabled by the Library of Integrated Networkbased Cellular Signatures (LINCS), a large drug perturbation database. In this study, the signatures of Lipopolysaccharide (LPS) were compared with the signatures of compounds contained in the LINCS dataset. To the top 100 compounds obtained, the Quantitative Structure-Activity Relationship (QSAR)based tool admetSAR was used to identify the top 10 candidate compounds with relatively high blood–brain barrier (BBB) penetration. Furthermore, the seventh-ranked compound, dutasteride, a 5α-reductase inhibitor, was selected for in vitro and in vivo validation of its anti-neuroinflammation activity. The results showed that dutasteride significantly reduced the levels of IL-6 and TNF-α in the supernatants of LPS-stimulated BV2 cells, and decreased the levels of IL-6 in the hippocampus and plasma, and the number of activated microglia in the brain of LPS administration mice. Furthermore, dutasteride also attenuated the cognitive impairment caused by LPS stimulation in mice. Taken together, this study demonstrates that the LINCS dataset-based drug repurposing strategy is an effective approach, and the predicted candidate, dutasteride, has the potential to ameliorate LPSinduced neuroinflammation and cognitive impairment.

3311. Luo, P. and Z. Fei (2015). "Twisted steel-induced penetrating head injury." Neurology **84**(18): 1909.

3312. Luo, W., et al. (2012). "Penetrating brain injury caused by nail guns: two case reports and a review of the literature." Brain injury **26**(13-14): 1756-1762.

BACKGROUND: To the best of the authors' knowledge, there are few case reports of penetrating brain injuries (PBI) caused by nail guns and these have usually involved incomplete penetration of the skull. Complete penetration of a nail into the intracranial cavity is extremely rare., CASE STUDY: Here, two such cases are presented. In the first, the nail entered through the right temporal bone, lodged in the right temporal lobe and was removed via craniotomy with intra-operative ultrasound guidance. In the second, the nail destroyed the left parietal bone, damaged the left internal capsule and lodged in the left temporal lobe near the left petrous apex and the brain stem. According to the latest literature retrieval, this is the first reported case of nail-gun injury to the internal capsule. The position of the nail precluded removal without further neurologic damage. Treatment strategies designed to optimize outcome, with or without surgery, and possible complications are discussed in this report.

3313. Lupariello, F., et al. (2018). "Staged crime scene determination by handling physical and digital evidence: Reports and review of the literature." Forensic science international **288**: 236-241.

Geberth in 2006 stated that "staging is a conscious criminal action on the part of an offender to thwart an investigation." In the present paper two crime scenes staged by handling digital evidence are reported. The first case involves a 50-year-old woman who had been living with the offender for three years before he murdered her at the end of their relationship. He staged the scene as a sex-related crime committed by an unknown perpetrator. The second case concerns a young woman who was found dead in Southern Italy in January 2004 with a gunshot on the forehead. The boyfriend, responsible for the murder, had staged the crime scene as a suicide. Three years earlier in Germany, he had also murdered the victim's mother. In both cases, the correlation of physical and digital forensic evidence was crucial in the definition of the manner of death.

3314. Lustenberger, T., et al. (2010). "Time course of coagulopathy in isolated severe traumatic brain injury." Injury **41**(9): 924-928.

BACKGROUND: Time aspects of coagulopathy following severe traumatic brain injury (sTBI) are ill defined throughout the literature. Thus, the aim of this study was to evaluate the time course of coagulopathy following isolated sTBI and its relationship to in-hospital outcomes., METHODS: Retrospective analysis of patients sustaining isolated sTBI (head AIS 3, extracranial injuries AIS < 3). TBI coagulopathy was defined as thrombocytopenia and/or elevated international normalised ratio (INR) and/or prolonged activated partial thromboplastin time (aPTT). Incidence, onset and duration of sTBI-coagulopathy and its impact on morbidity and mortality were analysed., RESULTS: Overall, 45.7% (n = 127) of the 278 patients included developed coagulopathy. Coagulopathy occurred 23.1 +/- 2.2 h [range: 0.1-108.2 h (0-4.5 days)] post-admission with a mean duration of 68.0 +/- 7.4 h[range: 2.6-531.4 h (0.1-22.1 days)]. The time interval to onset of coagulopathy decreased significantly with increasing head injury severity (p = 0.015). Early coagulation abnormalities occurring within 12 h of admission along with markers of devastating head injury including head AIS 5, penetrating injury mechanism, subdural hematoma, and a low GCS on admission proved to be independent risk factors for mortality., CONCLUSIONS: The sTBI-associated coagulopathy may ensue as late as 5 days after injury with a prolonged duration (>72 h) in 30% of patients. Early coagulopathy occurring within 12 h after injury is a marker of increased morbidity and poor outcomes. Pertinent prolonged screening of this sequela is warranted.

3315. Lux, C., et al. (2014). "Identification of gunshots to the head by detection of RNA in backspatter primarily expressed in brain tissue." Forensic science international **237**: 62-69.

Traces of backspatter recovered from the inside of the barrel of a gun that was used to deliver suicidal or homicidal contact shots may be a source of valuable forensic evidence and first systematic investigations of the persistence of victim DNA from inside firearms have been presented. The aim of the present study was to include victim RNA in such analyses to determine the origin of tissues in addition and parallel to standard DNA profiling for forensic identification purposes. In a first step, suitable mRNA (C1orf61) and micro-RNAs (miR-124a and miR-124*) that are primarily expressed in brain tissue were selected from potential candidates and confirmed using quantitative PCR (qPCR). Secondly, a co-extraction procedure for RNA and DNA was established and brain differentiability of the selected RNAs was demonstrated via qPCR using samples from experimental shots at ballistic models. In a third step, this procedure was successfully applied to analyse samples from real casework comprising eight cases of suicidal contact shots. In this pilot study, we are first to report the possibility of co-extracting mRNA, miRNA and DNA from ballistic trace samples collected from the inside of firearms and we demonstrate that RNA and DNA based analyses can be performed in parallel to produce informative and highly complementary evidence.

3316. L'Vovich, A. I. (2000). "[The descending cortical pathways of the frontal lobe to the nuclei of the hypothalamic mamillary bodies in human craniocerebral trauma]." Niskhodiashchie puti kory lobnoi doli k iadram sostsevidnykh tel gipotalamusa pri cherepno-mozgovoi travme cheloveka. **117**(2): 41-45.

Structural organization of conducting ways of the frontal lobe cortex to hypothalamic nuclei was studied in sections of brain from 5 patients who died in short terms after craniocerebral trauma and during the experiment in 5 macaque rhesus monkeys with unilateral destruction of different cortical fields of frontal area. Series of brain sections were processed using silver nitrate impregnation after Bielschowsky [correction of Bilshovsky] with counterstaining of nuclear structures after Kavamura with cresyl violet. The presence of direct corticohypothalamic ways from the cortex of

the orbital surface of inferior (field 47 and its subfields) and superior (field 11) frontal gyri and frontal pole (field 10) to nuclei of mamillary complex and lateral hypothalamus was established. Direct frontomamillary ways from these cortical areas terminate basically in medial mamillary nucleus. In monkey direct frontomamillary ways were distinguished in the cortex of field 47. In man widening of the area where corticohypothalamic ways arise is connected with progressive development of the telencephalic cortex and phylogenetically new formation of hypothalamus--mamillary bodies.

3317. Lyberg, T. and O. A. Olstad (1991). "The vascularized fibular flap for mandibular reconstruction." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **19**(3): 113-118.

Vascularized fibular bone grafts have advantages over other bone grafts in the restoration of the contour and function of defective mandibles. The fibular graft can be tailored to fit even major mandibular defects; in combination with preformed temporomandibular joint prostheses total mandibular reconstruction can be performed in a single procedure. The fibular transplant is considered ideal for the insertion of implants to support dental suprastructures to obtain maximal oral rehabilitation. We have used fibular grafts in eight cases for primary or secondary reconstruction of a variety of mandibular defects resulting from cancer, chronic osteomyelitis or gunshot injuries. The results have been most encouraging with respect to function and cosmetic appearance. There have been no transplant failures and minimal donor site complications.

3318. Lydiatt, D. D., et al. (1987). "Problems in evaluation of penetrating foreign bodies with computed tomography scans: report of cases." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **45**(11): 965-968.

Computed tomography is the best radiologic modality available in the evaluation of penetrating injuries to the soft tissues. The technique is the best available when the foreign body has a density similar to the surrounding tissues. Limitations of CT scanning include difficulty in identifying small foreign bodies, objects with densities similar to surrounding structures, and detecting vascular injury. Interpretation of postoperative changes is also difficult. Two cases have been presented to illustrate the advantages, and limitations of CT scanning in penetrating soft tissue trauma.

3319. Lyson, T., et al. (2013). "Transnasal endoscopic removal of intraorbital wooden foreign body." Journal of neurological surgery. Part A, Central European neurosurgery **74 Suppl 1**: e100-103.

INTRODUCTION: Traditionally retrobulbar lesions localized in the medial part of the orbit are removed using rather extensive extracranial approaches. A few cases were recently reported in which lesions of a certain type were removed using a transnasal endoscopic approach. We describe a patient in whom we managed to remove a sizable piece of wood from the orbit endoscopically after two former unsuccessful attempts., CASE REPORT: A 30-year-old male with a wooden foreign body localized medially behind the globe was operated on 5 days after trauma. His vision was preserved but motility of the eye globe was heavily restricted. An endoscopic transnasal, transethmoidal approach with neuronavigated tools was used to remove the foreign body successfully, using a "bimanual technique." The patient was discharged on day 1 postoperatively with intact vision. Movement restriction gradually resolved, and after 2 weeks he recovered completely., CONCLUSION: Foreign bodies localized close to the medial wall of the orbit can be safely removed using an endoscopic transnasal approach. The use of neuronavigation is essential for the precision, safety, and effectiveness of the procedure. Copyright Georg Thieme Verlag KG Stuttgart . New York.

3320. Lyson, T., et al. (2014). "Endoscopic transconjunctival surgical approach to intraconal space of the orbit: first clinical experience." Neurologia i neurochirurgia polska **48**(4): 248-253.

BACKGROUND AND PURPOSE: Recently, a transconjunctival, endoscope-assisted (TEA) approach to the medial intra-orbital space was developed based on cadaver preparations, with an ultimate goal of minimizing disturbances of the anatomic structures of the orbit. However, no report on clinical validation of this promising technique was published thus far. We present our experiences with the TEA approach in two patients., MATERIAL AND METHODS: In emergency conditions, we approached the lateral retrobulbar space of a 42-year-old male through a 180degree incision close to the corneal limbus; a scrap of metal, which had perforated the globe and resided at its posterior wall, was removed endoscopically. Moreover, we used the TEA approach to remove a tumor from the upper intraconal space in a 63-year-old woman., RESULTS: In both patients the surgical goal was achieved with no muscle transection and without additional

morbidity and complications., CONCLUSIONS: Our experiences with TEA approach suggest that the procedure is clinically feasible, produces no co-morbidity and yields good functional and cosmetic results. As a result, the whole circumference of the retrobulbar space can be conveniently explored.

3321. Ma, H. M., et al. (2015). "An oxytocin gene polymorphism affects social outcome after traumatic brain injury." PM and R **7**(9): S93-S94.

Objective: To assess the effects of patient oxytocin gene polymorphisms on caregiver burden. Design: A prospective study of combat veterans with penetrating traumatic brain injury (pTBI) enrolled in Phases 2 and 3 of the Vietnam Head Injury Study (VHIS). Setting: Outpatient evaluation of American combat veterans with pTBI injured between 1967-1970. Questionnaires, including the Katz Adjustment Scale (KAS), were mailed to the patients' primary caregivers in 1985-1986. Blood samples were collected during Phase 3 (2003-2006). Participants: 131 combat veterans with pTBI and their caregivers (completed the KAS in 1985-1986). Interventions: Not applicable Main Outcome Measures: KAS subscales: R1 measures psychiatric symptoms; R2 indicates how frequently subjects participate in 16 socially expected activities; R3 measures caregiver expectations of subject participation in R2 activities; R4 measures the frequency of subjects' involvement in 23 leisure activities; R5 measures caregiver satisfaction with subject participation in R4 activities. Oxytocin single nucleotide polymorphisms tested in combat veterans with pTBI included rs7632287, rs53576, and rs2254298 (A to G), as well as rs1042778 (G to T). Results or Clinical Course: There was a significant difference in R2 between oxytocin rs7632287 AG (mean 34) and G (mean 38, P=.011). Subjects with G (a polymorphism that is known to be associated with pair-bonding relationships) compared to the AG polymorphism participated significantly more in household activities. There was also a significant difference in R4 between oxytocin rs2254298 AG (mean 38) and G (mean 43, P=.024). Subjects with the G polymorphism (associated with emotion and amygdala size) participated more in leisure activities. Having the A allele at either location did not significantly effect caregiver ratings on R2 or R4. None of the other KAS subscales were significantly affected by oxytocin gene expression. Conclusion: Genetic endowment can affect social integration after brain injury and should be considered as part of an individually tailored approach to rehabilitation intervention.

3322. Ma, J., et al. (2012). "Transocular removal of a retrobulbar foreign body and internal patch of the posterior exit wound with autologous tenon capsule." Archives of ophthalmology (Chicago, Ill. : 1960) **130**(4): 493-496.

A case of perforating ocular injury with a retrobulbar foreign body and a large full-thickness posterior pole defect near the optic disc was scheduled for vitrectomy after primary corneal suturing. Because it was difficult to remove the retrobulbar foreign body by orbitotomy and perform the outside suture, the retrobulbar foreign body was removed through the posterior hole by a transocular approach, and an autologous Tenon capsule flap was used to internally patch the large full-thickness posterior pole defect, thus enabling silicon tamponade. After 3 months of follow-up, there was no immune response around the patch. The retina remained mostly attached with a maintained peripheral visual field, normal intraocular pressure, and good cosmetic appearance. This surgical technique may be valuable in patients with a perforating retrobulbar foreign body and a large full-thickness posterior pole defect.

3323. Ma, Y., et al. (2020). "Methotrexate plus idarubicin improves outcome of new diagnosed primary central nervous system lymphoma patients." HemaSphere **4**: 1012.

Aims: Primary central nervous system lymphoma (PCNSL) is a rare subtype of non-Hodgkin's lymphoma. Although approximately 90% of PCNSL are pathologically diffuse large B cell lymphoma (DLBCL), the prognosis of PCNSL is much worse than other extranodal DLBCLs. Conventionally, methotrexate (MTX)-based chemotherapy has been a first-line choice for newly diagnosed PCNSL, while MTX combined with other medications may improve therapeutic outcomes such as cytarabine (Ara-C), idarubicin (IDA), and temozolomide. These medications have been selected based on their capability to penetrate the blood-brain barrier (BBB) and their efficacy against systemic lymphomas. However, the precise superiority of these polychemotherapies remains to be determined. Therefore, in this study, we assessed MTX together with IDA as first-line regimens for newly diagnosed CNS lymphoma in patients. Methods: We established a prospective cohort of PCNSL patients (18-65y) newly diagnosed between 30th June 2016 and 30th June 2019. Patients were randomly separated in two group: MTX only group and MTX/IDA group. In MTX only group, patients were treated with MTX 8g/m2 on day 1, while in MTX/IDA group patients were treated with IDA 10mg/m2 on day 2 flowing with MTX

8g/m2 on day 1. Treatments were repeated every 3 weeks except in case of progression and/or unacceptable toxicity or patient refusal. The last follow-up was conducted on 1st December 2020. The Kruskal-Wallis and Mann-Whitney U tests were used for quantitative parameters and the X2 square test was used for non-quantitative parameters. Univariate analysis was performed using log-rank test, and survival distributions were analyzed by the Kaplan-Meier curve and log-rank test. Multivariate analysis was done by Cox regression model. Results: A total of 47 newly diagnosed PCNSL patients were enrolled, including 27 patients in MTX only group and 20 patients in MTX/IDA group. There were no significant differences between two groups including gender, age, ECOG and other clinical characteristics. Complete remission (CR) rate was identified in 60% of patients in the IDA/MTX group and 51.85% of patients who received MTX only. Overall response (ORR) rate was 65% in the IDA/MTX group and 66.67% in the MTX only group. Median progression-free survival (PFS) in MTX/IDA group and MTX only group was 9.9 months and 10.9 months, respectively (P = 0.75). Median OS was not reached (NR) in the IDA/MTX group and 24.3 months in the MTX group (P = 0.21). There were no significant differences in adverse effects between two groups. Multivariate analysis of COX model showed only number of lesion in brain was independent factors for OS and PFS between MTX/IDA group and MTX only group. Summary/Conclusion: For newly diagnosed PCNSL patients with multiple lesions in brain, MTX/IDA showed better OS and PFS than MTX only as first-line treatment. (Figure Presented) .

3324. Mabrouk, A., et al. (2014). "Incidence, etiology, and patterns of maxillofacial fractures in Ain-Shams University, Cairo, Egypt: A 4-year retrospective study." Craniomaxillofacial Trauma and Reconstruction **7**(3): 224-232.

Although there is a worldwide increase in maxillofacial trauma incidence; the pattern and etiology of these injuries varies from one country to another depending on socioeconomic, cultural, and environmental factors. This study aims to realize the epidemiological characteristics of maxillofacial fractures in our department. A retrospective cross-sectional study of all facial trauma patients admitted to our department during 2009 to 2012. Patients' data including gender, age, etiology of trauma, the pattern and demographic distribution of fractures of maxillofacial skeleton, and associated injuries were analyzed and compared with previously published data. The chi-square test was used with a p value of less than 0.05, which was considered statistically significant. There is a significant increase in maxillofacial fractures incidence in the past 2 years than former ones. There is a male predominance with highest incidence in the age group of 20 to 40 years. Road traffic accident is the most common etiological factor followed by violence. There is increase in mandibular fracture incidence compared with midface. The significant increased incidence of maxillofacial fracture due to motor car accidents and assaults in the past 2 years reflects a behavioral change within the community.

3325. MacAulay, L. E., et al. (2009). "Effects of decomposition on gunshot wound characteristics: under cold temperatures with no insect activity." Journal of forensic sciences **54**(2): 448-451.

Information on gunshot wound characteristics has been well documented; however, there is little documented information on the effects of decomposition or environmental conditions on gunshot wound characteristics. This study was conducted in order to determine if decomposition would obscure or alter the physical surface characteristics of gunshot wounds when exposed to a low temperature environment. The study was conducted from November 2005 to January 2006 in Nova Scotia, Canada in forested and exposed environments, with air temperatures between -10 degrees C and +10 degrees C. Pigs were used as human models and were shot six times each at three different ranges (contact, 2.5 cm, and 1.5 m). Gunshot wound characteristics persisted until the wounds were covered with ice and snow, after which changes were observed. The changes were recognized as being unique to the different ranges of gunshots and it was concluded that changes due to decomposition under the conditions tested would not affect the collection and interpretation of gunshot wound evidence.

3326. MacAulay, L. E., et al. (2009). "Effects of decomposition on gunshot wound characteristics: under moderate temperatures with insect activity." Journal of forensic sciences **54**(2): 443-447.

Previous studies document characteristics of gunshot wounds shortly after they were inflicted. This study was conducted to determine if the early stages of decomposition obscure or alter the physical surface characteristics of gunshot wounds, thereby affecting the quantity and quality of information retrievable from such evidence. The study was conducted in August and September, 2005 in Nova Scotia, Canada in forested and exposed environments. Recently killed pigs were used as research models and were shot six times each at three different ranges (contact, 2.5 cm, and 1.5

m). Under these test conditions, the gunshot wounds maintained the characteristics unique to each gunshot range and changes that occurred during decomposition were not critical to the interpretation of the evidence. It was concluded that changes due to decomposition under the conditions tested would not affect the collection and interpretation of gunshot wound evidence until the skin was degraded in the late active or advanced decay stage of decomposition.

3327. Macdonald, M. E., et al. (2008). "Signs of life and signs of death: brain death and other mixed messages at the end of life." Journal of child health care : for professionals working with children in the hospital and community **12**(2): 92-105.

Brain death is a medical, legal and cultural category constructed to fill an important need created by evolving medical technologies and practices. However, managing life and death via organ transplants and brain death criteria is not without controversy; there remains much confusion and ambivalence in both lay and medical populations regarding both organ donation and the diagnostic category of brain death. By way of a case study of cranial trauma taken from a larger study of bereaved parents, this article discusses how, from a parent's perspective, brain death and organ donation are neither morally nor medically straightforward concepts. The case study presented in this article demonstrates the necessity for more research and clinical training in communication issues regarding brain death and end-of-life care with families in critical care situations.

3328. Macdonald, R. L., et al. (2003). "Randomized, pilot study of intermittent pneumatic compression devices plus dalteparin versus intermittent pneumatic compression devices plus heparin for prevention of venous thromboembolism in patients undergoing craniotomy." Surgical neurology **59**(5): 363-364.

BACKGROUND: Unfractionated heparin and the low molecular weight heparin, dalteparin, are used for prophylaxis against venous thromboembolism in patients undergoing craniotomy. These drugs were compared in a randomized, prospective pilot study comparing intermittent pneumatic compression devices plus dalteparin to intermittent pneumatic compression devices plus heparin., METHODS: One hundred patients undergoing craniotomy were randomly allocated to receive perioperative prophylaxis with subcutaneous (SC heparin, 5000 units every 12 hours, or dalteparin, 2,500 units once a day, begun at induction of anesthesia and continued for 7 days or until the patient was ambulating. Entry criteria were age over 18 years, no deep vein thrombosis (DVT) preoperatively as judged by lower limb duplex ultrasound and no clinical evidence of pulmonary embolism preoperatively. Patients with hypersensitivity to heparin, penetrating head injury or who refused informed consent were excluded. Patients underwent a duplex study 1 week after surgery and 1 month clinical follow-up. All patients were treated with lower limb intermittent pneumatic compression devices., RESULTS: There were no differences between groups in age, gender, and risk factors for venous thromboembolism. There were no differences between groups in intraoperative blood loss, transfusion requirements or postoperative platelet counts. Two patients receiving dalteparin developed DVT (one symptomatic and one asymptomatic). No patient treated with heparin developed DVT and no patient in either group developed pulmonary embolism. There were two hemorrhages that did not require repeat craniotomy in patients receiving dalteparin and one that did require surgical evacuation in a patient treated with heparin. Drug was stopped in two patients treated with dalteparin because of thrombocytopenia. None of these differences were statistically significant., CONCLUSION: There was no significant difference in postoperative hemorrhage, venous thromboembolism or thrombocytopenia between heparin and dalteparin. The results suggest that, given the small sample size of this trial, both drugs appear to be safe and the incidence of venous thromboembolism by postoperative screening duplex ultrasound appears to be low when these agents are used in combination with intermittent pneumatic compression devices.

3329. Macdonald, R. L., et al. (1999). "Safety of perioperative subcutaneous heparin for prophylaxis of venous thromboembolism in patients undergoing craniotomy." Neurosurgery **45**(2): 245-242.

OBJECTIVE: To determine whether perioperative subcutaneous heparin is safe to use for patients undergoing craniotomy and to determine the incidence of venous thromboembolism in patients undergoing craniotomy., METHODS: Perioperative prophylaxis with subcutaneous heparin, 5000 U every 12 hours, was begun at induction of anesthesia for craniotomy and continued for 7 days postoperatively or until the patient was ambulating. Entry criteria to the study included patient age over 18 years and no evidence of deep vein thrombosis (DVT) preoperatively as judged by lower limb duplex ultrasound. Patients were excluded if they had duplex evidence of DVT or clinical evidence of pulmonary embolus (PE) preoperatively, had hypersensitivity to heparin or related products, had sustained a

penetrating head injury, or refused informed consent. Any patient undergoing craniotomy was eligible, including patients with a ruptured aneurysm or arteriovenous malformation and those with spontaneous intracranial hemorrhage. Patients underwent duplex study 1 week after surgery and 1 month of clinical follow-up. Records were also kept on 68 nonstudy patients who refused consent. All patients were treated with lower limb pneumatic compression devices., RESULTS: One hundred six patients were treated. No differences were noted between study and nonstudy patients in some individual risk factors for DVT or PE, such as obesity, smoking, paralysis, infection, pregnancy or postpartum state, varicose veins, heart failure, or previous DVT or PE. Significantly more (43 of 106) patients in the study group had a history of risk factors for DVT or PE, particularly malignancy, however, compared with nonstudy patients (20 of 68 patients; chi2, P < 0.01). There were no differences between groups in intraoperative blood loss, transfusion requirements, or postoperative platelet counts. Four clinically significant hemorrhages occurred during surgery in patients receiving heparin. Three resulted from intraoperative aneurysm rupture and one from intraventricular bleeding during resection of an arteriovenous malformation. These events were believed to be related to known complications of these operations, not to heparin. Of the study patients, two developed symptomatic DVT and one developed a nonfatal PE during the 1-month postoperative period. One additional study patient developed DVT below the popliteal veins, which was not treated. Four study patients developed DVT 1 to 2 months after surgery. In nonstudy patients, three developed DVT and two developed PE (one fatal, one nonfatal)., CONCLUSION: Perioperative heparin may be safe to administer to patients undergoing craniotomy, but a larger study is needed to demonstrate efficacy.

3330. MacEwen, C. J. and G. Fullarton (1986). "A penetrating orbitocranial stab wound." The British journal of ophthalmology **70**(2): 147-149.

An unusual case of intracranial penetration of a bread knife through the orbit is described. Despite the proximity of the blade to the internal carotids, the optic nerves and chiasm, and the pituitary the patient survived with only a minimal field defect affecting the eye opposite to the entry site; otherwise no neurological or endocrine deficit was evident.

3331. MacFarlane, C. (1999). "Management of gunshot wounds: the Johannesburg experience." International surgery **84**(2): 93-98.

The Johannesburg hospitals see large numbers of gunshot wounds and there is, therefore, considerable experience in their management. Historically, management has been dictated by experimental theories of wounding mechanisms. More modern work has indicated that some of these theories have been somewhat misleading, and some traditional means of management have changed. The basic military surgical lessons of the excision of dead tissue, delayed primary suture remain valid, it is the understanding of tissue damage and the more logical response which has changed. It is the wound as encountered which is managed, irrespective or the theoretical velocity of the bullet. The Johannesburg practice is outlined with regard to regions of the body, with discussion of, among others, the conservative management of gunshot wounds of the abdomen, primary repair of the colon, non operative management of certain limb wounds. The practice is summarised, based on considerable experience and the logistic implications of large numbers and may be useful to surgeons less experienced in gunshot wound management.

3332. MacGregor, A. J., et al. (2011). "Injury-specific correlates of combat-related traumatic brain injury in Operation Iraqi Freedom." The Journal of head trauma rehabilitation **26**(4): 312-318.

BACKGROUND: The prevalence of traumatic brain injury (TBI) has increased during the wars in Iraq and Afghanistan compared with 20th century military conflicts. The aim of this study was to elucidate injury-specific correlates of combat-related TBI that have yet to be clearly defined., PARTICIPANTS: Predominately Marine US service members who sustained brain injuries in Iraq between March 2004 and April 2008 identified from clinical records completed in the theater of combat operations (n = 2074)., MAIN OUTCOME MEASURES: Severity of TBI was classified as mild, moderate, or severe. Injury-specific factors, such as injury mechanism and type, were abstracted from the clinical records and were compared with severity of TBI., RESULTS: Of all TBIs observed in the sample, 89% were mild. Higher severity of TBI was associated with an increased likelihood of sustaining the injury by gunshot and a lower likelihood of helmet use. Improvised explosive devices were associated with a preponderance of mild TBIs, and frequency of injuries in locations in addition to the head was highest among those with moderate and severe TBIs. Concomitant injuries to the spine/back were associated with blast injury mechanisms., CONCLUSIONS: Most incidents of TBI occurring during

Operation Iraqi Freedom are mild in severity and a result of blast mechanisms. Multiple injuries were common, particularly as severity of TBI increased. Further research is needed to determine effects of combat-related TBI on rehabilitative and adverse health outcomes.

3333. Mackenzie, D. J., et al. (1993). "Fatal cerebral gunshot wounds: factors influencing organ donation." The American surgeon **59**(11): 764-768.

Patients with clinical brain death following head injury are important potential cadaveric organ donors. We analyzed our series of cranial gunshot wounds with particular attention to the frequency and patterns of organ donation after fatal injuries. Sixty-six patients with gunshot wounds to the head, including 59 with intracranial involvement (43 male, average age 26 years) were seen during a 4-year period. Injuries were limited to the head in 50 of 59 patients. Overall mortality was 66 per cent. Predictors of mortality included Glasgow Coma Scale (GCS) of six or less (93%), self-inflicted gunshot wounds (75%), and computed tomography (CT) findings of bihemispheric injury (87%) or ventricular injury (82%). Of the 39 patients who died, 28 met standard criteria for brain death, and nine of these went on to organ procurement. Thirteen families refused donation, and six patients were not harvested for reasons including old age, pregnancy, suspicion of AIDS, coroner refusal, and failure to pursue consent. Principles essential to maximal organ retrieval include: 1) Recognition that patients suffering cerebral gunshot wounds represent potential organ donors and that certain factors are predictive of mortality; 2) Critical care/trauma team approach with standardized management and timely declaration of brain death; 3) Early search for family members and prompt notification of organ procurement agencies; 4) Sensitivity to cultural issues influencing donation; and 5) Programs to increase public awareness of organ donation.

3334. Mackenzie, D. W., et al. (1988). "Meningitis caused by Absidia corymbifera." The Journal of infection **17**(3): 241-248.

A 56-year-old man developed mucormycotic meningitis caused by Absidia corymbifera and which followed a penetrating head injury. Antibodies to it were detected in the cerebrospinal fluid at titres higher than those found in the serum, thereby suggesting local production of antibody in the subarachnoid space.

3335. MacKenzie, K. A. and J. P. Lee (2011). "Review of outcome after repair of avulsion of the superior oblique tendon." Journal of AAPOS **15**(1): e24.

Introduction: To report the clinical characteristics and surgical outcome of patients undergoing repair of the superior oblique tendon, following traumatic avulsion. Methods: Review of 3 cases identified over the past 10 years. Results:We report on three patients, 2 male and 1 female, with a mean age of 11 years (range, 8 to 17) at the time of injury. All the patients presented with an ipsilateral superior oblique palsy following a penetrating injury to the supero-medial orbital area caused by dog-bite, metal hook and a ski pole. We explored the superior oblique tendon, which we found typically attached to sclera nasal to the superior rectus muscle. It was mobilised and brought under the superior rectus and sutured to the sclera, without complication. The delay from injury to surgery ranged from 8 months to 26 months. In all cases the initial superior oblique underaction (-2,5. -3, -3) improved post-surgery (-2, -1, -1), respectively. Despite all 3 patients demonstrating an abnormal head posture only 2 had demonstrable binocular functions pre and post operatively. Post-surgery, one patient underwent a combined recess-resect procedure to the contralateral inferior rectus, whilst another is considering an inverse Knapp procedure. Discussion: Injury to the trochlear area usually causes acquired Brown syndrome. These patients frequently have an associated superior oblique palsy, described by Knapp as having “canine-tooth syndrome”. However our series only presented with a superior oblique palsy, this may be due to the localisation of the injury. Conclusions: The superior oblique tendon was successfully reattached without complication.

3336. Mackerle, Z. and P. Gal (2009). "Unusual penetrating head injury in children: personal experience and review of the literature." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **25**(8): 909-913.

INTRODUCTION: A penetrating head injury belongs to the most severe traumatic brain injuries, in which communication can arise between the intracranial cavity and surrounding environment., DISCUSSION: The authors

present a literature review and typical case reports of a penetrating head injury in children. The list of patients treated at the neurosurgical department in the last 5 years for penetrating TBI is briefly referred. Rapid transfer to the specialized center with subsequent urgent surgical treatment is the important point in the treatment algorithm. It is essential to clean the wound very properly with all the foreign material during the surgery and to close the dura with a water-tight suture. Wide-spectrum antibiotics are of great use. In case of large-extent brain damage, the use of anticonvulsants is recommended., CONCLUSION: The prognosis of such severe trauma could be influenced very positively by a good medical care organization; obviously, the extent of brain tissue laceration is the limiting factor.

3337. Mackersie, R. C., et al. (1991). "Organ procurement in patients with fatal head injuries. The fate of the potential donor." Annals of surgery **213**(2): 143-150.

A 46-month, retrospective review of all victims of fatal head injury at a level 1 trauma center was undertaken to estimate donor organ availability, determine causes of procurement failure, and analyze the functional results of organs transplanted from this group of donors. Causes of procurement failure in 126 patients who died principally from their head injuries included failure of initial resuscitation (14%), ineligibility (28%), failure of physiologic support (14%), and denial of consent (20%). Of 73 eligible donors, 29 (41%) were able to donate one or more vascular organs (heart, liver, kidney). In only one instance was an eligible donor not appropriately identified as such. Failure of physiologic support to prevent early death (25%), and denial of consent (34%) were found to be the two major, potentially remediable causes of procurement failure in this series. Based on this data, an estimated 29 patients/million population/year will survive initially and meet all eligibility requirements for organ donation. Data on 47 kidneys transplanted from the donor group demonstrated a 77% overall graft survival rate at a follow-up period averaging 23 months. Prolonged donor hypotension, but not the use of high-dose vasopressors, adversely affected allograft survival. The current limitations of organ procurement in victims of fatal head injury stem from a limited ability to maintain cardiopulmonary function long enough for the procurement process to be completed and a high overall rate (46%) of denial of consent for organ harvest by next of kin.

3338. Macmillan, M. (2000). "Restoring Phineas Gage: a 150th retrospective." Journal of the history of the neurosciences **9**(1): 46-66.

September 13 1998 marked the 150th anniversary of the accident to Phineas Gage, one of the most famous cases of survival after massive injury to the brain, and certainly the most famous case of personality change after brain damage. For this article a sample of the current literature about Gage was examined. It was found that although his case is mentioned in about 60% of introductory textbooks in psychology, there is a good deal of inaccuracy in what has been written about him. Similar inaccuracy was found in a smaller sampling of the psychiatric, medical, physiological, linguistic, and general neuroscientific literature. The main basis of the inaccuracies is an ignorance or disregard of what is contained in the primary sources about Gage, coupled with a tendency to attribute to him characteristics that belong to other cases of frontal damage. The errors and their bases are discussed in an endeavour to restore the picture of Gage to its original state. The paper includes an Appendix of verbatim quotations from the primary sources that can be compared with the later, inaccurate renditions.

3339. Madaan, P., et al. (2019). "Neurocognitive outcomes and their diffusion tensor imaging (DTI) correlates in children with mild traumatic brain injury (MTBI)." Neurology **92**(15).

Objective: To study the neurocognitive outcomes and their DTI correlates in children (aged 6- 16 years) with mTBI at three months post injury. Background: mTBI is the commonest TBI in children. Persistent deficits after “mild” TBI can lead to significant functional disability; hence these should be evaluated. Design/Methods: This prospective analysis included 74 children with mTBI(M:F=52:22; mean age:9.5(±2.7)years). Wechsler's Intelligence Scale for children-Indian adaptation(WISC-IV), Child Behavioral Checklist(CBCL) and Children's Sleep Habit Questionnaire(CSHQ) were administered for 57 cases (at 3 months post injury) and controls of similar age. DTI (1.5 T scanner; Siemens, Erlangen, Germany), done within 7days of injury, were processed for mean diffusivity(MD) and fractional anisotropy(FA) for various Region of Interest (ROI) which were correlated with IQ and various indices. Results: All the patients had non-penetrating craniocerebral trauma. Common causes of mTBI were accidental falls(65%) and Road traffic accident(26%). Presenting features were loss of consciousness(53%), confusion/disorientation(47%) and post-traumatic amnesia(10%). Other clinical features in acute phase included drowsiness(86%), headache(78%), balance problems(62%), nausea(47%),

fatigue(45%), vomiting(35%), ENT bleed(12%), Sensitivity to sound/ light(12%) etc. Neuroimaging abnormalities were seen in 9 patients (12%). At 3months post-injury, Cases performed poorly in terms of Full scale IQ, Perceptual Reasoning Index and Processing Speed Index as compared to typically developing controls of similar age. Based on CBCL, 17% children with mild TBI had internalizing behavioural problems (in borderline and clinical range) in comparison to 4% controls. Prevalence of poor sleepers in mild TBI cohort and typically developing controls was 12.3% and 2%. Headache, reduced attention span, shortness of temper and fatigue were common post concussion symptoms. There was a positive co relation between Right Arcuate fasciculus MD (short term) and VCI (0.289) and PSI (0.299) Conclusions: Mild TBI is not that mild with neurobehavioral problems persisting beyond the acute phase of injury.

3340. Madathil, S. K., et al. (2017). "Penetrating ballistic-like brain injury activates neurogenic niches in adult rats." Journal of neurotrauma **34**(13): A137.

Active proliferative response is a common occurrence following traumatic brain injury (TBI) and contributes to both gliogenesis and neurogenesis. While post-injury neurogenesis stimulates neurorepair, gliogenesis may cause neuroinflammation that may be detrimental to reparative processes. To design strategies that promote neurorepair, we need to understand the changes in post-traumatic neurogenesis. Here we examined the effects of penetrating ballistic-like brain injury (PBBI) on immature neuronal population in two important neurogenic niches of the adult brain viz., forebrain sub-ventricular zone (SVZ) and hippocampal sub-granular zone (SGZ). Rats were subjected to PBBI (n = 6/time point) or sham craniotomy (n = 6/time-point). To capture proliferating cells, rats were injected with BrdU (50mg/kg) for 7 days and were euthanized at 10 day post-injury. Doublecortin (DCX) immunolabeling was used to identify immature neurons and BrdU/DCX double-labelling was performed to identify newborn immature neurons. Quantification of immunolabelled cells was done using a fluorescence microscope equipped with multi-channel filter set. To understand forebrain neurogenesis, total immature neurons and BrdU positive newborn immature neurons were counted separately in ipsilateral SVZ, striatum, subcortical white matter (SCWM) and cortex. In the hippocampus, DCX positive and Brdu/DCX co-labelled cells were counted from SGZ. DCX positive neurons and BrdU/DCX co-labelled newborn immature neurons were found in both SVZ and SGZ, regardless of the injury status. However, PBBI appeared to enhance the production of newborn neurons in both SVZ and SGZ areas. Furthermore, PBBI significantly enhanced the migration of newborn neurons from SVZ towards striatum, SCWM and cortex ($p < 0.05$ compared to sham). In the hippocampal SGZ, PBBI did not alter the total number immature neurons however, increased the number of BrdU/DCX co-labelled newborn neurons ($p < 0.05$ compared to sham). Overall, our results indicate an activation of neurogenesis in two major neurogenic niches of the adult rat brain following PBBI. Our findings also show that these newborn neurons can migrate to areas of injury, purportedly to modulate neurorepair. Further studies will characterize the anatomical integration of newborn neurons and their role in mediating functional recovery.

3341. Madathil, S. K., et al. (2019). "Widespread dendritic pathology is evident following severe penetrating brain injury in rats." Journal of neurotrauma **36**(13): A144.

Traumatic brain injury (TBI) has been shown to induce extensive dendritic pathology. Increasing evidence suggests that damaged dendrite and spines directly affect synaptic plasticity, which plays a critical role in neuronal function and behavioral modulation. The current study was designed to define the temporal and regional alterations in neuronal morphology and dendritic loss in the penetrating ballistic-like brain injury (PBBI) model. Adult Sprague- Dawley rats were subjected to PBBI (10% injury, n = 8/group) or sham craniotomy (n = 4/group) and euthanized at 1, 2, 3, 7, 14 or 28 days post-injury. Assessment and quantitation of dendritic injury was done using Golgi and microtubule associated protein-2 (MAP- 2) staining. For dendritic Sholl analysis, Golgi stained neuronal images were analyzed using Fiji Sholl analysis plugin for ImageJ. MAP-2 immunostaining intensity was quantified separately from cortex and hippocampus using ImageJ. The injury core was devoid of Golgi stained neurons and neurons in the injury penumbra showed reduced dendritic branching complexity. Significant changes in various Sholl parameters including number of intersections, maximum radius and Schoenen Ramification Index (SRI), were observed following PBBI at the majority of post-injury time points studied. We also observed dendritic beading/blebbing in penumbral neurons indicating the presence of degenerating dendrites. Reduced MAP-2 staining was seen in the cortex at acute time points following severe brain injury, demonstrating loss of neurites. Employing Golgi staining coupled with Sholl analysis we have been able to identify several morphological changes in neurons following PBBI. Extensive trauma induced alterations in dendrites show that these changes may underlie neurological symptoms following TBI. Moreover, loss of MAP-2 staining even in areas distal to the injury core indicate that dendritic derangement is widespread following PBBI, and may contribute to post-

traumatic behavioral dysfunction. Further studies in PBBI model will utilize therapeutic approaches to protect spared neural dendrites and spines in an effort to mitigate functional abnormalities following severe TBI.

3342. Madathil, S. K., et al. (2018). "Temporal and regional changes in vascular density following penetrating type brain injury." Journal of neurotrauma **35**(16): A192.

Traumatic brain injury (TBI) has been shown to produce cerebral vasculature changes including damage to blood vessels, haemorrhage, reduced blood flow and sprouting of new blood vessels. While some of these post-injury vascular changes may be detrimental to reparative processes, angiogenesis (formation of new blood vessels from preexisting ones) may promote neurorepair. To design strategies that promote angiogenesis, we need to understand the changes in posttraumatic angiogenic responses. Here we examined the temporal and regional alterations in vasculature following penetrating ballistic-like brain injury (PBBI) in rats. Adult Sprague-Dawley rats were subjected to PBBI (10% injury, n = 8/time point) or sham craniotomy (n = 4/timepoint) and euthanized at different time points (1, 3 and 7days postinjury). To label perfused blood vessels, anesthetized rats were injected with Tomato Lectin-FITC (100ug/rat, tail vein injection) 15 min prior to euthanasia. Following transcardial formalin perfusion, brains were collected and processed for histological studies. FITC immunolabeling was used to identify perfused blood vessels. Immunostaining intensity was quantified separately from cortex and hippocampus using Image J software. Brain regions proximal to the injury core showed reduced vascular density at all the time points studied. Notably, the perilesional cortex showed increased vascular staining intensity compared to sham ($p < 0.05$) at 1 and 3 days post-injury, indicating angiogenesis. However, these newly formed blood vessels were not evident at 7 days post-injury and thus appear to be transient. Instead, we observed reduced vascular staining in the perilesional cortex 7 day post-injury ($p < 0.05$ vs. sham). The hippocampus showed reduced vascular staining at all time points studied. Overall, our results indicate significant alterations in vascular density following PBBI. Our findings indicate that the brain upregulates angiogenic responses at acute time points following PBBI, presumably to replace damaged blood vessels and to bring oxygen and nutrients to injured area. However, this reparative process appears to be transient as we observed significant reduction in vascular density by 1 week postinjury. Further studies will characterise chronic changes in vascular density following TBI.

3343. Madden, L. K., et al. (2013). "Admission temperature does not predict extended glasgow outcome scale score following traumatic brain injury." Journal of neurotrauma **30**(15): A39.

Introduction There is a lack of clear and robust evidence to aid understanding of the impact of body temperature on outcome and to guide clinical management. Using the UC Davis Neurotrauma database, our goal is to identify whether admission temperature (hypothermia, normothermia, or fever) predicts outcome. Methods Prospectively collected TBI registry and EMR data for patients who consecutively presented to a single Level-I Trauma Center, were identified. Eligibility criteria included: blunt injury mechanism, initial post-resuscitation GCS score ≤ 12, and treatment as an adult (≥ 16 years of age). Patients were excluded if they had a penetrating TBI or were treated at another facility for > 12 hours prior to transfer. IRB approval was obtained prior to performance of any study procedures. Over a 48-month period 426 patients were identified and of these, 340 had complete data available at the time of analysis. For this study, aberrance in temperature was defined as a measured value outside of the normal range (36.5-37.5°C). Relative hypothermia is defined as temperature < 36.5°C. Fever is defined as temperature of > 37.5°C. Results For this study sample, median age was 44.86 years and gender distribution was 73.5% male and 26.5% female. Ethnicity reporting identified 20% as Hispanic or Latino, 78% non-Hispanic or Latino and 2% unknown. Mechanisms of injury for this sample included MVC (28.2%), Fall (23.7%), Auto vs. Pedestrian (15%), Assault (12.7%), Found down (8.2%), MCA (6.6%), and others (5.6%). Ordinal regression was performed using SPSS (version 21) considering the explanatory variable, admission body temperature, grouped into the above-noted categories with the dependent variable, 6-month GOS-E. Before considering the effects of the explanatory variable, we need to determine whether the model improves our ability to predict outcome. Comparing the baseline intercept-only model against the final model with temperature, we sought to identify if adding the explanatory variable improved the fit to the data. Model fitting analysis of the - 2 log-likelihood (- 2LL) values for the baseline and the final model, and a chi-square to test the difference between the two models provides a non-significant statistic ($p = .120$). The final model with the explanatory variable does not gives better predictions than a guess based on the probabilities for the outcome categories. In assessing Goodness-of-Fit, Pearson's chi-square statistic was used. This statistic tests whether observed data are consistent with the fitted model. Considering the null hypothesis, the fit is good. We do not reject this hypothesis ($p = .941$), can conclude that the data and the model predictions are similar, and that we have a good model. However, pseudo R2

values (Nagelkerke = 1.3%, Cox and Snell = 1.2%, McFadden 0.3%) indicate that admission temperature group scores explain a relatively small proportion of the variation between patients in their outcome scores. The R2 indicates that a model containing only admission temperature is likely to be a poor predictor of outcome for any particular individual patient. Conclusions The IMPACT model validated that, multiple variables are needed to accurately predict outcome. Our current analysis suggests that admission temperature, as currently collected, do not add value to prediction models of GOS-E. However, this negative finding does not suggest that temperature is not critical. In fact it is important to consider whether the selected temperature ranges are appropriate for TBI. In addition, duration of temperature dysregulation should be added as a variable. Therefore we suggest that further research is needed and should (1) characterize the dose of severity and duration of temperature alteration after TBI; (2) determine if temperature alteration influences or predicts neurologic outcome; and (3) determine if the rate of temperature correction (warming from relative hypothermia or cooling from relative fever) influences or predicts neurologic outcome.

3344. Maddileti, G. B., et al. (2020). "An autopsy study of Cranio-cerebral Injuriesdue to road traffic accidents." Medico-Legal Update **20**(1): 1-6.

Cranio-cerebral injuries are a morbid state, resulting from gross structural changes to the scalp, skull and the contents of the cranium. In present scenario, accidents are now considered as one of major contributing factors of Non-Communicable Diseases which have become major health problems of developing countries like India. According to the national crime bureau statistics In India, over 1,46,133 people were killed in various road traffic accidents during 2015 and the count raised to 1,50,785 in 2016. Information on the contributing factors is mandatory to reduce this burden. A prospective study of all Road Traffic accidents coming for autopsy at Government Medical College, Anantapuram. Majority of victims were male in the age group between 31-40 years. Most of them had Linear fractures of the skull along with Sub dural haemorrhage. Two Wheeler riders were the most common victims. Most of the victims died due to Cranio- Cerebral Injury. Most of the times, it is the negligence, which results in an accident. The negligence may be on the part of the victim or may be there on the part of other person who occupied the second vehicle. Sometimes innocent pedestrians are also victimized to these deaths. An accident for all practical purposes is preventable, provided if it is anticipated and proper precaution and preventive measures are adopted.

3345. Madea, B., et al. (2008). "Fall downstairs: accident, homicide or natural death?" Forensic science, medicine, and pathology **4**(2): 122-128.

In homicide cases a clear anatomical or toxicological cause of death is normally evident. In the following a case is described where, without clear anatomical or toxicological cause of death, the husband of the deceased-a trained anaesthesiologist-was charged with murder. Suspicion was raised since the autopsy findings did not correspond to a fatal fall downstairs but instead could be definitely ruled out as cause of death, since intracranial bleedings and cerebral contusions, the leading causes of death in fatal falls downstairs, were missing. Further suspicion was raised since electrocardiograms (ECGs), previously stated by the accused to have been recorded personally from his wife during cardiopulmonary resuscitation (CPR), were obviously faked. Additionally, an ampule of succinylcholine was missing from his emergency case. In a trial lasting more than three quarters of a year with several witnesses and experts heard by the court, the cause of death remained unclear. However, a natural cause of death and a fatal fall downstairs were ruled out. Subsequently the husband admitted during the trial to have killed his wife without elaborating on the circumstances for legal reasons. He was sentenced to prolonged imprisonment. Of special importance was that, based on the knowledge of typical autopsy findings in fatal falls downstairs, a lethal fall downstairs could be ruled out. Therefore even negative autopsy findings are of great forensic importance.

3346. Madea, B., et al. (2016). "[Fatal explosion injuries from blasting a cigarette machine]." Todliche Explosionsverletzungen bei Sprengung eines Zigarettenautomaten. **237**(3-4): 130-142.

In the last few years, a growing number of cases have been reported in Germany in which vending machines have been blasted by criminals to get at the money. Thus, it was only a question of time for the first fatalities to occur as a consequence of such careless explosions. We report on the death of a 16-year-old boy who died after triggering an explosion by spraying a deodorant into the coin slot of a cigarette machine. Death was caused by severe craniocerebral trauma due to tertiary blast-related injuries when the front plate of the machine hit the victim's cerebral and facial skull.

3347. Madea, B., et al. (2010). "Molecular pathology in forensic medicine--Introduction." Forensic science international **203**(1-3): 3-14.

Techniques of molecular biology have improved diagnostic sensitivity, accuracy and validity in forensic medicine very much, especially in the field of identification (paternity testing, stain analysis). Since more than 10 years these techniques - meanwhile well established in clinical disciplines - are used also for other applications in forensic medicine: determination of cause and manner of death, tissue identification by mRNA and microRNA, examination of gene expression levels (survival time, time since death, cause of death), toxicogenetics.

3349. Madei, W., et al. (1998). "[Endoscopic projectile extraction in treatment of a gunshot injury to the head]." Endoskopische Projektilextraktion zur Behandlung einer Kopfschussverletzung. **123**(39): 1139-1142.

HISTORY AND CLINICAL FINDINGS: A 14-year-old boy had in war-torn Bosnia sustained a transcranial gunshot wound from a 7.65 mm bullet. After primary medical care with craniotomy and the removal of bony fragments and cerebral debris followed by a duraplasty, he was transported to the French-German Field Hospital. On arrival he was breathing spontaneously and in stable cardiovascular state but with impaired responsiveness and somnolent. His pupils were moderately dilated with slight anisocoria (right > left). His gaze was deviated to the left and he had vertical gaze paralysis as well as right central facial nerve paresis. In addition he had a mild diencephalic syndrome, right hemiplegia and a right hemihypaesthesia with increased muscle tone, especially of the leg, paratonia and right positive Babinski reflex. There also was a marked ciliospinal reflex and he had a bulbar speech as well as cognitive and memory abnormalities., INVESTIGATIONS: Haemoglobin and haematocrit were below normal (12.1 g/dl and 35.0%, respectively), while biochemical tests were normal. Cranial computed tomography localized the bullet in the pineal recess of the 3rd ventricle and the lamina quadrigemina., DIAGNOSIS, TREATMENT AND COURSE: These findings indicated endoscopic transcranial removal of the bullet, achieved with a rigid endoscope and forceps along the entry track. Subsequent intensive care proceeded without complication. On discharge the boy was normal oriented and ready to make contact. The neurological defects were regressing., CONCLUSION: Endoscopic transcranial removal of a bullet wedged in the brain is a relatively sparing neurological procedure which, under unusual circumstances and conditions, can achieve a satisfactory result even with limited facilities.

3350. Madei, W. F. and H. P. Klieser (2000). "Intensive care medicine in the German Field Hospital during the implementation force mission in Trogir, Croatia." Military medicine **165**(6): 445-448.

To provide medical care for multinational personnel deployed during the Implementation Force mission, the German Army provided a mobile surgical hospital with sophisticated equipment to perform advanced resuscitation and lifesaving surgical procedures, as well as preoperative and postoperative intensive care, under conditions similar to those in rear hospitals. During an observation period of 4 months (December 1995 to April 1996), nearly 10,000 patients were treated at this facility. In addition to the presentation of statistical data from a unique critical care facility during the Implementation Force mission, this article discusses the usefulness of neurosurgical services as part of a forward field hospital.

3351. Mader, T. H., et al. (2006). "Ocular war injuries of the Iraqi Insurgency,January-September 2004." Ophthalmology **113**(1): 97-104.

PURPOSE: To document the types and causes of ocular and ocular adnexal injuries treated by United States Army ophthalmologists serving in Iraq during the Iraqi Insurgency., DESIGN: Prospective hospital-based observational analysis of injuries., PARTICIPANTS: All coalition troops, enemy prisoners of war, and civilians with severe ocular and ocular adnexal injuries., METHODS: We prospectively examined severe ocular and ocular adnexal injuries that were treated at the 31st Combat Support Hospital during the portion of the Iraqi Insurgency that took place from January 20 through September 12, 2004., MAIN OUTCOME MEASURES: Incidences and characteristics of ocular and ocular adnexal

injuries., RESULTS: During the time observed, 207 patients suffered severe ocular or ocular adnexal injuries, including 132 open globes. Blast fragmentation from munitions caused 82% of all injuries. The most common single cause of injury was the improvised explosive device (IED), which caused 51% of all injuries. Of 41 eye excisions, 24 were caused by IEDs., CONCLUSIONS: During the portion of the Iraqi Insurgency covered in our report, munitions fragments were the most common cause of ocular and ocular adnexal injuries. The single most common cause of injury was the IED, which produced devastating ocular and ocular adnexal injuries. The authors' findings indicate that polycarbonate ballistic eyewear could have prevented many, but not all, of the ocular injuries we report.

3353. Madson, A. Q., et al. (2013). "Non-battle craniomaxillofacial injuries from U.S. military operations." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **41**(8): 816-820.

INTRODUCTION: Non-battle injuries (NBIs) can be a source of significant resource utilization for the armed forces in a deployed setting. While the incidence and severity of craniomaxillofacial (CMF) battle injuries (BIs) have reportedly increased in the ongoing U.S. military conflicts in Iraq and Afghanistan, the prevalence and the nature of NBIs are not well described., MATERIAL AND METHODS: The Joint Theater Trauma Registry was queried from October 2001 to February 2011, covering Operations Enduring Freedom and Iraqi Freedom, for both NBIs and BIs to the CMF region. Patient demographics, injury severity score, mechanism and type of injury were included in the query. Using ICD-9 diagnosis codes, CMF injuries were classified according to type (wounds, fractures, burns, vascular injuries, and nerve injuries). Statistical analysis was performed for comparative analysis., RESULTS: NBIs constituted 24.3% of all patients with CMF injuries evacuated to a regional combat support hospital (CMF BIs 75.4%). These injuries were characterized by blunt trauma, most commonly motor vehicle collisions (37%), and falls (20%). As compared to CMF BIs, CMF NBIs resulted in less mortality (1.3% vs. 3.1%, $p < 0.0001$), fewer injuries per patient (1.87 vs. 2.26, $p = 0.055$), and a decreased severity score (ISS) (8.38 vs. 12.98, $p < 0.0001$). However, a significant percentage of CMF NBIs still required evacuation out of theater (27.8% of NBIs vs. 42.2% of BIs, $p < 0.0001$), depleting the combat strength of the deployed forces., CONCLUSIONS: CMF NBIs accounted for a substantial portion of total CMF injuries. Though characterized predominantly by blunt trauma with an overall better prognosis, its burden to the limited resources of a deployment can be significant. This descriptive study highlights the need to allocate appropriate resources for treatment of these injuries as well as strategies to reduce both its incidence and severity., LEVEL OF EVIDENCE: IV Prognostic.

3355. Magagi, A., et al. (2022). "Management of trauma White weapons penetrating Head and Neck in the anesthesia department of the national hospital of Zinder in Niger: About five reported cases." Annals of medicine and surgery (2012) **78**: 103840.

We report five cases of craniocervical trauma with knives. The occurrence circumstances were common to all injuries. The trauma was caused by a knife during a fight or an intentional injury. All the victims were farmers or ranchers. Their average age was 17 years, with extremes of 13 and 22 years. The cause was most often community conflict. Pre-hospital transport was non-medical for all patients. The average admission time was 3 h and the average management time was 4 h. General anesthesia with orotracheal intubation was the anesthetic technique used. The average length of hospital stay was seven days. The prognosis was overall favorable and the patients returned home without any sequels.

3356. Magee, G. A., et al. (2021). "Risk Factors for Stroke in Blunt and Penetrating Extracranial Carotid Trauma." Journal of the American College of Surgeons **233**(5): e245.

INTRODUCTION: This study aims to report outcomes of blunt and penetrating extracranial carotid trauma from the American Association of Surgery for Trauma (AAST) PROspective Observational Vascular Injury Trial (PROOVIT) registry. METHODS: All patients with extracranial cerebrovascular injuries in the AAST PROOVIT registry from 2012-2020 were evaluated. Isolated external carotid and vertebral artery injuries were excluded. Patients with blunt mechanism of injury were compared to those with penetrating, and subset analysis was performed to evaluate risk factors for post-injury stroke in the penetrating cohort. RESULTS: A total of 573 patients from 22 institutions met criteria for inclusion. Mean age was 38 (±17) and 372 (65%) were male. Average GCS on presentation was 9 (±5) with an ISS of 25 (±15). There were 471 (82%) blunt carotid injuries and 102 (18%) penetrating. Penetrating injuries were more likely to require operative intervention (51% penetrating, 6% blunt). Overall stroke rate was 11%, (17% penetrating vs. 10% blunt). For penetrating injuries, lack of postoperative antiplatelet therapy (23% vs. 11%, p=.03), need for completion angiography (62% vs 38%, p=.02) were associated with a significantly higher rate of stroke on univariate analysis. Time to repair, type of injury, carotid ligation, concomitant jugular vein injury, and jugular vein ligation were not associated with stroke. CONCLUSION: Penetrating extracranial carotid trauma has a higher rate of operative repair and stroke than blunt injuries. For penetrating injuries, lack of antiplatelet therapy and need for completion angiography are independently associated with in-hospital stroke.

3357. Maghami, S., et al. (2020). "Comparison of the causes of death and wounding patterns in urban firearm-related violence and civilian public mass shooting events." The journal of trauma and acute care surgery **88**(2): 310-313.

BACKGROUND: There are no reports comparing wounding pattern in urban and public mass shooting events (CPMS). Because CPMS receive greater media coverage, there is a connation that the nature of wounding is more grave than daily urban gun violence. We hypothesize that the mechanism of death following urban gunshot wounds (GSWs) is the same as has been reported following CPMS., METHODS: Autopsy reports of all firearm-related deaths in Washington, DC were reviewed from January 1, 2016, to December 31, 2017. Demographic data, firearm type, number and anatomic location of GSWs, and organ(s) injured were abstracted. The organ injury resulting in death was noted. The results were compared with a previously published study of 19 CPMS events involving 213 victims., RESULTS: One hundred eighty-six urban autopsy reports were reviewed. There were 171 (92%) homicides and 13 (7%) suicides. Handguns were implicated in 180 (97%) events. One hundred eight (59%) gunshots were to the chest/upper back, 85 (46%) to the head, 77 (42%) to an extremity, and 71 (38%) to the abdomen/lower back. The leading mechanisms of death in both urban firearm violence and CPMS were injury to the brain, lung parenchyma, and heart. Fatal brain injury was more common in CPMS events as compared with urban events involving a handgun., CONCLUSION: There is little difference in wounding pattern between urban and CPMS firearm events. Based on the organs injured, rapid point of wounding care and transport to a trauma center remain the best options for mitigating death following all GSW events., LEVEL OF EVIDENCE: Epidemiological, level IV.

3358. Maghin, F., et al. (2019). "A case of suicide by double gunshot wounds to the head: the ability to act after the first shot." International journal of legal medicine **133**(5): 1469-1476.

A single gunshot (or multiple) does (do) not necessarily lead to immediate loss of consciousness or rapid neurological deficits, so the victim may be able to repeatedly pull the trigger before achieving the lethal effect. Despite multiple gunshot wounds can lead to the suspicious participation of other person to the death of the victim, in the medico-legal literature suicides with multiple gunshot wounds are reported, demonstrating the ability of the victim to act after two or more gunshots. In this case, a 47-years-old man was found dead in a pool of blood in the kitchen of his house. According to findings and analysis, the victim modified a single-shot, pneumatic toy gun branded "Condor" Cal. 7 mm (a gun that is made mainly with "ZAMAK" zinc-based alloy, designed to shoot one soft-polymer bullet at a time, with an initial kinetic energy lower than 1 Joule) into an improvised firearm weapon. With this gun, the victim achieved shooting of two bullets into his head, both entering from the right temporal region of his head, with one stopped in the left occipital lobe and the other one in the left temporal lobe. His death was caused by cranium-meningo-encephalic gunshot wounds. The conditions supporting the hypothesis that the victim was able to fire two shots to his head before the onset of incapacitation (the type of bullets used, the location of injuries and their consequences) and the characteristics that typically allow to distinguish the manner of death (suicide vs homicide) were evaluated. Based on all the collected elements, it was possible to confirm that suicide was the manner of death. This case underlines the importance of evaluating all available elements (post-mortem imaging, autopsy and toxicological findings, ballistics and neuropathological evaluations) to distinguish suicide from homicide and to prevent incorrect conclusions.

3359. Magnuson, J., et al. (2012). "Neuropathology of explosive blast traumatic brain injury." Current neurology and neuroscience reports **12**(5): 570-579.

During the conflicts of the Global War on Terror, which are Operation Enduring Freedom (OEF) in Afghanistan and Operation Iraqi Freedom (OIF), there have been over a quarter of a million diagnosed cases of traumatic brain injury (TBI). The vast majority are due to explosive blast. Although explosive blast TBI (bTBI) shares many clinical features with closed head TBI (cTBI) and penetrating TBI (pTBI), it has unique features, such as early cerebral edema and prolonged cerebral vasospasm. Evolving work suggests that diffuse axonal injury (DAI) seen following explosive blast exposure is different than DAI from focal impact injury. These unique features support the notion that bTBI is a separate and distinct form of TBI. This review summarizes the current state of knowledge pertaining to bTBI. Areas of discussion are: the physics of explosive blast generation, blast wave interaction with the bony calvarium and brain tissue, gross tissue pathophysiology, regional brain injury, and cellular and molecular mechanisms of explosive blast neurotrauma.

3360. Magyar, C. T. J., et al. (2021). "Severe penetrating trauma in Switzerland: first analysis of the Swiss Trauma Registry (STR)." European journal of trauma and emergency surgery : official publication of the European Trauma Society.

PURPOSE: The purpose of this study was to examine the epidemiology, demographics, injury characteristics and outcomes of patients who presented to Swiss trauma centers following severe penetrating trauma., METHODS: Swiss Trauma Registry (STR)-cohort analysis including patients with severe (ISS >= 16 or AIS head >= 3) penetrating trauma between 2017 and 2019. Primary outcome was mortality. Secondary outcomes were hospital and intensive care unit (ICU) length of stay (LOS), and prehospital times., RESULTS: During the 3-year study period, 134 (1.6% of entire STR) patients with severe penetrating trauma were identified [64 (48%) gunshot wounds (GSW), 70 (52%) stab wounds (SW)]. Median age was 40.5 (IQR 29.0-59.0) and 82.8% were male. Mortality rate was 50% for GSW; 9% for SW. Overall, prehospital time [incident to arrival emergency department (ED)] was 65 (IQR 45-94) minutes. The median number of patients admitted for a severe GSW/SW per center and year was 2 (range 0-14). Of 64 patients who sustained a GSW, 42 (65.6%) were self-inflicted. Mortality in self-inflicted GSW reached 66.7%, with the head being severely injured in 78.6%. The 67 patients with severe isolated torso GSW/SW had an ISS of 20 (IQR 16-26) and a mortality of 15%. Multivariable analysis identified severe chest trauma, ED Glasgow Coma Scale <= 8, age, self-infliction, massive blood transfusion and ISS as independent predictors for mortality., CONCLUSION: Severe penetrating trauma is very rare in Switzerland. Mortality ranges from 9% in SW to 67% in self-inflicted GSW. Particularly in the setting of GSW/SW to the torso, reduction in prehospital time may further improve patient outcomes.

3361. Mah, L. W. Y., et al. (2005). "Deficits in social knowledge following damage to ventromedial prefrontal cortex." The Journal of neuropsychiatry and clinical neurosciences **17**(1): 66-74.

Patients with damage to the frontal lobes frequently exhibit impaired social behavior, but it is not clear which specific processes are disrupted. The authors investigated the ability to interpret nonverbal emotional expression in patients with lesions involving ventromedial (N=20) or dorsolateral prefrontal cortex (N=9) and in healthy volunteers (N=23). As hypothesized, only patients with ventromedial prefrontal lesions showed impaired task performance relative to normal comparison subjects. These results suggest that deficits in social knowledge, namely difficulty interpreting nonverbal emotional expression, contribute to the aberrant social behavior observed following ventromedial prefrontal cortex lesions.

3362. Mahajan, M. and N. Shah (2004). "Accidental lodgment of an air gun pellet in the maxillary sinus of a 6-year old girl: a case report." Dental traumatology : official publication of International Association for Dental Traumatology **20**(3): 178-180.

Air gun, although considered a toy, can cause injuries ranging from trivial to very grievous. The type and severity of injuries depend on the type of air gun used, the distance at which it is fired, and the anatomic site at which the pellet hits. An interesting case involving a young girl, who was accidentally hit by an air gun pellet at a village fair, is described.

The pellet penetrated the maxillary bone to be lodged in the sinus. The treatment strategy along with literature review on short- and long-term complications of air gun injuries is presented. Copyright Blackwell Munksgaard, 2004

3363. Mahajna, A., et al. (2002). "Blunt and penetrating injuries caused by rubber bullets during the Israeli-Arab conflict in October, 2000: a retrospective study." Lancet (London, England) **359**(9320): 1795-1800.

BACKGROUND: Low-velocity rubber bullets were used by Israeli police to control riots by Israeli-Arabs in early October, 2000. We aimed to establish the factors that contribute to severity of blunt and penetrating injuries caused by these missiles., METHODS: We analysed medical records of 595 casualties admitted. We assessed relation of severity of injury to type of bullet, anatomical region of injury, and final outcome. Severity of injury was established by the abbreviated injury scale, and we calculated injury severity score., FINDINGS: 151 males and one female (age range 11-59 years) were included in the study, in whom 201 proven injuries by rubber bullets were detected. Injuries were distributed randomly over the body surface and were mostly located in the limbs (n=73), but those to the head, neck, and face (61), chest (39), back (16), and abdomen (12) were also frequently noted. 93 (61%) patients had blunt injuries and 59 (39%) penetrating ones. Severity of injury was dependent on ballistic features of the bullet, firing range, and anatomic site of impact. Two casualties died after a penetrating ocular injury into the brain and one died as a result of postoperative aspiration after a knee injury., INTERPRETATION: Resistance of the body surface at the site of impact (elastic limit) is the important factor that ascertains whether a blunt or penetrating injury is inflicted and its severity. Inaccuracy of rubber bullets and improper aiming and range of use resulted in severe injury and death in a substantial number of people. This ammunition should therefore not be considered a safe method of crowd control.

3364. Mahalangikar, R., et al. (2016). "Transorbital Penetrating Intracranial Injury with an Umbrella Wire Causing Cavernous Internal Carotid Artery Injury and Thrombosis." World neurosurgery **86**: 513.e515-518.

BACKGROUND: Transorbital penetrating intracranial injuries, though rare, can have serious consequences. Intracranial penetration can be present even if orbital trauma is trivial., CASE DESCRIPTION: We report an unusual case of transorbital penetrating intracranial injury with umbrella wire, sustained while opening an umbrella, leading to internal carotid artery injury and thrombosis. The patient sustained only ipsilateral third nerve palsy that completely recovered during followup., CONCLUSION: Trivial orbital injuries can be associated with significant intracranial injury in a neurologically intact patient. This case emphasizes the potentially injury-prone opening mechanism of conventional umbrellas. A high index of suspicion is important while evaluating such patients.

3365. Mahalick, D. M., et al. (1996). "Pediatric trauma and head injury." Trauma **38**(1): 39-58.

Pediatric trauma is a common injury that occurs as a result of accidents and deliberate abuse. The cost of head injuries in children is high, and the far-reaching consequences potentially grave. Because head injury often results in pronounced long-term neurobehavioral impairment, early recognition is important. Treatment regimens must be devised taking into account the differences between children and adults and their neurobehavioral and psychosocial needs.

3366. Mahmoud, N. A. (1979). "Traumatic aneurysm of the internal carotid artery and epistaxis. (Review of literature and report of a case)." The Journal of laryngology and otology **93**(6): 629-656.

A review of 108 years of world literature revealed 69 cases fulfilling the picture of a clinical syndrome of head injury, a latent period followed by epistaxis and cranial nerve lesions. A similar case has been added which is the fourth case to be reported to be due to a bullet injury. The applied anatomy of the intracranial internal carotid artery (ICA) and the aetiology, clinical syndrome, pathology, diagnosis, prognosis and management of ICA aneurysms have been briefly discussed.

3367. Mahmud, M. R., et al. (2014). "Patterns and outcomes of nonmissile penetrating head injuries a multi-centre study." Brain injury **28**(5-6): 824-825.

Objectives: Non-missile penetrating intracranial injuries resulting from impalement with objects are quite uncommon; they result from a wide range of objects ranging from nails to farm implements. This study is aimed at finding out how these patterns of presentation and extent of neurological damage directly affect outcome. Methods: This is a retrospective descriptive study of patients presenting with non-missile penetrating head injuries to three neurosurgical centres for a period of 21 months from January 2012 to September 2013. This study analysed the patterns of presentation, type of impaled object, resulting neurologic deficit, brain lobes affected and the outcome at discharge using the Glasgow outcome score. Results: Sixteen patients were analysed, 15 being males. The age ranged from 21 months to 50 years, presentation was delayed in most patients, only three patients presented within 1, 5 and 6 hours of injury, one presented after 24 hours, one presented after 18 years, while the rest presented within the range of 2 days to 30 days. Impaled objects include nails (in two cases), arrows, screw driver, hoe, axe, toy part, aluminium pot fragment, metallic objects and rock fragment. Four patients presented with hemiplegia, two with aphasia and one with long-term seizure disorder. Others had no neurologic deficits. Nine out of the 16 patients had their injuries in the frontal lobes, three had it in the parietal lobes, two had it in the temporal lobes, one had it in the occipital lobe, while one had it in the frontal, parietal and occipital lobes. Only six patients presented with mild deterioration in level of consciousness (GCS 13-14), all the rest were fully conscious at the time of presentation. One patient had extraction of the four impaled nails at a local drug store under unsterile conditions prior to presentation. One presented with a metallic fragment around the basal ganglia for 18 years, presenting only for persistent seizure disorder; he subsequently absconded from further treatment. Eleven of the patients had a Glasgow outcome score of 5 at the time of discharge; only three had a score of 4, while two had a score of 3. Conclusion: Despite the perceived doom associated with non-missile penetrating injuries by the populace, delay in presentation and wide array of impaled objects, non-missile penetrating head injuries are associated with a relatively good outcomes.

3368. Mahoney, P., et al. (2018). "Ballistic impacts on an anatomically correct synthetic skull with a surrogate skin/soft tissue layer." International journal of legal medicine **132**(2): 519-530.

The aim of this work was to further develop a synthetic model of ballistic head injury by the addition of skin and soft tissue layers to an anatomically correct polyurethane skull filled with gelatine 10% by mass. Six head models were impacted with 7.62 x 39 mm full metal jacket mild steel core (FMJ MSC) bullets with a mean velocity of 652 m/s. The impact events were filmed with high-speed cameras. The models were imaged pre- and post-impact using computed tomography. The models were assessed post impact by two experienced Home Office pathologists and the images assessed by an experienced military radiologist. The findings were scored against real injuries. The entry wounds, exit wounds and fracture patterns were scored positively, but the synthetic skin and soft tissue layer was felt to be too extendable. Further work is ongoing to address this.

3369. Mahoney, P., et al. (2019). "Forensic reconstruction of two military combat related shooting incidents using an anatomically correct synthetic skull with a surrogate skin/soft tissue layer." International journal of legal medicine **133**(1): 151-162.

Six synthetic head models wearing ballistic protective helmets were used to recreate two military combat-related shooting incidents (three per incident, designated 'Incident 1' and 'Incident 2'). Data on the events including engagement distances, weapon and ammunition types was collated by the Defence Science and Technology Laboratory. The models were shot with 7.62 x 39 mm ammunition downloaded to mean impact velocities of 581 m/s (SD 3.5 m/s) and 418 m/s (SD 8 m/s), respectively, to simulate the engagement distances. The damage to the models was assessed using CT imaging and dissection by a forensic pathologist experienced in reviewing military gunshot wounds. The helmets were examined by an MoD engineer experienced in ballistic incident analysis. Damage to the helmets was consistent with that seen in real incidents. Fracture patterns and CT imaging on two of the models for Incident 1 (a frontal impact) were congruent with the actual incident being modelled. The results for Incident 2 (a temporoparietal impact) produced realistic simulations of tangential gunshot injury but were less representative of the scenario being modelled. Other aspects of the wounds produced also exhibited differences. Further work is ongoing to develop the models for greater ballistic injury fidelity.

3370. Mahoney, P. F., et al. (2020). "Shooting through windscreens: ballistic injury assessment using a surrogate head model-two case reports." International journal of legal medicine **134**(4): 1409-1417.

A synthetic head model developed to reproduce military injuries was assessed in two different scenarios involving shooting through intermediate targets (a laminated vehicle windscreen in scenario 1 and a military helicopter windscreen in scenario 2) with 7.62 x 39-mm mild steel core (MSC) ammunition. The injury patterns resulting from the two scenarios were assessed by a military radiologist and a forensic pathologist with combat injury experience and found to be clinically realistic.

3371. Mahoney, P. F., et al. (2017). "Does preliminary optimisation of an anatomically correct skull-brain model using simple simulants produce clinically realistic ballistic injury fracture patterns?" International journal of legal medicine **131**(4): 1043-1053.

Ballistic head injury remains a significant threat to military personnel. Studying such injuries requires a model that can be used with a military helmet. This paper describes further work on a skull-brain model using skulls made from three different polyurethane plastics and a series of skull 'fills' to simulate brain (3, 5, 7 and 10% gelatine by mass and PermaGel TM). The models were subjected to ballistic impact from 7.62 x 39 mm mild steel core bullets. The first part of the work compares the different polyurethanes (mean bullet muzzle velocity of 708 m/s), and the second part compares the different fills (mean bullet muzzle velocity of 680 m/s). The impact events were filmed using high speed cameras. The resulting fracture patterns in the skulls were reviewed and scored by five clinicians experienced in assessing penetrating head injury. In over half of the models, one or more assessors felt aspects of the fracture pattern were close to real injury. Limitations of the model include the skull being manufactured in two parts and the lack of a realistic skin layer. Further work is ongoing to address these.

3372. Mahoney, P. F., et al. (2017). "The effect of helmet materials and simulated bone and tissue layers on bullet behaviour in a gelatine model of overmatch penetrating head injury." International journal of legal medicine **131**(6): 1765-1776.

The aim of this work was to simulate an overmatch ballistic event against a head wearing a helmet. The experiments were designed to understand how layers of bone (or synthetic bone), synthetic skin and currently used helmet materials influence the behaviour of full metal jacket mild steel core (FMJ MSC) 7.62 x 39 mm bullets, impacting on targets with a mean velocity of 650 m/s. Bullet behaviour within 10% (by mass) gelatine blocks was assessed by measurements made of the temporary cavity within the blocks using high-speed video and of the permanent cavity by dissecting blocks post firing. While ANOVA did not find significant difference at the 0.05 level in the mean values of most of the measurements, there was a significant difference in neck length within the gelatine blocks. The addition of material layers did produce greater variability in the temporary cavity measurements under some of the conditions. One of the synthetic bone polymers with a synthetic skin layer produced similar results within the gelatine blocks to the horse scapulae (with residual tissue) and may be suitable for future ballistic experiments.

3373. Mai, X., et al. (2021). "Correlation Between Electroretinogram and Visual Prognosis in Metallic Intraocular Foreign Body Injury." Frontiers in medicine **8**: 688305.

Purpose: This study aims to investigate the correlation between electroretinogram (ERG) and visual outcome in eyes with metallic intraocular foreign body (IOFB) injury. Methods: Cases with metallic IOFB injuries with preoperative ERG from January 2008 to May 2020 were reviewed retrospectively. Five ERG responses were recorded, including rod response, maximal response, oscillatory potentials, cone response, and 30-Hz flicker. The results were compared between the affected and the contralateral eyes. All patients received surgery to remove IOFBs. The correlation between amplitudes, implicit times, and grades of ERG with final best-corrected visual acuity (BCVA) was analyzed. Results: A total of 33 eyes of 33 patients were included. The eyes with IOFB had generally delayed implicit time and reduced amplitude in all waves. The maximum change was found in oscillatory potentials S3 and N1 (0.42 +/- 0.42 and 1.95 +/- 1.97 of the fellow eyes, respectively, $p < 0.05$). All amplitudes were negatively correlated with the final BCVA (rs: -0.676 to -0.459, all $p < 0.05$). In contrast, all implicit times were positively correlated with final BCVA, although, some of them were not statistically significant (rs: 0.035 to 0.687). Among them, oscillatory potential P3 has the highest correlation coefficient ($rs = 0.687$, $p < 0.001$). All grades of ERG waves were statistically correlated with the final BCVA (rs: -0.596 to -0.664, all $p < 0.001$). Conclusions: ERG can be used to assess visual outcome in metallic IOFB injury after surgery. Oscillatory potentials provided the most significant responses.

3374. Maier, H., et al. (2011). "[Penetrating injuries in the face and neck region. Diagnosis and treatment]." Penetrierende Gesichts- und Halsverletzungen. Diagnostik und Therapie. **59**(8): 765-782.

Penetrating head and neck injuries often present with vascular lesions and airway compromise and may be life-threatening. Thus controlling bleeding and airway stabilisation take priority in emergency treatment. High-velocity projectiles, fragmentations from improvised explosive devices (IEDs) and shrapnel can cause severe tissue injury, representing a challenge for the head and neck surgeon. Since several organ structures, such as the eyes, midface, pharynx, larynx, trachea, esophagus, nerves, vessels and vertebral spine can be injured at the same time, patients should be referred to a specialized trauma center for interdisciplinary treatment following emergency treatment. High-speed ballistic injuries were once confined to the battle field and have been uncommon in Europe since World War II. For this reason, experience among civilian head and neck surgeons is at present limited. With the increased incidence of terrorism and the use of IEDs as the preferred weapon in terrorism it has become important for civilian head and neck surgeons to understand the role of ballistic injuries in mass casualty events. The present paper discusses current viewpoints in the diagnosis and treatment of penetrating head and neck injuries.

3375. Mainali, S., et al. (2022). "Prolonged Automated Robotic TCD Monitoring in Acute Severe TBI: Study Design and Rationale." Neurocritical care **37**(Suppl 2): 267-275.

BACKGROUND: Transcranial Doppler ultrasonography (TCD) is a portable, bedside, noninvasive diagnostic tool used for the real-time assessment of cerebral hemodynamics. Despite the evident utility of TCD and the ability of this technique to function as a stethoscope to the brain, its use has been limited to specialized centers because of the dearth of technical and clinical expertise required to acquire and interpret the cerebrovascular parameters. Additionally, the conventional pragmatic episodic TCD monitoring protocols lack dynamic real-time feedback to guide time-critical clinical interventions. Fortunately, with the recent advent of automated robotic TCD technology in conjunction with the automated software for TCD data processing, we now have the technology to automatically acquire TCD data and obtain clinically relevant information in real-time. By obviating the need for highly trained clinical personnel, this technology shows great promise toward a future of widespread noninvasive monitoring to guide clinical care in patients with acute brain injury., METHODS: Here, we describe a proposal for a prospective observational multicenter clinical trial to evaluate the safety and feasibility of prolonged automated robotic TCD monitoring in patients with severe acute traumatic brain injury (TBI). We will enroll patients with severe non-penetrating TBI with concomitant invasive multimodal monitoring including, intracranial pressure, brain tissue oxygenation, and brain temperature monitoring as part of standard of care in centers with varying degrees of TCD availability and experience. Additionally, we propose to evaluate the correlation of pertinent TCD-based cerebral autoregulation indices such as the critical closing pressure, and the pressure reactivity index with the brain tissue oxygenation values obtained invasively., CONCLUSIONS: The overarching goal of this study is to establish safety and feasibility of prolonged automated TCD monitoring for patients with TBI in the intensive care unit and identify clinically meaningful and pragmatic noninvasive targets for future interventions.

3376. Majumdar, M., et al. (2009). "Cerebritis: An unusual complication of Klebsiella pneumoniae." Indian Journal of Critical Care Medicine **13**(1): 37-40.

Cerebritis is part of a continuum of brain infection and is difficult to diagnose. Cerebritis caused by Klebsiella in immunocompetent adults without predisposing factors such as neurosurgery or penetrating brain injury has not been reported before. We report a case of Klebsiella cerebritis in an adult patient with a proven extracranial focus of infection. We suggest considering cerebritis as a differential diagnosis for altered level of consciousness in patients of severe sepsis, even if an extracranial source of infection is proven.

3377. Makarov, P. V. (2002). "[Surgical strategy of treatment of severe and extremely severe eye burns. I]." K khirurgicheskoi taktike lecheniia tiazheloi i osobo tiazheloi ozhogovoi travmy glaz (soobshchenie I). **118**(3): 10-12.

A total of 112 patients with severe and extremely severe burns of the eyes were treated. The author proves that one of the main causes of unsatisfactory results is the absence of clearly defined criteria for the choice of surgical

strategy during the early period. Based on the classification of interventions, the author suggests an algorithm of early surgical treatment of eye burns.

3378. Makarov, P. V., et al. (2007). "[Study of the efficacy of cyclosporine used in patients at high risk of keratograft rejection. Communication 1. Results of clinical monitoring]." Vestnik oftalmologii **123**(4): 14-19.

The paper presents the results of a long-term (up to 2-year) clinical monitoring of 30 patients operated on for leukomas of various etiology, who were a high risk group and received the oral cyclosporine HEXAL postoperatively. Three types of the course of a postoperative period were identified. These included: an absolutely favorable course in 33.3% of cases (Group 1), a relatively favorable one in 30% (Group 2), and an absolutely unfavorable course in 36.7% (Group 3). The studies demonstrated that cyclosporine diminished the degree of an inflammatory reaction and promotes its rapid relief and better functional results in the late postoperative period. Transparent and semi-transparent engraftment could be achieved in 63.3% of cases. The causes of poor outcomes (in 36.7%) may be the inadequate doses of the cyclosporine and the time of its administration (unsteady-state blood cyclosporine concentrations (TO), the inadequate efficiency or initial inefficiency of immunosuppressive therapy.

3379. Makarov, P. V., et al. (2004). "[Keratoplasty in the surgical treatment of eye burns and their complications]." O keratoplastike v khirurgicheskom lechenii ozhogovoi travmy glaz i ee oslozhnenii. **120**(3): 14-16.

The report contains the analysis results of 53 keratoplasty procedures in the treatment of patients with severe and extra severe burns of eyes (185 cases within 6 years). On the basis of the obtained results, the authors conclude that the active surgical approach, when used soon after trauma (necrectomy, autotenoplasty, bloody blepharorrhaphy), cut significantly the rate of indications for emergency keratoplasty (to 9% only in cases involving the presence of a deep defect caused by the thermal affection or the presence of burn-agent particles in the corneal stroma); an extra severe burn is the absolute indication for lamellar keratoplasty; indications for transplantation of the cornea, 1 week after trauma and more, arise, when there is ulceration (especially, perforation), due to a prolonged and ineffective therapy and due to an inadequate surgical tactics. The authors suggest the criteria for a substantiated and more effective use of transplantation of the cornea in the treatment of eye burns.

3380. Makarov, P. V., et al. (2004). "[An efficiency study of transplantation of allogenic fibroblasts cultivated in collagen gel for the treatment of corneal burn defects in experiment]." Izuchenie effektivnosti transplantatsii kul'tivirovannykh allogennykh fibroblastov v kollagenovom gele pri lechenii ozhogovykh defektov rogovitsy v eksperimente. **120**(4): 27-29.

The paper contains the results of using a mew method applicable to regulation of corneal regeneration, i.e. transplantation of allogenic fibroblasts cultivated in collagen gel within an experimental model of acute alkali corneal burns in rabbits. Two experimental stages, involving 120 animals, were undertaken. The above method was used, at stage 1, on day 2 after trauma and, at stage 2, it was applied in two weeks after ocular burns with profound corneal defects were inflicted. The clinical, morphological and immune-histochemical examinations were used to show a high efficiency of the method in healing the corneal burn wounds; the mechanism of the therapeutic action of the transplant components exerted on regeneration of the affected cornea was investigated; finally, good outlooks for using the discussed method in clinical practice were proven.

3381. Makdissi, J. (2004). "Ultrasound guided removal of an air gun pellet from the temporal fossa: a technical note." International journal of oral and maxillofacial surgery **33**(3): 304-306.

3382. Makhdoomi, S. M., et al. (2018). "Radiographic prediction of metallic foreign body penetration in the reticulum of cows and buffaloes." Veterinary world **11**(4): 488-496.

AIM: This study aimed to evaluate the role of radiography in the standing (right and left) and recumbent (right) lateral positions for the detection and prediction of metallic foreign body penetration in the reticular wall., MATERIALS AND METHODS: A total of 41 bovines (23 cows and 18 buffaloes) having at least one sharp metallic foreign body (>1 cm) detected on reticular radiographs were investigated, and their extent of penetration in the reticular wall was confirmed on the left flank laparorumenotomy., RESULTS: Of total sharp metallic foreign bodies retrieved on rumenotomy, the

maximum percent were detected on the right recumbent radiographic view (75.00% in cows and 57.14% in buffaloes) compared to the right standing (54.38% in cows and 40.42% in buffaloes) and left standing (51.06% in cows and 27.08% in buffaloes) radiographic views. The presence of gas pocket or nodule adjoining a foreign body, faintly visible foreign body, foreign body that appeared partially or completely out of the reticulum, and foreign body that appeared parallel, into, or directed toward the diaphragm indicated a high probability in the prediction of penetrating foreign body in the left standing (100%) followed by the right recumbent (85.71% in cattle and 90% in buffaloes) and right standing (94.74% in cattle and 55.56% in buffaloes) radiographic views., CONCLUSION: The right recumbent radiographic view is most reliable to detect sharp metallic foreign bodies in bovine. Buffaloes engulf more number of foreign bodies; however, comparatively, the number of completely or partially penetrating foreign bodies is high in cattle. The hypothesized radiographic parameters for the prediction of penetrability of the metallic foreign body were 100% reliable in the left standing radiographic view in both the species.

3383. Makhlouf, F., et al. (2013). "Gunshot fatalities: correlation between post-mortem multi-slice computed tomography and autopsy findings: a 30-months retrospective study." Legal medicine (Tokyo, Japan) **15**(3): 145-148.

In this study we compared retrospectively the autopsy and the CT-scan findings in 47 gunshot victims (96 wounds) in order to assess the accuracy of the two methods in injury and ballistic diagnoses. Firing distance was determined in 46 wounds (47.9%). Firing range was determined by autopsy alone in 37 cases (80.5%) and by CT-scan alone in three cases (6.5%). In the six remaining cases (13%), autopsy and CT-scan reports concluded both to the same firing range. Entrance wounds were detected concordantly by both CT-scan and autopsy in 63 of the 91 penetrating wounds (69.2%). Exit wounds were present in 69 shots. They were concordantly detected by autopsy and CT-scan in 36 cases (52.2%). It was possible at CT imaging to determine the track of the bullet in up to 62 wounds (72.1%). CT-scan was superior to autopsy in determining two items: face fractures and pneumencephalon. CT scan was of limited value in demonstrating skull base fractures and contusions of the brain. There was good correspondence in demonstrating subarachnoid hemorrhage. CT-scan was accurate to demonstrate presence of gas, either in the pleural cavity (pneumothorax) or in the vessels' lumen (air embolism). Both autopsy and CT-scan were concordant in demonstrating thoracic well injuries, heart lacerations and intra thoracic hemorrhage. CT-scan was far below autopsy in detecting solid organs injuries except for kidneys. The present survey shows that CT-scan is second to none in demonstrating features as pneumencephalon, facial fractures, midline shifts, air embolism, pneumothorax, and pelvic bones fractures. It may contribute to determine the firing range in cases of contact-range and of intermediate range though the firing range assessment remains beyond post-mortem imaging possibilities, at least at the current state of knowledge.

3384. Maki, M. H. (2009). "Management outline of oral and maxillofacial missile injuries in Iraq: the value of the intermediate phase." The Journal of craniofacial surgery **20**(3): 873-877.

Oral and maxillofacial surgeons in Iraq are practicing in a paradoxical situation where a high number of extensive injuries are accompanied by limited resources. Steps of management should be followed cautiously in attempts to reduce residual deformities that characterize the end results of severe missile injuries. This study elucidate lessons extirpated from surgical experience in the management of diversity of causalities with special emphasis on the intermediate phase of management as well as different modalities of treatment, trying to get best benefit from available resources.

3385. Makkar, R. M. (2013). "The faciocervicopectoral flap for non-oncological cases of cheek reconstruction." Annals of the Royal College of Surgeons of England **95**(6): 397-400.

INTRODUCTION: Major facial defect has been a challenging case for plastic surgeons in terms of wound healing and covering technique for a long time., METHODS: Eight faciocervicopectoral (FCP) flaps were performed for reconstruction of major cheek defects due to handmade explosive and gun injuries. They were evaluated perioperatively and postoperatively with regard to operative time and operative blood loss as well as the function and cosmetic appearance., RESULTS: The technique showed marvellous cosmetic results but encountered minor postoperative flap complications., CONCLUSIONS: The FCP flap is one of the best solutions for coverage of a simple or complex cheek defect. Application of the FCP flap is easy and rapid.

3386. Makkat, S., et al. (2001). "Multiple growing fractures and cerebral venous anomaly after penetrating injuries: delayed diagnosis in a battered child." Pediatric radiology **31**(5): 381-383.

A growing fracture usually results from a skull fracture with dural tear after blunt head trauma during infancy. We present a case of child abuse with multiple growing fractures resulting from penetrating head trauma by scissors. MR imaging confirmed the presence of growing fractures and revealed a presumably post-traumatic venous anomaly (occluded left cavernous sinus and aberrant posterior venous drainage via the internal cerebral veins). Diagnosis of the growing fractures and venous anomaly was delayed until the age of 15 years. Medical expertise should be more readily available to battered children, and MR imaging is advocated in growing skull fracture to exclude associated post-traumatic brain lesions.

3387. Makoshi, Z., et al. (2016). "Nail gun injuries to the head with minimal neurological consequences: a case series." Journal of medical case reports **10**: 58.

BACKGROUND: An estimated 3700 individuals are seen annually in US emergency departments for nail gun-related injuries. Approximately 45 cases have been reported in the literature concerning nail gun injuries penetrating the cranium. These cases pose a challenge for the neurosurgeon because of the uniqueness of each case, the dynamics of high pressure nail gun injuries, and the surgical planning to remove the foreign body without further vascular injury or uncontrolled intracranial hemorrhage., CASE PRESENTATION: Here we present four cases of penetrating nail gun injuries with variable presentations. Case 1 is of a 33-year-old white man who sustained 10 nail gunshot injuries to his head. Case 2 is of a 51-year-old white man who sustained bi-temporal nail gun injuries to his head. Cases 3 and 4 are of two white men aged 22 years and 49 years with a single nail gun injury to the head. In the context of these individual cases and a review of similar cases in the literature we present surgical approaches and considerations in the management of nail gun injuries to the cranium. Case 1 presented with cranial nerve deficits, Case 2 required intubation for low Glasgow Coma Scale, while Cases 3 and 4 were neurologically intact on presentation. Three patients underwent angiography for assessment of vascular injury and all patients underwent surgical removal of foreign objects using a vice-grip. No neurological deficits were found in these patients on follow-up., CONCLUSIONS: Nail gun injuries can present with variable clinical status; mortality and morbidity is low for surgically managed isolated nail gun-related injuries to the head. The current case series describes the surgical use of a vice-grip for a good grip of the nail head and controlled extraction, and these patients appear to have a good postoperative prognosis with minimal neurological deficits postoperatively and on follow-up.

3388. Maksoud, S., et al. (2020). "Penetrating traumatic brain injury resulting from a cockerel attack: case report and literature review." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **36**(5): 1067-1070.

Traumatic brain injury is common in children and can lead to death or considerable, long-lasting morbidity. We present the case of a 10-month-old female child who presented after being attacked by a cockerel in a chicken coop. Following a seizure, an MRI scan revealed an intracerebral haemorrhage underlying a stab-type wound inflicted by the bird. Animal bite injuries are common worldwide but they rarely cause intracranial injuries. Domestic hens are rarely dangerous but can become defensive or aggressive during breeding periods or when protecting their territory. To date, only a handful of articles have reported on wounds inflicted by chicken beaks. Those reported were largely facial or ocular injuries. Infectious complications have also been encountered post-injury. This is to our knowledge the first report of a bird attack resulting in significant penetrating traumatic brain injury. Children should be cautioned by guardians to avoid unsupervised contact with chickens, particularly during breeding. Attacks to the neurocranium when they occur must be taken seriously and not treated as humorous or insignificant. Imaging appropriate to the child's clinical condition should be pursued and appropriate intervention and antibiotic treatment should be implemented.

3389. Malandrini, A., et al. (2001). "Neuropathological findings associated with retained lead shot pellets in a man surviving two months after a suicide attempt." Journal of forensic sciences **46**(3): 717-721.

We describe the neuropathological findings in a 30-year-old man who died two months after attempting suicide with a shotgun. We focused our study on lesions associated with retained lead shot pellets and distant therefrom, as well as lesions distant from the principal site of injury. At the sites of the retained lead shot pellets, we found

macrophage proliferation and astrocyte activation, together with axonal spheroids and signs of neuronal damage. In the remaining white matter we observed axonal swellings, astrocyte activation and rarefaction of the neuropil; regressive phenomena of the neurons were also present. All axonal spheroids immunoreacted with antibodies against APP, alphaB-crystallin, NF subunits and ubiquitin. Most reactive astrocytes were positive for GFAP and alphaB-crystallin immunostaining. Some neurons immunoreacting with alphaB-crystallin were also found. These data indicated that an important local reaction developed at the sites of lead shot retention, and mild signs of diffuse axonal damage were found throughout the brain.

3390. Malav, R. A., et al. (2015). "Outcome of penetrating brain injury in civilian practice." Indian Journal of Neurotrauma **12**(2): 122-127.

Introduction There is a dramatic increase in the incidence and little is known about outcome and recovery of penetrating brain injuries. Our study is based on analysis of clinical-radiological profile and outcome of patients of penetrating brain injuries. Method This is a retrospective analysis of patients with penetrating head injury during the period from June 2004 to May 2013. Patients with penetrating head injury were selected from our hospital record. Their operative findings were evaluated and only those patients with documented penetration of the dura by a foreign material were selected for data collection and analysis. Results A total of 60 patients were recruited in the study. Their mean age was 27 years, and most patients were male. Most common clinical presentation was brain matter and cerebrospinal fluid (CSF) leak in 48 (60%) patients followed by decreased level of consciousness in 40 (66.67%) patients. Frontal lobe was most commonly involved part in 24 (40%) patients followed by multiple lobe injury noted in 16 (26.66%) patients. Twelve patients expired during the hospital stay. Thirteen patients were discharged in GOS-2, 15 in GOS-3, and 20 in GOS-4. Wound infection occurred in 11 (18.33%) patients, and seizure developed in 8 (13.33%) patients. Conclusion Penetrating brain injuries are most common in 11-to 30-year-old age group and occur more commonly in male. Most common presentations were brain matter or CSF leak and most common mode of injury was firearm. Frontal lobe was the most commonly injured part of the brain and mortality was 20%. Higher mortality was observed among patients with seizure than in other patients with penetrating brain injury.

3391. Malbranque, S., et al. (2014). "Bone-patch type secondary projectiles: A report on two shots fired at point-blank range using hollow point bullets." Forensic science international **245**: e6-e10.

The number of head wounds due to firearms remains low in France because these cases are primarily linked to suicide (or attempted suicide) and, to a lesser extent, to attacks or hunting accidents [1]. Characterized by the impact of a projectile, which in most cases is made of metal, at high levels of kinetic energy, such acts generally result in severe trans-cerebral lesions with significant levels of morbidity/mortality [2]. Seldom are cases reported in the literature that give a detailed study of intracranial foreign bodies made of bone in such situations [3]. Here we report on the case of two suicides resulting from a transcranial gunshot wounds caused by weapons and ammunition issued by the French police force. Each case helped distinguish a characteristic bone fragment, in the form of a "patch", equivalent in size to the caliber of the bullet.

3392. Male, K. R., et al. (2008). "Intracranial halo pin penetration causing brain injury secondary to poor halo care technique: a case report and literature review." Cases journal **1**(1): 380.

: This is a case report of intra cranial penetration by halo pins resulting in cerebritis and fits secondary to incorrect halo care by the patient and his family. Halo pin penetration into the skull with brain injury is itself a rare incident. Previously documented case reports were in patients with a previous cranioplasties and they were highlight the fact that halo not to be used in cranioplasty patients. Cranial penetration of the halo pins has generally been secondary to a fall/medical condition as epilepsy. This incident how ever highlights the fact the halo care itself along with proper techniques used for tightening the halo pins by the carer plays a crucial role in preventing complications such as this.

3393. Malec, K., et al. (2013). "[Unsuccessful suicidal attempt with use of self-prepared bullet -- case report]." Nieudana proba samobojcza z zastosowaniem naboju samodzialowego -- opis przypadku. **70**(9): 754-756.

Gunshot injuries of the viscerocranium are rarely reported during times of peace in Europe. Penetrating wounds to the maxillofacial region pose a significant challenge for surgeons as they often comprise serious soft and bone tissue defects. We present a case report of 38-year-old male with gunshot wound to the viscerocranium after suicidal attempt. The patient's general condition was stable. The inlet wound was found in the submental region in the central line penetrating deep into the floor of the mouth, to the left, avoiding large vessels and hypoglossal nerve. No exit wound was identified. The ophthalmic examination revealed the limitation of motion in the left eyeball and diplopia in the whole field of vision. The revision was performed under general anesthesia. Control CT scan revealed the presence of one metallic fragment wedged in the hard palate. Second look of oral cavity with particular emphasis on the hard palate was performed. Shrapnel proved to be wedged in the bone of the hard palate very firmly and complete removal without damaging the function of the palate was impossible. The decision was made to withdraw from surgical removal of the remaining piece of the projectile. In most cases, it is recommended to remove all foreign material from human body. However, in the illustrated case we decided to leave small debris in the craniofacial skeleton. In our opinion, further surgical revision would result in greater tissue damage, disproportionate to the benefits of the removal of all fragments of the projectile.

3394. Malec, R., et al. (1983). "[Penetrating injuries of the brain through the orbit. Importance of graphic examinations]." Penetrujici poraneni mozku pres ocnici. Vyznam grafickych vysetreni. **122**(11): 323-326.

3395. Malhotra, A., et al. (2018). "TO the editor." Spine **43**(6): E379-E380.

3396. Malhotra, K., et al. (2019). "TRANSPLANTING A POLYCYSTIC KIDNEY- TROJAN HORSE OR SILVER LINING?" American Journal of Kidney Diseases **73**(5): 699.

There were 703,243 patients with End Stage Renal Disease (ESRD) in the U.S. in 2015 (80% increase since 2000) while only 17,878 kidneys were transplanted in 2015 (31% increase since 2000). The Organ Procurement and Transplantation Network's kidney allocation system changed in December 2014. It prioritizes candidates in the top 20th estimated post-transplant survival (EPTS) percentile to receive kidneys from donors with a kidney donor profile index (KDPI) ≤20%. On the flip side, it allows people with higher EPTS score to receive kidneys from donors with higher KDPI. A 76-year-old Caucasian male with Chronic Kidney Disease (CKD) secondary to prior analgesic use and increasing fatigue and loss of appetite had decided to start peritoneal dialysis. His labs showed a BUN of 61 mg/dl, creatinine 4.63 mg/dl. The next day transplant center called patient with an offer for kidney. The donor was a 27-year-old male, victim of gunshot wound and head trauma, who was pronounced brain dead the day after the incident. The patient was known to have Autosomal Dominant Polycystic Kidney Disease (ADPKD) since childhood with history of hypertension and was non-compliant with medications. Donor's creatinine was 1.5 mg/dl with no proteinuria. Cold ischemic time was 15.25 hours. The transplanted kidney was 19 cm long with mild interstetial fibrosis and inflammatory process on biopsy. Patient's post-transplant creatinine improved from 4.7 mg/dl to 1 mg/dl in 5 days. At 3 months post transplant, he is asymptomatic, with normal blood pressure and stable creatinine of 1.3mg/dl. With increasing incidence and prevalance of ESRD and high cost of dialysis, increased efforts are needed to promote transplantation. Due to shortage of kidney donors, ADPKD donor kidney in selected patients should be allowed. More research is needed to define what level of donor kidney function and biopsy findings are considered optimal for safe and successful outcomes.

3397. Malik, T. G., et al. (2015). "Broken bones and blind eyes: Ocular and orbital injuries in craniofacial trauma." Pakistan Journal of Medical and Health Sciences **9**(1): 381-385.

Aim: To describe ocular, neuro-ophthalmological and imaging patterns of head trauma, with special reference to road traffic accidents (RTA) in an urban area of Pakistan. Study Design: Descriptive, retrospective study. Study period: 2007 to 2013 Subjects and settings: 42 Patients of cranio facial trauma from three different centers of Lahore were included in the study. History charts and neuro-imaging reports were reviewed. The data considered for the study was age, sex, ocular manifestations, neuro-ophthalmological findings and imaging reports Results: Male to female ratio was 6: 1. Craniofacial injuries were common in patients of ≤ 40 years of age. The commonest cause of trauma was road traffic accidents (RTA). 9 patients had severe vision loss (NPL= no perception of light). 50% patients (n=21) had left sided trauma. 5(11.9%) were normal with no clinical and neuro-imaging findings. Congested eyes, decreased vision, muscle

entrapment in orbital fracture and restricted extra ocular movements due to severe edema were common ocular findings. Other clinical signs were Enophthalmos, Hyphema, intra ocular foreign body, ocular motor nerve palsies, papilledema, retinal detachment, ruptured globe, traumatic optic neuropathy, vitreous hemorrhage, Carotico-cavernous fistula and chiasmal damage. Conclusion: In urban areas, RTA account for maximum ocular injuries secondary to craniofacial trauma. Proper and prompt actions in emergency department by multidisciplinary experts can not only save lives but also vision.

3398. Malin, J. P. and T. Grumme (1975). "Craniocerebral gunshot wounds in civilian life." Aktuelle Traumatologie **5**(4): 251-259.

Report on 41 male and 4 female patients with craniocerebral gunshot wounds is reported. In 80% a suicidal accident occurred. The injuries are categorized into three major types: penetrating wounds with metallic fragments retained in the brain (22 cases), through and through wounds (21 cases) and tangential injuries with in driven bone fragments (2 cases). Death rate: 53%, operative deaths: 31%. In deciding on neurosurgery procedure the result of neurological examination, especially the presence or absence of a traumatic midbrain syndrome, the location of the missile and if possible, the result of angiography have to be considered.

3399. Malivukovic, A., et al. (2016). "Cranial reconstruction with prefabricated 3D implant after a gunshot injury: A case report." Vojnosanitetski pregled **73**(8): 783-787.

Introduction: Complex defects of skull bones with different etiology, still present the challenge in reconstructive surgery. The goldstandard for cranioplasty is the autologous calvarial bone graft removed during surgery which cannot be always applied, especially in gunshot wounds for sometimes complete bone destruction. Autologous reconstruction with split calvarial, rib bones or iliac bone graft is also possible. Materials routinely used for reconstructions like titanium mesh, polymethyl metacrylate (PMMA), and other have numerous disadvantages and limitations., Case report: We presented a patient with gunshot injury to the head with residual large bone defect in the frontal region, with involvement of the skull base, and open frontal sinus. After conservative treatment, six months after the injury, reconstruction of the residual bone defect was performed. The chosen material was computerdesigned PEEK-OPTIMA R implant, manufactured on the basis of MSCT scan. This material has not been used in this region so far. The postoperative and follow-up period of the next 12 months passed without surgical complications, neurological deficit, with satisfactory functional and aesthetic results., Conclusion: Implanted bone replacement was designed and manufactured precisely according to the skull defect, and we found it suitable for the treatment of complex defects of the cranium. Early results are in favor of this cranioplasty method over standardized materials. Therefore, this material is expected to become a method of choice for reconstructive surgery of bony defects of the face and skull especially in complex cases.

3400. Mallak, C. T., et al. (2001). "Saddam's revenge: a post-Gulf War casualty." The American journal of forensic medicine and pathology **22**(1): 43-45.

Artillery weapons are designed to inflict death and destruction by way of fragmentary and blast injuries. As pieces of modern machinery, they are also capable of causing serious injury by their very complex nature. The authors present a case analysis of an artillery piece that caused a projectile death without a shell.

3401. Mallory, G. W., et al. (2016). "The rise and fall of the craniocervical junction relative to the hard palate: a lifetime story." Journal of neurosurgery. Spine **24**(4): 521-526.

OBJECT: Endoscopic approaches to the anterior craniocervical junction are increasing in frequency. Choice of oral versus endoscopic endonasal approach to the odontoid often depends on the relationship of the C1-2 complex to the hard palate. However, it is not known how this relevant anatomy changes with age. We hypothesize that there is a dynamic relationship of C-2 and the hard palate, which changes with age, and potentially affects the choice of surgical approach. The aim of this study was to characterize the relationship of C-2 relative to the hard palate with respect to age and sex., METHODS: Emergency department billing and trauma records from 2008 to 2014 were reviewed for patients of all ages who underwent cervical or maxillofacial CT as part of a trauma evaluation for closed head injury. Patients who had a CT scan that allowed adequate visualization of the hard palate, opisthion, and upper cervical spine (C-1 and C-2)

were included. Patients who had cervical or displaced facial/skull base fractures, a history of rheumatoid arthritis, or craniofacial anomalies were excluded. The distance from McGregor's palatooccipital line to the midpoint of the inferior endplate of C-2 (McL-C2) was measured on midsagittal CT scans. Patients were grouped by decile of age and by sex. A 1-way ANOVA was performed with each respective grouping., RESULTS: Ultimately, 483 patients (29% female) were included. The mean age was 46 +/- 24 years. The majority of patients studied were in the 2nd through 8th decades of life (85%). Significant variation was found between McL-C2 and decile of age ($p < 0.001$) and sex ($p < 0.001$). The mean McL-C2 was 27 mm in the 1st decade of life compared with the population mean of 37 mm. The mean McL-C2 was also noted to be smaller in females (mean difference 4.8 mm, $p < 0.0001$). Both decile of age ($p = 0.0009$) and sex ($p < 0.0001$) were independently correlated with McL-C2 on multivariate analysis., CONCLUSIONS: The relationship of C-2 and the hard palate significantly varies with respect to age and sex, descending relative to the hard palate a full centimeter on average in adulthood. These findings may have relevance in determining optimal surgical approaches for addressing pathology involving the anterior craniocervical junction.

3402. Malone, D. R., et al. (1982). "Prosopagnosia: a double dissociation between the recognition of familiar and unfamiliar faces." Journal of neurology, neurosurgery, and psychiatry **45**(9): 820-822.

Two cases of a dissociation between prosopagnosia and impaired capacity to match familiar faces were studied. Recognition of familiar faces recovered in the first patient, whereas prosopagnosia persisted in the second patient despite recovery of matching unfamiliar faces and other visuoperceptive skills. This double dissociation is discussed in relation to current views of prosopagnosia.

3403. Malta Pio, G., et al. (2019). "Sclerokeratoplasty for the early management of acquired anterior staphyloma." Romanian journal of ophthalmology **63**(4): 379-382.

Objective: To report a case of acquired anterior staphyloma after trauma and its first surgical management. Methods: This is a case report of a 17-year-old man who had a history of trauma by insect on the right eye, without a previous history of eye conditions, and evolved with local pain and low visual acuity. The ophthalmological exam showed light perception visual acuity in right eye and 1,0 in left eye, anterior staphyloma and impossibility to blink. The first surgical procedure proposed was sclerokeratoplasty and the second one an optical transplantation but, after step one, the patient did not return to the service and missed the follow-up. Results: Sclerokeratoplasty was proposed once the posterior segment and the crystalline were preserved in topical position. The anterior tumor was excised in free-cut and corneal-scleral graft sutured in single points with 10-0 mononylon. Gatifloxacin 0.3% with Prednisolone Acetate 1%, Epitezan R and Atropine 1% were prescribed immediately postoperative. After 60 postoperative days, he maintained the use of Dexamethasone 0.1% and Atropine 1% and the patient had visual acuity of perception of hand movement in the affected eye. Conclusion: Few treatment options are alternatives to evisceration. In this case report, the sclerokeratoplasty was the chosen technique for the initial management. The second step was not possible due to loss of follow-up. Despite the uncomplicated procedure, we need greater compliance by the patient to conclude the treatment.

3405. Maltzman, B. A., et al. (1976). "A survey of ocular trauma." Survey of ophthalmology **21**(3): 285-290.

A four-year survey of all ocular trauma cases admitted to a large metropolitan eye hospital was conducted for the purpose of generally documenting ocular trauma and evaluating prophylactic, demographic and etiologic factors. Of 6254 eye admissions, 7.5% were for ocular trauma; hyphema was the most common diagnosis. Injuries were evaluated according to site, cause, and age, sex and race distribution.

3406. Ma'luf, R. N., et al. (2003). "Orbital osteoma arising adjacent to a foreign body." Ophthalmic plastic and reconstructive surgery **19**(4): 327-330.

A 27-year-old man sustained a blast injury to the face in April 1996, with a resultant foreign body at the right medial orbital wall. He refused to undergo surgical removal of the foreign body at that time and was discharged on oral antibiotics. Five years later, he presented because of recurrent attacks of swelling, redness, and pain at the right medial canthal area. A repeat computed tomography (CT) scan revealed fragmentation of the original orbital foreign body and an adjacent radiodense lesion that appeared to blend smoothly with the orbital bone from which it arose. This lesion was not present on the initial CT scan done 5 years earlier immediately following the blast. The patient was started on oral antibiotics and surgical exploration was carried out. Three fragments of the foreign body were removed in addition to the adjacent orbital lesion, which proved to be an ivory-type osteoma on histopathology. We briefly review previously suggested factors in the pathogenesis of osteoma and present further evidence in favor of both traumatic and infectious factors.

3407. Mamadaliev, A. M., et al. (1988). "[Information value of initial clinical signs for the prognosis of outcome in the first 24 hours after craniocerebral injury]." Informativnost' klinicheskikh priznakov dlia prognozirovaniia iskhodov v 1-e sutki posle cherepno-mozgovoi travmy. **88**(5): 3-7.

The informativeness of clinical indicators for predicting lethal and favourable outcomes during the first 24 hours after a head trauma has been investigated. A pool of clinical findings about the status of 302 patients examined according to a uniform technique has been analyzed using a packet of the MEDSTAT-85 software. The authors present an optimal set of clinical signs for predicting fatal and favourable outcome within the first 24 hours after the trauma with an 83% probability rate.

3408. Mancuso, P., et al. (1988). "Craniocerebral gunshot wounds in civilians. Report on 40 cases." Journal of neurosurgical sciences **32**(4): 189-194.

The Authors report an analysis on 40 cases of craniocerebral gunshot wounds treated in a civil hospital over a 8-year period. The important role of CT for a correct diagnosis and treatment planning is stressed even though patients with a G.C.S. lower than 4 die regardless of their CT findings; subdural and intracerebral hematomas are not a serious complication unless patient's neurological status is poor; timing of surgical treatment plays a major role in order to avoid infection of the wound.

3409. Mandat, T., et al. (2002). "[Posttraumatic visual agnosia and epilepsy as a consequence of gunshot injury to the head. Case report]." Pourazowa agnozja wzrokowa i padaczka jako powiklanie rany postrzalowej glowy. Opis przypadku. **36**(2): 403-411.

Half million people in the world, each year have a gunshot injury to the head and eighty thousand of them are hospitalized. Gunshot injuries to the head have became in Poland second most frequent cause of death from head trauma, and in some countries during peace became the most frequent cause of death among patient with head injury. Glasgow Coma Scale (GCS) is a useful prognostic factor for patients with gunshot injury to the head. Injury to the eloquent regions of the brain, commotion and contusion of the brain, intracranial hematomas, subarachnoid hemorrhage, cerebro-vascular spasm, injuries to the major vessels, liquorrhea, infections, coagulopathies and epilepsy are the most important and influential factors in the clinical status of the patient with gunshot injury to the head. The operation is the preferred treatment to all patient, no matter of their clinical status at the moment of the admission. The report presents the history of treatment of a patient with gunshot injury to the head. During the treatment extremely infrequently occurring posttraumatic visual agnosia and posttraumatic epilepsy were observed. Twenty-two months after operation the patient is independent and professionally active.

3410. Mandat, T. S., et al. (2005). "Artistic assault: an unusual penetrating head injury reported as a trivial facial trauma." Acta neurochirurgica **147**(3): 331-333.

The authors report a case of penetrating head injury that presented with a deceptively mild complaint. To our knowledge, it is the first report of a paint brush penetrating the brain. The patient reported being punched in the left eye and presented with a minor headache, swelling around the left orbit, a small cut on the cheek and slightly reduced left eye abduction. After radiological evaluation, a penetrating head injury was diagnosed. Under general anesthesia, through a lateral eyelid incision a 10.5 cm long paint brush, which had penetrated from the left orbit to the right

thalamus, was removed. No post-operative infection was seen at six months follow-up. This brief report serves to highlight that penetrating brain injury can occur without neurological deficit and that a minimally invasive surgical approach was successful in avoiding any complications.

3411. Manganello-Souza, L. C. (1994). "Reconstruction of frontonasal region with postauricular flap and calvarial bone split graft. A case report." International journal of oral and maxillofacial surgery **23**(5): 276-278.

An unusual case of delayed reconstruction of the frontonasal region is described. The versatility of the postauricular flap is emphasized along with the use of free parietal bone grafts.

3412. Mangla, S. and S. J. A. Sclafani (2008). "External carotid arterial injury." Injury **39**(11): 1249-1256.

Carotid vascular trauma has high mortality. The two primary causes of death are associated head injury and vascular injuries that cause exsanguination or stroke. In the past two decades interventional radiology, i.e. techniques of transcatheter embolisation, has become a vital component of the care of these cases. External carotid artery injuries are complex and are often inaccessible causes of exsanguinating haemorrhage. Transcatheter techniques have been shown to be highly effective in controlling this haemorrhage. An overview of injuries of the external carotid artery and its branches is presented.

3413. Manh, T. H., et al. (2020). "Penetrating spinal cord injury caused by a Needlefish: A case report and review of Needlefish trauma to the head and neck." Interdisciplinary Neurosurgery: Advanced Techniques and Case Management **21**.

Needlefish are predatory schooling fish with long slender jaws that have been known to leap out of the surface of the water at high speeds. There are multiple documented instances of Needlefish causing injury to humans, and these injuries can be more severe than their external appearance would indicate. There are few cases of penetrating head or neck trauma caused by these fish, however, and the following is the first known report of a partial spinal cord injury caused by a Needlefish and illustrates the benefits of prompt neurosurgical intervention and antibiotic prophylaxis.

3414. Maniara, B. P. and I. Wells (2021). "Ceftolozane/Tazobactam-Induced Leukocytosis and Clinical Failure in a Patient Being Treated for Ventilator-Associated Pneumonia Caused by Carbapenem-Resistant Pseudomonas aeruginosa: a Case Report." SN Comprehensive Clinical Medicine **3**(2): 701-704.

Ceftolozane/tazobactam is an intravenous beta-lactam/beta-lactamase inhibitor that utilizes a novel oxyimino-cephalosporin with a traditional beta-lactamase inhibitor. It is approved by the Food and Drug Administration to treat complicated intra-abdominal infections in combination with metronidazole, complicated urinary tract infections, and, most recently, hospital-acquired bacterial and ventilator-associated bacterial pneumonias. It is commonly utilized to treat infections caused by multidrug-resistant Pseudomonas aeruginosa. This case report delineates the first published case of ceftolozane/tazobactam-induced leukocytosis (up to 36.9 × 109 cells/L) and clinical failure when utilized in a high-dose regimen for a patient being treated for ventilator-associated pneumonia secondary to carbapenem-resistant P. aeruginosa. The reaction occurred during initial challenge, resolved after discontinuation, and recurred during re-challenge. In patients who are appropriately being treated with ceftolozane/tazobactam for susceptible infections, consider a drug-induced reaction as a potential cause of rising leukocytosis; this should be differentiated from clinical failure if the patient is clinically stable.

3415. Manjila, S., et al. (2015). "Understanding Edward Muybridge: historical review of behavioral alterations after a 19th-century head injury and their multifactorial influence on human life and culture." Neurosurgical focus **39**(1): E4.

Edward Muybridge was an Anglo-American photographer, well known for his pioneering contributions in photography and his invention of the "zoopraxiscope," a forerunner of motion pictures. However, this 19th-century genius, with two original patents in photographic technology, made outstanding contributions in art and neurology alike, the latter being seldom acknowledged. A head injury that he sustained changed his behavior and artistic expression. The shift of his interests from animal motion photography to human locomotion and gait remains a pivotal milestone in our understanding of patterns in biomechanics and clinical neurology, while his own behavioral patterns, owing to an injury

to the orbitofrontal cortex, remain a mystery even for cognitive neurologists. The behavioral changes he exhibited and the legal conundrum that followed, including a murder of which he was acquitted, all depict the complexities of his personality and impact of frontal lobe injuries. This article highlights the life journey of Muybridge, drawing parallels with Phineas Gage, whose penetrating head injury has been studied widely. The wide sojourn of Muybridge also illustrates the strong connections that he maintained with Stanford and Pennsylvania universities, which were later considered pinnacles of higher education on the two coasts of the United States.

3416. Mankowski, B., et al. (2016). "Intraspinal migration of a Kirschner wire as a late complication of acromioclavicular joint repair: a case report." Journal of medical case reports **10**: 66.

BACKGROUND: Penetrating neck trauma involving foreign bodies is a rare event in European countries. Due to its relatively high mortality rate, the correct management strategy must be initiated from the beginning to prevent fatal complications. In the medical literature, there are only a few cases describing foreign bodies penetrating the cervical spine. Because of its rareness, many trauma centers lack the proper routine to adequately manage such injuries., CASE PRESENTATION: This case report describes a 34-year-old white man of Central European descent with Kirschner wire migration and perforation of his vertebral foramen. He underwent acromioclavicular joint repair surgery 7 years ago, presented with a painful sensation around the area of his left clavicle and left side of his neck after a motorcycle accident. No neurological deficit was detected., CONCLUSIONS: In such cases, a thorough radiological evaluation of the spinal cord and the surrounding vasculature is mandatory for a complete understanding of the extent of the injury and determining the proper surgical management. In cases of vertebral artery trauma both an endovascular and an open approach can be contemplated.

3417. Manley, N. R., et al. (2019). "Survival after Prehospital Traumatic Cardiac Arrest: A Comparison of Isolated Head and Non-Head-Penetrating Injuries." The American surgeon **85**(3): e123-e125.

3419. Manning, T. C., et al. (2008). "Survival with good outcome after traversing brainstem injury: case report." Neurosurgery **62**(3): E749-E749.

OBJECTIVE: A penetrating injury to the brainstem is usually a fatal injury. The number of cases in which the brainstem is traversed during the injury and the patient survives is exceedingly small., CLINICAL PRESENTATION: We report a case of an automobile collision in which blunt injury to the face of a 22-year-old man resulted in a fragment of the clivus being impacted posteriorly traversing through the pons in a left-sided through-and-through manner. The striking radiographic images demonstrate a potentially devastating brainstem injury. Surprisingly, the patient was able to follow commands and move his left side on arrival at the hospital., INTERVENTION: The patient required a temporary tracheostomy and underwent surgical repair of his facial fractures. His hospital course was complicated by meningitis, and he required a long stay on the rehabilitation service. The patient made a remarkable recovery and became able to converse and walk with assistance. He has been able to live independently., CONCLUSION: The striking radiographic images of this rare case illustrate an unusual pathology with an even more unusual outcome.

3420. Mannis, M. J. and D. R. May (1983). "Use of the temporary keratoprosthesis in the subacute management of massive ocular trauma." Annals of ophthalmology **15**(8): 773-777.

The Landers-Foulks temporary operating keratoprosthesis was used in the treatment of a severe double perforating injury involving both the cornea and retina in a 12-year-old boy. The use of the keratoprosthesis permitted surgical intervention at the optimal time for successful treatment of the retina and vitreous, providing the patient with useful visual acuity. The temporary keratoprosthesis is an excellent device for the subacute management of massive ocular trauma involving both anterior and posterior segments.

3421. Mannocci, F., et al. (1997). "Sealing ability of several restorative materials used for repair of lateral root perforations." Journal of endodontics **23**(10): 639-641.

Amalgam, IRM, Vitremer, Bisfil, and Ana Norm Liner were evaluated for repair of experimentally induced lateral perforations. Eighty-five sound, mandibular, and maxillary molars, extracted for periodontal reasons, were selected for this study. The sample teeth were randomly divided in five groups with 15 specimens each. Ten teeth were used as control groups. After the perforations were filled with the above-mentioned materials, the teeth were immersed in a 2% methylene blue solution for 48 h, sectioned, and dye penetration was measured. The results indicated that Bisfil 2 B provided a significantly better seal than the other materials.

3422. Manolidis, S., et al. (2002). "Classification and surgical management of orbital fractures: experience with 111 orbital reconstructions." The Journal of craniofacial surgery **13**(6): 726-738.

Orbital skeletal injuries are frequently associated with other significant injuries and require a substantial surgical effort to correct. The use of a unified classification of orbital injury may better predict the surgical effort required to correct such injuries and help with future comparisons of results. In an attempt to summarize the principles of reconstruction of the orbital skeleton following trauma and introduce a unified classification system for orbital injuries, a retrospective review of all consecutive orbital reconstructions in a tertiary care teaching hospital was conducted. The nasoethmoidal region was involved in 32%, the zygomatic complex in 50%, and the frontal region in 28% of orbital fractures. Of the orbital walls, four walls were involved in 5%, three walls in 17%, two walls in 30%, and one wall in 53%. Associated ocular and neurologic injury was encountered in 33% and 57% of patients, respectively. Regions of fixation ranged from one to eight. Bone grafts were used in 20% and titanium mesh in 34% of the orbits. In general, the authors recommend an aggressive approach to orbital injuries, addressing all associated injuries simultaneously.

3423. Manso, R. (2012). "Pourfour du Petit syndrome due to nodular thyroid hyperplasia." Journal of neurology **259**(1): S221.

Objectives: The classical signs of Pourfour du Petit syndrome (PDPS) are exactly the opposite of those of Horner Syndrome (HS) and comprise mydriasis, lid retraction and exophthalmos. It is produced by stimulation of the ipsilateral sympathetic cervical chain and has the same causes as HS. Some cases have been reported following intracranial aneurysms, non-penetrating injuries of the cervical sympathetic chain and brachial plexus, post-traumatic syringomyelia, severe cranioencephalic trauma, aortic malformation, thoracic tumors (first rib condrosarcoma, esophagus carcinoma and lung carcinoma), and maxillofacial surgery (parotidectomy, mandible tumor resection). We report a patient with PDSP due to nodular thyroid hyperplasia. Methods: A 38 year-old men presented with episodes of right blurred vision, without headache or ocular pain. Looking in a mirror, he could see a protrusion of his right eye and that his right pupil was larger than the left. On neurologic examination, the patient exhibited a difference in pupillary widths, 4 mm in light and 2 mm in darkness. Cocaine (10 %) testing revealed no dilation lag. The position of the right upper lid was 2 mm higher than that of the left upper lid, the right eye with proptosis. Direct, consensual light reaction and the pupillary near reaction were normal for both eyes. The optic discs showed no oedema. Visual acuity, near and distant, was 20/25 in both eyes. The eye movements were adequate in all directions. There was no abnormal sweating response. The rest of the neurological examination was normal. Results: Laboratory data including thyroid function tests were within the normal limits. The chest x ray and computerized tomography (CT) also were normal. A magnetic resonance imaging (MRI) study was unremarkable. A cervical ecography demonstrated two thyroid nodules in the right lobe, which measure 2 cm each one. The patient was treated with total thyroidectomy one year later. The pathology exam was reported as a nodular thyroid hyperplasia. The ophthalmic signs persisted but had improved. Conclusion: PDPS often could remain unrecognised, especially when the signs are minor or transient. Awareness of PDPS could support earlier detection of sympathetic disorders and the underlying etiology.

3424. Mansour, A., et al. (2021). "Cerebrovascular Complications in Early Survivors of Civilian Penetrating Brain Injury." Neurocritical care **34**(3): 918-926.

BACKGROUND: This study investigates the presence of cerebrovascular injuries in a large sample of civilian penetrating brain injury (PBI) patients, determining the prevalence, radiographic characteristics, and impact on short-term outcome., METHODS: We retrospectively reviewed patients with PBI admitted to our institution over a 2-year period. Computed tomography head scans, computer tomography angiograms and venograms of the intracranial vessels

were evaluated to determine the wound trajectory, intracranial injury characteristics, and presence of arterial (AI) and venous sinus (VSI) injuries. Demographics, clinical presentation, and treatment were also reviewed. Discharge disposition was used as surrogate of short-term outcome., RESULTS: Seventy-two patients were included in the study. The mechanism of injury was gunshot wounds in 71 patients and stab wound in one. Forty-one of the 72 patients (60%) had at least one vascular injury. Twenty-six out of 72 patients suffered an AI (36%), mostly pseudoaneurysms and occlusions, involving the anterior and middle cerebral arteries. Of the 72 patients included, 45 had dedicated computed tomography venograms, and of those 22 had VSI (49%), mainly manifesting as superior sagittal sinus occlusion. In a multivariable regression model, intraventricular hemorrhage at presentation was associated with AI (OR 9.9, p = 0.004). The same was not true for VSI., CONCLUSION: Acute traumatic cerebrovascular injury is a prevalent complication in civilian PBI, frequently involving both the arterial and venous sinus systems. Although some radiographic features might be associated with presence of vascular injury, assessment of the intracranial vasculature in the acute phase of all PBI is essential for early diagnosis. Treatment of vascular injury remains variable depending on local practice.

3425. Mansour, A., et al. (2022). "USE OF TRANEXAMIC ACID IN GUNSHOT WOUNDS TO THE HEAD." Journal of neurotrauma **39**(11-12): A88-A89.

Introduction: Available literature on use of tranexamic acid (TXA) in gunshot wounds to the head (GSWH) is limited. We describe its safety and efficacy in civilian patients with GSWH. Methods: Retrospective observation on use of TXA in GSWH at a level I trauma center over 2 years. Demographics, GCS, coagulation profile, and neuroimaging were reviewed before and after TXA administration. Thrombotic complications, GOSE at discharge, and mortality were noted. TXA receivers were compared to a severitymatched group who did not receive TXA (n-TXA). Results: 207 GSWH screened, 26 received TXA. 92% had isolated GSWH. Mean age 28± 4 yrs. Median GCS-motor (IQR) 4(4). Median time (IQR) from injury to in-hospital TXA administration 117(39) mins. All patients received 1g bolus and 1g maintenance of TXA. After TXA, there was a significant increase in fibrinogen level (363 (99)vs.263 (135), p = 0.001) and maximal amplitude on thromboelastography (TEG) (62 (5.1)vs.55.2 (12.9), p = 0.009). Compared to n-TXA (n = 26), neuroimaging was stable in 10/16 (62%)vs.8/15 (53%) of patients. GCSmotor remained stable in 18/22 (82%)vs.16/22 (73%). New coagulopathy (22%vs.28%), progression of cerebrovascular injury (38%vs.30%) and thrombotic complications (11%vs.17%) weren't different between groups (p > 0.05 for all). There was no statistical difference in mortality (63%vs.62%, p = 0.944) or GOSE <4 (71%vs.81%, p = 0.411) at discharge. Multiple variable logistic regression didn't suggest an association between TXA and mortality (OR:1.08, CI:0.25-4.70, p = 0.914). Conclusion: In our cohort of GSWH, administration of TXA appeared safe but had no impact on neurologic outcome or mortality. A prospective randomized trial is needed to determine the efficacy of TXA in GSWH.

3426. Mansour, A., et al. (2021). "Coagulopathy as a Surrogate of Severity of Injury in Penetrating Brain Injury." Journal of neurotrauma **38**(13): 1821-1826.

Penetrating brain injury (PBI) is the most devastating type of traumatic brain injury. Development of coagulopathy in the acute setting of PBI, though common, remains of unclear significance as does its reversal. The aim of this study is to investigate the relationship between coagulopathy and clinical presentation, radiographical features, and outcome in civilian patients with PBI. Eighty-nine adult patients with PBI at a Level I trauma center in Chicago, Illinois who survived acute resuscitation and with available coagulation profile were analyzed. Coagulopathy was defined as international normalized ratio [INR] >1.3, platelet count <100,000 /muL, or partial thromboplastin time >37 sec. Median age (interquartile range; IQR) of our cohort was 27 (21-35) years, and 74 (83%) were male. The intent was assault in 74 cases (83%). The mechanism of PBI was gunshot wound in all patients. Forty patients (45%) were coagulopathic at presentation. In a multiple regression model, coagulopathy was associated with lower Glasgow Coma Scale (GCS)-Motor score (odds ratio [OR], 0.67; confidence interval [CI], 0.48-0.94; p = 0.02) and transfusion of blood products (OR, 3.91; CI, 1.2-12.5; p = 0.02). Effacement of basal cisterns was the only significant radiographical features associated with coagulopathy (OR, 3.34; CI, 1.08-10.37; p = 0.04). Mortality was found to be significantly more common in coagulopathic patients (73% vs. 25%; p < 0.001). However, in our limited sample, reversal of coagulopathy at 24 h was not associated with a statistically significant improvement in outcome. The triad of coagulopathy, low post-resuscitation GCS, and radiographical effacement of basal cisterns identify a particularly ominous phenotype of PBI. The role, and potential reversal of, coagulopathy in this group warrants further investigation.

3427. Mansour, G., et al. (2021). "Traumatic cerebral dural sinus vein thrombosis/stenosis in pediatric patients-is anticoagulation necessary?" Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **37**(9): 2847-2855.

INTRODUCTION: Cerebral dural vein thrombosis/stenosis (CDVT/S) is a condition that affects the venous drainage of the brain. Risk factors and causes associated with CDVT/S include systemic risk factors that cause hypercoagulability, or local factors such as head trauma. While consensus is that non-traumatic sinus vein thrombosis should be treated with anticoagulation therapy, treatment of patients with TBI-induced CDVT is not yet established., METHODS: Retrospective review of clinical data of pediatric patients presented to our medical center from July 2017 to August 2020. Inclusion criteria were age, birth to 18 years, admission due to head trauma, head CT scan with positive traumatic findings, and follow-up in our clinic. Exclusion criteria were a normal head CT on admission and failure to follow-up. Data regarding demographics, clinical presentation, imaging findings, treatment, and status on follow-up were recorded. Study protocol was approved by our institutional ethics committee., RESULTS: One hundred sixty-two patients were enrolled. Falling accident occurred in 90.1%, a minority suffered from direct head trauma or gunshot wound. Of the patients, 95.1% suffered from mild TBI. Forty-two percent suffered from an associated intracranial injury. Fourteen cases with CDVT were included in the cohort. Linear fractures were significantly correlated with CDVT. Additionally, occipital/suboccipital fractures, associated intracranial injury, and proximity of injury to the sinus were correlated with CDVT. From this group, 12 were treated conservatively; one patient was treated surgically due to EDH. All patients with CDVT were neurologically intact at discharge. Only one patient was treated with therapeutic dose of LMWH. A total of 86.7% of patients with CDVT who were treated conservatively had full recanalization on follow-up imaging. Four patients had CDVS; all were neurologically intact at admission and discharge, and all were treated conservatively and had full recanalization on follow-up., DISCUSSION: Treatment with ACT is established in pediatric CDVT but not in the sub-group of TBI. While ACT prevents progression of thrombosis, it might cause worsening of extra-axial hemorrhage. In our study, no clinical deterioration was noted with expectant management; thus, we present an algorithm for diagnosis and treatment of trauma-induced CDVT/S in children with frequent clinical and radiologic imaging while avoiding anticoagulation., CONCLUSION: In most cases, anticoagulation therapy is not necessary in traumatic CDVT/S. Initial expectant management in children is safe. However, each case should be evaluated individually and further studies should be performed.

3428. Maragkos, G., et al. (2017). "Meta-analysis of the effect of intracranial infections on morbidity and mortality of civilian craniocerebral gunshot injuries." Clinical neurosurgery **64**: 252-253.

INTRODUCTION: Civilian gunshot wounds to the head (GSWH) are a significant cause of traumatic brain injury-related mortality in the US. Intracranial infections are feared delayed complications in civilian GSWH and the benefit of prophylactic antibiotics has not been thoroughly studied. METHODS: We conducted a meta-analysis of retrospective studies. A database search was conducted in PubMed, EMBASE, Scopus, Web of Science and Cochrane Library for articles after 2000 for intracranial infections (meningitis, cerebritis, ventriculitis and cerebral abscess) after civilian GSWH. We compared the intracranial infection rate in patients who received antibiotic prophylaxis with those who did not. We also compared the mortality of postoperative patients developing intracranial infections with the rest, and their morbidity, as evidenced by their Glasgow Outcome Scale (GOS), and grouped as favorable (GOS 4-5) or unfavorable (GOS 2-3). RESULTS: We identified 64 relevant articles, 7 of which had extractable information. Two articles compared intracranial infection rates with and without antibiotic prophylaxis in 219 GSWH patients. Prophylactic antibiotics did not decrease the risk of developing intracranial infections (OR 1.84; 95% CI 0.93-3.62; P = 0.08). Five articles reported 509 patients admitted with GSWH, 91.9% male, mean age 26.6 years old. 224 patients survived resuscitation and surgery. Postoperative intracranial infections did not significantly increase mortality (OR 0.67; CI 0.19-2.43; P = 0.55), but led to more unfavorable outcomes (OR 4.86; CI 1.19-19.79; P = 0.03). Of note, 160 out of the 224 initial survivors (71.4%) were reported to have received prophylactic antibiotics. CONCLUSION: Prophylactic antibiotics are routinely given to GSWHpatients to prevent infections. This meta-analysis of retrospective studies suggests that 1. prophylactic antibiotics did not decrease the risk of intracranial infections; 2. the presence of intracranial infections in a GSWH setting did not affect mortality and 3. patients developing intracranial infections had worse neurological outcomes.

3429. Maragkos, G. A., et al. (2018). "Civilian Gunshot Wounds to the Head: Prognostic Factors Affecting Mortality: Meta-Analysis of 1774 Patients." Journal of neurotrauma **35**(22): 2605-2614.

Civilian gunshot wounds to the head (cGSWH) are devastating, but there is no consensus regarding prognosis and management. Therefore, we conducted a meta-analysis to identify prognostic factors associated with mortality. PubMed, EMBASE, Scopus, Web of Science, and Cochrane Library were queried for retrospective cohort studies of isolated cGSWH reporting mortality prognostic factors. Meta-Analysis Of Observational Studies in Epidemiology (MOOSE) guidelines were followed. Study quality was assessed using the Newcastle-Ottawa scale. Primary outcome was mortality. Pooled estimates of odds ratios (ORs) and 95% confidence intervals (CIs) were derived using random-effects models. Seventeen (17) observational studies (1774 patients) were identified and included. Factors associated with mortality were: age >40 years (OR, 3.44; 95% CI [1.71-6.91]), suicide attempt (5.78; [3.07-10.87]), Glasgow Coma Scale (GCS) 3-8 compared with 9-15 (38.02; [21.98-65.77]), GCS 3-5 versus 6-8 (15.38; [6.72-35.23], bilateral fixed and dilated pupils versus normal (67.12; [16.67-270.22]), and versus unilateral fixed and dilated pupil (25.35; [5.82-110.41]), dural penetration (29.07; [4.30-196.53]) and bihemispheric (4.23; [2.32-7.68]), and multi-lobar injuries (6.53; [1.99-21.42]). Selection for operative management, according to expert neurosurgical opinion, was protective (0.06; [0.01-0.22]). This is the first meta-analysis on cGSWH mortality prognostic factors. Increasing age, suicide attempt, lower GCS, bilateral mydriasis, dural penetration, and bihemispheric and multi-lobar injury are associated with increased mortality. This study can serve as a guide to clinicians and will provide directions for future research to develop evidence-based management algorithms.

3430. Marais, A. A. S. and H. J. Dicks (2019). "Utilization of X-ray Computed Tomography for the Exclusion of a Specific Caliber and Bullet Type in a Living Shooting Victim." Journal of forensic sciences **64**(1): 264-269.

A bystander claimed to have been shot by a police officer, and CT scans were used to match qualitative and quantitative aspects of the unremoved bullet with police issued 9 mm Luger ammunition. CT scan methodology proved a valid approach for the measurement of bullets based on calculated measurement capability and correlation with "gold standard" physical measurement by vernier caliper. Measurements regarding length and base diameter, as well as length/diameter ratio, were insufficient to unambiguously identify a specific caliber, or a bullet of specific mass within a caliber class. It was, however, possible to exclude a bullet of specific design and mass with well-characterized precision and accuracy values under selected CT scan conditions. A 9 mm Luger bullet (115 gr FMJ RN) was excluded from involvement in a shooting based on qualitative bullet shape combined with length, base, and ratio measurements of the bullet in-situ for the victim.

3431. Marano, A. A., et al. (2015). "Patterns of Intracranial Hemorrhage in Pediatric Patients with Facial Fractures." Craniomaxillofacial Trauma and Reconstruction **9**(1): 35-39.

Intracranial hemorrhage (ICH) is a potentially fatal injury accompanying fractures of the cranium and facial skeleton. When occurring at a young age, ICH can lead to developmental delay, cerebral palsy, epilepsy, and death. It is therefore important for clinicians to recognize the presence of ICH early, and understand the factors that affect its prognosis. In this study, we aim to identify diagnostic and prognostic signs for ICH in pediatric facial fracture patients by examining aspects of patient presentation, concomitant injuries, and fracture patterns. Data were collected for all radiologically diagnosed facial fractures between January 2000 and December 2012 at a level I trauma center in Newark, NJ. This was then further refined to include only patients 18 years of age or younger who had a documented ICH. Patient age, Glasgow coma scale (GCS) on presentation, fracture location, type of hemorrhage, and certain aspects of management were collected from these records. Data were then analyzed by either Pearson chi-square test or a t-test to determine significant relationships. A total of 285 pediatric patients were found to have sustained a facial fracture during this time period, 67 of which had concomitant ICH; 46 of these patients were male and 21 were female, with average ages of 14.26 and 9.52 ($p < 0.01$), respectively. Causes of injury included motor vehicle accidents, pedestrians struck, assault, falls, gunshot injuries, and sports-related injuries. All patients who suffered injuries as a result of violent crimes (assault and gunshot injuries) were male. Although nearly all fracture patterns were significantly associated with the presence of ICH, mandibular fractures showed a significant negative association with the presence of ICH. In addition, patients who received surgical intervention were significantly younger than those who did not (7.7 vs. 13.7, $p < 0.05$). The GCS was significantly lower in patients who underwent ICP (intracranial pressure) monitoring or EVD (external ventricular drain) placement, suffered intraventricular hemorrhage, experienced worsening of hemorrhage on repeat imaging, and suffered fatal injuries. Our data also showed a significant association between the need for intubation in the emergency department and fatality. Because the consequence of ICH can be life threatening, proper diagnosis and

management are imperative. The purpose of this study is to describe patterns associated with ICH in pediatric facial fracture patients to promote early recognition of the injury and understanding of poor prognostic signs.

3432. Maras, D., et al. (2006). "Covered stent-graft treatment of traumatic internal carotid artery pseudoaneurysms: a review." Cardiovascular and interventional radiology **29**(6): 958-968.

OBJECTIVE: To review the literature concerning the management with placement of covered stent-grafts of traumatic pseudoaneurysms of the extracranial internal carotid artery (ICA) resulting from penetrating craniocervical injuries or skull base fractures., METHOD: We have reviewed, from the Medline database, all the published cases in the English literature since 1990 and we have added a new case., RESULTS: We identified 20 patients with traumatic extracranial ICA pseudoaneurysms due to penetrating craniocervical injuries or skull base fractures who had been treated with covered stent-graft implantation. Many discrepancies have been ascertained regarding the anticoagulation therapy. In 3 patients the ICA was totally occluded in the follow-up period, giving an overall occlusion rate 15%. No serious complication was reported as a result of the endovascular procedure., CONCLUSION: Preliminary results suggest that placement of stent-grafts is a safe and effective method of treating ICA traumatic pseudoaneurysms resulting from penetrating craniocervical injuries or skull base fractures. The immediate results are satisfactory when the procedure takes place with appropriate anticoagulation therapy. The periprocedural morbidity and mortality and the early patency are also acceptable. A surveillance program with appropriate interventions to manage restenosis may improve the long-term patency.

3433. Marcellino, C. R., et al. (2017). "Cavernous sinus syndrome and traumatic carotid-cavernous fistula attributable to a self-inflicted bb gunshot injury." Journal of Neurological Surgery Part B: Skull Base **78**.

Introduction: Ball bearing or “BB” guns are a class of gas- or spring-powered projectile weapons whose power and muzzle velocity are often underestimated by casual users and children. Present technology has advanced such that modern BB guns produce high velocity but small caliber ballistic injuries which can penetrate the intracranial space and cause focal central neurologic deficits. The small size of the projectile simultaneously complicates diagnosis and treatment, particularly if the entry wound is not appreciated by the layperson, resulting in delayed care. We report a unique case of cavernous sinus syndrome precipitated by a self-inflicted facial BB gunshot injury in a child. Methods: Case report. Results: A 9-year-old boy was playing with a BB gun when he accidentally suffered a self-inflicted BB gunshot injury to the face. Family believed that a superficial injury only had been sustained, and medical evaluation was correspondingly delayed more than 5 days. During that time, the patient was unable to completely open his eye and complained of diplopia, eventually prompting ED presentation. At that time, he had progressed to malaise, nausea and vomiting, and a right complete CN III and IV nerve palsy, with intact vision, and functioning CN V and VI. Diagnostic angiography revealed a BB retained in the medial cavernous sinus, as well as a small carotid cavernous fistula. The BB was in contact with the cavernous segment of the ICA, inducing minimal arterial stenosis. The projectile was confirmed to be ferromagnetic, and so MRI was deferred. The patient was managed expectantly, and one-month follow-up angiography was arranged to rule out migration of the retained BB and reevaluate the status of the carotid-cavernous fistula. His serum lead level was followed periodically in consideration of medical management, although as this was a spherical BB and not a pellet, the lead content is believed to be low. Conclusion: Modern BB guns can penetrate the cranium and injure skull base structures such as the cavernous sinus, potentially producing severe and highly focal neurological injuries, depending on the trajectory of the pellet. Traumatic vascular injuries causes by BB guns are managed similarly to other missile or penetrating trauma, although little is known about their specific natural history. Other specific management considerations are MRI safety and lead content, which vary significantly from other types of retained projectile injuries, due to differences in composition.

3434. Marcellino, C. R., et al. (2018). "Cortical surface intracranial electrodes identify clinically relevant seizures missed on scalp EEG after traumatic intracranial hemorrhage." Epileptic disorders : international epilepsy journal with videotape **20**(6): 551-556.

Seizures and other electrophysiological disturbances are an under-recognized cause of coma, focal deficits, and prolonged encephalopathy following subdural hematoma evacuation. In these patients, it is possible that seizures remain unrecognized on scalp EEG. It has been shown that a high burden of seizures and other electrophysiological disturbances exist following surgical evacuation and underlie the encephalopathy commonly seen in this patient

population, predisposing them to medical complications and confounding estimates of prognosis. As part of a research protocol, we are performing intraoperative placement of cortical surface (non-parenchyma penetrating) intracranial EEG on patients who present after trauma and require emergent decompressive hemicraniectomy. In this case report of a patient with high-velocity traumatic epidural, subdural, and subarachnoid hemorrhages, we identified frequent non-convulsive seizures or seizure-like SIRPIDs with intracranial cortical surface monitoring that were not identified on simultaneous scalp EEG. Stimulation consistently triggered these electrographic seizures in addition to rhythmic lateralized periodic discharges. His mental status improved rapidly after resolution of these electrographic seizures shortly after increasing antiseizure medications, suggesting that they may have been contributing to his encephalopathy. More research is needed to determine the frequency of this phenomenon and determine whether treatment of such seizures improves patient outcomes.

3435. Marchetti, D., et al. (2003). "Reconstruction of the angle of shot by using computed radiography of the head." The American journal of forensic medicine and pathology **24**(2): 155-159.

In a case of murder by a single .22 caliber bullet fragmented in the head, determination of the trajectory was a key issue in identifying which of 2 windows, 1 of which was associated with 2 suspects, was the site of fire. For this purpose, we processed the computed tomography of the victim's head by using a radiation therapy planning system called Plato, which is routinely used in radiation oncology. This tool provided a 3-dimensional reconstruction of the cranio-cerebral lesions and a spatial location of bullet and bone fragments. In this article is described the more intuitive relationship with forensic and ballistic data obtained from the 3-dimensional visualization and the physical and mathematical analysis used to calculate the angle of shot.

3436. Marchioni, D., et al. (2016). "Traumatic intraconal foreign body: Report of an injury corrected with combined surgical and endoscopic treatment." Operative Neurosurgery **12**(4): 14-18.

BACKGROUND: Management of penetrating ocular splinter injuries is very controversial. Penetrating wounds of the orbit represent a complex therapeutic problem that requires a multidisciplinary approach. Endoscopic approaches to the orbit are currently performed through the lamina papyracea to access the medial part, or through large orbitotomies to access the lateral part. OBJECTIVE: To describe a novel combined approach to the lateral part of the orbit. METHODS: Clinical and surgical findings of intraorbital foreign body removal are presented. A minimal supraorbital osteotomy was performed, combined with endoscopic intraorbital dissection. RESULTS: The foreign body was removed, no postoperative complications were reported, and visual acuity increased from 2/10 preoperatively, to 8/10 one month after surgery. CONCLUSION: The present technique can be considered a safe and novel surgical approach to access the retrobulbar space and to treat the pathology of this anatomic region.

3437. Marciani, R. D. and S. Israel (1997). "Diagnosis of blunt carotid injury in patients with facial trauma." Oral surgery, oral medicine, oral pathology, oral radiology, and endodontics **83**(1): 5-9.

OBJECTIVES: The purpose of this study was to review the clinical and diagnostic findings associated with blunt carotid artery injury, provide information related to clinical outcome, and report the findings of a retrospective study comparing patients with nonpenetrating and penetrating carotid artery injuries and the attendant facial injuries., STUDY DESIGN: Twenty-one patients admitted to the hospital nonelectively with a subsequent diagnosis of penetrating (11 patients) or nonpenetrating (10 patients) carotid artery injuries were included in the study. Records were analyzed for demographic data, mechanism of injury and time to diagnosis, neurologic status, presence of facial injuries, and outcome., RESULTS: Five patients had facial injuries associated with a blunt carotid artery abnormality; six patients had penetrating carotid wounds. Time from carotid injury by all mechanisms to diagnosis was 20 minutes to 12 hours (mean 4 hours). Seventeen patients survived their injury., CONCLUSION: Patients with completely asymptomatic head injuries and severe closed-head injuries must be given careful initial evaluation and subsequent secondary evaluation. The relatively high frequency of facial injuries associated with blunt carotid injury should alert the maxillofacial surgeon to consider the diagnosis.

3438. Marcikic, M., et al. (1998). "Management of war penetrating craniocerebral injuries during the war in Croatia." Injury **29**(8): 613-618.

From September 1991 to December 1992, during the war in Croatia, the General Hospital in Slavonski Brod served as an evacuation centre. During that period 197 patients with war-related penetrating craniocerebral injuries were admitted. They were analyzed according to wound characteristics, operability, mortality, operative and post-operative complications, and their condition after hospital discharge and follow-up. A less aggressive surgical approach was accepted in our surgical strategy, recommended in recent studies, followed by an aggressive intensive management. All patients received antibiotics ("war scheme") and anticonvulsants. Early results of treatment do not differ significantly from other recent studies (Vietnam, Israel) in respect to both mortality and complications. Follow-up was difficult. Most of the patients were Bosnia and Herzegovina citizens who were refugees and banished to foreign countries; thus their addresses were unknown. They are consequently lost to follow-up. A less aggressive surgical approach proved to be justified. Routine use of antibiotics and anticonvulsants lowered the infection rate and early seizure incidence to an acceptable level. Late seizure incidence is similar to those previously reported.

3439. Marcinkowski, T. (1974). "[Erroneous evaluation of missile's direction in cases of gunshot wounds of the head]." Mylna ocena kierunku lotu pocisku w przypadku ran postralowych glowy **25**(3): 457-459.

3440. Marcinkowski, T. (1974). "Erroneous evaluation of the direction of the missile in cases of gunshot wounds of the head (Polish)." Patologia Polska **25**(3): 457-459.

Histologic examination of fragments from the edges of shot wounds is insufficiently appreciated. It helps the investigation of the direction of shot wounds of the head, as is described in a case in which the surgeon assessed the direction of the missile erroneously.

3441. Margo, J. A., et al. (2016). "Open Globe Injuries Presenting With Normal or High Intraocular Pressure." Eye & contact lens **42**(4): 256-261.

OBJECTIVES: To determine the frequency, clinical characteristics, and visual outcomes of patients who present with high or normal intraocular pressure (IOP) and open globe injuries., DESIGN: Retrospective chart review., SETTING: University of Maryland Medical Center, a level 1 trauma center., PATIENT OR STUDY POPULATION: All cases of open globe injury presenting to The University of Maryland Medical Center from July 2005 to January 2014., OBSERVATION: Demographics, initial physical examination, computed tomography findings, IOP of the affected and unaffected eyes, and follow-up evaluations., MAIN OUTCOME MEASURES: (1) IOP 10 mm Hg or greater and (2) visual acuity., RESULTS: Of 132 eyes presenting with open globe injury, IOP was recorded in 38 (28%). Mean IOP for the affected and unaffected eyes was 14+/-10.3 mm Hg and 16.6+/-4.1 mm Hg, respectively. Twenty-three (59.4%) eyes had IOP greater than 10 mm Hg. Six eyes (16.2%) had IOP greater than 21 mm Hg. Using bivariate analysis, IOP greater than 10 mm Hg was associated with posterior open globe injury (P=0.01), posterior hemorrhage (P=0.04), and intraconal retrobulbar hemorrhage (P=0.05). Adjusting for age, sex, and race, IOP greater than 10 mm Hg was associated with the presence of posterior open globe injury on clinical examination (P=0.04). Higher presenting IOP was found to predict light perception or worse vision (P=0.01). Multivariate analysis showed that poor presenting vision was the best predictor of poor final vision (P<0.01)., CONCLUSIONS: High IOP does not exclude open globe injury. It is a frequent finding in patients with open globe injuries and may be associated with posterior injury and poor visual prognosis.

3442. Marhold, F., et al. (2022). "Surviving the Scene in Civilian Penetrating Brain Injury: Injury Type, Cause and Outcome in a Consecutive Patient Series in Austria." Frontiers in surgery **9**: 923949.

Background: Penetrating brain injury (PBI) is a heterogeneous condition with many variables. Few data exist on civilian PBI. In some publications, PBI differentiation between low-velocity injury (LVI) and high-velocity injury (HVI) is made, but exact definitions are not given yet. The incidence of PBI depends heavily on the country of origin. Furthermore, captive bolt pistol (CBP) injuries represent a rare type of LVI and almost no reports exist in the human medical literature. Treatment of PBI has been controversially discussed due to high morbidity and mortality with results varying considerably between series. Prognostic factors are of utmost importance to identify patients who presumably benefit from treatment., Methods: A retrospective, single-center analysis of a consecutive patient series was performed from September 2005 to May 2018. We included all patients with PBI who reached our hospital alive and received any neurosurgical operative procedure., Results: Of 24 patients, 38% died, 17% had an unfavourable outcome, and 46% had

a favourable outcome. In total, 58% of patients with PBI were self-inflicted. Leading causes of injury were firearms, while captive bolt pistols were responsible for 21% of injuries. LVI represented 54%, and HVI represented 46%. The outcome in HVI was significantly worse than that in LVI. A favourable outcome was achieved in 69% of LVI and 18% of HVI. Low GCS and pathological pupillary status at admission correlated significantly with an unfavourable outcome and death., Conclusions: PBI is a heterogeneous injury with many variables and major geographical and etiological differences. Differentiation between LVI and HVI is crucial for decision-making and predicting outcomes. In patients presenting with object trajectories crossing the midline, no favourable outcome could be achieved. Nevertheless, in total, a favourable outcome was possible in almost half of the patients who succeeded in surgery.

3443. Maricevic, A. and Z. Dogas (2004). "Land mine injury: functional testing outcome." Military medicine **169**(2): 147-150.

We present a case of a war patient treated with external fixation for a complex land mine injury involving the fracture of the tibial and fibular bones, which occurred at the front line during the war in Croatia and Bosnia and Herzegovina. Excessive destruction and foreign body penetration into the distal two-thirds of the right leg and foot endangered not only the patient's lower extremity but his life as well. Nevertheless, the patient's life, as well as extremity, was saved due to an intensive treatment. A 100-month follow-up showed a bridge callus between the tibia and fibula, tibial bone defects, tibial anterior angulation of 5 degrees, and arthrosis of the right upper ankle joint. Despite a relatively unsatisfactory X-ray finding, the functional testing on the dynamometry system Cybex 300 showed surprisingly good results. There was a satisfactory functional recovery of the treated extremity: the patient could walk without any help even on rocky grounds and was actively involved in his sheep farm duties.

3444. Marion, D. W. (2006). "Evidenced-based guidelines for traumatic brain injuries." Progress in neurological surgery **19**: 171-196.

An enormous amount of clinical and basic science brain injury research has been undertaken during the last several decades in an effort to improve outcomes following severe traumatic brain injury, but to date there still are no new therapies that have been clearly shown to be beneficial. There is, however, increasing evidence to suggest that evidence-based, protocol-driven, acute care can lead to improved outcomes. Evidence based guidelines for the medical and surgical management of severe brain injury, and for penetrating and pediatric brain injury, as well as for the pre-hospital management of brain injury, have all been published. In this chapter the conclusions of those guidelines is reviewed. In addition, the studies that demonstrate improved outcomes as a result of implementation of the guidelines are summarized.

3449. Marklund, N., et al. (2002). "Effect of traumatic brain injury and nitrone radical scavengers on relative changes in regional cerebral blood flow and glucose uptake in rats." Journal of neurotrauma **19**(10): 1139-1153.

Changes in regional cerebral blood flow (rCBF) and glucose metabolism are commonly associated with traumatic brain injury (TBI). Reactive oxygen species (ROS) have been implicated as key contributors to the secondary injury process after TBI. Here, pretreatment with the nitrone radical scavengers (alpha-phenyl-N-tert-butyl nitrone (PBN) or its sulfonated analogue sodium 2-sulfophenyl-N-tert-butyl nitrone (S-PBN) were used as tools to study the effects of ROS on rCBF and glucose metabolism after moderate (2.4-2.6 atm) lateral fluid percussion injury (FPI) in rats. S-PBN has a half-life in plasma of 9 min and does not penetrate the blood-brain barrier (BBB). In contrast, PBN has a half-life of 3 h and readily penetrates the BBB. Regional cerebral blood flow (rCBF) and glucose metabolism was estimated by using (99m)Tc-HMPAO and [(18)F]Fluoro-2-deoxyglucose (FDG) autoradiography, respectively, at 42 min (n = 37) and 12 h (n = 34) after the injury. Regions of interest were the parietal cortex and hippocampus bilaterally. As expected, FPI produced an early (42-min) hypoperfusion in ipsilateral cortex and an increase in glucose metabolism in both cortex and hippocampus, giving way to a state of hypoperfusion and decreased glucose metabolism at 12 h postinjury. On the contralateral side, a hypoperfusion in the cortex and hippocampus was seen at 12 h only, but no significant changes in glucose metabolism. Both S-PBN and PBN attenuated the trauma-induced changes in rCBF and glucose metabolism. Thus, the early improvement in rCBF and glucose metabolism correlates with and may partly mediate the improved functional and morphological outcome after TBI in nitrone-treated rats.

3450. Markowski, J., et al. (2012). "Intraorbital foreign bodies--5 own cases and review of literature." Otolaryngologia polska = The Polish otolaryngology **66**(4): 295-300.

Five patients were surgically treated for intraorbital foreign body: a 14-year-old girl had a door glass splinter, a 23-year-old man a metallic foreign body--gunshot pellet, a 55-year-old man a splinter from a metallic bar, a 48-year-old patient the splinters of circular saw and 61-year-old man with shot. Two foreign bodies were removed using the Kronlein-Reese-Berk lateral orbitotomy, two others by Sewell medial orbitotomy and one with superior orbitotomy of Dandy-Naffziger. Radiographs and CT scans were used to identify and localize intraorbital foreign bodies. In one case we found coexistence foreign body (shot) and tumor--inflammation pseudotumor of the orbita. It is possible, that in this case long-time occupy foreign body in the orbita was a cause of that tumor. All foreign bodies were successfully removed, and postoperative course was uneventful. The Kronlein-Reese-Berk orbitotomy provides a satisfactory access to the lateral and posterior orbit, which is of particular importance in the case of a deeply penetrating foreign body (metallic or glass). Surgical removal of intraorbital foreign bodies is a classic example of an interdisciplinary therapeutic approach. Best outcome is usually a result of a team of an ophtalmologist, ENT surgeon, maxillary surgeon and possibly also neurosurgeon performing the operation.

3451. Marmor, M., et al. (2009). "Bilateral heel panniculitis presenting as calcaneal osteomyelitis." Orthopedics **32**(1): 59.

Panniculitis is an inflammatory process of the subcutaneous adipose layer (panniculos adiposus). It is frequently a sign of systemic disease with a wide range of clinical presentations. The histopathological findings are diverse, making diagnoses difficult. We present a case of heel panniculitis, initially misdiagnosed as calcaneal osteomyelitis. Our intention is to make physicians, treating these type of patients, aware of the possibility of this rare disease, especially in situations when conventional therapy is not successful. A 66-year-old woman was admitted to the hospital with the initial diagnosis of suspected calcaneal osteomyelitis of her right heel, presumably due to a foreign body penetration a few months prior. Initial treatment with intravenous antibiotics was unsuccessful. When significant fluctuation developed, she underwent incision and drainage of her right heel. Postoperatively, her right heel condition did not improve and similar phenomena appeared on her left side. She continued to deteriorate up to the point when panniculitis was diagnosed and corticosteroid treatment was initiated. Her condition rapidly improved after this treatment.

3452. Marnerides, A., et al. (2013). "An unusual case of multiple-gunshot suicide of an alcohol-intoxicated cancer sufferer with prolonged physical activity." Journal of forensic sciences **58**(2): 537-539.

Multishot firearm suicides are relatively rare and suggest the possibility of homicide. Physical activity following gunshots to the head, the neck, and the thorax does occur, and immediate incapacitation does not occur in every fatal gunshot wound that penetrates the head or perforates the heart. Cancer patients appear to be at increased suicide risk,

but alcohol intoxication is less common in such cases. We present-to the best of our knowledge for the first time-a case of a 54-year old, male, liver cancer sufferer, who under the influence of alcohol, discharged his revolver three times, suffered, among other wounds, a heart-perforating wound, and died after c. 1.5 h, being able to talk until just before he died. Our case underlines the importance of keeping an open critical mind when dealing with multiple-gunshot fatalities, especially when posttraumatic physical activity might be crucial in differentiating homicide from suicide. 3454. Marquardt, G., et al. (2000). "Brain abscess decades after a penetrating shrapnel injury." British journal of neurosurgery **14**(3): 246-248.

We describe a patient who developed a brain abscess 52 years after sustaining a penetrating craniocerebral shrapnel injury. For 10 years he had suffered from diabetes mellitus, a disorder known to predispose to infections from a diminished body defence. The treatment and aetiology of this rare occurrence is discussed.

3455. Marshall, L. F., et al. (1983). "The National Traumatic Coma Data Bank. Part 1: Design, purpose, goals, and results." Journal of neurosurgery **59**(2): 276-284.

This paper describes the pilot phase of the National Traumatic Coma Data Bank, a cooperative effort of six clinical head-injury centers in the United States. Data were collected on 581 hospitalized patients with severe non-penetrating traumatic head injury. Severe head injury was defined on the basis of a Glasgow Coma Scale (GCS) score of 8 or less following nonsurgical resuscitation or deterioration to a GCS score of 8 or less within 48 hours after head injury. A common data collection protocol, definitions, and data collection instruments were developed and put into use by all centers commencing in June, 1979. Extensive information was collected on pre-hospital, emergency room, intensive care, and recovery phases of patient care. Data were obtained on all patients from the time of injury until the end of the pilot study. The pilot phase of the Data Bank provides data germane to questions of interest to neurosurgeons and to the lay public. Questions are as diverse as: what is the prognosis of severe brain injury; what is the impact of emergency care; and what is the role of rehabilitation in the recovery of the severely head-injured patient?

3456. Martens, D. (2012). "Essay: Beauty in the complexity of the brain." CMAJ. Canadian Medical Association Journal **184**(8): 925-926.

3457. Martin, D., et al. (1988). "[The osteocutaneous outer arm flap. A new concept in microsurgical mandibular reconstructions]." Le lambeau osteo-cutane brachial externe. Un nouveau concept dans les reconstructions mandibulaires microchirurgicales. **89**(5): 281-287.

The authors present five cases where the OCLAF technique was adapted to reconstruct large mandibular defects. Some significant advantages made us think about the possibility of the OCLAF as an acceptable alternative in that specific case. These are the ease and safety of the dissection, the respect of a bony vascularisation, a very valuable pedicle size, and a remarkable mobility of the skin paddle to the underlying bone. Of course we had to face some minor disadvantages: the microsurgical procedure, the donor site scar, the absence of cancellous bone in the transfer and the weakening of the bone shaft at the donor site. Nevertheless we think the OCLAF is to be considered whenever large mandibular defects have to be reconstructed with vascularized bone.

3458. Martin, E. M. and A. B. Hummelgard (1986). "Traumatic aneurysms." The Journal of neuroscience nursing : journal of the American Association of Neuroscience Nurses **18**(2): 89-94.

A traumatic aneurysm is a potentially lethal complication of head trauma. The problem is unusual but not rare. The majority of traumatic aneurysms are caused by blunt injuries to the head (62%), although penetrating wounds (27%) and iatrogenic trauma (11%) during intracranial surgery are also well recognized. The pathogenesis, diagnosis, and

management of traumatic aneurysm are discussed, with focus on the patient course and nursing implications of a case study.

3459. Martin, G. (2001). "The death of Henry II of France: a sporting death and post-mortem." ANZ journal of surgery **71**(5): 318-320.

In 1559 Henry II King of France was wounded in a tournament and died. A broken lance entered his right orbit, destroying his eye and leaving behind many splinters. The skull was not penetrated but infection spread intracranially. Both Ambroise Pare and Vesalius saw him and predicted death. Nine days after wounding, both attended the King's post-mortem. The story shows how difficult life was without antisepsis, anaesthesia, antibiotics or investigations. The King's stubbornness highlights the dangers of continuing to play after concussion.

3460. Martin, J. E., et al. (2010). "Care of pediatric neurosurgical patients in Iraq in 2007: clinical and ethical experience of a field hospital." Journal of neurosurgery. Pediatrics **6**(3): 250-256.

OBJECT: Care for host-nation pediatric casualties and disease or nonbattle injuries is an essential mission of deployed military medical assets. Clinical experience with pediatric patients at field hospitals has been increasingly reported since 2001, with neurotrauma identified as a major cause of morbidity and death in this population. A concentrated pediatric neurosurgical experience at a deployed medical facility has not been reported. The authors reviewed their experience with pediatric neurosurgical patients at a field hospital in Iraq in 2007 to provide insight into the management of this patient population., METHODS: A retrospective review was conducted using a prospective database constructed by the authors for quality improvement during a single combat rotation in 2007., RESULTS: Forty-two patients among 287 consultations were 17 years of age or younger. Twenty-six of these children were 8 years old or younger. Penetrating head injuries were the most common indication for consultation (22 of 42 patients). Twenty-eight of 130 surgical procedures were performed in the children. One patient died in the perioperative period, for a trauma-related operative mortality rate of 4%. Seven patients received palliative care based on the extent of presenting injuries. Twenty-five patients were discharged with minimal or no neurological deficits., CONCLUSIONS: Pediatric patients represent a significant proportion of the neurosurgical patient volume at field medical hospitals in the Iraqi theater. The mature medical theater environment present in 2007 allowed for remarkable diagnostic evaluation and treatment of these patients. Penetrating and closed craniospinal injuries were the most common indication for consultation. Disease and nonbattle injuries were also encountered, with care provided when deemed appropriate. The deployed environment presents unique medical and ethical challenges to neurosurgeons serving in forward medical facilities.

3461. Martin, R., et al. (2014). "Colombia: Social transition and peace process. Has the reduction in violence had any impact on organ procurement and transplantation? New society, new strategies." Transplantation **98**: 274-275.

Introduction: Colombia is known worldwide for its high rates of violence as the result of the narcotics war and the presence of political-rebel groups; guerrillas. The violence increased dramatically during the 1990s and early 2000s, which is when it achieved its greatest influence. Nowadays the situation has changed. The Colombian government has retaken control, acting to decrease the macro and micro narco-traffic and a peace process with the guerrillas is ongoing. Because of this, Colombia is undergoing a social transition and the rate of all types of violence has decreased substantially. Aim: To investigate and report the direct impact of the decreased rates of violence on organ procurement and transplantation in Colombia. Materials and Methods: A 10-year retrospective study of national and international data reports on interpersonal violence, intentional homicide and car accidents including the data of The National Institute of Coroners and Forensic Science of Colombia. Results: The homicide rate in Colombia has decreased from 67.5 per 100,000 inhabitants in 2002 to 33 per 100,000 inhabitants in 2012; 91% of murders occurred in males aged 20 to 35 years in the last decade. The primary homicide trigger was the guerrillas war in 2002 and now seems to be the interpersonal fights in 2012. Although shooting has declined substantially from >24,000 in 2002 to <12,000 in 2012, it remains the most common mechanism of death (75%). On the other hand, the rate of deaths due to car accident has also decreased. Regarding organ procurement, the number of effective brain-death donors has decreased substantially. Also, the main cause of brain death changed from trauma in 2002 to stroke in 2012. Conclusions: It is quite interesting to see how the social transition and the peace process that Colombia is undergoing directly impacts on the health system including the Colombian Network of Organ Procurement and Transplantation (CNOPT). There is a reduction in all types of violence; brain-death donors due to gunshot wounds and traffic accidents are less now than 10 years ago. Thus, the

transplants performed using living and extended-criteria donors are now fundamental. Designing new strategies has been necessary to adjust the CNOPT to a modern society, in order to increase the amount of effective donors. Those strategies may be an archetype to the countries that are living in a social transition like Colombia.

3462. Martin, R. R., et al. (1987). "Machete wounds to the head: report of three cases." Neurosurgery **20**(2): 270-272.

Three cases of machete wounds to the head are described. The resulting injuries from this unusual mode of trauma varied in severity and included transection of a previously placed ventriculoperitoneal shunt. Complications of these injuries resulted from delayed and inadequate treatment.

3463. Martin, S., et al. (2009). "Management of embedded foreign body: penetrating stab wound to the head." Journal of trauma nursing : the official journal of the Society of Trauma Nurses **16**(2): 82-86.

Penetrating craniocerebral trauma is an injury in which a projectile violates the skull but does not exit. The significance of penetrating injuries to the head depends largely on the circumstances of the injury, the velocity of impact, and attributes of the projectile. While most penetrating head injuries are caused by firearms, lower-velocity mechanisms of penetrating brain injury present unique challenges for the multidisciplinary team involved with the delivery of care. Appropriate management can lead to optimal outcomes and limit secondary brain injury.

3464. Martin, S. A., et al. (2016). "The negative impact of anemia on outcome from traumatic brain injury." Journal of neurosurgery **124**(4): A1177.

Introduction: Anemia's impact on outcome from traumatic brain injury (TBI) is controversial. We hypothesized TBI patient outcomes with concomitant anemia would be worse than without anemia, and investigated anemia effects on TBI considering hemoglobin sampling times, threshold values, gender and transfusion. Methods: Patients from 2009-2013 with non-penetrating TBI, head Abbreviated Injury Scale (AIS) <3, and abnormal head CT findings were reviewed. Relationships between initial hemoglobin and lowest hemoglobin during hospitalization threshold values of <7, <8, <9, and <10 g/dl were related to follow-up Glasgow Outcome Score within one-year. A duration effect of anemia was investigated using area-under-the-curve analysis. Results: Of 939 patients (mean age 46.75, 66.1% male gender) meeting inclusion criteria, initial and first hemoglobin were significant predictors of poor outcome ($p<0.0001$). Every 1g/dL higher hemoglobin value had a 33% good outcome increase. More severe anemia levels were associated with lower GCS, higher head AIS, and higher ISS ($p<0.0001$). Anemic patients had more surgery and blood transfusions ($p<0.0001$). Anemia duration did not appear to impact outcomes. Female patients had worse outcomes for initial hemoglobin between 7 and 8 g/dL ($p<0.05$). Blood transfusion was associated with poorer outcome at hemoglobin levels <9 and <10 g/ dl ($p<0.05$), but not at more severe anemia levels. Conclusion: TBI patient outcomes are worse with concomitant anemia. While anemic patients have more severe injuries, initial hemoglobin and lowest hemoglobin are independent factors affecting outcome. Female patients may be more susceptible to more severe anemia levels. These findings indicate packed red cell transfusion is appropriate with hemoglobin <8g/dl.

3465. Martin, T. (2018). "Neck trauma management." Surgery (United Kingdom) **36**(8): 429-434.

Neck trauma is common, and may result from blunt, penetrating or combined mechanisms. Although much of this trauma is minor, the complex and vulnerable anatomy of the neck predisposes to major life threatening complications from even relatively low energy transfer injury patterns. This article reviews mechanisms of injury along with investigation and management principles.

3466. Martin-Delgado, M. C., et al. (2019). "Summary of Spanish recommendations on intensive care to facilitate organ donation." American journal of transplantation : official journal of the American Society of Transplantation and the American Society of Transplant Surgeons **19**(6): 1782-1791.

With the aim of consolidating recommendations about the practice of initiating or continuing intensive care to facilitate organ donation (ICOD), an ad hoc working group was established, comprising 10 intensivists designated by the Spanish Society of Intensive Care and Coronary Units (SEMICYUC) and the Spanish National Transplant Organization (ONT). Consensus was reached in all recommendations through a deliberative process. After a public consultation, the

final recommendations were institutionally adopted by SEMICYUC, ONT, and the Transplant Committee of the National Health-Care System. This article reports on the resulting recommendations on ICOD for patients with a devastating brain injury for whom the decision has been made not to apply any medical or surgical treatment with a curative purpose on the grounds of futility. Emphasis is made on the systematic referral of these patients to donor coordinators, the proper assessment of the likelihood of brain death and medical suitability, and on transparency in communication with the patient's family. The legal and ethical aspects of ICOD are addressed. ICOD is considered a legitimate practice that offers more patients the opportunity of donating their organs upon their death and helps to increase the availability of organs for transplantation.

3467. Martinez, A. Y. (2012). "Gunshot injuries to the head and face. analysis of 144 cases." Journal of oral and maxillofacial surgery **70**(9): e-104.

Statement of the Problem: Gunshot wound injuries (GSW) have devastating effects in the head and maxillofacial region with fatal outcome and creating complex soft and hard tissue defects in the survivors. The purpose of this study was to analyze GSW in the head and face area treated in a level 1 urban trauma center with special emphasis in deceased subjects. Materials and Methods: A retrospective study using the trauma registry database for GSW from 1/1/2005 until 12/31/2011 was performed. Methods of Data Analysis: Subjects were grouped according to different categories: outcome (alive vs. deceased), age, gender, race, anatomic location and year of injury. Results: A total of 144 subjects with GSW were identified. 34 subjects died from their injuries and 110 survived. The most prevalent age group was 21- 40 years with 77 subjects, in contrast the least prevalent group was 61 years and older with 4 (table 1). Males outnumber females in a 6:1 ratio. 89 (62%) individuals were African american, 43 (29.7%) were caucasian, 11 (7.6%) hispanic and 1 (0.7%) asian. The most common location of injury was the head with 53 subjects (37%), followed by multiple sites (combination of head, midface and mandible) 43 (30%), midface 25 (17%) and mandible 23 (16%). Location of fatal GSW was predominantly head 25, multiple sites 6, midface 2 and mandible 1. The distribution of injuries per year is shown below (table 2). (table presented) Conclusions: GSW to the head in our series of cases resulted in fatal outcome in approximately 50 % of the cases. It is imperative to establish survival prognosis of patients with concomitant GSW to the head and face with the neurosurgeon before attempting large and complex facial reconstruction.

3468. Martínez, F. (2008). "To the editor [1]." Journal of the Chinese Medical Association **71**(2): 110.

3469. Martinez Ibanez, V., et al. (1981). "[Thoracic and abdominal trauma in children: study of 122 cases (author's transl)]." Traumatismos toracicos y abdominales en la infancia. Estudio de 122 casos. **15**(6): 527-534.

Authors present a review of patients under 7 years of age affected with thoracic and/or abdominal trauma not due to birth injuries, observed in the period 1966-1979. In these 122 patients, they observed 154 injuries, including 63 abdominal, 58 renal, 28 thoracic and 5 vertebral. Automobile accidents, falls and penetrating injuries, in this order are the etiological factors. Six patients died due to brain injuries (66%) and the rest of septic and hemorrhagic shock. Authors observed a high incidence of multiple injuries involving thehead, skeleton, abdomen and chest and the importance of recognizing these coexisting injuries to improve the prognosis. Finally, they point out that the pediatric surgeon's function is not only to treat the patient but to prevent the injuries through interdisciplinary meetings.

3470. Martinez-Bustamante, D., et al. (2015). "[Craniocerebral gunshot wounds in civilian population: Analysis of experience in a single center in Monterrey, Mexico]." Heridas craneales por proyectil de arma de fuego en poblacion civil: analisis de la experiencia de un centro en Monterrey, Mexico. **83**(2): 94-99.

BACKGROUND: Gunshot wounds in civilian population of Mexico were quite rare. Currently, conflicts amongst organized crime groups are carried out with weapons, which are considered as exclusive use by the nations army., OBJECTIVES: Describe the experience of our institution and share results of clinical and radiological factors influencing the prognosis of the patients., MATERIAL AND METHODS: Observational and retrospective study of patients with cranial gunshot wounds (GSW), which penetrated the duramater, treated from January 2009 - January 2013. We considered several demographic variables, Glasgow Coma Scale (GCS), upon admission, state of pupils, type of surgery and size of

decompression, Glasgow Outcome Score (GOS) upon discharge, and after 6 months., RESULTS: Of 68 patients, we excluded those whose duramater was not penetrated, leaving 52 patients. The average age was 28.7 years, and 80.8% were males. All were surgically intervened, with 8% of general mortality. Mortality in the GCS 3 to 5 points group was 43%, from the 6 to 8 points it was 6%, and no deaths in the 9 to 15 points. In patients with both pupils fixed, anisocoric and isocoric, mortality was 67%, 7%, and 3%, respectively. Bihemispheric, multilobar and unihemispheric trajectory of the bullet plus ventricular compromise was related to a Glasgow Outcome Score <= 3 upon discharge in 90.9% of the cases., CONCLUSIONS: GCS upon admission and state of the pupils are the most influential factors in the prognosis. Patients with a GCS > 8 < 13 points upon admission, normal pupillary response, without ventricular compromise can benefit with early and aggressive surgical treatment.

3471. Martinez-Lage, J. F., et al. (2011). "Depressed skull fracture by a three-pin head holder: a case illustration." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **27**(1): 163-165.

UNLABELLED: BACKGROUND AND CASE REPORT: Many surgical procedures require a rigid immobilization of the patients' head, which is usually achieved by using a pin-type head holder. We briefly illustrate the case of a 4-year-old girl who sustained a depressed skull fracture by penetration of a pin of the head holder. The fracture was noted at the end of the surgery performed for treatment of a cerebellar astrocytoma and was managed conservatively., DISCUSSION: Several factors seem to be involved in the production of this complication as are faulty application of the pins, excessive pin pressure, skull thinning, young patient's age, and pathological conditions that evolve with long-standing raised intracranial pressure. Prevention and management measures are briefly discussed.

3472. Martinez-Lage, J. F., et al. (2001). "Air-gun pellet injuries to the head and neck in children." Pediatric surgery international **17**(8): 657-660.

Air-gun pellet injuries to the head and neck are seldom reported in pediatric practice, although they typically occur in children. The adult skeleton stops these projectiles, but they can easily transverse the thin bones of children. If unnoticed, these apparently trivial injuries may have catastrophic consequences. We report three children who sustained a central nervous system injury resulting from a shot by a compressed-air gun. The true nature and extent of the lesion in two infants was established only by neuroradiological investigations. We also briefly review the management and prevention of this type of injury.

3473. Martinez-Lopez de Arroyabe, B., et al. (2015). "Ventricular assist devices: from bridge to transplantation to bridge to organ donation." Journal of cardiothoracic and vascular anesthesia **29**(3): 738-740.

3474. Martinez-Soba, F., et al. (2019). "Intensive Care to Facilitate Organ Donation: A Report on the Experience of 2 Spanish Centers With a Common Protocol." Transplantation **103**(3): 558-564.

BACKGROUND: The aim of this study is to report the experience with a program of Intensive Care to facilitate Organ Donation (ICOD) in 2 Spanish centers based on a common protocol., METHODS: Retrospective review of clinical charts of patients with a devastating brain injury whose families were approached to discuss the possibility of ICOD once further treatment was deemed futile by the treating team. Study period is from January 1, 2011, to December 31, 2015., RESULTS: ICOD was discussed with families of 131 patients. Mean age of possible donors was 75 years (SD = 11 years). The main cause of brain injury was an intracranial hemorrhage (72%). Interviews with families were held after the decision had been made not to intubate/ventilate in 50% of cases, and after the decision not to continue with invasive ventilation in the remaining cases. Most interviews (66%) took place in the emergency department. The majority of families (95%) consented to ICOD. Of the 125 consented cases, 101 (81%) developed brain death (BD), most in 72 hours or less. Ninety-nine (98%) patients transitioned to actual donation after BD, with 1.2 organs transplanted per donor. Of patients who did not evolve to BD, 4 died after an unexpected cardiac arrest and 18 after the withdrawal of life-sustaining measures. ICOD contributed to 33% of actual donors registered at both centers., CONCLUSIONS: ICOD is well accepted by families. Most patients evolve to BD within a short period of time. The practice substantially contributes to increasing organ donation and offers more patients the chance of donating their organs after death.

3475. Martins, C. B. d. G. and S. M. d. Andrade (2008). "[Accidents with foreign bodies in children under 15 years of age: epidemiological analysis of first aid services, hospitalizations, and deaths]." Acidentes com corpo estranho em menores de 15 anos: analise epidemiologica dos atendimentos em pronto-socorro, internacoes e obitos. **24**(9): 1983-1990.

This study aims to analyze accidents involving foreign bodies among children less than 15 years of age residing in Londrina, Parana State, Brazil, in terms of first aid, hospitalization, and death (2001). Data were obtained from general hospital records and the Municipal Mortality Database. A total of 434 accidents were analyzed, with a 3.7% hospitalization rate and 0.7% mortality. Boys predominated (53.7%), and the incidence rate was highest among children one to three years of age (7.2 per 1,000 children). Foreign body penetration in natural orifices (eyes, nostrils, and ears) accounted for 94%, inhalation/ingestion of food 2.8%, inhalation/ingestion of objects 2.5%, and aspiration of gastric contents 0.7%, and these causes accounted for all the deaths. The results contribute to epidemiological knowledge on such accidents and indicate the need to restructure health services in order to decentralize care for less complex injuries, besides emphasizing the need for preventive measures.

3476. Martins, I. P., et al. (1995). "Atypical dominance for language in developmental dysphasia." Developmental medicine and child neurology **37**(1): 85-90.

The authors report an association between developmental language disorder and acquired aphasia in a 13-year-old right-handed boy. Acquired aphasia was caused by a right-frontal abscess (crossed aphasia). It was non-fluent, with a disorder of auditory comprehension, an unusual feature of prerolandic lesions. This case shows that developmental language impairment can be associated not only with an atypical cerebral dominance, but also with unusual patterns of intrahemispheric specialization. The rapid and complete recovery of this boy's aphasia suggests that the cerebral plasticity for acquired lesions can be normal in such cases.

3477. Martins, R. S., et al. (2003). "Prognostic factors and treatment of penetrating gunshot wounds to the head." Surgical neurology **60**(2): 98-104.

BACKGROUND: In an attempt to evaluate the predictive factors of morbidity and mortality in patients who suffered from civilian gunshot wounds to the head, we reviewed a series of 319 patients admitted to the Hospital Santa Marcelina, Sao Paulo, Brazil, between 1994 and 2000., METHODS: Clinical and cranial computed tomography (CT) results are described. The initial Glasgow Coma Scale (GCS), the presence of an unilateral dilated pupil or medium fixed pupils, and five different findings in the CT scan were considered as variables. The Qui-Square Fisher test was utilized to verify the correlation between the presence of the variables and the occurrence of an increased mortality rate and of an unfavorable outcome (Glasgow Outcome Scale = 2 and 3)., RESULTS: In 265 cases the missile penetrated the dura (83%). In our study there was a significant correlation between the low GCS scores on admission and a higher mortality ($p < 0.001$). This kind of correlation was also noted with patients admitted with unilateral dilated pupil and medium fixed pupil. There were 187 patients (70.5%) evaluated by CT scan. There was a significant correlation between the presence of transventricular or bihemispheric central type trajectory and high mortality. The patients admitted with unilobar supratentorial wounds resulted in better outcome when compared to those with bilobar or multilobar wounds ($p < 0.001$). A group of 156 patients was submitted to an aggressive surgical protocol. The best results were seen in patients admitted with initial GCS score higher than 8., CONCLUSIONS: We conclude that low GCS scores at admission, unilateral dilated pupil or medium fixed pupil, transventricular or bihemispheric central type trajectory, and bilobar or multilobar wounds noted through CT scan are predictive factors of high morbidity and mortality in patients with gunshot wounds to the head, in our clinical experience. We also conclude that surgical treatment is not recommended for patients with penetrating wounds and GCS score of 3 to 5 in the absence of hematoma causing a mass effect.

3478. Martins, W. D. (1988). "[Technical note. Localization of foreign bodies using angular variation in cranial radiography]." Nota tecnica. Localizacao de corpo estranho utilizando variacao de angulacao em radiografias de cranio. **4**(1-2): 25-26.

3479. Martin-Saborido, C., et al. "Indomethacin for intracranial hypertension secondary to severe traumatic brain injury in adults." (11).

Background, Among people who have suffered a traumatic brain injury, increased intracranial pressure continues to be a major cause of early death; it is estimated that about 11 people per 100 with traumatic brain injury die., Indomethacin (also known as indometacin) is a powerful cerebral vasoconstrictor that can reduce intracranial pressure and, ultimately, restore cerebral perfusion and oxygenation. Thus, indomethacin may improve the recovery of a person with traumatic brain injury., Objectives, To assess the effects of indomethacin for adults with severe traumatic brain injury., Search methods, We ran the searches from inception to 23 August 2019. We searched the Cochrane Central Register of Controlled Trials (CENTRAL; 2019, Issue 8) in the Cochrane Library, Ovid MEDLINE, Ovid Embase, CINAHL Plus (EBSCO), four other databases, and clinical trials registries. We also screened reference lists and conference abstracts, and contacted experts in the field., Selection criteria, Our search criteria included randomised controlled trials (RCTs) that compared indomethacin with any control in adults presenting with severe traumatic brain injury associated with elevated intracranial pressure, with no previous decompressive surgery., Data collection and analysis, Two review authors independently decided on the selection of the studies. We followed standard Cochrane methods., Main results, We identified no eligible studies for this review, either completed or ongoing., Authors' conclusions, We found no studies, either completed or ongoing, that assessed the effects of indomethacin in controlling intracranial hypertension secondary to severe traumatic brain injury. Thus, we cannot draw any conclusions about the effects of indomethacin on intracranial pressure, mortality rates, quality of life, disability or adverse effects., This absence of evidence should not be interpreted as evidence of no effect for indomethacin in controlling intracranial hypertension secondary to severe traumatic brain injury. It means that we have not identified eligible research for this review.

3480. Martucciello, G. and R. Tripodi (2012). "A stray bullet in the brain." Lancet (London, England) **379**(9812): e19.

3481. Maruca-Sullivan, P. E., et al. (2016). "Missing the point: self-inflicted traumatic brain injury in psychosis." BMJ case reports **2016**.

A 36-year-old man was brought to the emergency department by emergency medical services after being found acting unusually at a gas station with blood on his head and clothing. He presented acutely psychotic and reported that he had a pen in his head. Medical evaluation was notable for a superficial puncture wound to the right temple, and he was medically cleared for psychiatric evaluation. After he developed nausea and headache later that evening, the CT scan revealed a temporal bone fracture, pneumocephalus, intraparenchymal haemorrhage and the presence of a metal pen tip lodged in the brain parenchyma. The full nature of the injury went undiscovered in the emergency department for 16 hours due to the superficial appearance of the injury and his acute psychosis with prominent delusional thought content and disorganisation. He underwent craniotomy with removal of the pen and subsequent hospitalisation for intravenous antibiotics, followed by a prolonged psychiatric hospitalisation for psychosis. Copyright 2016 BMJ Publishing Group Ltd.

3482. Marut, D., et al. (2020). "Evaluation of prophylactic antibiotics in penetrating brain injuries at an academic level 1 trauma center." Clinical neurology and neurosurgery **193**: 105777.

OBJECTIVE: Infections from penetrating brain injuries (PBI) lead to higher morbidity and mortality rates. The results of this research will be evaluated to develop institutional guideline for antibiotic prophylaxis in this patient population. The objective was to characterize the prophylactic antibiotic usage for patients presenting with PBI., PATIENTS AND METHODS: This retrospective chart review included patients with a PBI identified through the institution's trauma center registry between December 2015 and July 2018. The primary outcome was the proportion of patients that received prophylactic antibiotics. Secondary outcomes included antibiotic administration timing, selection and duration of antibiotic regimens, infection rates and patient outcomes., RESULTS: The study population included 33 patients, with 82 % males and an average age of 32 years. The most common mechanism of injury was a gunshot wound (94 %). Of the 33 patients, 24 (73 %) received at least one dose of prophylactic antibiotics. The median time to antibiotic administration was 52.8min (IQR, 18-120), while the median duration of prophylaxis was 24h (IQR, 7-84). The most common antibiotic regimen was a single cefazolin dose, with the next most common regimen included scheduled ceftriaxone and metronidazole. Overall, there were no documented central nervous system or skin and soft tissue infections during the initial admission, while 4 patients (12 %) were treated for pneumonia. Survivors (67 %) had a median hospital length of stay of 5.8 days., CONCLUSION: The median duration of prophylaxis was shorter than the

current data suggesting antibiotics for 5 days; however, there were no documented central nervous system infections, which is less than previously reported in the literature.

3483. Maruya, J., et al. (2002). "Brain abscess following transorbital penetrating injury due to bamboo fragments--case report." Neurologia medico-chirurgica **42**(3): 143-146.

A 56-year-old female presented with transorbital penetrating injury caused by bamboo fragments, which resulted in brain abscess 2 weeks after the injury. Initial computed tomography (CT) of the head did not reveal the foreign bodies. However, follow-up CT demonstrated a well-defined hyperdense abnormality of 1.0 cm length in the left orbit and brain abscess in the left temporal lobe. The lesion corresponding to the hyperdense abnormality on CT appeared isointense on T1-weighted magnetic resonance (MR) imaging and hypointense on T2-weighted MR imaging. The bamboo fragments were surgically removed, and aspiration and continuous drainage were performed for the brain abscess. The postoperative course was uneventful and the patient was transferred to a local hospital with minor neurological deficits. Bamboo foreign bodies may show changes in properties on CT and MR imaging in the subacute stage. Careful radiological examination and follow-up monitoring are required for the correct diagnosis and treatment of such injuries.

3484. Marvin, E. A., et al. (2020). "Response of Pembrolizumab Alone for Non-small Cell Lung Cancer With Brain Metastasis: A Case Report and Literature Review." Frontiers in Oncology **10**.

Treatment of brain metastases often includes surgical resection, chemotherapeutics and radiotherapy. Given the difficulty in obtaining therapeutic levels of medications within the immune-privileged central nervous system, chemotherapy as a stand-alone treatment modality for brain metastases is an uncommon option. However, there is a growing body of evidence to suggest that immunomodulatory agents can induce a robust immune response in the central nervous system. Here, we describe a 68-year old male who presented with radiographic evidence of new and enlarging lung nodules with mediastinal adenopathy. Lung biopsy was consistent with adenocarcinoma. Immunohistochemical staining demonstrated high expression of programmed cell death protein 1 with a tumor proportion score of 100%. Surveillance magnetic resonance imaging of the brain demonstrated a single enhancing 11 × 7 × 12 mm lesion along the mesial surface of the right frontal lobe. The patient deferred surgical resection as well as stereotactic radiosurgery but agreed to treatment with pembrolizumab. Repeat magnetic resonance imaging at 3-months after initiation of treatment demonstrated complete radiographic resolution of the brain lesion. To our knowledge, this is one of only a few reports in the current literature to document complete resolution of non-small cell lung cancer brain metastasis with pembrolizumab alone. We discuss the emerging literature regarding the efficacy of pembrolizumab in the treatment of brain metastases, central nervous system penetration, and emerging new treatment paradigms involving novel immunotherapy agents.

3485. Marx, R. E. and J. R. Ames (1982). "The use of hyperbaric oxygen therapy in bony reconstruction of the irradiated and tissue-deficient patient." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **40**(7): 412-420.

Eighteen bony reconstructions of the mandible or maxilla using a newly defined and specific hyperbaric oxygen protocol are reported. Eleven of 12 grafts in irradiated tissue met six rigid criteria for a 91.6% rate of success. All six grafts into scarred and deficient tissue beds also met the same criteria, for an overall success rate of 94%. The rationale for emphasizing preoperative tissue preparation using hyperbaric oxygen is discussed, as are the mechanisms of action of hyperbaric oxygen on a biochemical, cellular, and tissue level. Neovascularity and neocellularity are demonstrated histologically by human biopsy specimens, and this is suggested as being the reason for the excellent results of reconstruction in irradiated and/or deficient tissue beds.

3486. Masella, P. C., et al. (2014). "Posttraumatic lingual artery pseudoaneurysm treated with ultrasound-guided percutaneous thrombin injection." Annals of vascular surgery **28**(5): 1317.e1311-1315.

Pseudoaneurysms of the lingual artery are extremely rare and are commonly iatrogenic in nature or less frequently a result of blunt or penetrating trauma. Traditionally, these vascular abnormalities have been repaired with open or endovascular techniques. Although ultrasound-guided percutaneous thrombin injection has become a standard

treatment for superficial pseudoaneurysms, there are no reports of this being used in the treatment of lingual artery pseudoaneurysms. We report the case of a 26-year-old man who suffered a penetrating head and neck injury after an improvised explosive device blast in Iraq who presented with persistent oropharyngeal swelling. Color-flow Doppler ultrasonography revealed the classic yin/yang sign of a pseudoaneurysm, and a computed tomography scan was obtained that revealed a right lingual artery pseudoaneurysm. With the lack of endovascular capabilities and the excessive risk of open surgery, thrombin was injected directly into the pseudoaneurysm under ultrasound guidance. A computed tomography scan and Doppler ultrasonography revealed complete resolution of the aneurysm. This article presents the first reported case in the English literature of a lingual artery aneurysm after penetrating trauma managed successfully with ultrasound-guided percutaneous thrombin injection. 3487. Mashiyama, S., et al. (2006). "[Stab injury of the brain by kitchen knife]." No shinkei geka. Neurological surgery **34**(5): 497-502.

A 32-year-old male attempted suicide by stabbing his forehead with a kitchen knife, and was sent to our hospital. On admission, he was confused (20-30/JCS), but was able to move his both extremities. Skull X-p, CT scan indicated that the kitchen knife penetrated the frontal bone, reached the cerebrum by way of the frontal sinus. Cerebral angiography was performed, and showed no vascular lesions. Emergent craniotomy was performed and the kitchen knife was removed with minimum movement. Traumatic intracerebral hematoma was removed, and injured frontal sinus, dura mater and frontal bone were repaired. Postoperative course was excellent and he was discharged with the wounds well healded, no neurological deficits on the 17th day after the operation. There are several reported cases of such stab injury. Stab injury of the brain was discussed in the literature.

3488. Masimov, M. O. (2005). "Realization of surgery saving principle in grave gunshot wounds of limbs (war experience in Karabakh region of Azerbaijan Republic)." Azerbaijan Medical Journal(1): 164-170.

Aim of investigation. The goal of the present study concludes in improvement of morphological and functional issues of grave gunshot wounds of the limbs through realization of surgery saving principle (SV) in regard to affected tissues and on the basis of orthopedic and surgical rehabilitation of wounded men. Material & methods. The authors own data of treatment and study of 523 patients with grave fighting pathology of lower (80.3%) and upper limbs: complicated with deep wounds of soft tissues (5.2%), contact explosive cuttings and bashings (23.1%), fractures (71.7%), make basis of the present study. Fractures of "A" type-constitute 13.3%, of "B" type - 40.8%, of "C" type - 45.9%. Different neuro-vascular damages in bone fractures are noticed in 32.6% of cases, being mostly observed in fractures of "B" and "C" type. On the stage of specialized medical care 21.4% of patients were delivered with serious wound inflammation, 32.3% - with "typical" suppuration, while 46.3% - with primary and secondary complications. Results. The elaborated system of surgical rehabilitation, anticipating maximal shortening of stages of medical evacuation, is based on application of improved differentiated surgical tactics, methods of surgical wound treatment, general and local pathogenesis therapy, technology of early reconstructive and recovery (R&R) operations. The system optimizes wound process and allows prevention and cessation of suppurative and necrotic complications and, for this account, to realize in practice the offered concept concerning possibility formation of vital vascular and non-vascular bone, soft tissue, bone-soft tissue autographs from adapted to ischemia present tissue resources that are necessary for S&V therapy of damaged limb. Total lethal issues constituted 4.4%, the reasons of death were mostly grave injuries of brain and internal organs. In contact explosive wounds with limb cutting, the complications were eliminated in all patients; besides, in 78% cases the affected segments and adjoining joints were succeeded to save. In bone fractures amputations were realized in 13.5% cases, being conducted to vitality indications in relation to extremely grave pathology. In the rest wounded men, in spite of presenting relative indications to amputations, in 96.8% cases positive morphological and functional issues are achieved. The results show to an opportunity of realization of surgery SV in grave gunshot trauma of limbs with application of improved orthopedic and surgical rehabilitation of affected men.

3489. Maslinska, D., et al. (2002). "Proinflammatory cytokines in injured rat brain following perinatal asphyxia." Folia neuropathologica **40**(4): 177-182.

In contrast to astrogliosis, which is common to injuries of the adult CNS, in the developing brain this process is minimal. Reasons postulated for this include the relative immaturity of the immune system and the consequent insufficient production of cytokines to evoke astrogliosis. To explore this hypothesis, the study was undertaken to detect

the presence of some proinflammatory cytokines in the injured rat brain following perinatal asphyxia (ischaemia/hypoxia). The localisation of TNF-alpha, IL-15, IL-17 and IL-17 receptors was visualised by means of immunohistochemistry. In numerous neurones of the rat brain, the IL-17 appeared to be constitutively expressed. In the early period of inflammation the IL-15 was produced mainly by the blood cells penetrating the injured brain but later it was synthesised also by reactive astrocytes surrounding brain cysts and forming dense astrogliosis around necrotic brain regions. The direct effect on astrogliosis of other estimated cytokines seems to be negligible. All the results lead to the conclusion that from all cytokines identified in the injured immature rat brain the IL-15 plays the most important role during inflammatory response and participates in the gliosis of reactive astrocytes.

3490. Mason, A. C., et al. (2000). "Occult craniocerebral injuries from dog bites in young children." Annals of plastic surgery **45**(5): 531-534.

Although dog bite injuries to the head and scalp of children occur frequently, penetrating dog bite wounds to the cranial vault occur only occasionally and may go unnoticed on initial examination. Substantial morbidity and mortality can ensue if these penetrating injuries are not detected and treated. The authors detail the evaluation of dog bites of the scalp in young children. They highlight the ease with which puncture wounds of the calvarium may be missed during physical examination as a result of scalp displacement at the time of puncture. The cranial puncture may not be large and may later be covered by scalp that returns to its native position. Well-scrutinized skull films and a careful, methodical physical examination are advocated. Recognized craniocerebral injuries should be explored. Depressed cranial fractures should be irrigated, debrided, and elevated. Dural tears should be repaired. Expedient management is necessary to prevent meningitis and its associated sequelae.

3492. Massad, M. and M. S. Slim (1990). "Intravascular missile embolization in childhood: report of a case, literature review, and recommendations for management." Journal of pediatric surgery **25**(12): 1292-1294.

A collective review of 20 cases of missile embolization among children (1961 to 1988) is analyzed, one case added, and guidelines for diagnosis and management are outlined. Causative agents were bullets (14 patients), pellets (5), and fragments (2). Their trajectory was arterioarterial (11), venovenous (5), paradoxical (4), and mixed (1). Diagnosis was suspected when an exit wound was absent and the foreign body was traced on regional x-ray. Embolization was predominantly to the legs, with a tendency for the left (5 of 8 cases). Upper extremity emboli were exclusively to the right. Only one of five cardiac entries required closure to control bleeding compared with four of six aortic. Embolectomy was performed in 16 patients. The overall mortality rate was 9.5%. Factors predicting a favorable outcome are early presentation, diagnosis, and intervention; location of cardiovascular entry and embolus site; and presence of soft tissue tamponade at entry wound. Although embolectomy for cerebral, asymptomatic pulmonary arterial, and silent venous emboli is controversial, universal agreement prevails regarding removal of systemic arterial as well as venous emboli that are potentially problematic.

3493. Massarelli, O., et al. (2014). "Chimeric lateral supramalleolar artery perforator fibula free flap in the reconstruction of composite head and neck defects." Plastic and reconstructive surgery **133**(1): 130-136.

The authors evaluate the use of an osteomyocutaneous fibula free flap, combined in a chimeric fashion, with a lateral supramalleolar flap, in 10 patients with composite head and neck defects. All reconstructions were performed successfully. With the exception of one patient who died after disease recurrence, all patients were decannulated and resumed an oral diet. Speech intelligibility was good in seven of 10 patients. Dental implants were used in two of 10 patients, with a total of 10 fixtures placed successfully. The donor site healed without complications in all except one case, where necrosis of the skin graft occurred with fungal infection. The chimeric lateral supramalleolar artery perforator fibula free flap may be a valid option for maximizing the quality of life in patients with composite oromandibular defects.

3494. Mataro, M., et al. (2001). "Long-term effects of bilateral frontal brain lesion: 60 years after injury with an iron bar." Archives of neurology **58**(7): 1139-1142.

BACKGROUND: Harlow's report of the case of Phineas P. Gage in 1848 was one of the earliest description of the personality and behavioral changes following frontal lobe damage. Since Harlow's articles, a few more case reports of frontal lobe damage have been published. As standard neuropsychological and neurologic evaluations may reveal subtle defects, case reports have been particularly useful in characterizing the behavioral changes that follow frontal lobe damage., OBJECTIVE: To describe the long-term outcome of an 81-year-old patient who sustained a severe frontal brain lesion 60 years ago caused by the passage of an iron spike through his head., RESULTS: The patient has bilateral damage affecting the orbital and dorsolateral frontal regions. He displays many of the typical frontal behavioral disturbances described in the literature. His conduct is characterized by dependence on others, cheerfulness, planning difficulties, problems establishing realistic goals, lack of drive, and difficulties in initiating, continuing, and finishing activities. Although gross cognitive functioning is intact, neuropsychological deficits are present in the executive functioning, memory, and visuoconstructive domains., CONCLUSIONS: In contrast with the antisocial conduct pattern usually associated with frontal damage in the literature, this case suggests that large frontal lesions can produce behavioral and personality changes that are compatible with stable functioning in family, professional, and social settings. In addition to the localization of the lesion, many other factors should be considered in the long-term prognosis of frontal brain injured patients.

3495. Mathe, D., et al. (2015). "A novel SPECT-based approach reveals early effects of systemic inflammation on brain injury and peripheral organs after cerebral ischemia." European Journal of Nuclear Medicine and Molecular Imaging **42**(1): S289.

Introduction. Inflammation that develops in the brain and peripheral organs after stroke contributes profoundly to the outcome of patients. Clinical decision making would highly benefit from rapid assessment of central and peripheral inflammatory changes after acute brain injury, but appropriate medical imaging tools are not available yet. Here we show that singlephoton emission computed tomography combined with MRI (NanoSPECT/CT Plus, nanoScan MRI/SPECT) allows early visualization of blood brain barrier injury and inflammation in the brain after experimental stroke, well before signs of brain injury can be detected with magnetic resonance imaging (MRI).Materials and Methods. Whole-body 99mTc-DTPA SPECT/CT; 99mTc-HMPAO SPECT and MRI imaging was performed in groups of 5 mice with middle cerebral artery occlusion (MCAO) for 30 or 60 minutes. In one group LPS induced systemic inflammation was present before the MCAO to model pre-existing inflammatory diseases. Imaging was done 1, 3, 6 and 24, 72 hours post MCAO and was validated by IgG, CD45 and Iba1 immunofluorescent microscopy and H&E staining in respective brains and peripheral organs. Results. Penetration of 99mTc-DTPA into the brain parenchyma overlaps with areas of brain injury and perfusion deficits after cerebral ischemia. Systemic inflammation preceding experimental stroke leads to very early perfusion deficits and increased blood brain barrier injury (within 2 h) after the onset of ischemia. Acute brain injury also leads to infectious complications in peripheral organs such as the lung. We detected that SPECT imaging reveals early (within 1-3 h) changes in perfusion, barrier function and inflammation in the lungs and the gut of all mice after experimental stroke, with good predictive value for outcome. Discussion. Our results suggest that early inflammatory changes as detected by SPECT/MRI, SPECT/CT whole-body imaging precede injury in the brain and peripheral organs. Thus these hybrid nuclear medicine imaging methods are proposed to support decision making in the clinic.

3496. Mathew, M., et al. (2017). "Midline depressed skull fracture presenting with quadriplegia: A rare phenomenon." Surgical neurology international **8**(1).

Background: Midline depressed skull fractures (MDSFs) deserve a special mention among skull fractures and should always be treated with caution. Here, an extremely unusual clinical presentation of a case of MDSF is highlighted along with its successful surgical management. Case Description: A 26-year-old male presented with quadriplegia following assault on the head with sharp weapons. The patient had multiple lacerated wounds on the scalp with underlying cranial fractures. On evaluation, computerized tomography (CT) of the brain showed a midline depressed skull fracture compressing the superior sagittal sinus (SSS) causing bilateral frontoparietal venous infarction. CT venogram showed a filling defect of the SSS due to the penetrating bone fragment. He underwent elevation of the depressed fracture and repair of the sinus with pericranial graft. Patient improved neurologically, and follow-up magnetic resonance venogram showed a patent SS. Conclusion: MDSF can present with quadriparesis/quadriplegia due

to middle one-third SSS obstruction/thrombosis leading to bilateral motor cortical venous infarction. Such MDSFs may require emergent surgical elevation of the depressed bone fragment for restoration of the patency of the sinus.

3497. Mathew, P., et al. (2013). "Operative treatment of paediatric penetrating head injuries in southern Afghanistan." British journal of neurosurgery **27**(4): 489-496.

The operative management and early post-operative outcome of 16 consecutive cases of paediatric penetrating head injury treated by a single surgeon at a military trauma centre in Southern Afghanistan are retrospectively analysed. The majority of cases of injury were caused by fragments from exploding munitions. The aim of neurosurgical intervention in penetrating head injury is the prevention of wound infection and treatment or prevention of a critical rise in intracranial pressure. In 14 cases in this study, these aims were fulfilled without resort to brain resection, although a delayed cranioplasty procedure was required in 6 patients. Despite the ongoing conflict, families, local communities and coalition forces transport teams combine to make the latter a viable option in Southern Afghanistan, with an excellent short-term outcome.

3498. Mathew, P., et al. (2016). "Safe management of paediatric penetrating head injury without a CT scanner: A strategy for humanitarian surgeons based on experience in southern Afghanistan." Annals of the Royal College of Surgeons of England **98**(3): 198-205.

INTRODUCTION: In many parts of the world, access to a CT scanner remains almost non-existent, and patients with a head injury are managed expectantly, often with poor results. Recent military medical experience in southern Afghanistan using a well-equipped surgical facility with a CT scanner has provided new insights into safe surgical practice in resource-poor environments., METHODS: All cases of children aged under 16 years with penetrating head injury who were treated in a trauma unit in southern Afghanistan by a single neurosurgeon between 2008 and 2010 were reviewed. Based on a previously published retrospective review, a clinical strategy aimed specifically at generalist surgeons is proposed for selecting children who can benefit from surgical intervention in environments with no access to CT scanners., RESULTS: Fourteen patients were reviewed, of whom three had a tangential wound, 10 had a penetrating wound with retained fragments and one had a perforating injury. Two operations for generalist surgeons are described in detail: limited wound excision; and simple decompression of the intra-cranial compartment without brain resection or dural repair., CONCLUSIONS: In resource-poor environments, clinically-based criteria may be used as a safe and appropriate strategy for selecting children who may benefit from relatively straightforward surgery after penetrating brain injury.

3500. Mathewson, A. J. and M. Berry (1985). "Observations on the astrocyte response to a cerebral stab wound in adult rats." Brain research **327**(1-2): 61-69.

The temporal and spatial distribution of immunocytochemically identified reactive astrocytes is described following a cerebral stab wound in adult rats. Different patterns of reactivity were observed in the cerebral cortex, the corpus callosum and the deep structures of the hemisphere. In the cerebral cortex, the zone of astrocytic reactivity was initially limited to the vicinity of the wound but spread with time to encompass the entire ipsilateral cortex, then regressed; in the deep structures only a spreading phase was observed and this was slower than in the cortex; reactivity in the corpus callosum was slight and always restricted to the immediate vicinity of the lesion. Reactive astrocytes were never observed in the hemisphere contralateral to the lesion. The reorganization of reactive astrocytes in the immediate vicinity of the lesion into a membrana gliae limitans accessoria was also observed. On the basis of these observations, the hypothesis is proposed that astrocytes respond primarily to the mechanical disruption consequent to injury and that the response promotes the restoration of the structural integrity of the lesioned tissue.

3501. Mathisen, G. E. (2006). "Brain abscess: Avoiding diagnostic and management pitfalls." Infections in Medicine **23**(2): 72-81.

Brain abscess does not always present with the classic triad of headache, fever, and neurologic findings. The location of an abscess may provide clues to the underlying source and microbiology. Dental disease may be the source of a "cryptic" brain abscess. For a patient with a brain abscess, obtain a brain MRI scan and review it with a neuroradiologist whenever possible; obtain a neurosurgical consultation as soon as possible when a pyogenic abscess is suspected. For any abscess, start antibiotic therapy immediately if the patient appears septic or shows signs of progressive neurologic deterioration. Use a third-generation cephalosporin plus metronidazole for initial antibiotic coverage of a suspected pyogenic abscess. Patients should be warned about the long-term risk of seizures following a brain abscess.

3502. Mathog, R. H., et al. (1989). "Surgical correction of enophthalmos and diplopia. A report of 38 cases." Archives of otolaryngology--head & neck surgery **115**(2): 169-178.

Enophthalmos, hypophthalmos, and diplopia are complications of orbital injury. This article reviews the causes of these sequelae, describes a method of strategic implantation of bone grafts to the orbit (and malar bone), and reports the long-term (six months to eight years) results in 38 cases. As a result of bone grafting, all but two patients had a correction of the enophthalmos to within 1 to 2 mm of the opposite eye. Of the 20 patients with diplopia, 15 had correction, and an additional four had an improvement of diplopia so it occurred in only one field of gaze. Of the 22 patients with grafts to the malar bone, 16 were thought to have good to excellent results; however, six developed some degree of reabsorption at the graft site. No patients had any decrease in vision. The advantages and disadvantages of the surgical procedure are described and compared with other methods.

3503. Matschke, J., et al. (2002). "[Continued physical capacity after head gunshot injury]." Erhaltene Handlungsfahigkeit nach Kopfschuss. **209**(3-4): 88-94.

The human brain shows a very high density of functionally important structures. Even small lesions may therefore cause clinical symptoms. Penetrating gunshots to the head are presumed to cause immediate incapacitation by subsequent disturbance of cerebral functions. The authors discuss anatomical and functional principles of the terms action, capacity to act and incapacitation and report two illustrative cases with lack of incapacitation following gunshots to the head.

3504. Matsubara, M., et al. (2022). "Day 14 intervention for penetrating brain injury with a good Glasgow Coma Scale score: A case report." Clinical Case Reports **10**(1).

Penetrating brain injury is a rare pathology generally requiring emergency surgical intervention. We discuss a case of penetrating brain injury by the umbrella in which surgical intervention was performed 14 days after the injury, and obtained good clinical results.

3505. Matsuda, S., et al. (2017). "Post-Traumatic Trigeminal Neuropathy Caused by an Orbital Stab Wound." The Journal of craniofacial surgery **28**(1): e28-e30.

Sensory and motor neuropathy of the trigeminal nerve due to trauma is quite rare. Furthermore, there have been no detailed reports on occlusal abnormalities and trismus associated with post-traumatic trigeminal motor neuropathy. Here, the authors report a case of trigeminal motor neuropathy and trigeminal sensory neuropathy in all 3 divisions caused by an orbital stab wound. During kendo practice, a 61-year-old man was injured in his right medial canthus with the splinter of a broken bamboo sword. Imaging examinations did not show a brain injury or orbital bone fracture. Intraoral and extraoral examination and needle electromyography revealed trismus, posterior open bite, and denervation of the right masseter. After the injury, the patient strived to use the right molars during mastication and began chewing exercises in the right molar region. A follow-up examination 7 months after the injury revealed an improvement of the functional problems in the masticatory system. Although slight facial numbness in the right ophthalmic division remained, the patient was satisfied with the present status. Further knowledge concerning the natural history of trigeminal neuropathy as well as the treatment of choice should be explored in the future.

3506. Matsumoto, S., et al. (1998). "Intracranial penetrating injuries via the optic canal." AJNR. American journal of neuroradiology **19**(6): 1163-1165.

Two cases of intracranial penetration of a plastic or wooden chopstick via the optic canal are described. CT scans showed the chopsticks as linear hypodense structures in the suprasellar cistern contiguous with the optic canal. In one case, MR imaging was performed, which clearly depicted the foreign body and adjacent brain structures. Although they are extremely rare, transorbital intracranial penetrating injuries via the optic canal require physicians' awareness.

3507. Matsushima, K., et al. (2017). "Surgical outcomes after trauma pneumonectomy: Revisited." The journal of trauma and acute care surgery **82**(5): 927-932.

BACKGROUND: Trauma pneumonectomy has been historically associated with an exceedingly high morbidity and mortality. The recent advent of standardized reporting and data-collecting measures has facilitated large volume data analysis on predictors and outcomes of trauma pneumonectomy. The purpose of this study is to describe patient characteristics and outcomes of the patients who underwent trauma pneumonectomy in the modern era and identify clinical factors associated with postoperative mortality., METHODS: Data between 2007 and 2014 from the National Trauma Data Bank were used for analysis, which included patients with both blunt and penetrating trauma who underwent pneumonectomy within 24 hours after admission. Patient characteristics, injury data, and outcomes were analyzed. Postoperative survival was estimated using the Kaplan-Meier method. Multivariate logistic regression analysis was performed to identify variables associated with postoperative mortality., RESULTS: A total of 261 patients were included for analysis. Of those, 163 (62.5%) patients sustained penetrating trauma. Less invasive lung resections were performed before pneumonectomy in 12.6% of patients. First 24-hour and in-hospital mortality were significantly higher in blunt trauma patients compared with penetrating trauma patients (54.1% vs. 34.1% and 77.6% vs. 49.1%, respectively; $p < 0.01$). In our multivariate logistic regression analysis, an admission Glasgow Coma Scale of less than 9 (odds ratio [OR], 2.16, 95% CI: 1.24-3.77, $p < 0.01$) and associated brain injury (OR, 2.11, 95% CI: 1.01-4.42, $p = 0.048$) were significantly associated with in-hospital death, whereas penetrating mechanism (OR, 0.36, 95% CI 0.19-0.70, $p < 0.01$) and less invasive lung resections before pneumonectomy (OR, 0.39, 95% CI: 0.17-0.87, $p = 0.02$) were significantly associated with survival to hospital discharge., CONCLUSION: Trauma pneumonectomy remains a highly morbid procedure even in the modern era and should be reserved for carefully selected patients., LEVEL OF EVIDENCE: Prognostic study, level IV.

3508. Matsuyama, T., et al. (2001). "Transorbital penetrating injury by a chopstick--case report." Neurologia medico-chirurgica **41**(7): 345-348.

A one-year-old boy presented with orbitocranial penetrating injury by a chopstick. Neurological examination did not reveal abnormal findings. Skull radiography did not reveal any sign of fracture and there were no abnormal findings. Initially, computed tomography (CT) of the head did not reveal any intracranial lesions. However, bone window CT showed a well-defined low-density abnormality measuring 2.5 cm in length in the right orbit and parasellar region. Magnetic resonance imaging clearly revealed a low-intensity structure extending from the orbit to the prepontine area. Surgical exploration was emergently performed and the wooden fragment was removed. The postoperative course was uneventful. Transorbital penetrating injury by a wooden foreign body is relatively rare. The wound may be superficial and trivial. Major neurological deficit does not usually manifest immediately, so the penetrating injury may be overlooked. If the foreign body is retained in the orbit and cranium, severe infectious complications may occur later.

3509. Matteini, C., et al. (2004). "Surgical timing in orbital fracture treatment: experience with 108 consecutive cases." The Journal of craniofacial surgery **15**(1): 145-150.

Orbital fractures can lead to esthetic deformities and functional impairments, and adequate surgical timing is considered important in obtaining good results from surgery. By means of chart review, a retrospective analysis was carried out in 108 consecutive cases of pure orbital fractures to investigate the differences in surgical timing and the correlations with patient age and clinical and radiographic findings. In this analysis, surgical timing of pure orbital fractures was strongly related to the combination of parameters such as anatomical location of the fracture, eventual exposure of the fracture, cerebrospinal fluid (CSF) leakage or penetrating wounds, age of patients, eventual functional impairments or muscle entrapment, and serious conditions of compression or ischemia. As the data confirmed, an urgent approach was considered indispensable in severe orbital apex fractures and in orbital fractures with CSF leakage,

penetrating objects, or exposure. Early surgery was necessary within 3 days in children with diplopia (type IIIb) and mainly within 7 days in adults with double vision (type IIIa). Delayed surgery, within 12 days in all cases, was performed orbital wall fractures with no impairments (type II) or in orbital rim fractures (type I). Data from this retrospective analysis confirm the need for an aggressive approach to all orbital fractures. In our experience, surgery was performed within 12 days and most orbital fractures were treated during the first week after trauma, which is earlier than previously reported.

3510. Maull, K. I. (1989). "Cranial impalement injury." Journal of the Tennessee Medical Association **82**(9): 481-482.

3511. Mavrogiannis, L. A. and A. O. M. Wilkie (1993). "Enlarged Parietal Foramina
GeneReviews R."

CLINICAL CHARACTERISTICS: Enlarged parietal foramina are characteristic symmetric, paired radiolucencies of the parietal bones, located close to the intersection of the sagittal and lambdoid sutures, caused by deficient ossification around the parietal notch, which is normally obliterated by the fifth month of fetal development. Enlarged parietal foramina are usually asymptomatic. Meningeal, cortical, and vascular malformations of the posterior fossa occasionally accompany the bone defects and may predispose to epilepsy. In a minority of individuals, headaches, vomiting, or intense local pain are sometimes associated with the defects, especially on application of mild pressure to the unprotected cerebral cortex., DIAGNOSIS/TESTING: Typically oval or round, enlarged parietal foramina resemble a "pair of spectacles" on postero-anterior skull radiographs. They may be less apparent on lateral skull radiographs because the lucencies are projected obliquely through normal bone. In young children, the disorder may present as a persistently enlarged posterior fontanelle caused by a single large central parietal bone defect (cranium bifidum). 3D CT scanning using bone windows clearly reveals the defect. MRI is useful in defining associated intracranial anatomic changes. Heterozygous pathogenic variants in either ALX4 or MSX2 are established causes., MANAGEMENT: Treatment of manifestations: Treatment is generally conservative. Persistent cranium bifidum may warrant operative closure. Associated headaches or seizures should be treated appropriately. The risk for penetrating injury to the brain is small but may cause anxiety; education of parents, teachers, and the affected child to avoid risky behaviors that could result in injury suffices in most circumstances. Agents/circumstances to avoid: Contact sports in those with a persistent midline bony defect., GENETIC COUNSELING: Enlarged parietal foramina are inherited in an autosomal dominant manner with high, but not complete, penetrance. Most individuals diagnosed with enlarged parietal foramina have an affected parent. The proportion of cases caused by de novo pathogenic variants appears to be small. Each child of an individual with enlarged parietal foramina has a 50% chance of inheriting the pathogenic variant. Detailed fetal ultrasound examination at 18 to 20 weeks' gestation can usually detect the defects in a fetus at risk; fetal MRI is also an option. When the pathogenic variant has been identified in an affected family member, prenatal diagnosis of a pregnancy at increased risk and preimplantation genetic testing are possible.

3512. Maximova, N., et al. (2020). "Standard treatment–refractory cytomegalovirus encephalitis unmasked by immune reconstitution inflammatory syndrome and successfully treated with virus-specific hyperimmune globulin." Clinical and Translational Immunology **9**(11).

Objectives: Cytomegalovirus (CMV)-related encephalitis is a rare but potentially life-threatening complication of CMV infection in immunocompromised patients. The high mortality rate is associated with deficient immune system reconstitution after hematopoietic stem cell transplant (HSCT) and poor bioavailability of antiviral drugs in cerebrospinal fluid (CSF). CMV-related central nervous system (CNS) infection may occur with aspecific symptoms, without evidence of either blood viral load or magnetic resonance imaging (MRI) signs of encephalitis. Methods: Here, we describe a 10-year-old girl who underwent an allogeneic HSCT and subsequently developed CMV encephalitis. Because of the absence of CMV antigen in the blood, the diagnosis of encephalitis was proposed only after a delay, following the onset of immune reconstitution inflammatory syndrome (IRIS). Two months of combined dual antiviral therapy with ganciclovir and foscarnet proved ineffective against CMV and caused significant bone marrow and renal toxicity. To avoid further toxicity, the girl was given daily treatment with CMV-hyperimmune globulins alone. Results: After three weeks, the CSF viral load dropped significantly and was undetectable within three more weeks. In the meantime, the renal impairment resolved, and there was a complete bone marrow recovery. Conclusion: We suggest that this patient succeeded in

achieving CMV CSF clearance with high dose of CMV-hyperimmune globulin, given alone, because of the ability of immunoglobulins to penetrate the blood–brain barrier (BBB).

3513. Maxwell, A. K., et al. (2022). "Management of the facial nerve following temporal bone ballistic injury." Laryngoscope Investigative Otolaryngology.

Objective: To understand the patterns of temporal bone fracture and facial nerve injury from ballistic trauma. Study Design: Retrospective case series. Methods: Retrospective review of 42 patients evaluated following temporal bone ballistic injury at a single institution, university-based level-one trauma center between 2012 and 2021. Demographics, facial nerve status, CT images, interventions, complications, and outcomes were reviewed. Results: Mean age 30.3 years (range 5–58 years); 79% male. Racial demographics reflected the surrounding community. Seven mortalities occurred. Nineteen patients (54%) demonstrated facial nerve injury. Of those, 13/19 displayed immediate paralysis, 1 delayed, 5 unknown (due to altered mental status). On consultation, House-Brackmann grade 6 paralysis was common (13/19). Fracture was otic capsule-sparing in 17/19 (90%), universally comminuted, with significant disruption along the mastoid tip (16/19), external auditory canal (EAC) (15/19), and periauricular soft tissues (13/19). Nine patients underwent surgical intervention: Transmastoid facial nerve decompression to remove compressive bony spicules (n = 5); eye protection surgery (n = 3); and peripheral facial nerve exploration (n = 1), noting transection at the pes. One required middle cranial fossa and transmastoid repair of cerebrospinal fistulae in setting of severe meningitis. House-Brackmann scores improved in 80% following transmastoid nerve decompression despite CT evidence of likely additional injury in its extratemporal course. Conclusions: Common patterns of temporal bone fracture seen in blunt trauma (longitudinal/transverse, otic capsule-sparing/disrupting) were not found in patients with ballistic facial nerve injury. Rather, injury was commonly apparent in the EAC, mastoid tip, and periauricular soft tissues. Clinicians should have high suspicion for extratemporal facial nerve injury following ballistic trauma.

3514. Maxwell, W. L. and J. McGadey (1988). "Response of intraventricular macrophages after a penetrant cerebral lesion." Journal of anatomy **160**: 145-155.

The response of epiplexus and supraependymal cells to extravasated blood after a penetrant cerebral lesion was investigated. Epiplexus cells respond more actively than supraependymal cells. The epiplexus cells tend to aggregate near areas of extravasation of erythrocytes, this being most marked 6 hours after injury. Epiplexus cells lose their smooth surface appearance, retract their filopodia and adopt a more spherical form, with short microvilli or blebs. Numerous inclusion vesicles develop; some contain disrupted erythrocytes 6-12 hours after injury and these are still present 24-30 hours after injury. By 8-16 days after injury epiplexus cells resume a smooth surface appearance and the number of inclusion vesicles is much reduced. This suggests reversion to a quiescent state, from an earlier active state.

3516. May, M. (1985). "Facial reanimation after skull base trauma." The American journal of otology **Suppl**: 62-67.

Three basic types of procedures are used by the author to reanimate the face paralyzed by interruption of the facial nerve at the skull base. In order of choice they are direct nerve repair or grafting; hypoglossal-facial nerve anastomosis; and regional facial reanimation (brow lift, implantation of a gold weight or spring in the eyelid, tightening of the lower eyelid, and temporalis muscle transposition to reanimate the mouth). The indications for and expected results of each approach are presented with special emphasis on the usefulness of regional reanimation.

3518. Mayfrank, L., et al. (1993). "Bilateral chronic subdural haematomas following traumatic cerebrospinal fluid leakage into the thoracic epidural space." Acta neurochirurgica **120**(1-2): 92-94.

This report describes a patient who developed bilateral chronic subdural haematomas after a stab injury to the thoracic meninges causing prolonged cerebrospinal fluid leakage into the epidural space. Diagnostic findings and therapeutic management are presented and possible pathogenic mechanisms are discussed. This case suggests that patients who have symptoms or signs of increased intracranial pressure after a penetrating spinal injury should be studied for subdural haematoma.

3520. Mayo, W., et al. (2022). "Facial defects reconstruction by titanium mesh bending using 3D printing technology: A report of two cases." Annals of Medicine and Surgery **78**.

Introduction: Facial injuries and deformities have received special attention during the previous decades for their functional, esthetic impairment, surgical challenges related to the location of the intervention, and their relationship to a lower survival rate. Moreover, there have been many surgical reconstructive methods due to the different materials and tools available and thus the final results following the surgical intervention. Case presentation: This study was conducted on two patients with severe war injuries; they both suffered from a significant loss in one or more of the following bones: the zygomatic bone, maxilla, nasal bone, infraorbital rim, and mandible. They were treated using preshaped 3D titanium mesh implants that were made using polylactic acid (PLA) material. The final shape was identified depending on pregenerated multislice 3D modeling using computed tomography (CT) scan. Clinical discussion and conclusion: The patient-specific titanium implants produced using polylactic acid (PLA) have been an important option for reconstructive surgical interventions in facial injuries. It has achieved a better outcome in comparison with manual bent titanium mesh in terms of anatomical symmetry, overall operating time, functional and esthetic impairment. These points helped achieve better care for both civilian and war injuries associated with bone loss.

3521. Mayr, L., et al. (2021). "Response to avapritinib in a pediatric spinal cord H3K27M-mutant glioma patient." Neuro-Oncology **23**(SUPPL 6): vi108.

H3K27M-mutated diffuse midline glioma (H3K27M-DMG) may arise in the pons, thalamus and spinal cord generally having a dismal prognosis. Notably, H3K27M-DMG are driven by oligodendrocyte precursor-like cells which are partly sustained by PDGFRA signaling. Co-mutations including TP53, ACVR1, PDGFRA, KIT and PI3K pathway alterations are present in a subset of cases, and molecular profiling may allow detection of additional targetable alterations. However, small-molecule inhibitors often have limited efficacy associated with low blood-brain-barrier (BBB) penetration. Here, we report on a patient with spinal, leptomeningeal disseminated H3K27M-DMG treated with avapritinib, an orally administered, BBB-penetrant and highly selective KIT and PDGFR inhibitor, provided through a compassionate-use program. Initial therapy consisted of subtotal resection, focal radiotherapy and temozolomide (TMZ) resulting in disease stabilization. Ten months after diagnosis, leptomeningeal metastases were detected, biopsied and treated with local irradiation and TMZ. The patient subsequently received systemic and intrathecal chemotherapy augmented with dasatinib. Molecular analyses of the biopsy revealed the H3F3A and TP53 mutations present in the primary tumor, as well as de novo PDGFRA and KIT amplifications with gene copy numbers of 25 and 21, respectively. Upon further disease progression, therapy with avapritinib was initiated. Assessment of treatment response according to RANO criteria after four months revealed stable disease of the target lesion in the cerebellum and partial response of all non-target lesions. Avapritinib was generally well tolerated with lower limb edema (Grade 2), small intratumoral bleeding (Grade 1) and unrelated hydrocephalus (Grade 3) as reported adverse events. As precaution, treatment was interrupted and re-initiated after one week as the bleeding was stable. A ventriculoperitoneal shunt was implanted resolving the hydrocephalus. Pharmacokinetic analyses revealed up to 65% avapritinib plasma exposure and clinically relevant levels in cerebrospinal fluid. In summary, we report on first effective therapy of treatment-resistant H3K27M-DMG with avapritinib as clinical proof of concept.

3522. Mazieres, J., et al. (2021). "P85.01 Activity of Tepotinib in Brain Metastases (BM): Preclinical and Clinical Data in MET Exon 14 (METex14) Skipping NSCLC." Journal of Thoracic Oncology **16**(3): S668-S669.

Introduction: Approximately 20% of METex14 skipping NSCLC cases involve brain lesions at diagnosis. Tepotinib is an oral, once-daily, highly selective MET inhibitor that has shown clinical activity in MET-driven tumors. We investigated the activity of tepotinib in preclinical models and patients with baseline BM in the Phase II VISION study. Methods: Brain penetration was assessed in Wistar rats (n=3) at tepotinib dose 3.66 mg/kg/h intravenously by determining unbound brain (fu br) and plasma (fu pl) concentrations using liquid chromatography with tandem mass spectrometry. Preclinical efficacy was assessed in two patient-derived xenografts (PDX) obtained from BM harboring high MET amplification (MET copy number gain: 11 for LU5349 and 24 for LU5406). NOD-SCID mice with PDX orthotopically implanted into the brain (n=10/group) were treated with tepotinib 125 mg/kg or vehicle control orally once daily. Intracranial tumor growth was monitored by gadolinium-based MRI. Patients enrolled in VISION Cohort A with METex14 skipping NSCLC and asymptomatic BM (prior brain-specific therapy allowed) received tepotinib 500 mg once daily. Endpoints included systemic response per RECIST v1.1, duration of response (DOR), and progression-free survival (PFS) by independent review committee (IRC). Results: The fraction of unbound tepotinib in rat brain tissue (fu br = 0.4%) was low compared with plasma (fu pl = 4%), indicating high binding in the brain. Upon treatment with tepotinib, both PDX tumors from MET-driven NSCLC BM regressed significantly in orthotopic brain models (mean tumor volume reduction of 63% for LU5406 and 84% for LU5349). VISION Cohort A enrolled 22 patients with baseline BM (identified by IRC or investigator assessment), whose demographic characteristics were similar to the overall population (N=152). As of July 1, 2020, 21 patients with baseline BM had ≥9 months' follow-up and were included in efficacy analyses. Confirmed systemic best overall response was partial response in 11 patients for an ORR (95% confidence interval [CI]) of 52.4% (29.8, 74.3), which was comparable to that in overall population (table). Median DOR (95% CI) was 9.5 months (5.5, not estimable), and median PFS (95% CI) was 9.5 months (5.7, 11.2). Case studies illustrating response of brain lesions in VISION patients will also be presented. [Formula presented] Conclusion: Tepotinib administration resulted in regression of orthotopic BM in preclinical models. Patients in the VISION study with baseline BM had a comparable systemic response to that in the overall population. Tepotinib activity against BM will be further assessed by follow-up brain scans in the confirmatory VISION Cohort C. Keywords: MET exon 14 skipping, Brain metastases, tepotinib

3524. McCabe, C. T., et al. (2021). "Mental and physical health, and long-term quality of life among service members injured on deployment." Health and quality of life outcomes **19**(1): 220.

BACKGROUND: More than 52,000 casualties have been documented in post-9/11 conflicts. Service members with extremity injuries (EIs) or traumatic brain injury (TBI) may be at particular risk for long-term deficits in mental and physical health functioning compared with service members with other injuries., METHODS: The present study combined medical records with patient reports of mental health and health-related quality of life (HRQOL) for 2,537 service members injured in overseas contingency operations who participated in the Wounded Warrior Recovery Project. Combined parallel-serial mediation models were tested to examine the pathways through which injury is related to mental and physical health conditions, and long-term HRQOL., RESULTS: Results revealed that injury was indirectly related to long-term HRQOL via its associations with physical health complications and mental health symptoms. Relative to TBI, EI was associated with a higher likelihood for a postinjury diagnosis for a musculoskeletal condition, which were related to lower levels of later posttraumatic stress disorder (PTSD) symptoms, and higher levels of physical and mental HRQOL. Similarly, EI was related to a lower likelihood for a postinjury PTSD diagnosis, and lower levels of subsequent PTSD symptoms, and therefore higher physical and mental HRQOL relative to those with TBI. Despite this, the prevalence of probable PTSD among those with EI was high (35%). Implications for intervention, rehabilitation, and future research are discussed.

3527. McCollum, N. and S. Guse (2021). "Neck Trauma: Cervical Spine, Seatbelt Sign, and Penetrating Palate Injuries." Emergency medicine clinics of North America **39**(3): 573-588.

Pediatric cervical spine, blunt cerebrovascular, and penetrating palate injuries are rare but potentially life-threatening injuries that demand immediate stabilization and treatment. Balancing the risk of a missed injury with radiation exposure and the need for sedation is critical in evaluating children for these injuries. Unfortunately, effective clinical decision tools used in adult trauma cannot be uniformly applied to children. Careful risk stratification based on history, mechanism and examination is imperative to evaluate these injuries judiciously in the pediatric population. This article presents a review of the most up-to-date literature on pediatric neck trauma.

3528. McCoy, E. and H. Sontheimer (2010). "MAPK induces AQP1 expression in astrocytes following injury." Glia **58**(2): 209-217.

Aquaporin-4 (AQP4) is the principle water channel and the primary route for water transport across astrocytic membranes. AQP4 co-localizes with Kir4.1 channels at astrocytic endfeet, and it has been suggested that these channels cooperate in K(+) and water homeostasis. In response to injury, two additional aquaporins, AQP1 and AQP9, can be detected in astrocytes, yet neither is found in cultured astrocytes, and therefore their contribution to astrocyte water uptake and biology is poorly investigated. In this study, we used a cortical stab wound assay to demonstrate an upregulation of AQP1 following injury in reactive glia. We were able to mimic such injury in astrocytic cultures and show that AQP1 expression is induced within 16 h following injury in vitro. This induction could be blocked by inhibition of MEK1/2 using U0126, and suggests that AQP1 is specifically induced in reactive astrocytes via the mitogen-activated protein kinases signaling pathway.

3529. McCutcheon, V., et al. (2014). "Development and validation of two zebrafish models of TBI." Journal of neurotrauma **31**(5): A49.

Traumatic brain injury (TBI) is a leading cause of death and morbidity in industrialized countries with considerable associated direct and indirect health care costs. Zebrafish (ZF) are an emerging model organism for studies of disease and development owing to their unique advantages in genome manipulation, whole animal in vivo imaging, rapid rate of procreation and amenability to large scale preclinical drug validation. We developed a ZF model of chemically-induced brain injury in 4 dpf larvae using a 10mM dose of glutamate. The NMDA receptor antagonist, MK-801, applied at of 62.5 nM, 125 nM, and 250nM concentrations resulted in a dose-dependent delayed larval survival.We are currently evaluating other known neuroprotective compounds as validation of the larvae ZF model. Candidate compounds will be further evaluated in an adult ZF model.We use a targeted 1-MHz pulsed high intensity focused ultrasound (pHIFU) system applied to adult ZF to produce a non-penetrating head injury to the brain. Preliminary results indicate that pHIFU pressure amplitude at 10MPa results in a 70.5 ± 1%and 102 ± 1%change in NF160 expression at 5,000 and 10,000 cycles respectively. Beta-III tubulin shows a 14 ± 1%and 16 ± 1%increase at the same parameters.We also found a 30 ± 1%increase in cleaved caspase-3 in injured brains compared to controls. Post-injury recovery times show a linear increase with increasing injury severity. Our preliminary results indicate that the ZF response to brain trauma exhibits similar mechanisms of secondary injury to mammalian pathophysiology after TBI. Further refinement of the model is in progresswith the aim to use themodel to identify pharmacotherapeutic compounds via high throughput compound library drug screening.

3530. McCutcheon, V., et al. (2014). "Development and validation of two zebrafish models of TBI." Journal of neurotrauma **31**(12): A120.

Traumatic brain injury (TBI) is a leading cause of death and morbidity in industrialized countries with considerable associated direct and indirect healthcare costs. The cost and time associated with preclinical development of TBI therapeutics is lengthy and expensive. The Zebrafish (ZF) is an emerging model organism for studies of disease and

development owing to its similarity in genome and cell signalling pathways in mammalian species, ease of genome manipulation, capacity for whole animal in vivo imaging, rapid rate of procreation, and amenability to large scale automated preclinical drug validation. We have developed a two-stage model of TBI in ZF using larvae and adult fish. In larval ZF, we developed a highthroughput method of screening therapeutic compounds in a chemically-induced brain injury model. As proof-of-concept, we demonstrate dose-dependent larval survival with known neuroprotective compounds (eg. MK-801). We are currently validating other known neuroprotective compounds in the larvae ZF model. Compound libraries of FDA-approved drugs are currently being screened for repurposing in our larval model. Candidate compounds will be further evaluated in an adult ZF model. We use a targeted 1-MHz pulsed high intensity focused ultrasound (pHIFU) system applied to adult ZF to produce a non-penetrating injury to the brain. Preliminary results indicate that pHIFU pressure amplitude at 10MPa results in a 70.5 ± 1% and 102 ± 1% change in NF160 expression at 5,000 and 10,000 cycles respectively. b-III tubulin shows a 14 ± 1% and 16 ± 1% increase at the same parameters. We also found a 30 ± 1% increase in cleaved caspase-3 expression in injured brains compared to controls. The adult ZF injury model allows whole animal behaviour outcome measures such as post-injury recovery times which demonstrate a dose dependent effect with increasing injury severity. Adult ZF subject to pHIFU also show locomotor swim deficits at 24 h post injury. Our preliminary results indicate that the ZF exhibits similar responses to injury and pharmacotherapeutic manipulation as found in mammalian pathophysiology after TBI. This suggests the possibility of using a two-step ZF injury model system to screen compound libraries to quickly identify potential therapeutic candidates at a fraction of the time and cost of studies in mammalian species.

3531. McDonald, L. (1978). "Determination of brain death via pulsatile echoencephalography." Journal of neurosurgical nursing **10**(4): 150-155.

For cerebral death to occur there must be many levels of cerebral function destroyed. Cortical and subcortical irreversible damage is evident by unresponsiveness to any stimuli. Brain stem and basal ganglia damage is indicated by absence of spontaneous respirations, cephalic reflexes, and thus cerebral circulation. All elements of the criteria for cerebral death must be met. The decision should be made by the attending physician in consultation with his peers. The life support mechanisms should be discontinued after the diagnosis of cerebral death has been made. Absence of pulsatile echoes means absence of cerebral circulation and cerebral function, or a definitive diagnosis of cerebral death. It is a final parameter in the criteria and allows definite measures to be taken. But it behooves one to remember that this phenomenon of cerebral death makes organ donation and transplantation possible. It has not been created in order to supply the needs for organ transplant!

3532. McDonald, V., et al. (2017). "Networks underlying trait impulsivity: Evidence from voxel-based lesion-symptom mapping." Human brain mapping **38**(2): 656-665.

Impulsivity is considered a multidimensional construct that encompasses a range of behaviors, including poor impulse control, premature decision-making, and the inability to delay gratification. In order to determine the extent to which impulsivity and its components share a common network, a voxel-based lesion-symptom mapping (VLSM) analysis was performed in a large sample of patients (N = 131) with focal, penetrating traumatic brain injuries (pTBI). Impulsivity was assessed using the Barratt Impulsiveness Scale (BIS-11), a standard self-report measure that allows for unique estimates of global impulsivity and its factor analysis-derived components (e.g., "motor impulsivity"). Heightened global impulsivity was associated with damage to multiple areas in bilateral prefrontal cortex (PFC), left superior, middle and inferior temporal gyrus, and left hippocampus. Moreover, a cluster was identified within the left PFC associated specifically with motor impulsivity (defined as "acting without thinking"). The results were consistent with the existing literature on bilateral prefrontal cortical involvement in behavioral impulsivity, but also provided new evidence for a more complex neuroanatomical representation of this construct, characterized by left-lateralized temporal and hippocampal involvement, as well as a left-lateralized prefrontal network specifically associated with motor impulsivity. Hum Brain Mapp 38:656-665, 2017.

3534. McFadden, J. T. and C. E. Horton (1971). "Stereotaxic localization of extracranial foreign bodies in the head." The American surgeon **37**(6): 353-356.

3535. McGaha, P., 2nd, et al. (2020). "Factors that predict the need for early surgeon presence in the setting of pediatric trauma." Journal of pediatric surgery **55**(4): 698-701.

INTRODUCTION: Evidence based variables predicting the need for surgeon presence (NSP) on arrival of an injured child are limited. We sought to identify prehospital factors that best correlate with NSP and highest level of activation in pediatric trauma. A secondary analysis was also performed to determine whether injury severity score (ISS) was predictive of NSP in pediatric trauma., METHODS: This was a retrospective, single institution study of injured patients age<=16years delivered from scene to our Pediatric Level I trauma center between January 2016 and June 2017. 526 patients had complete data available for analysis. NSP was previously described as the presence of any of these factors: intubation, transfusion, emergent operation with the trauma team/craniotomy with the neurosurgery team, vasopressors, interventional radiology, spinal cord Injury, chest tube, emergency department thoracotomy, intracranial pressure monitor, pericardiocentesis, or death in the trauma bay. Multivariable analysis was performed with covariates of interest including scene and ED arrival vitals and interventions., RESULTS: Independent predictors of NSP and highest level of activation were GCS of <=12 (OR 22.3), penetrating trauma (OR 5.4), and hypotension (age adjusted) (OR 10.2). We also found that ISS>=16 was a poor indicator of NSP with a sensitivity of only 61%., CONCLUSION: A validated model based on these variables may be useful in predicting NSP and highest level of activation prior to arrival of pediatric trauma patients. NSP may augment assessment of over and undertriage in pediatric trauma patients as compared to the ISS/Cribari system alone. Level of evidence Level III, retrospective cohort study.

3536. McGee, W. T. and P. Mailloux (2011). "Ventilator autocycling and delayed recognition of brain death." Neurocritical care **14**(2): 267-271.

BACKGROUND: Improvements in technology play an important role in caring for critically ill patients. One example is the advance in ventilator design to facilitate triggering of mechanical breaths. Minimal changes in circuit flow unrelated to respiratory effort can trigger a ventilator breath and may mislead caregivers in recognizing brain death., METHODS: We observed patients with devastating brain injuries in a mixed medical/surgical intensive care unit (ICU) with a high clinical suspicion for brain death including the absence of cranial nerve function with apparent spontaneous breathing during patient-triggered modes of mechanical ventilation. Further clinical observation for spontaneous respirations was assessed upon removal of ventilatory support., RESULTS: Nine patients with brain injury due to multiple etiologies were identified and demonstrated no spontaneous respirations when formally assessed for apnea. Length of time between brain death and its recognition could not be determined., CONCLUSION: When brain-dead patients who are suitable organ donors are mistakenly identified as having cerebral activity, the diagnosis of brain death is delayed. This delay impacts resource utilization, impedes recovery and function of organs for donation, and adversely affects donor families, potential recipients of organs, and patient donors who may have testing and treatment that cannot be beneficial. Patients with catastrophic brain injury and absent cranial nerve function should undergo immediate formal apnea testing.

3537. McGonigal, L. J., et al. (1995). "Posttraumatic meningioma: explanation of an epidemiologic dichotomy." Military medicine **160**(2): 92-94.

A 23-year-old soldier sustained a penetrating gunshot wound to the right frontoparietal region of the head in 1971 while serving in Vietnam. In 1984, he developed headaches and seizures, and a meningioma was found at the cranioplasty site. Recurrent meningiomas, requiring resection, developed at this site in 1988 and 1990. In 1994, he developed right proptosis. An extensive mass involving the right intraorbital region and the anterior and middle cranial fossa was found. Pathological examination of this tumor demonstrated malignant meningioma. Although antecedent head trauma has been implicated as a risk factor for meningioma, epidemiological studies of this association have yielded divergent conclusions. An explanation for this epidemiologic dichotomy is suggested.

3538. McGuinness, M. J., et al. (2021). "Nail gun injuries: not just an occupational hazard." The New Zealand medical journal **134**(1540): 56-63.

INTRODUCTION: Nail guns are commonly used in the construction industry. They represent an occupational hazard, and in the context of mental illness can pose a threat to life., AIM: To determine the number of patients admitted to Auckland City Hospital (ACH) with a nail gun injury, and to review the current New Zealand legislation surrounding nail guns., METHODS: A 25-year retrospective review of patients admitted to ACH with a nail gun injury was performed by searching the ACH Trauma Registry. New Zealand legislation was reviewed., RESULTS: Between 1994 and 2019, 45 patients were admitted to ACH with a nail gun injury. Two subgroups were identified: 31% with an intentional injury; 69% with an unintentional injury. All patients were male. The mean age was 36.3. Patients with an intentional injury had a higher mortality rate (21.4% vs 9.5%), Injury Severity Scores (24.2 vs 3.4) and ICU admission rate (50% vs 3%) and required more intensive post-injury care when compared to unintentional injuries. There is currently no legislation in New Zealand specifically governing the use of nail guns. Only powder-actuated nail guns require certification., CONCLUSION: The continued occurrence of unintentional nail gun injuries and the high lethality of intentional injuries represent two distinct areas of concern. The Government should publish guidance aimed at improving safety and reducing the rate of intentional injury.

3539. McGuire, A. (1986). "Issues in the prevention of neurotrauma." The Nursing clinics of North America **21**(4): 549-554.

Over one half of all neurotrauma occurs in or by motor vehicles. The other causes of neurotrauma are falls, violent assaults, sports and recreation, and firearms. The victims who survive are left with paralysis, disfigurement, loss of sight and hearing, seizures, epilepsy, psychiatric disorders, amnesia--in short, significant and often permanent impairment. To permanently prevent this annual human destruction, the prevention agenda should include advocating for air bags in all cars, helmet use for all motorcyclists, the elimination of handguns, and the regionalization of all trauma care. After this is accomplished, we can continue working on preventing other neurotrauma problems.

3540. McGuone, D., et al. (2017). "Penetrating gunshot head injuries with prolonged survival: A potential risk factor for chronic traumatic encephalopathy." Journal of neurotrauma **34**(13): A21.

Post-traumatic neurodegeneration in the form of chronic traumatic encephalopathy (CTE) is associated with a history of traumatic brain injury in susceptible individuals, although the types and number of insults required to initiate neurodegeneration remain incompletely defined. Penetrating gunshot head trauma has not previously been considered a risk factor for neurodegeneration despite being a major cause of traumatic brain injury in many urban centers in the United States. Penetrating gunshot head wounds do not perforate the head and kinetic energy possessed by the projectile is entirely absorbed by the head (including brain). We hypothesized that in penetrating gunshot head wounds with a survival interval, the crushing and stretch injury of brain tissue by the bullet and the contusion of cortical surfaces from rapid, brief expansion of skull contents, might act as substrates for aggregation of hyperphosphorylated tau. In New York City, gunshot lethalities are investigated by the Office of the Chief Medical Examiner (OCME). Over a 6-month period we prospectively examined brains of all gunshot head wounds referred to the forensic neuropathology consultation service at the NYC OCME. Of these, 4 had retained bullet(s) or fragments, and a survival period after injury; these underwent full neurodegenerative disease workup including Bielschowsky silver preparation and immunohistochemistry for tau, beta-amyloid, alpha-synuclein and ubiquitin. All 4 cases were male. Age range at injury was 14 to 29 years and at death was 19 to 50 years. Survival periods ranged from 1 month to 30 years. All victims had neurologic deficits following injury and two had post-traumatic seizure disorder. Neuropathologic evaluation revealed tau deposition in 2: one with rare threads in the bank of the middle frontal gyrus (survival, 1 month), the other with rare threads around cortical vessels in the wound cavity and rare tangles in the locus ceruleus and thalamus (survival, 30 years). No other abnormal protein expression was detected. Detection of tau at autopsy suggests penetrating gunshot trauma represents an independent risk factor for CTE among injured survivors.

3542. McIlwaine, G. G., et al. (1989). "Spontaneous recovery of vision following an orbital haemorrhage." The British journal of ophthalmology **73**(11): 926-927.

A 73-year-old man presented to casualty with a penetrating orbital injury and total loss of vision in the affected eye. He subsequently spontaneously recovered full vision. We stress the need for frequent assessment of vision before considering potentially hazardous surgical intervention.

3543. McKee, A. C. (2013). "Interneuronal spreading of tau pathology in chronic traumatic encephalopathy." Prion **7**: 9.

Chronic traumatic encephalopathy (CTE) is a progressive tauopathy that occurs as a consequence of repetitive mild traumatic brain injury.1 In the earliest stages of CTE, focal perivascular clusters of hyperphosphorylated tau (p-tau) neurofibrillary tangles are found at the depths of the sulci in the cerebral cortex. Even in the absence of additional trauma, CTE appears to progress over decades to become a severe tauopathy affecting widespread regions of the cerebral cortex, basal ganglia, diencephalon and brainstem and medial temporal lobes. How focal tau pathology spreads slowly to involve other brain regions in CTE might involve multiple mechanisms, including a prion-like templated misfolding of tau. Under normal conditions in the mature human central nervous system, tau is primarily associated with microtubules in axons, where it is neither toxic nor associated with neurofibrillary pathology. Brain trauma causes some tau to become dissociated from microtubules in axons via mechanisms that probably include intracellular calcium influx, glutamate receptor-mediated excitotoxicity, and kinase activation mediating hyperphosphorylation of intracellular tau. Tau dissociated from microtubules becomes abnormally phosphorylated, misfolded, aggregated and proteolytically cleaved by calpains and caspases, all of which are associated with neurotoxicity. Direct and indirect evidence for interneuronal tau transfer in animal models has recently suggested that interneuronal spreading of tau pathology may be due to transfer of toxic tau species between neurons.2-5 This might be mediated by either a prionlike templated misfolding of tau, or by calcium dysregulatory effects of oligomeric or toxic N-terminal tau in the receiving neuron.6 While spreading of tau pathology is generally thought to occur in association with neuronal synapses, glial to glial spread, periventricular and diffuse extracellular tau migration patterns involving the cerebrospinal fluid represent additional pathways by which lesion spreading could occur in CTE.7 Cerebrospinal fluid enters the brain parenchyma along the Virchow-Robin spaces surrounding penetrating arteries and brain interstitial fluid is cleared along paravenous drainage pathways. Recent studies have demonstrated that Aß peptide is cleared through this route.8 Clearance through paravenous flow and the cerebrospinal fluid might also regulate extracellular levels of p-tau and explain the frequent perivascular, subpial and periventricular localization of tau protein in CTE. Interneuronal spreading of tau pathology in CTE is complex and likely involves a variety of non-synaptic mechanisms as well as synaptically mediated mechanisms.

3544. McKee, D. M. (1978). "Microvascular bone transplatation." Clinics in plastic surgery **5**(2): 283-292.

A technique has been presented for the transplantation of bone with its own vascular system. Microvascular techniques have been developed to the point that this procedure is feasible in both the laboratory animal and in humans. Using this technique or the fibula transplantation technique of Taylor and colleagues, it should be possible to reconstruct many bone dificits that are refractory to free bone grafting.

3545. McKee, J. L., et al. (2019). "The iTClamp in the treatment of prehospital craniomaxillofacial injury: a case series study." Journal of injury & violence research **11**(1): 29-34.

BACKGROUND: Craniomaxillofacial (CMF) injuries are very common in both civilian and military settings. Nearly half of all civilian trauma incidents include a scalp laceration and historical rates of CMF battle injuries increased from 16%-21% to 42.2%. The scalp is highly vascular tissue and uncontrolled bleeding can lead to hypotension, shock and death. Therefore, enabling on-scene providers, both military and civilian, to immediately manage scalp and face lacerations, in a manner that allows them to still function in a tactical way, offers operational advantages. This case series examines how effectively a wound-clamp (iTClamp) controlled bleeding from CMF injuries pre-hospital environment., METHODS: The use of the iTClamp for CMF (scalp and face laceration) was extracted from iTrauma Care's post market surveillance database. Data was reviewed and a descriptive analysis was applied., RESULTS: 216 civilian cases of iTClamp use were reported to iTrauma Care. Of the 216 cases, 37% (n=80) were for control of CMF hemorrhage (94% scalp and 6% face). Falls (n=24) and MVC (n=25) accounted for 61% of the mechanism of injury. Blunt accounted for 66% (n=53), penetrating 16% (n=13) and unknown 18% (n=14). Adequate hemorrhage control was reported in 87.5%

(n=70) of cases, three respondents reported inadequate hemorrhage control and in seven cases hemorrhage control was not reported. Direct pressure and packing was abandoned in favor of the iTClamp in 27.5% (n=22) of cases., CONCLUSIONS: CMF injuries are common in both civilian and military settings. Current options like direct manual pressure (DMP) often do not work well, are formidable to maintain on long transports and Raney clips are a historical suggestion. The iTClamp offers a new option for control of external hemorrhage from open wounds within compressible zones.

3546. McKendy, K. M., et al. (2017). "Epidural analgesia for traumatic rib fractures is associated with worse outcomes: a matched analysis." The Journal of surgical research **214**: 117-123.

BACKGROUND: The optimal method of pain control for patients with traumatic rib fractures is unknown. The aim of this study was to determine the effect of epidural analgesia on respiratory complications and in-hospital mortality in patients with rib fractures., METHODS: Adult patients at a level I trauma center with >=1 rib fracture from blunt trauma were included (2004-2013). Those with a blunt-penetrating mechanism, traumatic brain injury, or underwent a laparotomy or thoracotomy were excluded. Patients who were treated with epidural analgesia (EPI) were compared with those were not treated with epidural analgesia (NEPI) using coarsened exact matching. Primary outcomes were respiratory complications (pneumonia, deep vein thrombosis/pulmonary embolus, and respiratory failure) and 30-d in-hospital mortality. Secondary outcomes were total hospital and intensive care unit length of stay, and duration of ventilator support., RESULTS: About 1360 patients (EPI: 329 and NEPI: 1031) met inclusion criteria (mean age: 54.2 y; standard deviation [SD]: 19.7; 68% male). The mean number of rib fractures was 4.8 (SD: 3.3; 21% bilateral) with a high total burden of injury (mean Injury Severity Score: 19.9 [SD: 8.9]). The overall incidence of respiratory complications was 13% and mortality was 4%. After matching, 204 EPI patients were compared with 204 NEPI patients, with no differences in baseline characteristics. EPI patients experienced more respiratory complications (19% versus 10%, P = 0.009), but no differences in 30-d mortality (5% versus 2%, P = 0.159), duration of mechanical ventilation (EPI: 148 h [SD: 167] versus NEPI: 117 h [SD: 187], P = 0.434), or duration of intensive care unit length of stay (6.5 d [SD: 7.6] versus 5.8 d [SD: 9.1], P = 0.626). Hospital stay was higher in the EPI group (16.6 d [SD: 19.6] vs 12.7 d [SD: 15.2], P = 0.026)., CONCLUSIONS: Epidural analgesia is associated with increased respiratory complications without providing mortality benefit after traumatic rib fractures. Alternate analgesic strategies should be investigated to treat these severely injured patients.

3547. McKennan, K. X. and R. A. Chole (1992). "Facial paralysis in temporal bone trauma." The American journal of otology **13**(2): 167-172.

A retrospective review of 36 patients with delayed-onset (19 patients) and immediate-onset (17 patients) traumatic facial paralysis was performed. We hypothesized that traumatic delayed-onset facial paralysis does not necessitate surgical decompression under any routine circumstances. Of 19 patients in this group, normal recovery (House grade 1) occurred in 94 percent of the patients without surgical intervention. The small percentage (6%) of these patients who failed to recover completely demonstrated mild degrees of weakness and synkinesis (House grade 2). Immediate-onset paralysis occurred in 17 patients. It has a much poorer prognosis. Seven patients with penetrating wounds had facial nerve transections, usually of the vertical portion of the facial nerve. Closed head injured patients with immediate-onset facial paralysis sustained injuries usually to the horizontal and perigeniculate portion of the facial nerve. For those cases in which surgical exploration of the traumatized facial nerve is indicated, the operating surgeon should have the capacity to enlarge the exposure with a translabyrinthine or middle-fossa dissection.

3548. McKenzie, J., et al. (2019). "Imaging characteristics and treatment of a penetrating brain injury caused by an oropharyngeal foreign body in a dog." Veterinary radiology & ultrasound : the official journal of the American College of Veterinary Radiology and the International Veterinary Radiology Association **60**(3): E24-E28.

A 4-year-old Border collie was presented with one episode of collapse, altered mentation, and a suspected pharyngeal stick injury. Magnetic resonance imaging (MRI) and computed tomography showed a linear foreign body penetrating the right oropharynx, through the foramen ovale and the brain parenchyma. The foreign body was surgically removed and medical treatment initiated. Complete resolution of clinical signs was noted at recheck 8 weeks later. Repeat MRI showed chronic secondary changes in the brain parenchyma. To the authors' knowledge, this is the first

report of the advanced imaging findings and successful treatment of a penetrating oropharyngeal intracranial foreign body in a dog. Copyright © 2017 American College of Veterinary Radiology.

3549. McKeon, A. B., et al. (2019). "Traumatic brain injury and sleep disturbances in combat-exposed service members and veterans: Where to go next?" NeuroRehabilitation **45**(2): 163-185.

OBJECTIVE: To synthesize the current evidence on sleep disturbances in military service members (SMs) and veterans with traumatic brain injury (TBI)., METHODS: An electronic literature search first identified abstracts published from 2008-2018 inclusively referencing sleep, TBI, and military personnel from Operation Enduring Freedom, Operation Iraqi Freedom, Operation New Dawn, and Persian Gulf veterans. Selection criteria eliminated studies on non-combat TBI, open or penetrating injuries, and articles where the relationship between sleep and TBI was not directly examined. Articles on all military branches and components, those currently serving and veterans-ranging from medical chart reviews to clinical trials, were included. Forty-one articles were selected for full text-review., RESULTS: Twenty-four papers estimated the prevalence of sleep disturbances in TBI. Eight studies demonstrated the contribution of common co-occurring conditions, most notably posttraumatic stress disorder, to the relationship between disrupted sleep and TBI. Ten studies differentiated sleep profiles between military SMs and veterans with and without acute TBI and detected significant differences in sleep disturbances across the course of injury. Longitudinal studies were scarce but helped to establish the temporal relationship between sleep disturbances and TBI and isolate sleep-related mechanisms influencing TBI prognosis. Only three studies reported on interventions for improving sleep quality and TBI symptoms. Systematic research testing assessments and interventions that target sleep disturbances for improving sleep, TBI symptoms, and long-term functional outcomes were identified as critical knowledge gaps., CONCLUSION: Findings unequivocally establish that sleep disturbances are highly prevalent in SMs and veterans with TBI. However, studies testing the effectiveness of treatments for improving sleep in military groups with TBI have been limited and their results inconsistent. This review highlights a critical opportunity for advancing military medicine through future research aimed at identifying and testing sleep-focused treatments in SMs and veterans with combat-related TBI.

3550. McKinlay, J. and J. E. Smith (2013). "Penetrating brain injury: a case of survival following blast fragmentation injuries to the head." Journal of the Royal Naval Medical Service **99**(2): 55-56.

We present a case of penetrating head injuries caused by blast fragmentation, along with other serious injuries (including to the arms, face and neck), where a good recovery was made despite an Injury Severity Score (ISS) of 75. We suggest that survival and outcome are reliant on several factors and cannot be predicted from ISS, velocity of penetrating injury or presenting Glasgow Coma Scale (GCS) alone.

3551. McKinley, W. O., et al. (1999). "Clinical presentations, medical complications, and functional outcomes of individuals with gunshot wound-induced spinal cord injury." American journal of physical medicine & rehabilitation **78**(2): 102-107.

Gunshot wounds are currently the second leading cause of spinal cord injury in the United States, and coexisting injuries or complications accompanying penetrating wounds often increase patient morbidity. A review of 217 traumatic spinal cord injury rehabilitation admissions to a tertiary care hospital during a 5-yr period revealed 49 individuals (23%) with gunshot wound-induced spinal cord injury. A single bullet entry site was seen in 54%, whereas 17% had greater than 3 sites of entry. Common (>25%) sites of bullet entry included the back, abdomen, neck, and chest. Common gunshot wound-related medical complications included pain (54%), infections (40%), pneumothorax (24%), nonspinal fractures (22%), colonic perforation (17%), cerebrospinal fluid leak (10%), and retroperitoneal hematoma (10%). When compared with nonviolence-related traumatic spinal cord injury (motor vehicle accidents and falls), patients with gunshot wound-induced spinal cord injury were significantly more frequently ($P < 0.01$) younger, non-Caucasian, unmarried, and unemployed. Injury characteristics revealed significantly ($P < 0.01$) more paraplegia and complete spinal cord injury within the gunshot wound-induced spinal cord injury group. Gunshot wound-induced spinal cord injury and nonviolent traumatic spinal cord injury groups had similar lengths of stay, Functional Independence Measure scores, and discharge to home rates. This article adds to the growing body of literature examining clinical, medical, and functional outcome characteristics of individuals with spinal cord injury secondary to violence-related cause.

3552. McKinney, R. A. (2017). "Maxillofacial gunshot wound & delayed psuedoaneurysm: Recognition & endovascular intervention." Journal of oral and maxillofacial surgery **75**(10): e409.

Introduction: Pseudoaneurysms of the extracranial head and neck vasculature are rarely encountered. However, they bring significant risks when present. There is an adequate buffer of soft tissue in the maxillofacial region reducing the incidence. Most trauma to the external carotid artery and its branches will predominately cause complete transection rather than partial laceration. The process of a pseudoaneurysm formation is a partial vessel wall breach resulting in leakage of arterial blood into surrounding tissues. Tamponade with partial clot formation will follow. Some pseudoaneurysms self-resolve, however others require treatment to prevent uncontrolled hemorrhage. The most vulnerable of the External Carotid Artery branches are the superficial temporal, internal maxillary, and facial arteries. Case Description: This case reviews the initial treatment and perioperative management of a young healthy male who sustained a .40 caliber handgun round to the left midface. Consistent with most low velocity gunshot injuries, there was no exit wound. His injuries included: avulsion of left midface epidermis and lateral nasal ala, comminution of left maxillary sinus and pterygoid plate, obliteration of left posterior dentition with dentoalveolar fractures, left mandibular coronoid process fracture, and C1 fracture of foramen transversarium. Carotid space involvement was noted through the tract of the projectile. Vascular lacerations or psuedoaneurysms of cervical circulation could not be ruled out until angiogram on post injury day 4. He was then taken to the operating room for facial debridement and archbar placement for DA fractures. His clinical progression improved daily until PID 10 when delayed clinical signs lead to an additional angiogram order. Likely due to late cavitation injury, an 8.5mm traumatic pseudoaneurysm of the distal segment of left IMAX artery was discovered. The psuedoaneurysm was embolized and the distal IMAX artery was occluded with a combination of detachable coils and Onyx liquid embolic agent. Discussion: This case exemplifies the importance of vigilant perioperative patient management. It also displays the strengths of angiography and catheter based embolization, which can be both diagnostic and therapeutic. This alternative allows rapid access to surgically inaccessible vessels, as well as superior cosmesis by preventing facial scars and wound-related complications. Parent vessel sacrifice (IMAX) in this case proved to be a safe and effective treatment alternative.

3553. McKintosh, E., et al. (2011). "Delayed and spontaneous intracranial foreign body migration." British journal of neurosurgery **25**(1): 140-141.

We present a case of spontaneous migration of a metal rod into the brain. No causative factor was identified but possible mechanisms for this occurrence are considered, and the importance of correct early management of this unusual injury emphasised.

3554. McLean, J. N., et al. (2005). "Gunshot wounds to the face--acute management." Facial plastic surgery : FPS **21**(3): 191-198.

The complex facial trauma victim poses a genuine therapeutic challenge as a whole, and may be particularly challenging to the medical team. The literature on acute management of gunshot wounds to the face is scarce. We performed an extensive review of the English-language literature in an effort to better delineate the diagnosis and acute management of these injuries. Most of these injuries do not present with initial threat to life and can safely be managed non-operatively. Definitive treatment is often deferred in patients with multiple, or more severe, injuries. Airway compromise is the most frequent and most life-threatening early problem reported in most series. CT scan remains the most useful method in the evaluation of these types of injuries and associated cervical spine lesions. Facial bleeding is best controlled by angiography and subsequent embolization. Anatomic repair of soft tissue and bony injuries is recommended to obtain an optimal functional and aesthetic outcome. Despite the creation of some algorithms, no clear correlation has been found between the site of entrance wound and the injuries and outcome of gunshot wounds to the face.

3555. McLoughlin, R. J., et al. (2020). "Toy Guns, Real Danger: An Update on Pediatric Injury Patterns Related to Nonpowder Weapons." Journal of pediatric surgery **55**(1): 146-152.

BACKGROUND: Design changes of nonpowder guns, including BB and air guns, have significantly increased their potential to injure. We sought to characterize the demographics of children injured with nonpowder weapons and the specific injuries suffered., METHODS: A cross-sectional analysis of the study years 2006, 2009, and 2012 was performed by combining the Kids' Inpatient Database into a single dataset. We identified cases (age<21years) of air gun injuries

using external cause of injury codes. Patient characteristics and injuries were analyzed using ICD-9 codes, and national estimates were obtained using case weighting., RESULTS: There were 1028 pediatric admissions for nonpowder weapon related injuries. The victims were predominately male (87.0%), non-Hispanic white (52.3%), resided in the South (47.3%), and in the lowest income quartile (39.2%). Half required a major surgical procedure. The predominant injuries were open wounds to the head, neck, or trunk (40.3%), and contusion (22.5%). Notable other injuries were intracranial injury (9.1%) and blindness or vision defects (3.3%)., CONCLUSIONS: The nonpowder weapons available to this generation can paralyze, blind, and cause lasting injury to children. Injuries frequently require surgical intervention, and these weapons should no longer be considered toys. Further research and legislation should be aimed at limiting children's access to these weapons., LEVEL OF EVIDENCE: III.

3556. McMullan, J. T., et al. (2011). "Prevalence of hypoxemia and oxygen use in trauma patients prior to hospital arrival." Annals of emergency medicine **58**(4): S242.

Background: Trauma patients of ten receive oxygen (O2) before hospital arrival but the true need for O2 is unknown. Knowing the prevalence of O2 need would assist logistical planning for care delivery in mass casualty, military, and austere environments. Methods: An IRB-approved study prospectivelyenrolled a convenience sample of injured adults taken to a trauma center by 6 EMS agencies in 2010. During transport, O2 saturation (SpO2) was recorded every 6 seconds by a Nonin oximeter. Study assistants noted in-hospital O2 use. Aconservative threshold for O2 need was used to estimate maximum prevalence and defined per local EMS protocols as SpO2<95%, traumatic brain injury, hemorrhagic shock, EMS intubation, or hospital O2 use within 24 hours. Analysis using the Trauma Combat CasualtyCare threshold ofSpO2<90% was also performed. Categorical comparisons used Chi-Square or Fisher's Exact tests; medians were compared with the Mann-Whitney U test. Results: Of 290 screened patients, 154 met inclusion criteria, consented and had complete data. Median age was 37 (range 18-84) years, 77/154 (50%) were white, 121/154 (79%) were male. Median injury severity score (ISS) was 5 (range 1-43), 55/154 (36%) had a penetrating injury, 82/154 (53%) were admitted. 128 of 154 subjects (83%, 95%CI 76-88%) had a need for O2. 113/154 (73%) had SpO2<95% and 52 (34%) were <90%. 86/154 subjects (67%) received O2 during EMS transport. Those with O2 need were older (38 v 27 years; p= 0.019) and had higher ISS scores (9 v 1; p= 0.001). There was no difference in O2 need for those with or without penetrating (36% v 40%, p= 0.684) or chest (27% v 19%, p= 0.469) injuries. Conclusion: At thresholds ofSpO2<95% and SpO2<90%, manyinjured patients brought to a trauma center required O2. The need for O2 remains sufficient to deploy some oxygen into austere environments and have it available for mass casualty incidents. Further study is required to understand the effects of reducing oxygen availability on clinical outcomes and to forecast which casualties may benefit from supplemental oxygen.

3557. McNamara, J. J., et al. (1972). "Lipid metabolism after trauma. Role in the pathogenesis of fat embolism." The Journal of thoracic and cardiovascular surgery **63**(6): 968-972.

3558. McNamara, R. M. and J. J. Kelly (1992). "Impact of an emergency medicine residency program on the quality of care in an urban community hospital emergency department." Annals of emergency medicine **21**(5): 528-533.

STUDY OBJECTIVES: To assess the impact of the introduction of an emergency medicine residency program on the quality of care in an urban community hospital emergency department., DESIGN: A retrospective chart review of all ED encounters for a three-month period beginning six months before and six months after the introduction of an emergency medicine residency., SETTING: A 27,000-visit-per-year urban community hospital ED., TYPE OF PARTICIPANTS: All patients who presented to the ED with one of five complaints and subsequently were discharged home. The five presenting categories examined were nontraumatic chest pain when age 30 years or more, lower abdominal pain in women aged 15 to 40 years, recent head trauma, headache of nontraumatic origin, and extremity laceration., INTERVENTIONS: None., MEASUREMENTS AND MAIN RESULTS: The frequency of physician documentation on the ED record of explicit criteria related to the five presenting complaints was used as a measure of the quality of care. Items sought for documentation included elements of the history and physical examination and diagnostic evaluations. The explicit criteria lists were drawn from the literature, including clinical policy guidelines. For each of the presenting complaints evaluated, documentation of the majority of items reflecting the quality of care was higher during the residency period. In no instance did the level of documentation decrease., CONCLUSION: As measured by a process

evaluation, documentation of the medical record, the introduction of an emergency medicine residency significantly improved the quality of care in this urban community hospital ED.

3559. McNickle, A. G., et al. (2020). "Cervical Spine Injury is Rare in Self-Inflicted Craniofacial Gunshot Wounds: An Institutional Review and Comparison to the US National Trauma Data Bank (NTDB)." Prehospital and disaster medicine **35**(5): 524-527.

BACKGROUND: Cadaveric and older radiographic studies suggest that concurrent cervical spine fractures are rare in gunshot wounds (GSWs) to the head. Despite this knowledge, patients with craniofacial GSWs often arrive with spinal motion restriction (SMR) in place. This study quantifies the incidence of cervical spine injuries in GSWs to the head, identified using computerized tomography (CT). Fracture frequency is hypothesized to be lower in self-inflicted (SI) injuries., METHODS: Isolated craniofacial GSWs were queried from this Level I trauma center registry from 2013-2017 and the US National Trauma Data Bank (NTDB) from 2012-2016 (head or face abbreviated injury scale [AIS] >2). Datasets included age, gender, SI versus not, cervical spine injury, spinal surgery, and mortality. For this hospital's data, prehospital factors, SMR, and CTs performed were assessed. Statistical evaluation was done with Stata software, with P <.05 significant., RESULTS: Two-hundred forty-one patients from this hospital (mean age 39; 85% male; 66% SI) and 5,849 from the NTDB (mean age 38; 84% male; 53% SI) were included. For both cohorts, SI patients were older (P < .01) and had increased mortality (P < .01). Overall, cervical spine fractures occurred in 3.7%, with 5.4% requiring spinal surgery (0.2% of all patients). The frequency of fracture was five-fold greater in non-SI (P < .05). Locally, SMR was present in 121 (50.2%) prior to arrival with six collars (2.5%) placed in the trauma bay. Frequency of SMR was similar regardless of SI status (49.0% versus 51.0%; P = not significant) but less frequent in hypotensive patients and those receiving cardiopulmonary resuscitation (CPR). The presence of SMR was associated with an increased use of CT of the cervical spine (80.0% versus 33.0%; P < .01)., CONCLUSION: Cervical spine fractures were identified in less than four percent of isolated GSWs to the head and face, more frequently in non-SI cases. Prehospital SMR should be avoided in cases consistent with SI injury, and for all others, SMR should be discontinued once CT imaging is completed with negative results.

3560. McPherson, S. J. (2011). "Thorax and supra-aortic vessels." Cardiovascular and interventional radiology **34**: 346.

Learning Objectives: 1. To understand the relevant anatomy and mode of injury 2. To review the potential and results for stent graft in large and medium vessel trauma 3. To review the indications for embolization in smaller vessels using target vessel occlusion The reduced physiological insult of interventional radiology (IR) techniques, along with high rates of bleeding control, has led to them becoming the treatment of choice for most thoracic and supra-aortic vessel injuries. Stent-grafts (SG) of 3mm to 46mm are now widely available to treat vessels ranging from the vertebral artery to the thoracic aorta and have become the dominant device for injuries in this territory. Thoracic aortic injury (TAI) is the leading cause of death within 15 minutes of blunt and penetrating injuries. TAI occurs due to a complex of compression, horizontal shear and hydrostatic forces. Untreated the 10-20% pre-hospital survivors have a poor prognosis. The commonest injury site is at the aortic isthmus distal to the left subclavian artery but injuries to the aorta at the diaphragmatic hiatus should be looked for. A ductus diverticulum has obtuse angles and is readily distinguished from TAI. Great vessel injures may be coincident with TAI. Multislice CT has revealed the wide spectrum of injuries seen including intimal flaps, circumferential out-pouching (the group at highest risk of rupture), pseudo-coarctation and dissection. Not all require intervention. Even when intervention is indicated it should occur after control of other sites of active bleeding [1]. TAI is a potential site of catastrophic haemorrhage but rarely the cause of haemodynamic compromise in polytrauma patient. Young and female patients may have femoral arteries which are too small for SGs and iliac or abdominal aortic conduits may be necessary. Injuries to the iliac arteries on removal of SG systems are a significant cause of morbidity and mortality. Access for rapid balloon control must be available in every case. In lower risk TAI intervention can be delayed until the next working day if interval aggressive blood pressure control can be achieved this is not suitable for patients with traumatic brain injury who require augmentation of cerebral perfusion [2]. Smaller vessel injuries include active extravasation, pseudoaneurysms, dissection, complete transection with or without active bleeding, embolisation of metallic fragments and arterio-venous fistulation. The over-riding consideration for most great vessel injuries is to preserve ante-grade flow to vital structures whilst excluding the section of injured vessel from the circulation. SGs are the mainstay of endovascular treatment. Small subclavian branches and pulmonary arterial injuries can be treated by embolization. Uncovered stents may be used to treat occlusive dissections. Balloon tamponade may be used to control bleeding prior to IR or surgical treatment.

3561. McQuirter, J. L., et al. (2003). "Elevated blood lead resulting from maxillofacial gunshot injuries with lead ingestion." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **61**(5): 593-603.

PURPOSE: The purpose of this study was to identify the contribution of ingested lead particles to elevated blood lead concentrations in victims of gunshot injury to the maxillofacial region., PATIENTS AND METHODS: As part of a larger study of the effects of retained lead bullets on blood lead, a retrospective review of study findings was completed on 5 of 8 patients who sustained injuries to the maxillofacial region. These 5 patients were recruited into the larger study within 11 days of injury and showed a penetration path for the projectile that engaged the upper aerodigestive tract. All subjects were recruited from patients presenting for care of their gunshot injuries to a large inner-city trauma center with a retained bullet resulting from a gunshot injury. An initial blood lead level was measured for all recruited patients and repeated 1 to 17 weeks later. Medical history was taken along with a screening and risk factor questionnaire to determine other potential or actual sources (occupational/recreational) of lead exposure. (109)Cd K-shell x-ray fluorescence determinations of bone lead were completed to determine past lead exposure not revealed by medical history and risk factor questionnaire. Radiographs taken of the abdomen and chest, required as a part of the patient's hospital care, were retrospectively reviewed for signs of metallic fragments along the aerodigestive tract., RESULTS: All 5 patients retained multiple lead pellets or fragments at the site of injury, sustained fractures of the facial bones, and showed increases in blood lead. Three of the 5 study subjects who sustained maxillofacial gunshot injuries involving the mouth, nose, or throat region showed metallic densities along the gastrointestinal tract indicative of ingested bullet fragments. Each patient with ingested bullet fragments showed rapid elevation of blood lead exceeding 25 microg/dL and sustained increases well beyond the time when all ingested fragments were eliminated. A 3-year follow-up on these 3 patients showed significantly sustained elevation of blood lead but less than that observed during the initial 6 months after injury. None of the 5 study subjects showed any evidence of metallic foreign bodies within the tracheobronchial regions indicative of aspiration., CONCLUSION: Ingestion of lead fragments can result from gunshot injuries to the maxillofacial region and may substantially contribute to a rapid increase in blood lead level. Prompt diagnosis and elimination of ingested lead fragments are essential steps necessary to prevent lead being absorbed from the gastrointestinal tract. Increased blood lead in victims after gunshot injuries must be fully evaluated for all potential sources, including recent environmental exposure, absorption of lead from any remaining bullets in body tissues, and the possibility of mobilization of lead from long-term body stores such as bone. 3562. Meco, C., et al. (2010). "Transfacial transsphenoidal gunshot wound: endonasal endoscopic management." The Journal of trauma **68**(4): E94-98.

3563. Medel, N. A., et al. (2014). "Comparing early and late reconstruction of gunshot injuries to the upper and lower face." Journal of oral and maxillofacial surgery **72**(9): e228-e229.

Gunshot injuries represent one of the most challenging injury patterns to the head and neck region because they are often complex depending on the velocity and caliber of the bullet and the type of firearm. Some surgeons prefer early reconstruction including open reduction and internal fixation of osseous deformities while others advocate delayed reconstruction. The purpose of this study examined the postoperative morbidity and mortality associated with early and late reconstruction of the upper and lower face associated with gunshot injuries. We conducted a chart review of 42 cases (33 male, 9 female) of gunshot injuries to the mandible and/or midface who required operative intervention from 2007- 2013 at Parkland Memorial Hospital in Dallas Texas. Patients were stratified into two groups depending on timing of reconstruction. Reconstruction was defined as closed or open reduction in an operating room enviorment with or without debridement. The following treatments were included: 34/42 with open reduction internal fixation, 2/42 with external fixation, and 6/42 cases in closed fashion with application of arch bars. The primary outcome, minor and severe adverse events in the post operative course were compared by dividing the patients into two groups. Group 1 including patients who underwent reconstruction within first week from injury (early reconstruction or group ER). Group 2 including patients who underwent reconstruction after the first week from injury (late reconstruction or group LR). There was a total of 24 subjects in group ER and 18 subjects in group LR. The primary outcome was further stratified by the event in the post-operative courses. Normal or no adverse events (NAE) including those patients who had no

adverse events during the postoperative period and patients who required additional surgical intervention due to minor or major adverse events (MAE). Minor adverse events were defined as wound dehiscence or infection requiring local debridement or washout, in contrast to major adverse events which were defined as wound infection requiring removal of hardware and/or failure of bone graft. There were 22 subjects in group NAE, and 20 subjects in group MAE. Of the 24 subjects within group ER- 13 were in NAE, 11 in MAE. Of the 18 subjects within group LR- 9 were in NE, 9 in MAE. We conclude that both early and late reconstruction of gunshot injuries had similar post-operative course in the occurances of postoperative presence or absence of minor and major adverse events.

3564. Medicke, I. and K. Muller-Jensen (1998). "[Prognosis in orbital gunshot injuries]." Prognose orbitaler Schussverletzungen. **95**(3): 172-175.

UNLABELLED: No reviews of orbital gunshot injuries have been published in German ophthalmological journals. In this article biomechanical and prognostic factors of this rare type of injury are analysed., PATIENTS AND METHODS: We report on 4 patients, aged 20-63 years, who tried to commit suicide by shooting themselves in the right temple. Clinical and radiological diagnosis as well as treatment by an interdisciplinary team are reported., RESULTS: All patients became blind on the right side despite immediate surgery including reconstruction of the injured bones and soft tissues. Three of four patients suffered severe functional defects in the left eye; one of them is now blind., CONCLUSION: Orbital gunshot wounds are severe injuries. The prognosis depends on the course of the bullet and the interdisciplinary care.

3565. Medina, M., et al. (1992). "Clinical and neuroradiological correlations in a patient with a wandering retained air gun pellet in the brain." Surgical neurology **38**(6): 441-444.

The authors present the case of a patient with an air gun pellet that moved from the ventricular system into the subarachnoid space of C2-C3, from where it was successfully removed by interlaminotomy.

3566. Medina-Pestana, J. O., et al. (2007). "Deceased organ donation in Brazil: how can we improve?" Transplantation proceedings **39**(2): 401-402.

METHODS: We retrospectively analyzed the registry data from one organ procurement organization obtained between January 1 and December 31, 2005., RESULTS: Among the 378 potential deceased donors, 182 (48.2%) were lost, mainly due to clinical conditions (27%) or cardiac arrest (19.3%). Of the remaining 196 (51.8%) potential donors, family consent was obtained in 94 cases (48%). Family refusal was higher for potential donors aged between 18 and 59 years (70%). Of the 94 donors, 72 (77%) had their organs harvested. Cardiac arrest before harvesting (56.5%) and positive viral serology (26%) were the main reasons for further losses. The mean donor age was 40 years and 51% were men. Causes of death were cerebral vascular accidents (55.5%), cranium encephalic traumas (29%), and gun shot wounds (8%). The rate of organ donation was 100% for kidneys and livers, 96% for hearts, 86% for pancreatas, 76% for lungs, and 74% for corneas. After assessment of organ viability, 94% of corneas, 91% of kidneys, and 88% of livers were transplanted, but only 52% of pancreata and 42% of hearts. The most frequent causes of discarded organs were age and concomitant donor infection., CONCLUSION: Areas for potential improvements are: (1) earlier identification and adequate maintenance of potential donors; (2) campaigns for organ donation; and (3) careful evaluation of donated organs and selection of a suitable population to increase utilization of expanded criteria organs.

3567. Medzon, R., et al. (2005). "Stability of cervical spine fractures after gunshot wounds to the head and neck." Spine **30**(20): 2274-2279.

STUDY DESIGN: Retrospective chart review., OBJECTIVES: To determine the frequency of stable and unstable cervical spine fractures after gunshot wounds to the head or neck; to identify potential risk factor(s) for an unstable versus stable cervical spine fracture., SUMMARY OF BACKGROUND DATA: Cervical spine fractures after gunshot wounds to the head and neck are common. Because of the nature of their injuries, patients often present with concomitant airway obstruction and large blood vessel injury that can necessitate emergent procedures. In some cases, acute treatment of these problems can be hindered by the presence of a cervical collar or strict adherence to spinal precautions (i.e., patient laying supine). In such situations, information regarding the probability of a stable versus unstable cervical spine fracture would be useful in emergency treatment decision making., METHODS: A search for patients with gunshot wounds to the head or neck potentially involving the cervical spine over a 13-year period was

performed using a trauma registry. Individuals with cervical spine fractures were identified and their records reviewed in detail. Data collected included information about neurologic deficits, mental status, airway treatment, entrance wounds, fracture level/type, initial/definitive fracture treatment, and final disposition at hospital discharge., RESULTS: A total of 81 patients were identified; 19 had cervical spine fractures. There were 5 patients who were not examinable because of altered mental status (severe head trauma, hemorrhagic shock, or intoxication). All 5 patients had stable cervical spine fractures. There were 11 patients who had an acute spinal cord injury, 3 (30%) of whom underwent surgery for an unstable fracture. Of the 65 awake, alert patients without a neurologic deficit, only 3 (5%) had a fracture, none of which were unstable., CONCLUSIONS: Gunshot wounds to the head and neck had a high rate of concomitant cervical spine fracture. Neurologically intact patients have a lower rate of fracture than those presenting with a spinal cord injury or altered mental status. In this small series of patients, the only unstable cervical spine injuries were detected in patients with a spinal cord injury. The data suggest that spinal precautions and/or a hard cervical collar should not be maintained at the expense of delaying or hindering emergent life-saving airway or hemodynamically stabilizing procedures, particularly in awake, neurologically intact patients. However, the cervical collar and spinal precautions should be resumed after such procedures are completed and continued until a more definitive evaluation of spinal stability can be performed.

3568. Meer, E., et al. (2021). "Clinical presentation and outcomes for gunshot wounds to the orbit." Investigative Ophthalmology and Visual Science **62**(8).

Purpose : To characterize the clinical presentation, surgical management, long-term complications and outcomes of gunshot wounds to the orbit. Methods : A retrospective chart review was conducted of all cases of gunshot wounds involving the orbit at an academic institution with a level 1 trauma center. Data included patient demographics, clinical presentation and exam over time, surgical intervention, and long-term outcomes. Descriptive statistics were calculated using mean and standard deviation for continuous measures and frequency and percentage for categorical measures. Tests of associations included Fishers exact tests for categorical data, KruskalWallis rank sum tests, ANOVA, and in the case of repeated measures, generalized estimating equations. Results : 88 patients with a history of gunshot wound involving the orbit were included with average age of 32.6 years old. Patient were 85.2% male, 75% African-American, 25% Caucasian, and 5.7% Hispanic. Mean follow up was 8.25 years. While injury varied, 53.4% presented with intracranial injury, 21.6% presented with open globe rupture, 80.7% with orbital fracture, 89.8% with lid laceration, 88.6% with vision loss, 92% with pain, and 76.1% with bullet fragments in the orbit on imaging.Surgery occurred for 59.1% of patients, of which 26.9% underwent primary enucleation, 11.5% evisceration, 44.2% fracture repair, and 17.3% another procedure (craniotomy, complex laceration repair, etc). Long-term complications included abnormal lid or globe position in 26.1% of patients, reduced visual acuity in 55.2%, and persistent pain in 50.6%. Predictors on initial presentation for persistent pain included intracranial injury (p=.003), pain (p=.006), presence of radiographic intraorbital foreign body (bullet/ bullet fragments) (p=.002), abnormal CNV2 sensation (p=.041), and corneal abrasion (p=.031) on clinical exam. Visual acuity improvement over time in individuals who did not receive enucleation or evisceration on presentation was not significant (p = .09). Worsening visual acuity was significantly associated with hyphema, vision loss, and presence of intraorbital foreign body on presentation (p<.05) Conclusions : To our knowledge, this represents the first, largest clinical epidemiologic study that serves to provide insight into the clinical presentation, surgical intervention, and long-term outcomes of gunshot wounds to the orbit, which will guide both ophthalmologists and trauma physicians.

3569. Meer, M., et al. (2010). "Knife inflicted penetrating injuries of the maxillofacial region: a descriptive, record-based study." Injury **41**(1): 77-81.

UNLABELLED: Penetrating knife injuries of the face are more common in South Africa than the rest of the world. These injuries can be life-threatening, especially where the major blood vessels of the face are involved. The approach to treatment should be multidisciplinary, beginning with the trauma unit to provide airway maintenance and haemodynamic stabilisation. An interventional radiologist may be consulted for angiography. The aim of the present study was to retrospectively analyse all cases of knife-inflicted penetrating injuries to the maxillofacial region with the knife in situ and subsequently develop a management protocol to be used by maxillofacial surgery registrars when presented with such cases., MATERIALS AND METHODS: It was a retrospective, cross-sectional and record-based study, analysing all penetrating knife injuries reported at various hospitals for a period of 11 years. In this study, 24 cases of knife injuries were analysed., RESULTS: Twenty-one patients (87.5%) in this series were male and three (12.5%) were

female. Of these 24 patients, 13 (54.2%) were coloured and 11 (45.8%) were black. There were no white or Indian patients. Post-surgical recovery of all patients was rapid and uneventful, and there were no fatalities., CONCLUSION: Patients with knife injuries to the face with no definite signs of vascular injury can thus be safely and accurately managed on the basis of physical examination and plain-film radiography. An angiogram is mandatory if the patient presents with excessive bleeding, an expanding haematoma or if the knife blade is in the region of any large vessels.

3570. Megele, R., et al. (1990). "[Trans-sphenoid gunshot injury of the head. Anatomic viewpoints]." Die transsphenoidale Kopfschussverletzung. Anatomische Gesichtspunkte. **20**(1): 44-47.

The transsphenoidal gunshot injury of the head is a subgroup of the temporal gunshot injury, generally with a bad prognosis quoad vitam. Important neural and vascular structures could be damaged by penetration of the missile. In our case the important structures were "missed" exactly and the patient survived without severe neurological deficits. With this case anatomical considerations of the transsphenoidal gunshot injury are made.

3571. Meguro, K. and D. W. Rowed (1985). "Traumatic aneurysm of the posterior inferior cerebellar artery caused by fracture of the clivus." Neurosurgery **16**(5): 666-668.

The authors present a case of traumatic aneurysm of the posterior inferior cerebellar artery produced by fracture of the clivus. Varieties of clival fractures reported in the literature are reviewed. Associated basilar or carotid arterial lesions have been reported, but traumatic aneurysm, so far as we are aware, has not. The authors emphasize the importance of a high index of suspicion of undetected traumatic intracranial aneurysm when an unusual amount of subarachnoid hemorrhage is noted on the initial computed tomographic scan, particularly if associated with displaced basal skull fracture.

Amniotic membrane grafts are used extensively for ocular surface reconstruction. We describe the case of a 66-year-old man with traumatic, restrictive strabismus. Amniotic membrane was applied to resolve symblepharon between the globe and lids and also to prevent re-formation of adhesions between extraocular muscles and adjacent titanium plates placed during prior surgery.

3573. Mehta, A. I. and C. A. Bagley (2011). "Gunshot wound to the clivus." British journal of neurosurgery **25**(1): 136-137.

A 14 year old boy presents with a gunshot wound into the roof of his mouth to lodge into the clivus, and miraculously he is neurologically intact.

3574. Mehta, Z. and F. Newcombe (1996). "Dissociable contributions of the two cerebral hemispheres to judgments of line orientation." Journal of the International Neuropsychological Society : JINS **2**(4): 335-339.

A previous study of the performance of men with chronic unilateral focal brain lesions (due to wartime missile injury) on a standard test of line orientation suggested a left hemisphere (LH) as well as a right hemisphere (RH) contribution to visuospatial processing. The present study was designed to fractionate the variables that could underlie this unexpected finding and thereby to tease out the mechanisms involved in LH as compared with RH processing. A simpler ("purer") version of the standard line orientation task was used, as were two other versions in which matching in an array and matching with distractors were measured. The findings confirmed the hypothesis of RH involvement in the purer task of metric measurement and suggested that the LH has an important role in keeping track decisions and updating decisions in more complex aspects of line orientation judgment.

3575. Mehta, Z. and F. Newcombe (1996). "Selective loss of verbal imagery." Neuropsychologia **34**(5): 441-447.

This single case study of the ability to generate verbal and non-verbal imagery in a woman who sustained a gunshot wound to the brain reports a significant difficulty in generating images of word shapes but not a significant problem in generating object images. Further dissociation, however, was observed in her ability to generate images of living vs non-living material. She made more errors in imagery and factual information tasks for non-living items than for living items. This pattern contrasts with our previous report of the agnosic patient, M.S., who had severe difficulty in generating images of living material, whereas his ability to image the shape of words was comparable to that of normal control subjects. Furthermore, with regard to the generation of images of living compared with non-living material, M.S. shows more errors with living than nonliving items. In contrast, the present patient, S.M., made significantly more errors with non-living relative to living items. There appear to be two types of double dissociation which reinforce the growing evidence of dissociable impairments in the ability to generate images for different types of verbal and non-verbal material. Such dissociations, presumably related to sensory and cognitive processing demands, address the problem of the neural basis of imagery.

3576. Mehvari, J., et al. (2014). "Cardiac arrest associated with epileptic seizures: A case report with simultaneous EEG and ECG." Epilepsy & behavior case reports **2**: 145-151.

Ictal asystole is a rare, probably underestimated manifestation of epileptic seizures whose pathophysiology is still debated. This report describes two patients who had cardiac asystole at the end of their seizure. The first patient was a 13-year-old boy with complex partial seizures.. His MRI showed symmetrical signal abnormality in the bilateral parietooccipital lobe accompanied by mild gliosis and volume loss. During a 3-day long-term video-EEG monitoring, he had cardiac arrest at the end of one of his seizures that was secondarily generalized. The second one was a 42-year-old veteran with penetrating head trauma in the left frontal lobe due to shell injury. During long-term video-EEG monitoring, he had one generalized tonic-clonic seizure accompanied by bradycardia and cardiac asystole. Asystoles could have a role in the incidence of sudden unexpected death in epilepsy (SUDEP), meaning that the presence of ictal bradycardia is a risk factor for SUDEP. In cases of epileptic cardiac dysrhythmia, prolonged simultaneous EEG/ECG monitoring may be required. Cardiological investigation should be included in epilepsy management.

3577. Mei, Q.-Y., et al. (2017). "Combination of dura turning-over and decompressive craniectomy: a new pattern of surgery for cerebral infarction caused by craniocerebral gunshot injury." Military Medical Research **4**: 26.

BACKGROUND: Craniocerebral gunshot injury refers to a wound caused by a bullet passing through or lodged in brain tissue, resulting in the loss of function of a certain area or other fatal damage to the human brain. Craniocerebral gunshot injury is usually life-threatening and is very common in modern warfare, accounting for the majority of battle casualties. Most of the patients suffer from acute cerebral infarction caused by vascular injury. Lack of early and solid battlefield emergency medical interference adds to the risk of death among the wounded., CASE PRESENTATION: We present a 24-year-old man who was shot with a shotgun from a distance of 15 m in an accidental injury. Forty-seven grapeshots were found on his body surface by physical examination. A computed tomography (CT) scan demonstrated large areas of low-density shadows in his right parietal lobe and right temporal lobe with the midline shifting to the left side 2 days later. Afterwards, the patient was transferred to our emergency medical center at Changzheng Hospital in Shanghai. Cranial computed tomography angiography (CTA) showed a high-density shadow in the initial part of the right middle cerebral artery. The branches after the initial part were obliterated. Prompt medical attention and decompressive craniotomy (DC) surgery contributed to the final recovery from cerebral infarction of this patient., CONCLUSION: Bullets can penetrate or be lodged in the brain, causing intracranial hypertension. The bullets lodged in the brain can result in stenosis and embolism of a cerebral artery, causing acute cerebral infarction. Combining dura turning-over surgery with DC surgery can not only decrease intracranial pressure, which can increase the blood supply for hypertension-induced vessel stenosis, but also help vessels outside the dura mater grow into ischemic areas of the cerebral cortex. However, this new pattern of surgery needs further support from evidence-based medicine.

3578. Meier, U., et al. (1987). "[Penetrating craniocerebral injury]." Die penetrierende Schadel-Hirn-Verletzung. **112**(23): 1473-1480.

Through a ten-year period, treatment was applied to 145 patients for open craniocerebral injuries in the calottal region. Mortality amounted to 35 per cent and postoperative infections to 16 per cent. Early or, in cases of intracranial invasive growths, immediate surgery with purpose-oriented osteoplastic trepanation is the optional method.

3579. Meirowsky, A. M. (1956). "Increased intracranial pressure in penetrating craniocerebral trauma." Military medicine **118**(5): 488-492.

3580. Meirowsky, A. M. (1968). "The retention of bone fragments in brain wounds." Military medicine **133**(11): 887-890.

3581. Meirowsky, A. M. (1982). "Secondary removal of retained bone fragments in missile wounds of the brain." Journal of neurosurgery **57**(5): 617-621.

Secondary operations for the removal of retained bone fragments have been performed in 116 of the 1133 casualties with craniocerebral missile wounds incurred in the war in Vietnam, 1967 to 1970. Various complications developed in 19 of these 116 casualties. Dehiscence of the wound occurred in eight patients, five of whom developed a cerebrospinal fluid fistula. Infection manifested itself in 16 cases with retained bone fragments prior to their secondary removal; however, infection first became apparent after the secondary operation in seven patients. Two of the seven patients with infection died. The neurological deficit became worse in four of the 116 patients following the secondary removal of a bone fragment: there was complete resolution of that deficit in one, and return to the neurological status existing after the initial operation in another; the other two patients developed a permanently disabling neurological deficit, an incidence of 1.7%.

3582. Meirowsky, A. M., et al. (1981). "Cerebrospinal fluid fistulas complicating missile wounds of the brain." Journal of neurosurgery **54**(1): 44-48.

The records of 101 casualties of the war in Vietnam have been analyzed, with particular attention to missile wounds of the brain complicated by a cerebrospinal fluid (CSF) fistula. Fifty-four developed CSF drainage at the wound site, 30 presented with rhinorrhea, and 23 with otorrhea. Fifty of the 101 men developed infection, an incidence of 49.5%. The occurrence of a fistula in vertex wounds can usually be traced to failure to close the dura, or to achieve watertight closure of the dura primarily, or by graft. Approximately two-thirds of compound basilar fractures, complicated by rhinorrhea or otorrhea, are due to direct fractures of the anterior, middle, or posterior fossa. The remaining one-third are due to elusive "discrete" fractures of the base of the skull, occurring at a distance from the entry wound, and not in continuity with the fracture of the vault. While direct basilar fractures can readily be recognized, facilitating repair of the dura overlying the basilar fractures, "discontinuous" fractures pose a challenging diagnostic problem. More commonly occurring in vertex wounds crossing the midline, discontinuous fractures producing rhinorrhea or otorrhea may be identified with the aid of tomograms of the base of the skull. Their early diagnosis may well prove to be a significant factor in the reduction of morbidity and mortality of missile wounds of the brain complicated by a CSF fistula.

3583. Meizoso, J. P., et al. (2016). "Effect of time to operation on mortality for hypotensive patients with gunshot wounds to the torso: The golden 10 minutes." The journal of trauma and acute care surgery **81**(4): 685-691.

INTRODUCTION: Timely hemorrhage control is paramount in trauma; however, a critical time interval from emergency department arrival to operation for hypotensive gunshot wound (GSW) victims is not established. We hypothesize that delaying surgery for more than 10 minutes from arrival increases all-cause mortality in hypotensive patients with GSW., METHODS: Data of adults (n = 309) with hypotension and GSW to the torso requiring immediate operation from January 2004 to September 2013 were retrospectively reviewed. Patients with resuscitative thoracotomies, traumatic brain injury, transfer from outside institutions, and operations occurring more than 1 hour after arrival were excluded. Survival analysis using multivariate Cox regression models was used for comparison. Hazard ratios (HRs) and 95% confidence intervals (CIs) are reported. Statistical significance was considered at $p <= 0.05$., RESULTS: The study population was aged 32 +/- 12 years, 92% were male, Injury Severity Score was 24 +/- 15, systolic blood pressure was 81 +/- 29 mm Hg, Glasgow Coma Scale score was 13 +/- 4. Overall mortality was 27%. Mean time to operation was 19 +/- 13 minutes. After controlling for organ injury, patients who arrived to the operating room after 10 minutes had a higher likelihood of mortality compared with those who arrived in 10 minutes or less (HR, 1.89; 95% CI, 1.10-3.26; $p = 0.02$); this was also true in the severely hypotensive patients with systolic blood pressure of 70 mm Hg or

less (HR, 2.67; 95% CI, 0.97-7.34; p = 0.05). The time associated with a 50% cumulative mortality was 16 minutes., CONCLUSIONS: Delay to the operating room of more than 10 minutes increases the risk of mortality by almost threefold in hypotensive patients with GSW. Protocols should be designed to shorten time in the emergency department. Further prospective observational studies are required to validate these findings., LEVEL OF EVIDENCE: Therapeutic study, level IV.

3584. Melada, A., et al. (2002). "Cerebrospinal fluid fistula as a consequence of war head injury." Military medicine **167**(8): 666-670.

Cerebrospinal fluid (CSF) fistula as a consequence of brain missile injury and following infectious complications has been recognized for years. Different methods of treatment have been advocated. Missiles used in war cause extensive destruction of the skull and brain as a result of their high kinetic energy. On its transfer through the skull, such high kinetic energy causes fractures called "discontinuous fractures," which are distant from the entry wound and not related to the fracture of the vault. The role of the timely diagnosis of CSF fistulas and their early repair in the management of these wounds is emphasized. Data on 312 patients with missile injuries of the brain inflicted during the war in Croatia were retrieved and analyzed, with special reference to the complications of CSF fistulas and infection. Forty-five patients developed CSF fistula, 15 (33%) of them at the wound site, 23 (51%) as CSF rhinorrhea, and seven (15%) as CSF otorrhea. Six patients developed infectious complications. The presented strategy and operative approach resulted in a low incidence of infectious complications in the study series.

3585. Melada, A., et al. (1993). "Analysis of projectile destructive effect in missile injury to the brain." Acta medica Croatica : casopis Hravatske akademije medicinskih znanosti **47**(3): 135-140.

During the war in Croatia so far, more than 250 casualties having missile wounds of the brain, spinal chord and peripheral nervous system were admitted to the Neurosurgical Clinic, University Hospital-Rebro. These injuries were mainly caused by low-velocity missiles. However, the high-velocity ones, used nowadays, in direct injury to the head, cause destruction of the brain that is incompatible with survival in most of the cases. This paper deals with a patient injured by a 7.62 mm projectile. The mechanism of the brain destruction is not completely clear since the missile was found at the very entrance of the missile wound, while the brain was destroyed up to the opposite side of the endocranium. Four mechanisms of the missile's effect aimed at explaining the cause of death of the patient, as well as the bizarre position of the missile, were taken into consideration. The review shows how perilous a wound from a direct missile injury to the head could be, regardless of its speed.

3586. Melinosky, C., et al. (2018). "Modeling autonomic dysfunction during acute resuscitation to predict neurological worsening after isolated head injury." Journal of neurotrauma **35**(16): A149-A150.

Introduction: Early recognition of neurologic worsening (NW) after traumatic brain injury (TBI) could allow for the development of targeted therapies aimed at preventing secondary injury after TBI. We hypothesized that autonomic nervous system (ANS) dysfunction measured by variables derived from electrocardiogram (ECG) or photoplethysmogram (PPG) within first hour of arrival to the Trauma Resuscitation Unit (TRU) may enhance the ability to predict NW in the initial 48 hours after TBI. Methods: Patients enrolled in the prospective study Oximetry and Noninvasive Predictors Of Intervention Need after Trauma (ONPOINT) who had isolated head injury were analyzed. NW was defined as any of the following occurring in the first 48 hours: new asymmetric pupillary dilatation(>2mm), 2 point GCS decline, interval worsening of CT scan as assessed by the Marshall score, or intervention for cerebral edema. Beat-to-beat variation of ECG or PPG, as well as waveform features during the first 15 minutes and 60 minutes after arrival in the TRU were analyzed to determine physiologic parameters associated with future NW. Physiologic factors along with admission clinical variables were combined in multivariable logistic regression models predicting NW and inpatient mortality. Results: There were 191 patients (mean age 43 years old, GCS 13, ISS 12, 69% men) who met study criteria. NW occurred in 33(17%) patients and was associated a greater likelihood of ICU admission (P < 0.001) and inpatient mortality (P < 0.001). Both ECG (AUROC: 0.84, 95% CI: 0.76,0.93) and PPG (AUROC: 0.87, 95% CI: 0.80, 0.93) analyses during the first 15 minutes of resuscitation demonstrated a greater ability to predict NW then clinical characteristics alone (AUROC: 0.69, 95% CI: 0.59, 0.8). Age (P = 0.02), Marshall score (P = 0.001), penetrating injury(P = 0.02), and predictive probability for NW by PPG analysis at 15 minutes (P = 0.03) were independently associated with inpatient mortality. Conclusion: ANS

dysfunction assessed by continuous ECG or PPG variability and waveform analysis in the first hour of resuscitation may represent a non-invasive early marker of future neurological deterioration and inpatient mortality after TBI.

3587. Melinosky, C., et al. (2018). "Continuous vital sign analysis to predict secondary neurological decline after traumatic brain injury." Frontiers in neurology **9**(SEP).

Background: In the acute resuscitation period after traumatic brain injury (TBI), one of the goals is to identify those at risk for secondary neurological decline (ND), represented by a constellation of clinical signs that can be identified as objective events related to secondary brain injury and independently impact outcome. We investigated whether continuous vital sign variability and waveform analysis of the electrocardiogram (ECG) or photoplethysmogram (PPG) within the first hour of resuscitation may enhance the ability to predict ND in the initial 48 hours after traumatic brain injury (TBI). Methods: Retrospective analysis of ND in TBI patients enrolled in the prospective Oximetry and Noninvasive Predictors Of Intervention Need after Trauma (ONPOINT) study. ND was defined as any of the following occurring in the first 48 h: New asymmetric pupillary dilatation (>2 mm), 2 point GCS decline, interval worsening of CT scan as assessed by the Marshall score, or intervention for cerebral edema. Beat-to-beat variation of ECG or PPG, as well as waveform features during the first 15 and 60 min after arrival in the TRU were analyzed to determine physiologic parameters associated with future ND. Physiologic and admission clinical variables were combined in multivariable logistic regression models predicting ND and inpatient mortality. Results: There were 33 (17%) patients with ND among 191 patients (mean age 43 years old, GCS 13, ISS 12, 69% men) who met study criteria. ND was associated with ICU admission ($P < 0.001$) and inpatient mortality ($P < 0.001$). Both ECG (AUROC: 0.84, 95% CI: 0.76,0.93) and PPG (AUROC: 0.87, 95% CI: 0.80, 0.93) analyses during the first 15 min of resuscitation demonstrated a greater ability to predict ND then clinical characteristics alone (AUROC: 0.69, 95% CI: 0.59, 0.8). Age ($P = 0.02$), Marshall score ($P = 0.001$), penetrating injury ($P = 0.02$), and predictive probability for ND by PPG analysis at 15 min ($P = 0.03$) were independently associated with inpatient mortality. Conclusions: Analysis of variability and ECG or PPG waveform in the first minutes of resuscitation may represent a non-invasive early marker of future ND.?

3588. Melki, J. A. D., et al. (2011). "Scanning electron microscopy as an auxiliary method in the study of exhumed bones." Forensic science international **206**(1-3): e67-70.

Scanning electron microscopy (SEM) has been used in forensic science in many ways. The reports of cases in which SEM has been used as an auxiliary method in the investigation of exhumed bones are rare. In this article, we report an exhumation that was made to determine if a seized weapon could have been used in a homicide. We used SEM to analyze a fracture in the interior of the skull of the victim. The findings described in this article showed us that it is possible to develop new researches in this field.

3589. Meller, D., et al. (1993). "Immunohistochemical studies with antibodies to neurofilament proteins on axonal damage in experimental focal lesions in rat." Journal of the neurological sciences **117**(1-2): 164-174.

Immunohistochemistry with monoclonal antibodies against neurofilament (NF) proteins of middle and high molecular weight class, NF-M and NF-H, was used to study axonal injury in the borderzone of focal lesions in rats. Focal injury in the cortex was produced by infusion of lactate at acid pH or by stab caused by needle insertion. Infarcts in substantia nigra pars reticulata were evoked by prolonged pilocarpine-induced status epilepticus. Immunohistochemical staining for NFs showed characteristic terminal clubs of axons in the borderzone of lesions. Differences in the labelling pattern occurred with different antibodies which apparently depended on molecular weight class of NFs and phosphorylation state. These immunohistochemical changes of NFs can serve as a marker for axonal damage in various experimental traumatic or ischemic lesions.

3590. Mellington, F. E., et al. (2014). "Orbital compressed air and petroleum injury mimicking necrotizing fasciitis." The Journal of emergency medicine **47**(3): e69-72.

BACKGROUND: Orbital injury secondary to petroleum-based products is rare. We report the first case, to our knowledge, of a combined compressed air and chemical orbital injury, which mimicked necrotizing fasciitis., CASE REPORT: A 58-year-old man was repairing his motorcycle engine when a piston inadvertently fired, discharging compressed air and petroleum-based carburetor cleaner into his left eye. He developed surgical emphysema, skin

necrosis, and a chemical cellulitis, causing an orbital compartment syndrome. He was treated initially with antibiotics and subsequently with intravenous steroid and orbital decompression surgery. There was almost complete recovery by 4 weeks postsurgery. WHY SHOULD AN EMERGENCY PHYSICIAN BE AWARE OF THIS?: Petroleum-based products can cause severe skin irritation and necrosis. Compressed air injury can cause surgical emphysema. When these two mechanisms of injury are combined, the resulting orbitopathy and skin necrosis can mimic necrotizing fasciitis and cause diagnostic confusion. A favorable outcome is achievable with aggressive timely management.

3591. Melmer, P., et al. (2021). "Managing Craniomaxillofacial Injury Without Inpatient Consult: Outcomes and Patient Cost Savings." The American surgeon **87**(11): 1836-1838.

BACKGROUND: We hypothesized that trauma surgeons can safely selectively manage traumatic craniomaxillofacial injuries (CMF) without specialist consult, thereby decreasing the overall cost burden to patients., METHODS: A 4-year retrospective analysis of all CMF fractures diagnosed on facial CT scans. CMF consultation was compared with no-CMF consultation. Demographics, injury severity, and specialty consultation charges were recorded. Penetrating injuries, skull fractures, or patients completing inpatient craniofacial surgery were excluded., RESULTS: 303 patients were studied (124 CMF consultation vs 179 no-CMF consultation), mean age was 47.8 years, with 70% males. Mean Glasgow Coma Scale and Injury Severity Score (ISS) was 14 +/- 3.4 and 10 +/- 9, respectively. Patients with CMF consults had higher ISS ($P < .001$) and needed surgery on admission ($P < .001$), while no-CMF consults had shorter length of stay ($P < .002$). No in-hospital mortality or 30-day readmission rates were related to no-CMF consult. Total patient charges saved with no-CMF consultation was $26 539.96., DISCUSSION: Trauma surgeons can selectively manage acute CMF injuries without inpatient specialist consultation. Additional guidelines can be established to avoid tertiary transfers for specialty consultation and decrease patient charges.

3592. Melo, A. R., et al. (2012). "Conservative treatment of comminuted mandibular fracture involving maxillomandibular fixation with miniplates." The Journal of craniofacial surgery **23**(3): 893-895.

Bars and steel wires are the most commonly used methods to achieve maxillomandibular fixation, although there are numerous alternatives described for this same purpose. In cases of edentulous candidates for the conservative treatment of facial fractures, none of the conventional methods can be instituted for maxillomandibular fixation. Fixation in such cases is achieved with the aid of the total dentures of the patient or the confection of splints, but these methods lead to eating and oral hygiene problems. This article reports the case of an edentulous patient with a comminuted mandible fracture treated with a rarely described technique in which intermaxillary fixation was achieved with titanium miniplates.

3593. Meloni, S. M., et al. (2015). "Guided implant surgery after free-flap reconstruction: Four-year results from a prospective clinical trial." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **43**(8): 1348-1355.

AIM: The aim of this prospective clinical study is to assess the 4-year outcomes of implant-supported restorations performed using a computer-guided template-assisted flapless implant surgery approach in patients reconstructed with fibula or iliac crest free flaps., MATERIALS AND METHODS: Twelve jaws in 10 patients were reconstructed with osteomyocutaneous free flap after tumour resection or gunshot wound, after complete healing computer-assisted template-based flapless implant placement, based on prosthetic and aesthetic analysis, was performed using a customized protocol. Treatment success was evaluated using the following parameters: survival of implants/prostheses, prosthetic and biologic complications, marginal bone remodelling, soft tissue parameters and patient satisfaction., RESULTS: A total of 56 implants were placed; the implants ranged between 8 and 16 mm in length and were either 3.5, 4.3 or 5 mm wide. All the patients have reached the 4-year follow-up. Three implants were lost accounting for an overall implant survival rate of 94.6%. No prosthesis were lost. Some complications were recorded. Four years after loading the mean marginal bone loss was 1.43 +/- 0.49 mm at the palatal/lingual site and 1.48 +/- 0.46 mm at the vestibular site. All the patients showed healthy soft tissues with stable probing depth (4 .93 +/- 0.75%) and successful bleeding on probing values (12 +/- 5.8%); 90% of patients were satisfied of the treatment at the 4-year follow-up., CONCLUSIONS: Computer-guided template-assisted flapless implant surgery seems to be a viable option for patients undergoing reconstruction with free flaps after tumour resection or gunshot trauma, although many challenges remain.

A high degree of patient satisfactorily was reported.

3594. Menawat, S. S., et al. (1992). "Are arteriograms necessary in penetrating zone II neck injuries?" Journal of vascular surgery **16**(3): 397-391.

The evaluation and management of potential arterial injuries in penetrating neck trauma are controversial. Routine surgical exploration or arteriography can be very expensive and time-consuming and can overburden available resources if used in all patients. We reviewed the records of 4035 patients seen in our trauma center during a 20-month period and identified a total of 110 patients (2.7%) with penetrating wounds to zone II of the neck; 50 were from gunshot wounds, 43 from stab wounds, 7 from shotgun injuries, and 10 from lacerations. In 42 (39%) patients there was no arteriogram or surgery based on location of the wounds or lack of any physical findings. None of these patients later had any evidence of an arterial injury. Forty-five patients (40%) had arteriograms based on proximity or a "soft" sign of vascular injury, which included evidence of significant bleeding or a stable hematoma. A total of 15 injuries to major arteries were identified: 3 common carotid, 5 internal carotid, and 7 vertebral. One patient died during initial resuscitation, and four patients went directly to surgery with no preoperative arteriogram for active bleeding and expanding hematoma (n = 1), an expanding hematoma (n = 2), and a large, stable hematoma (n = 1). Only one patient (of the 110) had a significant major arterial injury requiring surgery that was not predicted by physical findings. Nine arterial injuries were treated nonoperatively: six vertebral, two common carotid intimal flaps, and one small distal internal carotid pseudoaneurysm (diagnosed late). Three additional minor external carotid artery injuries were observed with no adverse sequelae.(ABSTRACT TRUNCATED AT 250 WORDS)

3595. Meng, F.-W., et al. (2021). "New lymphatic cell formation is associated with damaged brain tissue clearance after penetrating traumatic brain injury." Scientific reports **11**(1): 10193.

We characterized the tissue repair response after penetrating traumatic brain injury (pTBI) in this study. Seventy specific pathogen-free Kunming mice were randomly divided into the following groups: normal control, 1, 3, 7, 15, 21, and 30 days after pTBI. Hematoxylin and eosin (H&E) staining, immunohistochemistry, and immunofluorescence were performed to examine and monitor brain tissue morphology, and the distribution and expression of lymphatic-specific markers lymphatic vessel endothelial receptor-1 (LYVE-1), hematopoietic precursor cluster of differentiation 34 (CD34) antigen, and Prospero-related homeobox-1 (PROX1) protein. H&E staining revealed that damaged and necrotic tissues observed on day 1 at and around the injury site disappeared on day 7, and there was gradual shrinkage and disappearance of the lesion on day 30, suggesting a clearance mechanism. We explored the possibility of lymphangiogenesis causing this clearance as part of the post-injury response. Notably, expression of lymphangiogenesis markers LYVE-1, CD34, and PROX1 was detected in damaged mouse brain tissue but not in normal tissue. Moreover, new lymphatic cells and colocalization of LYVE-1/CD34 and LYVE-1/PROX1 were also observed. Our findings of the formation of new lymphatic cells following pTBI provide preliminary insights into a post-injury clearance mechanism in the brain. Although we showed that lymphatic cells are implicated in brain tissue repair, further research is required to clarify the origin of these cells.

3596. Meng, X., et al. (2013). "A telemetry-based neuromonitoring system: Validation in a swine model of closed-head rotational acceleration-induced TBI." Journal of neurotrauma **30**(15): A127.

Introduction Invasive neuromonitoring is common practice in neurointensive care, sometimes involving intracranial pressure (ICP), brain temperature, pH, and oxygen measurements. These currently use wired probes that penetrate the brain for short periods; however, an implanted wireless monitor may simplify clinical and research protocols by offering semi-invasive, long-term measurement following brain injury. Methods A custom-built, fully implantable, wireless device was used to measure ICP and temperature that consisted of a 2.4 GHz transceiver and ultra-low-power microcontroller, a custom designed PIFA/Annular Slot antenna (to transmit data up to 17m), with pressure readings from a capacitive MEMS sensor. All electronics and battery were maintained in a titanium case (2.2cm × 2.8cm) and encapsulated with medical grade epoxy. Devices were implanted into anesthetized Yorkshire swine ~24 hours prior to injury, which required a minimally invasive surgical procedure with the device placed over the skull with a 5.1-mm diameter transcranial burr hole to allow sensor contact with the cerebrospinal fluid (CSF). Non-impact TBI was induced via rapid head rotational velocity/acceleration using the Hyge pneumatic actuator. Head rotation was in the sagittal

plane at levels established to be moderate-to-severe (peak rotational velocities: 105 ± 138 rad/s). Animals were sacrificed within 6 hours and the brains processed for gross and histopathology. Results We developed a small fully embedded wireless device capable of continuously measuring ICP following brain injury. In particular, brain injury may result in devastating increases in ICP due to vascular compromise and secondary sequelae causing edema, and the control of increased ICP is a major therapeutic goal across a range of TBI severities. To validate these custom-built devices, dynamic ICP changes were measured in a swine model of closed-head rotational TBI. Following implant, baseline ICP readings were relatively stable over the 8 hours prior to injury at 16.7 ± 4.6mm Hg (mean - standard deviation). We found that closed-head rotation TBI induced a rapid and extreme ICP spike occurring directly upon injury (max ICP > 115mm Hg). Notably, device integrity and positioning remained suitable for dynamic post-injury ICP readings, which is impressive given the forces necessary to generate the rapid head rotation in swine (peak angular acceleration of over 50,000 rad/sec2). The acute elevation in ICP generally lasted for 40-60 minutes, followed by a gradual decline to maintain an elevated level over several hours post-injury. This trend of an immediate ICP spike before decreasing to persist at elevated levels has not previously been observed following closed-head injury. To confirm our measurements, the gold standard Camino ICP monitor (1104B, Integra Life Sciences) was introduced into the parenchyma 1-3 hours post-injury (placed contralateral to wireless device). Over multiple trials, Camino measurements were within 10% of concurrent measurements with wireless devices, with discrepancies potentially attributed to different placement (intraparenchyma versus subdural). Gross pathology revealed subdural hematoma in animals experiencing immediate ICP changes, whereas persistently elevated ICP was likely influenced by both cytotoxic and vasogenic edema. Conclusions We have validated a novel implantable wireless device capable of measuring ICP changes following brain injury. Specifically, we have demonstrated dynamic ICP increases as an immediate consequence of moderate-to-severe head rotational acceleration-induced TBI in swine. This miniature, implantable device may be utilized as a tool to diagnose and track ICP changes following TBI for a range of severities with diminished risk of infection. Moreover, this telemetrybased neuromonitoring system serves as a robust platform that may be expanded to include other critical physiological modalities such as cerebral oxygen and blood flow. Based on experimental objectives, these data can be transmitted continuously (up to 17 meters) o er extended time periods following injures at a range of severities, during acute recovery as well as later in awake, behaving animals post-injury.

3597. Menger, R., et al. (2017). "A Political Case of Penetrating Cranial Trauma: The Injury of James Scott Brady." Neurosurgery **81**(3): 545-551.

James Brady, the White House press secretary during President Ronald Reagan's first term in office, was 1 of 4 people (including the President) wounded during an attempted assassination attempt on President Reagan's life on March 30, 1981. John Hinckley, Jr. was found not guilty of this attempt by reason of insanity. The assassination attempt was a ploy by Hinckley, Jr. to impress the actress Jodie Foster. Brady was the most seriously injured of the 4 who were wounded. He suffered a gunshot wound to the left forehead that traveled through the left frontal lobe, corpus callosum, and then into the right frontal and temporal lobes. He initially required a bifrontal craniotomy for evacuation of a right frontotemporal intraparenchymal hemorrhage and debridement of tract. His postoperative course was complicated by seizures, cerebrospinal fluid leakage (necessitating multiple reparative procedures), aspiration pneumonia, and pulmonary emboli. Despite the severity of his injury and perioperative morbidities, Mr. Brady made good recovery. Although permanently left with residual weakness on the left side of his body, making a wheelchair necessary, Brady maintained cognitive and personality traits that were very close to his preinjury baseline. As a result, James Brady and his wife, Sarah, led a call to create legislative reform subsequently known as the "Brady Bill." This bill controversially made mandatory background checks for the purchase of firearms from licensed dealers. Our work aims to describe the assassination attempt, the neurosurgical injury and management of Mr. Brady's case, and the brief historical sequel that followed.

3600. Menon, D. K. (2009). "Unique challenges in clinical trials in traumatic brain injury." Critical care medicine **37**(1 Suppl): S129-135.

Clinical trials in traumatic brain injury have shown little success in providing an evidence base for the introduction of successful new therapies into clinical practice. In addition to the problems that are common to all such studies in critical illness, trials in traumatic brain injury are complicated by the extremely short temporal window for intervention, failure of many candidate drugs to cross the blood-brain barrier, ethical and regulatory obstacles associated with research in subjects who cannot provide consent, the tendency to use small sample sizes in anticipation of unrealistic treatment benefits, and difficulty in translating experimental success into clinical practice. This article reviews the potential causes of these problems and suggests some solutions. These include the changes in regulatory frameworks that are making waived consent an acceptable strategy once more, and an increasing trend toward appropriately large trials. Other encouraging developments include the increasing use of human experimental medicine strategies before phase III trials to assess blood-brain barrier penetration and dose ranging, and provide proof of concept and proof of mechanism. Novel approaches to trial design, such as sliding dichotomy, coupled with robust outcome prediction models, can increase statistical power and improve trial design.

3601. Menon, K. V., et al. (2015). "Orbital roof fracture and orbital cellulitis secondary to halo pin penetration: Case report." Global Spine Journal **5**(1): 63-67.

Study Design Case report. Objective To report and discuss a rare complication after a patient was treated conservatively with a halo vest. Methods A 51-year-old man sustained a hangman's injury of the C2 vertebra following a motor vehicle collision. He was treated conservatively in a halo vest appliance and following mobilization was discharged from the hospital. Two weeks after discharge, the patient presented to the emergency department complaining of proptosis, ptosis, diplopia, and pin loosening. He was readmitted to the hospital, the halo vest was removed, and urgent imaging studies including computed tomography scan and magnetic resonance imaging were performed. They revealed that one of the halo pins had penetrated the orbital roof with active infection of the extraocular soft tissues. In consultation with the ophthalmologist, he was treated conservatively with antibiotics for 10 days. Results His ophthalmologic complaints resolved gradually and his eye returned to normal appearance and function. In the meantime, he was immobilized in a sterno-occipital mandibular immobilizer brace. Conclusion Though rare, penetrating injuries after cranial pin insertion can occur. Halo devices must be applied by, or under close supervision of, experienced personnel to avoid such complications, and halo vests should be reviewed frequently to detect such incidents early.

3602. Mercier, F., et al. (2012). "Meninges as potential organizers of neurogenesis, neuro-inflammation, neuro-immune axis, response to injury, and key players in neurological disorders." Journal of Neuroimmune Pharmacology **7**: S73-S74.

Meninges are typically described as brain coverings without a role in brain function. In fact, meninges deeply penetrate the brain structure as the falx cerebri, tentorium cerebelli, vascular adventitia, choroid plexus stroma, and sulci. Meningeal cells connect to each other by gap junctions to form a continuous network throughout the dura, pia-arachnoid, and internal meninges. We found that internal meninges comprise a developed system of extracellular matrix (ECM), including fractones, the specialized ECM of the subventricular zone (SVZ). Fractones contain collagens, laminins, and heparin sulfate proteoglycans (HSPG), and appear as ultrastructurally visible fragments (fractals) contacting multiple processes of glia, neurons, and neural stem cells. We have shown that fractone-associated HSPG capture and promote growth factor activity in the brain ventricle walls; 6O HDA ablation of meningeal cells at the brain surface modifies neurogenesis in the SVZ, the principal neurogenic niche; mechanical brain injury raises expression of HSPG in the meninges of the wounded site. We also found deep anatomical alterations of the meninges and fractones in BTBR T+tf/J mice, an animal model for autism. Together, our results support the view that meninges and fractones form a functional apparatus that organizes growth factor/cytokine activity throughout the brain and plays a crucial role in autism.We are currently investigating whether meninges/fractones are deteriorated by substances of abuse, and are developing mathematical models to understand the role of meninges/fractones in neural alterations leading to autism.

3603. Merck, L. H., et al. (2011). "Physiologic parameters in goal-directed therapy for traumatic brain injury at a level I trauma center." Academic emergency medicine **18**(5): S179.

Background: 1.2 million cases of traumatic brain injury (TBI) are reported per year in the United States (U.S.), or 1/3 of U.S. trauma-related mortality. The Brain Trauma Foundation has published goal-directed therapy (GDT) guidelines to mitigate secondary brain injury from TBI. Provider utilization of GDT is variable. Objectives: The relationship between the physiologic parameters de?ned in GDT and outcome is assessed in an urban emergency department (ED). Methods: Retrospective chart review of ED encounters from 1/1/2008-1/1/2010 was conducted at a Level I trauma center (census >100,000 patients/year). Patients (n=210) with diagnosis of blunt head trauma and initial GCS 3-12 were identi?ed via the Trauma Registry of the American College of Surgeons. Patients (n=41) age <18 years, with penetrating trauma, initial GCS >12, or missing ED charts were excluded. In the total sample of 169 patients, data were collected on demographics, physical exam, clinical management, and disposition (ordinal outcome: discharge home, discharge to rehabilitation, and death). The relationships between physiologic goals and outcome were assessed via ordinal regression analysis (95% CI), adjusting for age, ISS, and polytrauma (SAS software version 9.2). This study was IRB-approved. Results: Absence of hypoxia (80.5%) and/or hypotension (65.1%) was associated with an 84% and 52% decrease in the odds of death, respectively (ordinal regression analyses $p<0.001$, $p<0.05$). GCS score was inversely related to mortality ($p=0.003$). Lab abnormalities were not related to outcome. ED documentation of intracranial pressure was limited, precluding analysis. Conclusion: Prior research has documented variability in management of TBI. In our sample of patients with moderate/severe TBI, patients whose physiological parameters met the recommended guidelines had improved patient outcome. Future research is needed to prospectively apply GDT for treatment of moderate/severe TBI in the ED setting.

3604. Mercurio, I., et al. (2019). "Suicide by a rifle with a muzzle brake: a particular entrance wound." Australian Journal of Forensic Sciences **51**(4): 395-406.

The authors describe a case in which a 21-year-old male committed suicide using a rifle equipped with a muzzle brake, placed in contact with his head. A muzzle brake for firearms is a device positioned at the mouth of a weapon, which dissipates the gases, that are generated subsequent to the gun being discharged. Generally, when a gun is pressed against an anatomical region, where the skin lies on the bone surface without interposition of other soft parts, the entrance wound consists of many lacerated branches, originating from a central lack of tissue. In this case report, the use of a rifle with a muzzle brake generated an unexpected wound, circular in shape, with a diameter of 0.8 cm. This lesion was surrounded by a bruised area, circular in shape, and an abrasion collar of the height of 0.5 cm. In addition, a muzzle imprint mark consisting of intradermal bruises, composed of a narrow red line concentrically encircling the entrance hole, was found. In order to analyze in detail if this particular entrance wound could be associated with a weapon equipped with the muzzle brake, ballistic tests–with weapons compatible with that used by the victim–were performed.

3605. Mertz, M. (1986). "[Traumatology of the midface--diagnostic and therapeutic guidelines for the practicing ENT physician from the viewpoint of the ophthalmologist]." Traumatologie des Mittelgesichts--Diagnostische und therapeutische Leitlinien fur den praktizierenden HNO-Arzt aus der Sicht des Ophthalmologen. **34**(1): 15-20.

Fractures of the midface combined with orbital injuries endanger vision, binocular vision, and the lacrimal system. The best results of primary surgical management are advised if the surgeon adheres to a strict time schedule. For example, a perforating injury of the eye must be diagnosed as early as possible, and be repaired immediately. Otherwise, all manipulations necessary for reconstruction of the bone and soft tissue of the face worsen the condition of the opened eyeball, including loss of its contents and function. On the other hand, competent repair of the lacrimal system may be done at the end of the operation, and management of disordered eye mobility as seen in the "blow-out" fracture may sometimes be postponed for days or even weeks. The optimal chronological order of diagnostic and surgical management as seen from the ophthalmologist's view is given in tables, and discussed in detail.

3606. Merville, L. C. and J. P. Real (1981). "Fronto-orbito nasal dislocations. Initial total reconstruction." Scandinavian journal of plastic and reconstructive surgery **15**(3): 287-297.

The craniofacial trauma can produce compound fractures with bone displacement in the central part of the upper face, i.e. the bones constituting the forehead, orbit, and nose. such dislocations are called fronto-orbito-nasal dislocations. A total and definite surgical reconstruction in one stage offers advantages such as good aesthetic and functional results. An injured person can enter professional and social life without further delay. A major advantage is also the minimizing of the risk of meningeal fistula with infectious mortal risk. A prerequisite for this surgery is accurate

clinical and radiological examination to permit a preoperative three-dimensional visualization of the lesions as a basis for careful planning of the operation. The surgical team should include neurosurgeons and plastic surgeons with experience in the maxillofacial area. The operative procedure should start with repair of the orbital frame, beginning at the upper and lateral side, followed by exploration of the four walls of the orbital chamber and of the lacrimal system. The reconstruction then proceeds with the eyelid ligaments and the nervous and vascular pedicles, especially the infra-orbital one, followed by reconstruction of the sinus maxillaris. Afterwards transnasal internal canthopexy wires are placed, the nose reconstructed and bone grafts are used to restore the orbital chamber behind the frame. The lacrimal system is repaired before the tightening of the canthopexies. In cases where neurosurgical intervention is necessary, such as suturing of dura sores or reconstruction of the anterior cranial fossa by bone grafting, this will precede the facial reconstruction. Without a strong frontal cornice it is impossible to restore the nose and orbit. Ocular injuries are treated by ophthalmic surgeons when the orbit is repaired. The last phase of the reconstruction is suturing of the muscular, mucosal and cutaneous lacerations.

3607. Messina, A. D., et al. (2013). "Fatal cranial injury in an individual from Messina (Sicily) during the times of the Roman Empire." Journal of forensic and legal medicine **20**(8): 1018-1023.

Forensic and archaeological examinations of human skeletons can provide us with evidence of violence. In this paper, we present the patterns of two cranial lesions found on an adult male (T173) buried in a grave in the necropolis 'Isolato 96', Messina, Sicily, dating back to the Roman Empire (1st century BC - 1st century AD). The skull reveals two perimortem traumatic lesions, one produced by a sharp object on the right parietal bone and the other one on the left parietal bone, presumably the result of a fall. The interpretation of fracture patterns found in this cranium are an illustration of how forensic approaches can be applied with great benefit to archaeological specimens.

3608. Messmer, J. M. (1984). "Massive head trauma as a cause of intravascular air." Journal of forensic sciences **29**(2): 418-424.

Three examples of intravascular air caused by massive head trauma are presented. The basic types of air embolism are discussed and the pathophysiology in the three cases is offered. The association should be recognized to avoid misinterpretation of the radiographs.

3609. Metter, D., et al. (1989). "[Forensic medicine roentgen studies in gunshot wounds of the skull]." Rechtsmedizinische Rontgenuntersuchungen bei Schadelschussen. **47**: 473-477.

14 X-ray examined deaths caused by cranial bullet injuries are described. Three of them are demonstrated. In all cases with bullet injuries X-ray examination should be done prior to the post mortem. With radiographs bullets can be localised quickly. An antero-posterior and a lateral view are necessary. Little parts of the bullet and bone meal particles may be visible in radiographs along the path of the bullet; using normal technique of autopsy those details may not be visible.

3610. Metzger, K., et al. (2016). "Epidemiologic Investigation of Injuries Associated With the 2013 Fertilizer Plant Explosion in West, Texas." Disaster medicine and public health preparedness **10**(4): 583-590.

OBJECTIVE: On April 17, 2013, a fire and subsequent explosion occurred at the West Fertilizer Company plant in West, Texas, and caused extensive damage to the adjacent neighborhood. This investigation described the fatal and nonfatal injuries caused by the explosion., METHODS: Persons injured by the fertilizer plant explosion were identified through death certificates, medical examination reports, medical records, and survivor interviews. Data on patient characteristics, type of injury, and location of injury were collected., RESULTS: Medical record review indicated that 252 individuals sought medical care for nonfatal injuries directly related to the explosion immediately after the explosion. Fifteen patients died of injuries sustained by the blast. Almost one-quarter of patients were admitted for treatment of injuries. Injuries sustained in the explosion included abrasions/contusions, lacerations/penetrating trauma, traumatic brain injuries/concussions, tinnitus/hearing problems, eye injuries, and inhalational injuries. Patients located closer to the explosion were more likely to be admitted to the hospital for treatment of injuries than were those who were located further away., CONCLUSION: Explosions of this magnitude are rare, but can inflict severe damage to a

community and its residents. This investigation could be a useful planning resource for other communities, public health agencies, first responders, and medical facilities. (Disaster Med Public Health Preparedness. 2016;10:583-590).

3611. Meyer, C., et al. (2003). "Indication for and technical refinements of submental intubation in oral and maxillofacial surgery." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **31**(6): 383-388.

INTRODUCTION: In maxillofacial injuries, a choice has often to be made between different ways of intubation when surgical access to both the nasal and the oral cavities is necessary. Submental intubation is an interesting alternative to tracheotomy, especially when short-term postoperative control of the airway is foreseeable, and as control of the dental occlusion is complete, and access to the nose and mouth is undisturbed., MATERIAL: This kind of intubation has been used in our department in 25 cases since 1997. All patients had fractures disturbing the dental occlusion plus either an associated fracture of the skull base, or a displaced nasal fracture., RESULTS: There was no intra-operative complication, average intubation duration was 1.5 days. Post-operative complications consisted of one case with hypertrophic scarring and two cases of abscess formation in the floor of the mouth. All these completely healed following local conservative treatment., CONCLUSION: Submental intubation demands certain technical skills but it is simple, rapid and may avoid tracheotomy in selected patients.

3612. Meyer, J., et al. (2016). "Initial characterization of [11C]-GSK1482160 as radioligand for P2X7 receptors." Journal of Nuclear Medicine **57**.

Objectives Neuroinflammation is an essential step in the progression of brain diseases [1], where pro-inflammatory cytokines play a central role [2]. Recent work has shown that the pathogenesis of neuroinflammation is mediated in part by the release of adenosine/uridine derivatives from the damage site, involving a family of ionotropic purinergic receptors including P2X7 with elevated receptor expression [3], microglial proliferation and phagocytosis of the injured site [4, 5]. This mechanism is common amongst a wide array of neurodegenerative inflammatory diseases which include: Alzheimer's, Parkinson's, Huntington's Disease, frontotemporal dementia, Atrophic Lateral Sclerosis, Multiple Sclerosis, and Traumatic Brain Injury [6-8]. The P2X7 receptors represent a novel molecular target for imaging neuroinflammation via PET. GSK1482160 is an ideal starting point for evaluation of the P2X7 receptors, has high receptor affinity, and ideal blood-brain barrier penetration [9]. Moreover, recent work from our institution has radiolabeled this compound [11C]-GSK1482160 [10] yielding a potential biomarker for neuroinflammation. Therefore, we report the initial physical and biological characterization of this novel ligand. Methods Radiosynthesis of [11C]-GSK1482160 was according to published methods [10]. To determine receptor density (Bmax), saturation kinetics was employed with using cell membrane homogenate from human embryonic kidney cells (HEK) transfected with human P2X7R gene. Receptor binding potential (Bp) was determined by association kinetics. Secondary confirmation was performed via Radiologic-IHC (RIHC) on facing sections, probed with P2X7R monoclonal antibodies (mAb), and detected via [125I]-Protein-A. Tertiary confirmation was performed via Immuno-fluorescence Assay (IFA) using P2X7 mAb conjugated to NIR-fluorophore. Whole animal biodistribution was performed in 3 mice/time point at 15, 30, and 60min post IV injection. Tissue activity (%ID/g) was determined for brain, blood, heart, lung, liver, spleen, intestines, kidney, and muscle. In addition, in vivo PET/CT (n=3) images were acquired dynamically in listmode, regions segmented manually, and time series analyzed with a 2 compartment 4 parameter tracer kinetic models. Results Using high specific activity [11C]-GSK1482160, saturation kinetics revealed a Bmax and Kd of 923fmol/mg and 1.1nm in hP2X7R-HEK cells, respectively. Association kinetic determination of kon, koff, and Bp in hP2X7R-HEK cells were 0.231/min[asterisk]nM, 0.272/min, and 0.91, respectively. These results were confirmed via P2X7 binding and IFA in hP2X7R-HEK cell blocks, showing high sensitivity and specificity in this system. Biodistribution of [11C]-GSK1482160 showed a time dependent tissue distribution in all tissues studied, with the liver (36.8±5.0), intestines (16.9±2.6) and kidney (29.1±5.4) showing the highest uptake by 30min. The brain, blood, heart, lung, spleen, and skeletal muscle all had uptake which showed similar temporal patterns, and uptake levels of 2.5±0.27, 8.16±0.90, 11.6±1.25, 12.1±1.5, 8.2±1.1, and 6.9±0.82%ID/g at 30min. To characterize tracer kinetics, in vivo PET/CT [11C]-GSK1482160 was performed in normal mice and time courses modeled for brain, liver, intestines, kidney, muscle and bladder (R2=0.933±0.021). Determination of total volumes of distributions (Vt) for brain, heart, liver, intestine, kidney, and muscle were 0.068±.0008, 0.2±0.003, 0.45±0.02, 0.21±0.02, 0.24±0.02, and 0.11±0.04, respectively. Conclusions Initial characterization of [11C]-GSK1482160 shows high affinity and favorable association/disassociation kinetics, and were confirmed via two different in vitro assays. In vivo

biodistribution indicated that the liver, intestine and kidney uptake were maximal by 30 min, and in vivo PET/CT tracer kinetic modeling indicated that Vt followed expected trends for non-diseased mice.

3613. Meyer, K., et al. (2008). "Severe and penetrating traumatic brain injury in the context of war." Journal of trauma nursing : the official journal of the Society of Trauma Nurses **15**(4): 185-181.

Our data suggests that traumatic brain injury (TBI) may account for up to one third of battle-related injuries in today's war. Although the majority of these injuries are classified as mild in severity, service members with severe or penetrating TBI can be faced with many challenges. Injuries sustained on the battlefield require a slightly different approach than the TBI care that is traditionally seen in a civilian setting. This article presents the range of care that occurs beginning on the battlefield and continuing to state-of-the-art rehabilitation within the Department of Defense and Veterans Affairs Polytrauma System of Care.

3614. Meyer, R. M., et al. (2016). "Early venous thromboembolism chemoprophylaxis in combat related penetrating brain injury." Journal of neurosurgery **124**(4): A1176.

Introduction: Traumatic Brain Injury (TBI) is independently associated with deep vein thrombosis and pulmonary embolism (DVT/PE). Based upon numerous studies of civilian closed head injury, the Brain Trauma Foundation recommends venous thromboembolism chemoprophylaxis (VTC) in severe TBI. There have been no studies to date examining this practice in penetrating brain injury (PBI). Methods: The Kandahar Airfield neurosurgery service managed over 900 consults January 2010-March 2013. 156 patients were US active-duty members; 80 of these suffered PBI, 13 of whom were excluded because they presented with frankly non-survivable CNS injury, or died during initial resuscitation from other causes. This is a retrospective analysis of the remaining 67 US active-duty PBI patients, examining the safety and efficacy of early VTC with respect to worsened intracranial hematoma (ICH) and DVT/PE. Results: 32 patients received early VTC (intervention), 35 did not (control). Mean time to first dose was 24 hours. 29 received LMWH, 3 UFH. 52 had blast mechanism PBI, 15 had gunshot wounds to the head. The incidence of worsened ICH was 16% in the intervention group and 17% amongst the controls, with the relative risk approaching one (RR=0.91, 95% CI 0.31-2.7). The incidence of DVT/PE was 12% in the intervention group, and 17% in the controls, for absolute risk reduction of 5% and number needed to treat to prevent one DVT/PE of 22; however, this was not statistically significant (RR=0.73, 95% CI 0.23-2.4). Conclusion: Early VTC was safe in this population with regards to worsened ICH. The data suggest early VTC may be efficacious for preventing DVT/PE, though not statistically significantly. This is the first study to examine early VTC in PBI, and though the results are non-generalizable (military trauma, mostly blast mechanism) there is no other data available to guide practice.

3615. Meyer, R. M., et al. (2017). "Early venous thromboembolism chemoprophylaxis in combat-related penetrating brain injury." Journal of neurosurgery **126**(4): 1047-1055.

OBJECTIVE Traumatic brain injury (TBI) is independently associated with deep vein thrombosis (DVT) and pulmonary embolism (PE). Given the numerous studies of civilian closed-head injury, the Brain Trauma Foundation recommends venous thromboembolism chemoprophylaxis (VTC) after severe TBI. No studies have specifically examined this practice in penetrating brain injury (PBI). Therefore, the authors examined the safety and effectiveness of early VTC after PBI with respect to worsening intracranial hemorrhage and DVT or PE. METHODS The Kandahar Airfield neurosurgery service managed 908 consults between January 2010 and March 2013. Eighty of these were US active duty members with PBI, 13 of whom were excluded from analysis because they presented with frankly nonsurvivable CNS injury or they died during initial resuscitation. This is a retrospective analysis of the remaining 67 patients. RESULTS Thirty-two patients received early VTC and 35 did not. Mean time to the first dose was 24 hours. Fifty-two patients had blast-related PBI and 15 had gunshot wounds (GSWs) to the head. The incidence of worsened intracranial hemorrhage was 16% after early VTC and 17% when it was not given, with the relative risk approaching 1 (RR = 0.91). The incidence of DVT or PE was 12% after early VTC and 17% when it was not given (RR = 0.73), though this difference was not statistically significant. CONCLUSIONS Early VTC was safe with regard to the progression of intracranial hemorrhage in this cohort of combat-related PBI patients. Data in this study suggest that this intervention may have been effective for the prevention of DVT or PE but not statistically significantly so. More research is needed to clarify the safety and efficacy of this practice.

3616. Mezue, W. C., et al. (1991). "Barbed spear injury to the skull base: case report." Neurosurgery **28**(3): 428-430.

A case of a barbed spear injury to the left orbit and skull base is presented. The unusual nature and circumstances of the injury and the management problems related to the proximate neurovascular bundles are discussed.

3617. Michael, A. P., et al. (2020). "The clinical efficacy and direct healthcare cost of repeat head CT in mild traumatic brain injury." Journal of neurosurgery **132**(4): 56.

Introduction: Intracranial hemorrhage (ICH) is frequently found on head CT imaging after mild traumatic brain injury (mTBI), prompting transfer to a trauma center with repeat imaging to confirm hemorrhage stability.1,2 Several studies suggest that repeat imaging has little clinical utility in patients with minimal ICH, who do not use anticoagulant/antiplatelets and who have no change in neurologic status.3-7 We sought to assess the clinical utility and cost effectiveness of repeat head CT's in low-risk mTBI patients. Methods: A retrospective evaluation of patients receiving a neurosurgical consultation for mTBI during a 5-year period was performed at a level 1 trauma center. Exclusion criteria included GCS≤13, current anticoagulant/antiplatelet use, displaced skull fracture, ≥ 8 mm ICH, scattered subarachnoid hemorrhage or intraventricular hemorrhage. Clinical efficacy and associated healthcare costs of repeat head CT and transfer from outlying hospitals were assessed. Results: Of 531 eligible patients, 121 met inclusion criteria. Thirty-one patients (25.6%) had one head CT, 90 patients (74.4%) received two or more. Direct cost of all repeat imaging was $281,111. Thirty-seven patients (30.6%) were transferred from tertiary medical centers. Direct cost of ground transfer via emergency medical services was $55,944. Four patients developed evolution of ICH on repeat CT. No patient had neurosurgical intervention (i.e. craniotomy, placement of intracranial pressure monitor) or in-hospital mortality. Two patients had a mTBI related 30-day readmission for seizure. Conclusion: Repeat head CT did not change management of low risk mTBI patients in this study. Serial neurological examinations without repeat imaging appears to be safe and effective for select mTBI patients. Additionally, telemedicine may eliminate the need to transfer low-risk mTBI patients from small outlying hospitals and could provide future cost savings. A larger prospective analysis is warranted for further evaluation.

3618. Michaud, L. J. and A. C. Duhaime (1995). "Gunshot wounds to the brain in children." Journal of Head Trauma Rehabilitation **10**(5): 25-35.

Firearm injuries to children, including those involving the brain, are increasing in frequency. Most studies of brain injury in children, from epidemiological through outcome studies, have excluded gunshot wounds. The literature available on gunshot wounds to the brain in children will be reviewed, as well as pertinent literature on gunshot wounds to the brain in adult civilian and military populations. Ballistics, epidemiology, types and mechanisms of primary and secondary injuries resulting from gunshot wounds to the brain, management, and prognostic factors associated with outcome will be discussed. Cases with outcomes that would not have been predicted from information available in the literature will be presented and discussed, along with the implications for need for further research.

3619. Michon, J. and D. Liu (1994). "Intraorbital foreign bodies." Seminars in ophthalmology **9**(3): 193-199.

A high index of suspicion is important in evaluating any penetrating orbital injury. Likewise, any chronically infected orbit must be suspected of harboring an IOrbFB. Careful history and examination are mandatory for both clinical and medicolegal purposes. Appropriate imaging studies, usually including CT scanning, must be employed. Antibiotic therapy may be crucial in preventing infectious complications, including those involving the central nervous system. The decision regarding surgery must be individualized and should consider visual status, form and composition, and localization of an IOrbFB. The possibility of orbitocranial extension should always be considered and ruled out. Following these general rules, an injury with a small but real potential for clinical disaster may be mitigated, and visual and neurological outcome may be optimized.

3621. Midlenko, A. I., et al. (2000). "[Circulating immune complexes in acute concussion of the brain]." Tsirkuliruiushchie immunnye kompleksy v ostrom periode sotriaseniia golovnogo mozga u detei.(4): 21-23.

The aim of the study was to study the count of circulating immune complexes (CIC) in the blood of children with acute concussion of the brain. The fact that CIC at high concentrations that can penetrate into the brain through the blood-brain barrier and cause complications as vasculitis, microangiopathy, proliferative processes in the meninges, enlarged ventricles of the brain, and atrophy of its tissue was borne in mind. The studies revealed a significant progressive CIC increase within 3 weeks. For correction of blood CIC levels, laser exposure was applied to the carotid and vertebral arteries and acupuncture points. For comparison, thymaline in age-specific doses was used. Laser radiation showed a significant fall of CIC at days 19-21, particular when applied to the acupuncture points. Thymaline did not affect blood CIC levels. Laser application to the acupuncture points in children with acute brain concussion should reduce the incidence of complications of brain injury disease.

3622. Mielniczek, P., et al. (2016). "[Treatment methods of atypical gunshot wounds to the head--case reports]." Sposoby leczenia nietypowych obrazen postrzalowych glowy--opisy przypadkow. **40**(239): 318-324.

Due to a high mortality rate, headshot injuries pose serious diagnostic and clinical problems. In this work, we wanted to describe four atypical headshot injuries. The first patient with a headshot injury using a nail gun mishap; the second one after a headshot injury, as a result of attempted murder (the bullet came to a parasagittal halt in the left parietal area); the third victim, after a suicide attempt (the bullet was removed from clivus area, below the pituitary gland); in the case of the fourth patient, after shooting himself with a self-constructed weapon in the chin, the metal body was surgically removed - a bearing pellet from the corpus callosum. Males dominate among victims of headshot injuries. Alcohol is one of the elements that facilitate suicidal behaviour. Anti-spasm, antibacterial, anti-tetanus prophylaxes are incredibly important. In some cases, the metallic body does not have to be removed from the brain. Pulmonary embolism can be a cause of death after 7 days from injury.

3624. Mihailovic, Z., et al. (2007). "Firearm suicide committed using an unusual combination of tandem missiles: a bullet, a nail, and a screw." The American journal of forensic medicine and pathology **28**(3): 220-222.

An interesting case of firearm suicide carried out using an unusual type of handmade weapon and a peculiar combination of tandem missiles is presented. A nail and a screw were placed in the rifle barrel ahead of a bullet, and all 3 were simultaneously discharged. The inflicted injury began with 1 common channel, which later split in 2 separate channels, both directed backwards and upwards; one was caused by the screw, ending in the epistropheal body, and the other, caused by the bullet and the nail, penetrated into the cranial cavity, where it bifurcated in 2 branches, one from the bullet, ending in the cerebellar tissue, and the other from the nail, penetrated through the brain stem. The established site of the entrance suicidal wound, the appearance of the weapon, and the unusual missiles are discussed with regard to the available references dealing with different types of nail injuries to the head.

3625. Mihic, J., et al. (2011). "Head injury in children." Acta clinica Croatica **50**(4): 539-548.

Nowadays, head injuries are becoming more frequent in children. The most common cause of head injuries in children is fall, and, in more severe injuries, traffic accident trauma. In traumatic brain injuries in infants and small children, the most common symptoms are paleness, somnolence and vomiting, the so called "pediatric contusion syndrome". After the first year of age, light head trauma occurs after minor falls, whereas the most severe injuries are caused by car accidents, including pedestrians, or fall from the height. As the child grows, severe head trauma is more likely to occur after bicycle or car accidents. Brain injuries involving or penetrating the brain by broken bone fragments include contusions and lacerations of the brain. Unconsciousness need not always occur during contusion, as it may also appear after swelling of the brain or high intracranial pressure complications. Despite comprehensive injuries in such types of accidents, the outcome of survivors is surprisingly good. Such severe neurocranium injuries usually include heavy bleeding with hematoma (epidural bleeding, subdural bleeding, intracerebral bleeding, and traumatic subarachnoid hemorrhage). Improved prehospital care, readiness and accessibility of multidisciplinary teams,

establishment of regional centers, and efforts to prevent and decrease traffic accidents contribute to mortality rate reduction.

3626. Mikati, A. G., et al. (2018). "Validation of the survival after acute civilian penetrating brain injuries (SPIN) score in a multi-center cohort." Annals of neurology **84**: S111.

Introduction Using a large two-center cohort of 413 pene-trating traumatic brain injury (pTBI) patients, we previously developed the Survival after Acute Civilian Penetrating Brain Injuries (SPIN) Score, a logistic regression-based parsimonious risk stratification scale for estimating survival after civilian pTBI. The objective of the present study was to externally validate the SPIN-Score. Methods Our multi-center validation cohort comprised 362 pTBI patients retrospectively identified from the local trauma registries at three U.S. level-1 trauma centers. The SPIN score variables (motor GCS, sex, pupillary reactivity, self-inflicted pTBI, transfer status, Injury Severity Score (ISS) and INR) were collected from the trauma registries supplemented by chart review. Using the SPIN-score multivariable logistic regression model from the original study, receiver-operating-characteristic area-under-the-curve (ROC-AUC) analysis and Hosmer-Lemeshow Goodness-of-fit testing was performed. Results The mean age was 32 ± 15 years, and patients were predominantly male (85%), with 41% white and 28% black. In-hospital mortality was 52%, and 6-month mortality of hospital survivors was 3.1%. INR was missing in 105 patients, leaving 257 pTBI patients for full SPIN-model validation. The full SPIN-model with numerical variables entered linearly had a ROC-AUC of 0.88 with a Hosmer-Lemeshow Goodness-of-fit p-value=0.43, with p>0.05 indicating excellent model calibration. In a post-hoc sensitivity analysis, we removed INR from the model to include all 362 patients (SPINminus-INR), resulting in a ROC-AUC of 0.82 with a Hosmer-Lemeshow Goodness-of-fit p-value=0.007, indicating less ideal calibration. Validation of the full SPIN-model at 6-months resulted in similar discrimination and calibration (ROC-AUC=0.91; Hosmer-Lemeshow Goodness-of-fit p-value=0.92). Conclusions In this multi-center external validation study, the full SPIN-model predicts in-hospital and 6-month survival after pTBI with excellent discrimination and calibration. After removing INR from the model, discrimination remained excellent, but model calibration diminished. The full SPIN-score may provide important information to guide families and physicians after civilian pTBI.

3627. Mikati, A. G., et al. (2017). "Validation of the survival after acute civilian penetrating brain injuries (SPIN) score in a multicenter cohort." Neurocritical care **27**(2): S100-S101.

Introduction Using a large two-center cohort of 413 penetrating traumatic brain injury (pTBI) patients, we previously developed the Survival after Acute Civilian Penetrating Brain Injuries (SPIN) Score, a logistic regressionbased parsimonious risk stratification scale for estimating survival after civilian pTBI. The objective of the present study was to externally validate the SPIN-Score. Methods Our multicenter validation cohort comprised 362 pTBI patients retrospectively identified from three U.S. Level-1 trauma center registries. The SPIN score variables (motor GCS [mGCS], sex, pupillary reactivity, self-inflicted pTBI, transfer status, Injury Severity Score [ISS] and INR) were collected from the trauma registries supplemented by chart review. Using the SPIN-score multivariable logistic regression model from the original study, receiver-operating-characteristic area-under-the-curve (ROC-AUC) analysis and Hosmer-Lemeshow Goodness-of-fit testing was performed. Results The mean age was 32±15 years, and patients were predominantly male (85%), with 41% white and 28% black. In-hospital mortality was 52%, and 6-month mortality of discharge survivors was 3.1%. INR was missing in 105 patients, leaving 257 pTBI patients for full SPIN-model validation. The full SPIN-model with numerical variables entered linearly had a ROC-AUC of 0.88 with a Hosmer-Lemeshow Goodnessof- fit p-value=0.43, with p>0.05 indicating good model calibration. In a post-hoc sensitivity analysis, we removed INR from the model to include all 362 patients (SPINminus-INR), resulting in a ROC-AUC of 0.82 with a Hosmer-Lemeshow Goodness-of-fit p-value=0.007, indicating less ideal calibration. Using mGCS, Neurocrit Care (2017) 27:S1-S491 S101 POSTER PRESENTATIONS INR and ISS as categorical variables (as applied in the SPIN-score) resulted in ROC-AUC of 0.89 with a Hosmer-Lemeshow Goodness-of-fit p-value=0.67 (good calibration). Conclusions In this multicenter external validation study, the full SPIN-model predicts in-hospital survival after pTBI with excellent discrimination and calibration. After removing INR from the model, discrimination remained excellent, but model calibration diminished. The full SPIN-score may provide important information to guide families and physicians after civilian pTBI.

3628. Mikati, A. G., et al. (2018). "Validation of the survival after acute civilian penetrating brain injuries (SPIN) score in a multi-center cohort." Journal of neurotrauma **35**(16): A109.

Introduction: Using a large two-center cohort of 413 penetrating traumatic brain injury (pTBI) patients, we previously developed the Survival after Acute Civilian Penetrating Brain Injuries (SPIN) Score, a logistic regression-based parsimonious risk stratification scale for estimating survival after civilian pTBI. The objective of the present study was to externally validate the SPIN-Score. Methods: Our multi-center validation cohort comprised 362 pTBI patients retrospectively identified from the local trauma registries at three U.S. level-1 trauma centers. The SPIN score variables (motor GCS, sex, pupillary reactivity, self-inflicted pTBI, transfer status, Injury Severity Score (ISS) and INR) were collected from the trauma registries supplemented by chart review. Using the SPINscore multivariable logistic regression model from the original study, receiver-operating-characteristic area-under-the-curve (ROCAUC) analysis and Hosmer-Lemeshow Goodness-of-fit testing was performed. Results: The mean age was 32±15 years, and patients were predominantly male (85%), with 41% white and 28% black. In-hospital mortality was 52%, and 6-month mortality of hospital survivors was 3.1%. INR was missing in 105 patients, leaving 257 pTBI patients for full SPIN-model validation. The full SPIN-model with numerical variables entered linearly had a ROC-AUC of 0.88 with a Hosmer-Lemeshow Goodness-of-fit p-value = 0.43, with $p > 0.05$ indicating excellent model calibration. In a post-hoc sensitivity analysis, we removed INR from the model to include all 362 patients (SPINminus-INR), resulting in a ROCAUC of 0.82 with a Hosmer-Lemeshow Goodness-of-fit p-value = 0.007, indicating less ideal calibration. Validation of the full SPIN-model at 6-months resulted in similar discrimination and calibration (ROCAUC= 0.91; Hosmer-Lemeshow Goodness-of-fit p-value = 0.92). 3629. Mikati, A. G., et al. (2019). "Multicenter Validation of the Survival After Acute Civilian Penetrating Brain Injuries (SPIN) Score." Neurosurgery **85**(5): E872-E879.

BACKGROUND: Civilian penetrating traumatic brain injury (pTBI) is a serious public health problem in the United States, but predictors of outcome remain largely understudied. We previously developed the Survival After Acute Civilian Penetrating Brain Injuries (SPIN) score, a logistic, regression-based risk stratification scale for estimating in-hospital and 6-mo survival after civilian pTBI with excellent discrimination (area under the receiver operating curve [AUC-ROC = 0.96]) and calibration, but it has not been validated., OBJECTIVE: To validate the SPIN score in a multicenter cohort., METHODS: We identified pTBI patients from 3 United States level-1 trauma centers. The SPIN score variables (motor Glasgow Coma Scale [mGCS], sex, admission pupillary reactivity, self-inflicted pTBI, transfer status, injury severity score, and admission international normalized ratio [INR]) were retrospectively collected from local trauma registries and chart review. Using the original SPIN score multivariable logistic regression model, AUC-ROC analysis and Hosmer-Lemeshow goodness of fit testing were performed to determine discrimination and calibration., RESULTS: Of 362 pTBI patients available for analysis, 105 patients were lacking INR, leaving 257 patients for the full SPIN model validation. Discrimination (AUC-ROC = 0.88) and calibration (Hosmer-Lemeshow goodness of fit, P value = .58) were excellent. In a post hoc sensitivity analysis, we removed INR from the SPIN model to include all 362 patients (SPINNo-INR), still resulting in very good discrimination (AUC-ROC = 0.82), but reduced calibration (Hosmer-Lemeshow goodness of fit, P value = .04)., CONCLUSION: This multicenter pTBI study confirmed that the full SPIN score predicts survival after civilian pTBI with excellent discrimination and calibration. Admission INR significantly adds to the prediction model discrimination and should be routinely measured in pTBI patients.

3630. Mikhael, M., et al. (2018). "Perioperative Care for Pediatric Patients With Penetrating Brain Injury: A Review." Journal of neurosurgical anesthesiology **30**(4): 290-298.

Traumatic brain injury (TBI) continues to be the leading cause of death and acquired disability in young children and adolescents, due to blunt or penetrating trauma, the latter being less common but more lethal. Penetrating brain injury (PBI) has not been studied extensively, mainly reported as case reports or case series, due to the assumption that both types of brain injury have common pathophysiology and consequently common management. However, recommendations and guidelines for the management of PBI differ from those of blunt TBI in regards to neuroimaging, intracranial pressure (ICP) monitoring, and surgical management including those pertaining to vascular injury. PBI was one of the exclusion criteria in the second edition of guidelines for the acute medical management of severe TBI in infants, children, and adolescents that was published in 2012 (it is referred to as "pediatric guidelines" in this review).

Many reviews of TBI do not differentiate between the mechanisms of injury. We present an overview of PBI, its presenting features, epidemiology, and causes as well as an analysis of case series and the conclusions that may be drawn from those and other studies. More clinical trials specific to penetrating head injuries in children, focusing mainly on pathophysiology and management, are needed. The term PBI is specific to penetrating injury only, whereas TBI, a more inclusive term, describes mainly, but not only, blunt injury.

3631. Miki, K., et al. (2019). "How to Remove a Penetrating Intracranial Large Nail." World neurosurgery **127**: 442-445.

BACKGROUND: The incidence of penetrating intracranial foreign bodies is rare, and to date, not many relevant studies have been published worldwide. In particular, a nail penetrating intracranially, just near the superior sagittal sinus (SSS), is extremely rare. We treated the case of a large nail that penetrated the middle of the head and strategized its removal., CASE DESCRIPTION: A 70-year-old man had experienced headache lasting a day. Computed tomography of the brain revealed a nail penetrating the middle of his head; in particular, the tip of the nail had penetrated the right ventricle, causing a slight subarachnoid hemorrhage. Angiography showed that the nail was very close to the SSS and that the venous flow was normal. However, there was a risk of the nail penetrating through the SSS or injuring other arteries, and we removed the nail directly from the intracranial view to stop bleeding from the SSS or other vessels. Fortunately, there was no bleeding, and we washed the hole created by the nail penetration and concluded the surgery., CONCLUSIONS: Our technique is useful and safe for removing large nails penetrating the head.

3632. Milano, F., et al. (2019). "A rare case of suicide by multiple gunshot wounds to the head." Medico-Legal Update **19**(1): 99-103.

Firearm injuries represent a significant topic of forensic pathology. The literature in this regard is innumerable, and can seem to have extensively covered the topic of this paper. However, the biological reality and the unpredictability of the concrete cases, continue and will always continue to present unusual circumstances that are worth examining for forensic pathologists. In this case report, we performed a comparative analysis between a particular case and the scientific literature. The case in question concerns suicide by single-shot short firearm, in which the subject shot himself three times on two sides of the head, without affecting the brain during its self-suppressive intent. Cases similar to this are always cause for reasonable doubt, which can only be solved with the contribution of forensic pathology and in-depth research.

3633. Milhorat, T. H., et al. (1993). "Spontaneous movement of bullets in the brain." Neurosurgery **32**(1): 140-143.

We report two patients in whom bullets in the brain migrated into the adjacent lateral ventricle and moved freely as a consequence of gravity. A review of the literature suggests that the spontaneous migration of intracerebral bullets is influenced by cerebral softening, the specific gravity of the bullet compared with brain tissue, and the sink function of the cerebral ventricles. In patients undergoing the surgical removal of intracerebral or intraventricular bullets, it is recommended that an x-ray be obtained after the final positioning of the head.

3634. Miller, C. F., et al. (1977). "The danger of intracranial wood." Surgical neurology **7**(2): 95-103.

Peri-orbital puncture wounds by sharp wooden objects are not rare, but can be dangerous when there is intracranial penetration by and retention of the wooden foreign body. Days to years after an apparently trivial initial wounding, serious intracranial complications can occur. The authors have reviewed 42 case reports from the literature. Morbidity-defined as permanent neurologic sequelae-occurred in 74% of the cases. Intracranial suppuration was the major complication, with brain abscess having occurred in nearly one-half of the cases. Mortality occurred in 25% of 28 cases occurring in the post-antibiotic era. The qualities of wood which make it especially hazardous as a wounding agent and foreign body are discussed. The role of orbital anatomy in affording easy access to the cranial contents is described. Surgical exploration in all those cases in which there is a reasonable suspicion of intracranial injury is recommended.

3635. Miller, K. E. and E. B. Coan (2016). "Penetrating Orbital Injury From a Needlefish." Military medicine **181**(8): e962-964.

Orbital penetrating injuries are an unfortunately common occurrence; however, those from marine animals are rare. Injuries from marine animals can be quite profound and there are no known reports of complete visual recovery after an orbital penetrating injury. Complications range from secondary infection to a carotid-cavernous fistula, which can complicate the management of these patients. We report a case of penetrating orbital injury from a needlefish with complete return of visual function after surgical removal of foreign debris and an extended course of antibiotics. 3636. Miller, K. R., et al. (2011). "The evolving management of venous bullet emboli: a case series and literature review." Injury **42**(5): 441-446.

Bullet emboli are an infrequent and unique complication of penetrating trauma. Complications of venous and arterial bullet emboli can be devastating and commonly include limb-threatening ischaemia,pulmonary embolism, cardiac valvular incompetence, and cerebrovascular accidents. Bullets from penetrating wounds can gain access to the venous circulation and embolise to nearly every large vascular bed. Venous emboli are often occult phenomenon and may remain unrecognised until migration leads to vascular injury or flow obstruction with resultant oedema. The majority of arterial emboli present early with end-organ or limb ischaemia. We describe four separate cases involving venous bullet embolism and the subsequent management of each case. Review of the literature focusing on the reported management of these injuries, comparison of techniques of management, as well as the evolving role of endovascular techniques in the management of bullet emboli is provided. Copyright 2010 Elsevier Ltd. All rights reserved.

3637. Miller, P. and R. Lipschitz (1987). "Transclival penetrating injury." Neurosurgery **21**(1): 92-94.

A case of a stab wound of the cranium with a retained knife blade is presented. The blade had an unusual course through the base of the skull--the point of the knife penetrated the clival line to end in the posterior fossa. Although the blade was in close proximity to the basilar artery, it was judged safe to extract the knife by blind removal. The patient had no neurological deficit postoperatively.

3638. Miller, R., et al. (2014). "Pediatric falls from open windows: What are the injuries a radiologist will encounter?" Emergency radiology **21**(5): 448-449.

Purpose: A recent national public awareness issue has been pediatric falls from building windows. To our knowledge, no case series identifying the types of injuries incurred due to accidental falls from windows has been published. The purpose of this study is to review the injuries the radiologist may encounter and to correlate with clinical outcomes. Materials and Methods: Consecutive patients evaluated at our institution from 1/1/2011-12/31/2012 were retrospectively reviewed. The study included patients aged 0-8 years with a trauma history of fall from an open building window. Demographics analyzed included age, sex, fall height, type of surface landed on, types of injury sustained, length of stay in hospital, emergent interventions, and long term clinical outcomes. Results: Thirty-six pediatric patients populated our trauma registry database query. Thirty-two met inclusion criteria. The average age was 3.3 years, with the majority of patients male (22/32). The majority (24/ 32) fell from 2nd story windows, with a screen present in 10/32 falls. The majority of accidents occurred during the summer months (17/32). Twenty-nine patients were imaged. The most commonly encountered radiologic findings included: scalp contusion (12), non-displaced/minimally displaced skull fracture (12), epidural hematoma (6), subdural hematoma (6), subarachnoid hemorrhage (5), and lung contusion (4). Disposition included 9 discharges from ED, 12 overnight observations, and 11 extended hospitalizations-the majority (7) due to intracranial hemorrhage. All patients survived, with one patient requiring a decompressive craniectomy and long-term neurosurgical follow-up. Conclusion: Accidental falls from windows in the pediatric population are a relatively common, but preventable trauma encountered by the radiologist. Awide variety of injuries are sustained, with the potential for serious trauma even from relatively short heights. This study shows that the majority of injuries presenting in the emergency setting include skull fractures and associated intra- and extra-axial hemorrhage, with the majority of patients requiring hospitalization. Severalmajormetropolitan areas have successfully curtailed accidental falls from windows.With increased awareness, the goal is to eliminate these preventable accidents across the country.

3639. Millis, S. R. and J. H. Ricker (1995). "Verbal learning and memory impairment in adult civilians following penetrating missile wounds." Brain injury **9**(5): 509-515.

Verbal memory and learning patterns, as measured by the California Verbal Learning Test (CVLT), following penetrating head injury (PHI) from gunshot wound were studied in 10 acutely injured patients (mean age 25.3 years) at a mean of 2.1 months post-injury. Primary impairment was found on measures of free recall of new verbal information which appeared to be related to deficits in organisational and retrieval functions: (1) the group's learning characteristics were marked by disorganization and an underutilization of active learning strategies; (2) rate of acquisition also appeared to be mildly decreased; (3) nevertheless, the PHI group did not show severe disruption in all aspects of learning and memory. In fact, the group showed a relatively intact capacity to store new information in memory.

3640. Mills, V. A., et al. (1982). "Central nervous system Nocardia infection." Clinical pediatrics **21**(4): 248-250.

3641. Milne, E. and J. Grafman (2001). "Ventromedial prefrontal cortex lesions in humans eliminate implicit gender stereotyping." Journal of neuroscience **21**(12): RC150.

Patients with prefrontal cortex lesions and controls were administered an implicit association task (IAT) that measured the degree of association between male and female names and their stereotypical attributes of strength and weakness. They also completed three questionnaires measuring their explicit judgment regarding gender-related stereotypical attributes. There were no between-group differences on the explicit measures. On the IAT, patients with dorsolateral lesions and controls showed a strong association, whereas patients with ventromedial prefrontal cortex lesions had a significantly lower association, between the stereotypical attributes of men and women and their concepts of gender. This finding provides support for the hypothesis that patients with ventromedial prefrontal lesions have a deficit in automatically accessing certain aspects of overlearned associated social knowledge.

3642. Milton, J. and V. Awuor (2017). "A Unique Presentation of an Intracranial Abscess Secondary to Retained Projectile after Debridement with Dural Closure." Cureus **9**(6): e1328.

Patients with penetrating head trauma with retained projectiles develop intracranial abscesses as a common complication. The most common presentation is a suddenly worsening headache. The most common pathogen identified is staphylococcus. Outcomes are related to adherence of Matson's tenets. This case study details the presentation of a 19-year-old patient that presented to the neurological surgery clinic without neurologic deficits. Further questioning revealed complaints of intermittent diffuse headaches with bilateral upper extremity shock-like sensation for two weeks. Eight weeks prior he had undergone right craniotomy, after a gunshot wound, for debridement and watertight dural closure. The patient denied symptoms of fever, chills, nausea, vomiting, diarrhea, or seizure. The patient presented with a noncontrast head computed tomography (CT) which revealed retained projectile fragments without clear evidence of abscess. On physical exam, the patient was without any neurological deficit. Laboratory investigation revealed normal white blood cell count, erythrocyte sedimentation rate, C-reactive protein, and negative blood cultures. Head CT with contrast revealed a large intracerebral abscess adjacent to the thalamus. The patient was taken to the operating room for repeat craniotomy with resection of the abscess and removal of the intracranial projectile fragments. Post-operatively, the patient remained neurology intact. Intraoperative cultures were not significant for the growth of any bacteria. In eight weeks time, the patient returned to his employment and his baseline level of activity. This case underscores the importance of thorough assessment in patients with retained intracranial projectiles as well as the need to routine follow-up. The unique presentation of this patient prompted further investigation which elucidated a lesion which correlated to his symptoms although laboratory assessment was without abnormality.

3643. Milton, J., et al. (2017). "A Case-Based Review of the Management of Penetrating Brain Trauma." Cureus **9**(6): e1342.

Principles of penetrating head trauma management were established by Harvey Cushing in relation to the management of penetrating brain injuries of World War One. Cushing radically debrided the scalp and skull and aggressively irrigated wound tracks to remove foreign bodies. He would then obtain water-tight closure. Cushing significantly decreased infection rates which reportedly limited the major cause of mortality due to penetrating head

injuries. Many advances have been made by contributions from World War Two, Korean War, Vietnam War, and Iran/Iraq conflicts. Early radical decompression, with conservative debridement and duraplasty applied to blast-induced penetrating injuries during Operation Iraqi Freedom, has resulted in increased survivability and neurological improvement. Each advance in the management of these injuries is based upon more effectively addressing one or more components of Matson's tenets. This case series reviews the successful management of three patients that presented to a level I trauma center with a penetrating head injury from high-velocity projectiles. Management principles of each patient begin with a proper patient assessment, application of Matson's tenets from the time of injury, and airway control. Surgical management is based upon adherence to Grahm's Guidelines which emphasize criteria centered upon post-resuscitative Glasgow Coma Scale score and appropriate imaging. This case series suggests that proper patient evaluation, adherence to Matson's tenets and to Grahm's Guidelines, and appropriate patient selection for operative management leads to improved survival of patients with penetrating head trauma from high-velocity projectiles.

3644. Milwood Hargrave, J., et al. (2019). "Blast injuries in children: A mixed-methods narrative review." BMJ Paediatrics Open **3**(1).

Background and significance Blast injuries arising from high explosive weaponry is common in conflict areas. While blast injury characteristics are well recognised in the adults, there is a lack of consensus as to whether these characteristics translate to the paediatric population. Understanding blast injury patterns in this cohort is essential for providing appropriate provision of services and care for this vulnerable cohort. Methods In this mixed-methods review, original papers were screened for data pertaining to paediatric injuries following blasts. Information on demographics, morbidity and mortality, and service requirements were evaluated. The papers were written and published in English from a range of international specialists in the field. Results Children affected by blast injuries are predominantly male and their injuries arise from explosive remnants of war, particularly unexploded ordinance. Blasts show increased morbidity and mortality in younger children, while older children have injury patterns similar to adults. Head and burn injuries represent a significant cause of mortality in young children, while lower limb morbidity is reduced compared with adults. Children have a disproportionate requirement for both operative and non-operative service resources, and provisions for this burden are essential. Conclusions Certain characteristics of paediatric injuries arising from blasts are distinct from that of the adult cohort, while the intensive demands on services highlight the importance of understanding the diverse injury patterns in order to optimise future service provisions in caring for this child blast survivor.

3645. Mimbella, P. C., et al. (2016). "Remarkable recovery of function in a young adult female after low-velocity penetrating head injury and arrival with retained foreign body: A case report." PM and R **8**(9): S241.

Case/Program Description: This is a 29-year-old woman with severe, open, penetrating, traumatic brain injury and a hammer embedded 3.5cm into the cranial vault after assault. She was GCS3T in the field. Upon her presentation to the emergency department, she was noted to have a foreign object 'stuck' in her left occipital skull. Her injuries included: depressed calvarial fracture with intrusion of the hammer mallet, multiple depressed, displaced, comminuted facial fractures, pneumocephalus, traumatic subarachnoid hemorrhage, bilateral frontal hemorrhagic contusions, malignant hypertension, and frontal/ superior sagittal sinus injuries. She was emergently taken to the OR and underwent hemicraniectomy, removal of foreign body, sinus repair, and insertion of ICP monitor. On post-operative day 10, the patient was admitted to the rehabilitation unit. On admission, her functional scores were max-assist. Setting: Tertiary Care Hospital. Results: The patient required a 14-day acute inpatient rehabilitation stay. Her functional scores improved to supervision/modified-independent. She demonstrated increased problem solving and abstract reasoning. She ambulated 5,000ft on discharge with supervision. Her neuropsychiatric scores significantly improved. Further developments will be discussed. Discussion: Low velocity penetrating head injuries, especially those with retained foreign bodies, are rare. These injuries pose significant challenges to the care of these victims and, if not managed properly, can lead to serious consequences. One such consequence developed in this patient during her rehabilitative stay but was rapidly identified and treated appropriately, relieving any further burden for the patient. Conclusions: Accurate initial prognosis following low velocity penetrating TBI remains exceedingly challenging. This is not only due to the rarity of such injuries in non-developing countries, but also due to the serious potential associated complications. Remarkable neurological recovery remains possible even in the face of exceptionally violent cranial injuries. Appropriate medical, surgical, and rehabilitative treatment can combine to yield extraordinary functional recovery.

3646. Minard, G., et al. (2000). "Early versus delayed feeding with an immune-enhancing diet in patients with severe head injuries." JPEN. Journal of parenteral and enteral nutrition **24**(3): 145.

BACKGROUND: Although early enteral feeding clearly reduces septic morbidity after blunt and penetrating trauma, data for head-injured patients are conflicting. This study examines the effects of early vs delayed enteral feedings on outcome in patients with severe closed-head injuries with a Glasgow Coma Scale (GCS) score greater than 3 and less than 11., METHODS: Thirty patients were prospectively randomized to receive an immune-enhancing diet (Impact with fiber) early (initiated < 72 hours after trauma) delivered via an endoscopically placed nasoenteric tube (Stay-Put) or late (administered after gastric ileus resolved). This formula was continued for 14 days or until the patient tolerated oral feeding. Goal rate of nutrition was 21 nonprotein cal/kg/d and 0.3 g N/kg/d., RESULTS: Two patients in the early group were excluded due to inability to place the tube, and one patient in the late group died before 72 hours. Five of the remaining 27 died, 1 in the early group and 4 in the late group. There were no significant differences between the groups in length of stay, intensive care unit (ICU) days, significant infection, or GCS score. However, major infection correlated inversely with admission GCS score ($R = -0.6$, $p < .003$). Time to reach a GCS score of 14 was significantly longer in patients with significant infections compared with those without ($p < .02$)., CONCLUSIONS: No difference in length of stay or infectious complications is shown in patients with severe closed-head injury when they are given early vs delayed feeding using an immune-enhancing formula. Severity of the head injury is closely associated with significant infection.

3647. Miner, A. and A. T. Smith (2018). "A Suicide Attempt by Nail Gun." The Journal of emergency medicine **55**(3): 415-416.

3648. Miner, M. E., et al. (1986). "Intracranial penetration due to BB air rifle injuries." Neurosurgery **19**(6): 952-954.

The toy BB gun that was commonly available 20 years ago has been modernized into a weapon with lethal potential. We report four children who had intracranial penetration by BBs. Three were shot by another young child, and the fourth child was injured by an intoxicated adult. Two of the children have permanent, severe neurological sequelae. BB rifles should require the same safety precautions and considerations as more traditional firearms.

3649. Miner, M. E., et al. (1990). "The results of treatment of gunshot wounds to the brain in children." Neurosurgery **26**(1): 20-25.

Thirty-three children ranging in age from 8 months to 15 years were treated for gunshot wounds to the brain. Half of the children were less than 10 years old. Fifty-eight percent died. Mortality was influenced by the trajectory of the bullet, intent to commit suicide, and the neurological status immediately after injury. The age and sex of the child and the caliber of the bullet did not influence survival. Three-fourths of the deaths occurred within 24 hours of injury, suggesting these patients had a mortal wound from the onset. Eleven of the children were attempting suicide, 9 of whom died; 13 were playing with a gun, 5 of whom died; 2 were shot as innocent bystanders to crimes in progress; 1 was shot while involved in a criminal act; 1 was shot in a hunting accident; and in 2 who died within minutes of arrival, the circumstances of the shooting were not documented. Of the survivors, none was left vegetative after 6 months, 3 had severe disabilities, 9 were moderately disabled, and 2 had a good outcome. The mortality rate is strikingly similar to that of adults with similar injuries; however, the morbidity appears to be less. On the other hand, with simple preventative measures, virtually each injury would have been avoided.

3650. Ming-Kun, Y., et al. (2011). "Treatment strategies for penetrating orbitocranial injuries: Two case reports and literature review." Journal of neurotrauma **28**(5): A40.

Background: Here we report two cases of penetrating orbito-cranial injuries. One case was operated by early surgical debridement. The other patient experienced a third operation for cellulitis in the orbit, brain abscess, and subperiosteal abscess present after two operations. We discuss key points of treatment of penetrating orbito-cranial injuries and infectious complications. Methods: The relationship of preoperative evaluation and treatment strategies with curative effect is analyzed in a case of early debridement. At the same time, the treatment process and operative strategy of another patient with cellulitis of the orbit, brain abscess, and subperiosteal abscess, are also discussed. The

second patient initially experienced debridement for orbito-cranial penetrating wounds, followed by resection of a right frontal brain abscess, and then was transferred to our hospital for the third operation. Results: The first patient experienced early complete debridement, foreign body excision, optic canal and supraorbital split decompression, and cranium reconstruction at the same time, and his wound was healed at phase 1. Follow-up has been for 11 months post-surgery. He had good recovery of eyesight, eye movement, and satisfactory appearance, and with no postoperative complications. The second patient experienced one operation for puncture drainage of brain abscesses, surgical debridement, and drainage of intraorbital and frontal subperiosteal abscesses, and was cured with good recovery without relapse at 10 months follow-up. Conclusion: The treatment of penetrating orbito-cranial wounds is complicated, and they can cause brain injury, accompanied by ocular trauma, cranial nerve and vascular injury, and may lead to orbitocranial deformities and nerve dysfunction. Thus treatment is very difficult. Once infectious complications occur, they are difficult to handle and may directly endanger life. The ideal treatment of penetrating orbitcranial wounds includes early thorough debridement, effective hemostasis, and skull base reconstruction, in order to recover a satisfactory appearance and to prevent complications. Early complete debridement is the key, and often requires multidisciplinary cooperation.

3651. Minkley, A. R., et al. (2020). "Holocord post-traumatic syringomyelia presenting with bulbar involvement: A case report." PM and R **12**(SUPPL 1): S129.

Case Description: 41-year-old male with a 23-year history of incomplete lumbar paraplegia presenting with progressive sensory and motor deficits, urinary retention, dysphagia and diplopia whose symptoms initially started 15 years prior to presentation. Setting: Tertiary Care Center Patient: 41-year-old male with L2 ASIA impairment scale (AIS) D spinal cord injury secondary to a gunshot wound Assessment/Results: MRI of the brain was unremarkable, with no evidence of infarction, Chiari malformation or hydrocephalus. However, MRI of the entire spine demonstrated a holocord syrinx extending from the medulla through the conus at L2-3. A videofluoroscopic swallow study showed mild pharyngeal dysphagia without evidence of aspiration. Despite a successful syringosubarachnoid shunt placement and subsequent inpatient rehabilitation stay, the patient did not show any significant return of motor or sensory function, though he did report subjective improvement in his swallowing function. ISNCSCI was C1 AIS D at the time of discharge from rehabilitation. Discussion: Post-traumatic syringomyelia is a well-recognized late complication of spinal cord injury, with an estimated prevalence of over 50% in all spinal cord injury cases. Symptomatic syringomyelia only presents in 1-7% of cases, and holocord involvement of the syrinx occurs even more rarely, with only a few cases reported in the literature. Here we present a rare case of holocord syringomyelia with bulbar involvement. Conclusion: Timely recognition of the signs and symptoms of progressive syringomyelia is important to prevent extensive and potentially irreversible neurologic damage, particularly in those demonstrating bulbar dysfunction and signs of holocord involvement. Clinicians must remain vigilant when working up new neurologic deficits in a patient with distant spinal cord injury.

3652. Minnick, J. M., et al. (2013). "The incidence of fever in US Critical Care Air Transport Team combat trauma patients evacuated from the theater between March 2009 and March 2010." Journal of emergency nursing **39**(6): e101-106.

INTRODUCTION: Most critically ill injured patients are transported out of the theater by Critical Care Air Transport Teams (CCATTs). Fever after trauma is correlated with surgical complications and infection. The purposes of this study are to identify the incidence of elevated temperature in patients managed in the CCATT environment and to describe the complications reported and the treatments used in these patients., METHODS: We performed a retrospective review of available records of trauma patients from the combat theater between March 1, 2009, and March 31, 2010, who were transported by the US Air Force CCATT and had an incidence of hyperthermia. We then divided the cohort into 2 groups, patients transported with an elevation in temperature greater than 100.4degreeF and patients with no documented elevation in temperature. We used a standardized, secure electronic data collection form to abstract the outcomes. Descriptive data collected included injury type, temperature, use of a mechanical ventilator, cooling treatment modalities, antipyretics, intravenous fluid administration, and use of blood products. We also evaluated the incidence of complications during the transport in patients who had a recorded elevation in temperature greater than 100.4degreeF., RESULTS: A total of 248 trauma patients met the inclusion criteria, and 101 trauma patients (40%) had fever. The mean age was 28 years, and 98% of patients were men. The mechanism of injury was an explosion in 156 patients (63%), blunt injury in 11 (4%), and penetrating injury in 45 (18%), whereas other trauma-related injuries accounted for 36 patients (15%). Of the patients, 209 (84%) had battle-related injuries and 39 (16%) had non-battle-

related injuries. Traumatic brain injury was found in 24 patients (24%) with an incidence of elevated temperature. The mean temperature was 101.6degreeF (range, 100.5degreeF-103.9degreeF). After evaluation of therapies and treatments, 80 trauma patients (51%) were intubated on a mechanical ventilator (P < .001). Of the trauma patients with documented fever, 22 (22%) received administration of blood products. Nineteen patients received antipyretics during their flight (19%), 9 received intravenous fluids (9%), and 2 received nonpharmacologic cooling interventions, such as cooling blankets or icepacks. We identified 1 trauma patient with neurologic changes (1%), 6 with hypotension (6%), 48 with tachycardia (48%), 33 with decreased urinary output (33%), and 1 with an episode of shivering or sweating (1%). We did not detect any transfusion reactions or deaths during flight., CONCLUSION: Fever occurred in 41% of critically ill combat-injured patients evacuated out of the combat theater in Iraq and Afghanistan. Fewer than 20% of patients with a documented elevated temperature received treatments to reduce the temperature. Intubation of patients with ventilators in use during the transport was the only factor significantly associated with fever. Serious complications were rare, and there were no deaths during these transports.

3653. Mirabet, V., et al. (2021). "Cranioplasty with Autologous Bone Flaps Cryopreserved with Dimethylsulphoxide: Does Tissue Processing Matter." World neurosurgery **149**: e582-e591.

OBJECTIVE: The aim of this article was to study the outcome of patients who underwent cranioplasty with cryopreserved autologous bone after decompressive craniectomy., METHODS: Data from 74 patients were retrospectively analyzed. They were divided into groups according to the storage time and the age at cranioplasty. To assess the predictive potential for complication, factors were related to successive stages (preoperative, craniectomy, tissue processing, cranioplasty, and postoperative). Cooling and warming rates applied on bone flap were calculated. The ability to inhibit microbial growth was determined exposing bone fragments to a panel of microorganisms. The concentration of antibiotics eluted from the bone was also determined. A bone explant culture method was used to detect living cells in the thawed cranial bone., RESULTS: Hydrocephalus was significantly more frequent in pediatric patients (26.7%) than in adults (5.1%). The overall rate of bone flap resorption was 21.6% (43.7% of which required reoperation). Surgical site infection after cranioplasty was detected in 6.8% of patients. There was no correlation between infection as a postoperative complication and previous microbiological-positive culture during processing. The cause of craniectomy did not influence the risk of bone flap contamination. Vancomycin was the only antibiotic detected in the supernatant where the bone was incubated. Outgrowth from bone explants was observed in 36.8% of thawed skulls. An early start of bone flap processing at the tissue bank had a positive effect on cell viability., CONCLUSIONS: The outcome after autologous cranioplasty is a multifactorial process, which is modulated by patient-related, surgery-related, and bone-related factors.

3654. Miraflor, E., et al. (2011). "Timing is everything: delayed intubation is associated with increased mortality in initially stable trauma patients." The Journal of surgical research **170**(2): 286-290.

BACKGROUND: The indications for immediate intubation in trauma are not controversial, but some patients who initially appear stable later deteriorate and require intubation. We postulated that initially stable, moderately injured trauma patients who experienced delayed intubation have higher mortality than those intubated earlier., METHODS: Medical records of trauma patients intubated within 3 h of arrival in the emergency department at our university-based trauma center were reviewed. Moderately injured patients were defined as an ISS < 20. Early intubation was defined as patients intubated from 10-24 min of arrival. Delayed intubation was defined as patients intubated >=25 min after arrival. Patients requiring immediate intubation, within 10 min of arrival, were excluded., RESULTS: From February 2006 to December 2007, 279 trauma patients were intubated in the emergency department. In moderately injured patients, mortality was higher with delayed intubation than with early intubation, 11.8% versus 1.8% (P = 0.045). Patients with delayed intubations had greater frequency of rib fractures than their early intubation counterparts, 23.5% versus 3.6% (P = 0.004). Patients in the delayed intubation group had lower rates of cervical gunshot wounds than the early intubation group, 0% versus 10.7% (P = 0.048) and a trend toward fewer of skull fractures 2.9% versus 16.1%, (P = 0.054)., CONCLUSIONS: These findings suggest that delayed intubation is associated with increased mortality in moderately injured patients who are initially stable but later require intubation and can be predicted by the presence of rib fractures.

3655. Mirza, G. E., et al. (1993). "Diagnosis and management of a biorbital pencil injury." Acta ophthalmologica **71**(2): 266-269.

A 9-year-old girl was wounded by a pencil which entered the right orbit and passed towards the left. The broken part remained inside. The diagnosis was delayed for 9 months since the history and the symptoms were misleading. The pencil, which could not be detected with plain X-rays, was demonstrated with computerized tomography (CT) and removed from the orbit successfully. The case is presented to emphasize the contribution of CT to the perforating injuries of the orbit with wooden particles. Importance of orbital foreign bodies in the differential diagnosis of proptosis in the pediatric age group is also discussed.

3656. Mirzadeh, S. M. (2021). "Endoscopic management gunshot wound at the face: Fact or fiction?" Trauma case reports **35**.

Shrapnel or gunshot injuries in Maxillofacial Region are highly considered to be challenging which leads to death in most cases, and even in the case of no mortality, they will cause morbidity and appearance impairment due to complex injuries to bone and soft tissue. Herein, in a particular case, the patient was a person injured by a gunshot of a Kalashnikovs bullet in his face; the bullet was located at the end of the medial wall of the maxillary sinus and was removed through the functional endoscopy of the nose and sinuses. The bullet was removed without causing any additional incisions on the face and further damage through endoscopic ligation of severe bleeding from the sphenopalatine artery. The clinical approach to patients with penetrating trauma from a bullet to head and face demands prompt action. Functional endoscopic nasal and sinus surgery can maintain the patient's face cosmetic appearance.

3657. Mirzaei, F., et al. (2019). "An unusual case of intra orbital foreign body; diagnosis, management, and outcome: a case report." BMC surgery **19**(1): 76.

BACKGROUND: An orbitocranial injury with a penetrating Intraorbital Foreign Body (IOFB) is listed as a rare cause of penetrating trauma. Since this type of trauma is considered a surgical emergency, taking a thorough history along with careful examination to find out the mechanism and cause of the trauma is crucial towards correct diagnosis and management of the disease., CASE PRESENTATION: A 35-year-old male patient was presented to the ER with an occupational craniofacial injury because of an IOFB. The patient underwent an extra-dural orbitocranial craniotomy procedure to remove the foreign body. Interestingly, a plastic foreign body (a piece of a plastic pipe) was removed from the orbital cavity, which was suspected to be a fractured orbital bone, at first place., CONCLUSION: In this study, we demonstrated that plastics could mimic bone structure in a Computerized Tomography (CT) scan leading to possible initial misdiagnosis. Hence high clinical suspicion is necessary for the correct diagnosis of such cases. However, despite the prompt intervention, our patient ended up with permanent vision loss in his injured eye.

3658. Mishaeva, N. P., et al. (2013). "[A new approach to postexposure treatment of rabies by complex of immuno- and chemotherapy in belarus]." Antibiotiki i khimioterapiia = Antibiotics and chemoterapy [sic] **58**(11-12): 31-37.

A method for preventive treatment of rabies with a complex of immuno- and chemotherapeutics was developed. Rifampicin was used a an etiotropic drug. In the experiments on laboratory animals infected with fixed and street strains of rabies virus it was shown to prolong the incubation period and to increase the survival rate. The protective mechanisms of rifampicin against rabies should be associated with inhibition of RNA transcription, as well as immunomodulating function of macrophages, dendritic cells, B- and T-cells. Since 1992, after the approval of the Ministry of Health of Belarus rifampicin is used in complex with antirabic vaccine for postexposure treatment of rabies in people after severe bites by infected animals (wolves, foxes, dogs). For an 18-year period (1992-2009) of integrated application of chemo- and immunotherapy in Belarus there was not registered any case of hydrophobia in people even after the heaviest wolf bites, incompatible with life (penetrating injuries of the skull, scalping, multiple bites).

3659. Misis, M., et al. (2008). "Bispectral index monitoring for early detection of brain death." Transplantation proceedings **40**(5): 1279-1281.

OBJECTIVE: We sought to determine the utility of the bispectral index (BIS) as a tool for clinical evaluation of the moment of brain death (BD)., MATERIALS AND METHODS: During a period of 12 months, 54 BDs were registered in our

unit, of which 28 were included in the organ donation protocol; 24 fulfilled the requirements of our retrospective observational study. Continuous BIS monitoring was performed using an XP BIS monitor and BIS Quatro sensor evaluating the BIS and the suppression ratio (SR). In almost all cases, sonographic monitoring with transcranial Doppler ultrasound (TCD) was performed every 8 to 12 hours until the diagnosis of BD., RESULTS: We detected a gradual decrease in BIS and increase in SR when the patients underwent clinical progression to BD. At the moment of BD diagnosis, all cases showed BIS 0 and SR 100. In 9 cases the follow-up TCD showed a BD pattern, moments before a BIS 0 and SR 100 appeared. In 18 cases, at the moment of BIS 0/SR 100, TCD showed BD. In all 24 cases, BD diagnosis was confirmed by means of neurological examination and electroencephalogram (EEG)., CONCLUSIONS: BIS monitoring is a continuous, simple method that is easy to interpret. It can help in clinical evolution and the decision of the BD moment. In our series, cerebral circulatory cessation (TCD) preceded BIS 0 and SR 100 values. The BIS prematurely detected the start of cerebral circulatory cessation, alerting us of BD.

3660. Misra, M., et al. (1992). "An unusual orbito-cranial foreign body." Indian journal of ophthalmology **40**(3): 94-95.

The rarity of orbito-cranial gun shot injury in both war and civilian practice has been reported. In a large series of 351 missile head injuries in the Vietnam war, orbital penetration was noted in 0.6% cases only. Review of literature shows that orbital injury was ipsilateral to the cerebral injury in most reported cases. We have previously reported a rare case of left parieto-occipital lobe injury due to gun shot wound of the contralateral (right) orbit. The case reported here sustained a bullet injury to the left frontal bone but the missile was located below the contralateral (right) optic canal. The rarity of the case prompted this report.

3661. Misra, S., et al. (2010). "An arrow penetrating at base of the skull successfully removed." Journal of the Indian Medical Association **108**(3): 176-177.

A 30-year-old male presented with accidental injury with an arrow which referred to us from a peripheral village hospital. It was found that the arrow was penetrating through the nasal bones. An xray skull lateral view showed the tip of the arrow penetrating into the posterior wall of the sphenoid sinus. As the patient had no clinical evidence of neurological or vascular injury, he was immediately operated upon and the arrow was removed. Patient was discharged in good condition and a 3-month follow-up was normal.

3662. Misrahi, S. and K. Reuter-Rice (2020). "Transcranial Doppler Ultrasound Use in Pediatric Patients With Penetrating Traumatic Brain Injuries." Journal of Radiology Nursing **39**(1): 39-43.

The purpose of this article is to increase awareness of the usefulness of transcranial Doppler (TCD) ultrasound as a noninvasive neuromonitor and bedside ultrasound in pediatric patients who have experienced a penetrative traumatic brain injury (TBI) as a result of a firearm. To date, the use of TCD is not standard of care in pediatric TBI patients. TCD is a portable ultrasound that can be performed in any care environment. The use of TCD in pediatric TBI studies have demonstrated abnormalities in cerebral blood flow velocity, autoregulation, and embolic events; all of which have been associated with poor neurocognitive and functional outcomes. A penetrating brain injury as a result of a firearm is associated with ongoing vascular injury and thereby an increased risk for poor neurologic sequelae. We discuss two exemplars of TCD use in children who experienced a firearm-related penetrating TBI and their TCD findings. Both exemplars identified the unique insights provided by TCD that were unappreciated by clinical observation. This article provides early evidence for the use of TCD as a neuromonitor in pediatric penetrating TBI.

3663. Missaka, H., et al. (2009). "Implementation of the protocol of decompressive craniectomy: Does it really improve outcome?" Critical Care **13**.

Introduction: Treatment of traumatic brain injury (TBI) and other conditions that increase intracranial pressure (ICP) continues to be a challenge for intensivists and neurosurgeons. Despite adequate monitoring, the mortality and morbidity rate remain high. Decompressive craniectomy (DC) can be performed where maximum medical therapy has failed to reduce ICP. Objective: To analyze the viability of the DC protocol, since implementation, in the former 23 months. To identify the applicability of the protocol as an instrument for DC indication. Methods: A prospective, descriptive, series study, realized by the UPG-UCI of the Emergency and Neurosurgery Service. Criteria for ICU admission: age >18 years and <60 years, <48 hours at admission (except patients with tumor), Glasgow Coma Scale (GCS)

>4, decline for 3 points with the first GCS, extensive unilateral brain trauma, intraoperative evidence of brain swelling; image evidence of intracranial hypertension (ICH), stroke or brain trauma with mass effect and midline shift. Maximum medical therapy to reduce ICP, when possible: drainage of cerebrospinal (figure presented) fluid; induced hyperventilation; intravenous hyperosmotic solutions; head elevation; sedation and neuromuscular paralysis; barbiturate coma; and hypothermia. The protocol includes clinical, neurological and image signs. The patients' evolution was appraised by 3-month mortality, GCS and modified Rankin Scale. Results: Since the implementation of the DC protocol, from January 2007 to November 2008, seven clinical cases were admitted, all males, mean age of 39 years (21 to 60). Amongst them, three patients (42.8%) received specialized neurointensive care since admission. The primary mechanisms of injury include: fall of 2 m with severe concussion, fall of 6 m with subdural hematoma, carotid occlusion with hemispheric ischemia, tumor (glioblastoma multiforme), two motorcycle collisions with TBI, and gunshot with temporal contusion and subdural hematoma. The mean time between the admittance and DC was 29 hours 30 minutes (2 to 48 hours) (one tumor). None of the patients died. The mean GCS was: on admittance, 12 (8 to 15); pre-DC, 9 (6 to 15); 1 week, 12 (9 to 15); 3 months, 14 (11 to 15). The admittance GCS was higher than the pre-DC in all patients, and also the 1-week GCS was higher than the pre-DC. The mean modified Rankin scale was 1.75 (0 to 3). (See Figure 1.) Conclusions: Implementation of the protocol, based on recent studies, allows one to establish, with more accuracy, the best indication for DC, improving outcome. Despite small casualties, DC was effective to treat otherwise uncontrollable ICH and improved cerebral perfusion pressure. All patients presented a satisfactory clinical evolution and outcome after the procedure. The neurointensive care unit allowed an adequate treatment indication and management of these complex patients.

3664. Missault, S., et al. (2016). "Evaluation of [18F]BR420 and [18F]BR351 as potential PET ligands for in vivo imaging of MMP-9 activity in an animal model of traumatic brain injury." European Journal of Nuclear Medicine and Molecular Imaging **43**(1): S228-S229.

Aim: Matrix metalloproteinase-9 (MMP-9), a zinc-dependent endopeptidase, is a modulator of the brain extracellular matrix. Increased expression and activity ofMMP-9 has been reported after traumatic brain injury (TBI) and is associated with blood-brain barrier disruption and inflammation. Due to its involvement in synaptic plasticity, a role forMMP-9 in the development of posttraumatic epilepsy has been proposed. This study evaluated the potential of radiolabeled broad-spectrum MMP inhibitors [18F]BR420 and [18F]BR351 for in vivo visualisation of MMP-9 after TBI. Methods: Adolescent male Sprague-Dawley (SD) rats were subjected to either Controlled Cortical Impact (CCI) injury over the left parietal cortex (impact depth: 2.5mm, velocity: 4m/s, dwell time: 500ms; n=10) or sham injury (craniotomy only; n=10). Metabolite studies were performed for both [18F]BR420 (IC50= 7nM) and [18F]BR351 (IC50= 50nM) in healthy rats sacrificed at 5min and 1h post-intravenous (iv) tracer injection (35.2±0.3MBq; n=3/time point). Plasma and brain were analysed by reversed-phase HPLC and collected fractions were counted in an automated γ-counter. CCI and sham-operated rats were subjected to T2-weighted MR imaging, followed by 60min dynamic PET-CT imaging at 7d post-injury. Rats were injected iv with either [18F]BR420 (24.9±3.7MBq; n=7/group) or [18F]BR351 (37.1±0.7MBq; n=3/group). After scanning, brains were resected, counted and processed for ex vivo autoradiography. Tracer uptake in different brain regions was quantified by region of interest (ROI) analysis using PMOD software and expressed as Standardised Uptake Values (SUV). Results: In plasma, [18F]BR420 proved to be more stable than [18F]BR351 (50.3±15.7% and 3.5±3.7% of intact tracer remaining 1h post injection (pi), respectively). However, both compounds presented a relatively fast metabolism in the brain with a polar brain penetratingmetabolite (≥40%) already present for both tracers 5min pi. Furthermore, at 1h pi, only 11.4±0.3% and 6.1 ±4.1% of intact [18F]BR420 and [18F]BR351 were measured. However, due to low brain extraction yields (respectively 43% and 46%) those results might be misinterpreted. PET imaging revealed no difference in [18F]BR420 or [18F]BR351 uptake at the lesion site, in perilesional cortex, ipsilateral hippocampus, contralateral cortex and contralateral hippocampus between CCI- and sham-injured rats. Brain uptake was 0.069 ±0.012 %ID/g and 0.055±0.002 %ID/g for [18F]BR420 and [18F]BR351 respectively. Ex vivo autoradiography revealed a homogeneous tracer distribution throughout the brain. Conclusion: Studies are ongoing to confirm the increase ofMMP-9 at this time point in our model. Due to the rather fast metabolism of these tracers, it seems unlikely that they will be suited for in vivo brain imaging of MMP-9.

We present the case of a 19-year-old man who suffered a penetrating injury to the brain with a large-calibre steel industrial prybar approximately 1 m long and 2.5 cm wide that was retained in his cranium. The management of this type of injury is discussed, based on our experience with penetrating brain injuries with large-calibre retained objects, from initial presentation to surgical removal of the object to post-operative care. Additionally, given the similarities of the injuries suffered by our patient with those of Phineas Gage, we discuss the extensive lessons learned in treating this type of large-calibre injury. © The Author(s) 2012.

3668. Mitchell, K.-A. S., et al. (2020). "First-In-Human Experience With Integration of Wireless Intracranial Pressure Monitoring Device Within a Customized Cranial Implant." Operative neurosurgery (Hagerstown, Md.) **19**(3): 341-350.

BACKGROUND: Decompressive craniectomy is a lifesaving treatment for intractable intracranial hypertension. For patients who survive, a second surgery for cranial reconstruction (cranioplasty) is required. The effect of cranioplasty on intracranial pressure (ICP) is unknown., OBJECTIVE: To integrate the recently Food and Drug Administration-approved, fully implantable, noninvasive ICP sensor within a customized cranial implant (CCI) for postoperative monitoring in patients at high risk for intracranial hypertension., METHODS: A 16-yr-old female presented for cranioplasty 4-mo after decompressive hemicraniectomy for craniocerebral gunshot wound. Given the persistent transcranial herniation with concomitant subdural hygroma, there was concern for intracranial hypertension following cranioplasty. Thus, cranial reconstruction was performed utilizing a CCI with an integrated wireless ICP sensor, and noninvasive postoperative monitoring was performed., RESULTS: Intermittent ICP measurements were obtained twice daily using a wireless, handheld monitor. The ICP ranged from 2 to 10 mmHg in the supine position and from -5 to 4 mmHg in the sitting position. Interestingly, an average of 7 mmHg difference was consistently noted between the sitting and supine measurements., CONCLUSION: This first-in-human experience demonstrates several notable findings, including (1) newfound safety and efficacy of integrating a wireless ICP sensor within a CCI for perioperative neuromonitoring; (2) proven restoration of normal ICP postcranioplasty despite severe preoperative transcranial herniation; and (3) proven restoration of postural ICP adaptations following cranioplasty. To the best of our knowledge, this is the first case demonstrating these intriguing findings with the potential to fundamentally alter the paradigm of cranial reconstruction. 3669. Mitchum, B. (2018). "Interprofessional pediatric treatment model plays critical role in recovery process: Case study of 8-year-old child with catastrophic brain injury from gunshot." Journal of Head Trauma Rehabilitation **33**(3): E88.

Too often a child with traumatic brain injury is discharged to home once a hospital deems him medically stable even if that child is still incontinent, wheelchair-bound, on a Gtube, hearing and vision impaired, and has severe language deficits. This is understandable from the hospital's perspective of medical cost. It is understandable also that parents would want nothing more than to tuck their child in his own bed again every night. For the child who goes directly from the hospital to home, however, there is no way to measure the functional gains missed by skipping the step of post-acute inpatient rehabilitation where an interprofessional pediatric team guides the intervention: one cannot quantify what one doesn't have. Children with traumatic brain injury who are discharged straight to home can present a burden of dependence on caregivers already buckling under tremendous financial and emotional strain. The less able a child is to participate in life independently, the greater the burden on communities, families, and health care providers alike. The scope of dependence in childhood post injury can have an inverse relationship to the scope of independence in adulthood: the less dependent a child becomes, the better the prognosis for independence in adulthood. This presentation will report on a case study of a child who suffered unspeakable trauma at the hands of his mother, and will discuss the interprofessional pediatric treatment model which enabled the rehabilitation team to facilitate the child's recovery across every domain in ways it would be hard to argue could have been attained had he discharged straight to home from the hospital once he was medically stable.

3670. Mitilian, D., et al. (2009). "Removal of a chopstick out of the cavernous sinus, pons, and cerebellar vermis through the superior orbital fissure." Acta neurochirurgica **151**(10): 1295-1297.

Penetrating non-missile orbito cranial injuries are rare in a civilian pediatric setting. We describe a case of a trans-orbital penetration by a wooden chopstick deep down into the cerebellar vermis detected at neuroradiological examination in a child presenting for head injury. The foreign body was successfully pulled out in one piece surgically.

3673. Miyagi, A., et al. (1996). "[Intraorbital conjunctival cyst after a penetrating orbital injury: a case report]." No shinkei geka. Neurological surgery **24**(7): 649-653.

We report a case of intraorbital conjunctival cyst following a penetrating orbitocranial injury. The patient was a 28-year-old male who was hospitalized with exophthalmos, retrobulbar pain and upper gaze disturbance of his left eye. When he was 4 years old, a thin iron rod had penetrated intracranially through the inner angle of his left orbit. He was hospitalized and treated conservatively for about two weeks. The left eye ball was intact and visual acuity was normal, although bloody fluid had continuously flowed out from the left inner angle of the conjunctival wound for a few days. He had been febrile to 39 degrees C and complained of headache for one week. Subsequentry, the symptoms gradually improved through conservative therapy. When he was a junior high school student, he noticed exophthalmos of his left eye. However, he had never been examined closely, until he was 28 years old. We suspect that he had suffered from meningitis caused by the penetrating orbitocranial injury, and had fortunately improved under the conservative therapy. On admission to our hospital, a craniogram showed fracture of the left orbital roof, and coronal and three-dimensional computed tomography (CT) scans clearly demonstrated the orbital fracture. CT revealed a cystic mass in the retrobulbar space, and a porencephalic cyst in the medial basal frontal lobe. On magnetic resonance imaging (MRI) scans, both cysts were of low intensity on T1-weighted imaging, and of high intensity on T2-weighted images. Coronal and sagittal MRI scans showed that the two cysts were connected with each other through the fracture in the orbital roof. We diagnosed therefore that the orbital cyst was a herniated porencephalic cyst of the frontal lobe. Surgery was performed by a transcranial approach. The porencephalic cyst adhered to the fractured lesion of the frontal base but did not extend into the orbita. The intraorbital cyst was totally removed by opening the orbital roof including the fractured lesion. The cyst contained milky fluid. Postoperatively, the exophthalmos, retrobulbar pain and upper gaze disturbance showed gradual improvement. On histological examination, the cyst was found to be lined by non-keratinized stratified squamous epithelium and was diagnosed as a conjunctival cyst. This case was considered to be one of traumatic conjunctival cysts caused by a penetrating orbitocranial injury. Orbital conjunctival cysts have been reported to comprise about 10% of orbital epidermoid and dermoid cysts. Of these cysts, traumatic conjunctival cysts are rare, and only a few cases have been described. The etiology and therapy of orbital conjunctival cysts are discussed.

3674. Miyahara, M., et al. (2016). "[An Extremely Rare Case of Penetrating Head Injury Caused by a Nasal Implant Made of an Ivory Chip and a Review of the Literature]." Brain and nerve = Shinkei kenkyu no shinpo **68**(6): 661-666.

Although penetrating head injuries are very rare in Japan, an extremely rare case is reported in which an ivory chip, embedded in the subcutaneous tissue by a cosmetic rhinoplasty, penetrated the cranium. A 69-year-old woman with a psychiatric disorder suddenly jumped down from a window and bruised her face. The ivory chip went into her left frontal lobe via the frontal sinus. At surgery, it was completely removed via the nasion. There were no postoperative complications after adequate frontal sinus repair and closure of dura mater with a piece of pericranium. The literature dealing with Japanese penetrating head injuries was also reviewed. (Received May 27, 2015; Accepted December 1, 2015; Published June 1, 2016).

3675. Miyaishi, S., et al. (1994). "Massive pulmonary embolization with cerebral tissue due to gunshot wound to the head." Brain injury **8**(6): 559-564.

Autopsy findings in a 22-year-old man who received a gunshot wound to the head and died at the scene are presented. Massive white-grey emboli were found in the pulmonary arteries, and these were identified as cerebral cortical or glial tissue by histological examination. It was thought that the momentary severe increase of intracranial pressure and simultaneous rupture of the superior sagittal sinus due to the kinetic energy of the bullet had caused the lacerated cerebral tissue to enter the blood stream.

3676. Miyake, Y., et al. (2009). "Treatment model of CNS lymphoma using complement-dependent cytotoxicity induced by rituximab and autoserum." Blood **114**(22).

Background: Primary central nervous system lymphoma (PCNSL) is almost exclusively CD20-positive non-Hodgkin lymphoma (NHL). Although rituximab (R) is widely used for CD20-positive NHL, it is not considered to reach brain lesions effectively beyond the blood brain barrier. Intraventricule administration (ivt) of R is reported to be effective in meningeal lymphoma but the effect on lesions in the brain parenchyma seems to be limited. Recently, a case of refractory PCNSL that was successfully treated with ivt of R with autologous serum was reported (Takami A, et al. Cancer Science, 2006). Because the cerebrospinal fluid does not contain complements which exists in the serum, induction of complement-dependent cytotoxicity by ivt of R plus autoserum was speculated. To investigate this effect, we developed an animal treatment model of CNSL. Materials and methods: Raji, CD20-positive Burkitt lymphoma cell line, was inoculated into the deep frontal lobe of the brain of 8-week old F344 (nru-/nru-) nude rats, using brain stereotaxic apparatus. At the same time, a cannula was placed into the ipsilateral lateral ventricle. After several days, R or control immunoglobulin (cIg), plus human serum or saline, was administrated into the lateral ventricle. Results: The brain was extracted 24 hours after the last administration and frozen section was made. Human CD20-positive Raji cell tumor was also positively stained with FITC-conjugated anti-human IgG antibody when R but not cIg was administrated. Consequently, R in the lateral ventricle was considered to penetrate ependymal cells and brain parenchyma, and bound to lymphoma cells. Next, these rats were treated with ivt of R plus serum (R + Serum), cIg plus serum (cIg + Serum), or R plus saline (R + saline). These were administrated once a day from day 5 to day 9 after inoculation of Raji, and then survival was monitored. When an obvious weakness, such as marked and consecutively loss of activity or weight, was observed, these rats were euthanized and this is defined as dead day. In each case, the brain was extirpated and examined whether lymphoma existed or not. Death without lymphoma or from technical problem was excluded from the analysis. Survival of each group was analyzed by Kaplan-Meier method and log-lank test. R + Serum group had longer survival than cIg + Serum ($p = 0.049$). Long-term survivors were only seen in R + Serum and this group seemed to be superior to R + saline but statistical difference was not detected ($p = 0.083$). There were no difference between cIg + Serum and R + saline ($p = 0.382$) and neither group had long-term survivor. Conclusion: The possibility of novel treatment of CNSL with ivt of R and autoserum was shown in the rat CNSL model. To confirm this approach, clinical trials are warranted.

3677. Miyamoto, S., et al. (2010). "Risks and causes of cervical cord and medulla oblongata injuries due to acupuncture." World neurosurgery **73**(6): 735-741.

BACKGROUND: Acupuncture has become one of the most popular alternative medicines in the world today. Some acupuncturists still intentionally embed entire needles deep in the tissue for treatments, and some patients stick needles into their own bodies on their own., CASE DESCRIPTION: Surgical removal of an accidentally broken acupuncture needle due to self-acupuncture that was embedded in the medulla oblongata and cerebellum was performed. The broken needle migrated further into the brain in a few days. Contrary to expectation, it was extremely laborious to find the needle, which turned out to be completely embedded in the brain. No postoperative complications developed. The patient denied any symptoms and was subsequently discharged., RESULTS: Previously reported cases of 25 patients, in addition to our patient, who suffered from cervical or brain injuries due to acupuncture needles, were retrospectively studied. Embedded needles were the most frequent cause of the injuries and comprised 15 patients (57.7%). Accidentally broken needles came in second, comprising 11 patients (42.3%). Five cases (19.2%) were attributed to self-acupuncture. Sixteen (61.5%) patients developed symptoms more than 30 days after the accident. Twenty-three (88.5%) patients complained of sensory deficits, whereas 11 (42.3%) presented with motor weakness. Surgical removals were performed in 21 patients (80.8%), and 10 patients showed signs of recovery. On the other hand, no patients showed improvements in conservatively treated cases., CONCLUSIONS: Embedded needles in the brain should be urgently removed if possible. Both embedded needle acupuncture and self-acupuncture are extremely dangerous and hazardous to health.

3678. Mizraji, R., et al. (2009). "Brain death epidemiology in Uruguay and utilization of the Glasgow coma score in acute brain injured patients as a predictor of brain death." Transplantation proceedings **41**(8): 3489-3491.

OBJECTIVE: The knowledge of brain death (BD) epidemiology and the acute brain injury (ABI) progression profile are relevant to improve public health programs, organ procurement strategies, as well as intensive care unit (ICU) protocols aiming to increase the detection of potential donors. The aim of this study was to analyze the BD epidemiology and the ABI progression profile among subjects admitted to ICUs with a Glasgow Coma Score (GCS) < or = 8., MATERIALS AND METHODS: This was a prospective, observational study of BD reported to the National Institute of Donation and Transplantation from 2000-2006. The patients with ABI and GCS < or = 8 who were admitted to 5 ICUs with In-hospital Transplant Coordination were analyzed over the period of 2005-2007., RESULTS: The BD detection increased from 28.7 in 2000 to 58.5 BD pmp in 2006. The real donor global rate increased from 10 to 24.6 pmp from 2000 to 2006. The ABI patients with GCS < or = 8 had a global mortality rate of 56%, including 23.4% who evolved to BD., CONCLUSIONS: This study showed a 200% increment of detected BD and 150% of real donors, although these results are still below the international figures. GCS follow-up appeared to be a good tool to predict the BD outcome. The follow-up of patients with ABI allowed us to improve our BD detection strategy.

3679. Mnejja, M., et al. (2012). "[Bronchoscopy for foreign body inhalation in the pediatric population: lessons learned from 223 cases]." Bronchoscopie pour inhalation de corps etrangers chez l'enfant : a propos de 223cas. **19**(6): 670-674.

INTRODUCTION: Inhalation of foreign body in children is a serious accident that may compromise the vital prognosis of the child. The diagnostic was difficult in the absence of a recognizable penetration syndrome. Bronchoscopy is still recommended as the appropriate diagnostic and treatment of foreign bodies. The purpose of this study was to analyze the diagnostic and the treatment result of bronchoscopy and discuss its indications., MATERIAL AND METHODS: [corrected] A retrospective study analyzing data related to 223 children undergoing bronchoscopy due to suspicion of foreign body aspiration over a period of 10 years (2000-2009). The average age of the children was 29 months (range: one month-13 years). Approximately, two thirds of these patients were boys. The penetration syndrome was reported in 79.8% of cases., RESULTS: During bronchoscopy, the foreign body was confirmed only in 57.4%. Foreign bodies were found in the bronchus in 79.7% of cases. Among the foreign bodies, 78.1% were of vegetal origin. The average time of stay of the foreign body was of 16.1 days. Penetration syndrome and abnormal physical exam were the most sensitive parameters (79.7% and 82.8%, respectively) but with low specificity (24.2% and 35.8%, respectively). The combination of clinical and radiological signs suggestive of foreign body was the most specific sign (74.7%). Similarly, we found a statistically significant correlation between positive bronchoscopy and simultaneous suggestive clinical and radiological signs (P=0.03). The multivariate study showed that predictors factors of positivity of the bronchoscopy were: abnormal physical exam (P=0.016), abnormal radiological exam (P=0.003) and type of indication (P=0.005)., DISCUSSION: The diagnosis of laryngotracheobronchial foreign body recures an array of arguments. It is suspected on the clinical interview specially penetration syndrome and on the clinical and radiological presentation. Any suspicion should lead to a bronchoscopy.

3680. Mobbs, R. J. and K. N. Chandran (2001). "Traumatic middle cerebral artery occlusion: case report and review of pathogenesis." Neurology India **49**(2): 158-161.

Traumatic occlusion of the middle cerebral artery (MCA) is a rare cause of cerebral infarct. We describe a case of MCA occlusion following blunt head trauma. The literature reports some 65 cases of MCA occlusion following non-penetrating blunt trauma to the head. Arterial dissection, cerebral vasospasm and thrombosis have been some of the theories discussed in the pathogenesis of this condition. We review the pathogenesis based on anatomy of the M1 segment.

3682. Modaboyina, S., et al. (2021). "Intraorbital wooden foreign body, legacy of a notorious scrap: a case report." BMJ case reports **14**(4).

Wooden foreign bodies are notorious to be fragile and get retained as bits and bobs in the orbit. A 50-year-old woman presented to casualty with complaints of loss of vision and pain in the right eye associated with discharge from a wound in right eye upper lid. On imaging, a wooden foreign body was seen as continuous track of air. Meticulous dissection and search were done to remove bits and bobs of the wood. Patient, however, after 15 days of primary surgery reported with pus collection over wound site. Keeping suspicion of remnant wooden body piece(s), imaging and further exploration were carried out, removal of a 1 cm residual wooden piece was done. Retained wooden foreign body should always be suspected in postoperative cases of intraorbital wooden foreign body with infection. A close follow-up and knowledge of the same stay useful to remove any needless apprehension both of patient and surgeon.

3683. Modi, H., et al. (2022). "POST-INJURY TIME-COURSE OF MITOCHONDRIAL CALCIUM DYNAMICS, MEMBRANE INTEGRITY AND APOPTOSIS MARKERS FOLLOWING SEVERE PENETRATING TBI." Journal of neurotrauma **39**(11-12): A65.

Traumatic brain injury (TBI) remains a significant and urgent medical concern for the US military. From moderate to severe TBI, the most common mitochondria-centered cellular excitotoxic responses involved are calcium (Ca2+), oxidative stress and energy homeostasis. Their imbalance subsequently prompt the downstream cellular processes such as apoptotic/ necrotic cell death and ultimately alters behavioral outcomes after TBI. However, the time-course analysis of mitochondrial excitotoxic responses are lacking in the pre-clinical penetrating TBI (PTBI). Anesthetized adult male Sprague-Dawley rats (280-350 g) were subjected to either 10% unilateral PTBI or Sham craniectomy, followed by excitotoxic responses evaluated at 30min, 3h, 6h, 24h, 3d, 7d and 14d (n = 6-10 animals/groupX7 time-points). At each-time point, animals were euthanized and mitochondria isolated from ipsilateral frontal cortex and striatum areas. Time-course of PTBI groupmitochondrialCa2+ dynamics resulted in a “U-shaped” loss in Ca2+ buffering capacity (12-76%, vs. Sham) during the 2 weeks postinjury period, with maximum loss noted at 24h post-PTBI. Mitochondrial membrane integrity markers cytochrome c (Cyt C) and voltage-dependent anion channel (VDAC) revealed significant loss (20-50% vs. Sham) during the 2 weeks post-injury period. Additionally, the glyceraldehyde 3- phosphate dehydrogenase (GAPDH) expression elevated significantly (∼2-4 folds) in the PTBI group, which was reported as an indicator of apoptosis following injury. Following PTBI, brain region mitochondria showed loss of Ca2+ dynamics and early opening of permeability transition pore following PTBI. The current time-course data demonstrated that an early therapeutic intervention is necessary to mitigate mitochondrial excitotoxic responses for achieving neuroprotection following PTBI.

3684. Modi, M., et al. (2014). "Penetrating brain injury with machete, stuck to calvarium: Hurdles in imaging and solutions." Journal of neurosciences in rural practice **5**(Suppl 1): S63-65.

Penetrating brain injury is a less common form of traumatic brain injury in civilian set up, with a higher mortality and morbidity. A detailed preoperative imaging is warranted to ascertain the extent of injury and involvement of neurovascular structures. We present a rare case of penetrating brain injury with a long machete, who underwent emergency craniotomy, removal of the weapon, debridement and evacuation of the brain contusion and dural repair. Due to the sheer size of the weapon stuck to the calvarium, only X-rays could be performed preoperatively. The difficulties posed by the case, requiring modifications in standard imaging, possible solutions to address the problem and individualized management techniques are discussed in this report.

3686. Mohamed, H. A. R. (2019). "The neurotoxicity of titanium dioxide nanoparticles in mice." Research Journal of Pharmaceutical, Biological and Chemical Sciences **10**(6): 168-176.

Titanium dioxide (TiO2) nanoparticles (NPs) are the second NPs in the industry worldwide.TiO2 is widely used in chemical, electrical and electronic industries. TiO2NP penetrate directly into the brain through the olfactory bulb and can be deposited in the hippocampus region consequently, the present study was investigated the toxic effect of TiO2 NPs on brain of mice. Male mice were exposed to intraperitoneal injection (i.p) with (50 and 100 mg/kg body weight

(BW) TiO2 NPs for 21 successive days. At the end of experiment animals were sacrificed, brains were isolated for estimation of Neurotransmitters (dopamine (DA) and norepinephrine (NE)), Malondialdehyde (MDA), Antioxidant enzymes (superoxide dismutase (SOD) and glutathione peroxidase (GPx), Inflammatory mediators (interlukine-6 (IL-6) and tumor necrosis factor-α (TNF-α)) and Apoptosis biomarker (Bcl-2). The results showed that exposure to these nanoparticles induced a significant increase of DA and NE, decrease of SOD and GPx, raise of IL-6 and TNF-α and down regulation of Bcl-2 level. In conclusion, TiO2 nanoparticles could be translated to the brain and in turn caused the brain damage includes oxidative stress that leads to an change in the level neurotransmitters, lipid peroxidation, reduce the activities of antioxidative enzymes and activation of inflammatory cytokines resulted the stimulation of apoptosis.

3687. Mohamed, O. S., et al. (2022). "Effect of Dexmedetomedine on Oxidative Stress Accompanying Trumatic Brain Injury." NeuroQuantology **20**(8): 4185-4187.

Traumatic brain injury (TBI) is a leading cause of death and disability allover the world. It is caused by a blow to the head from blunt or penetrating trauma (1). The burden of TBI is more prominent in Developing Countries which face a higher prevelance of risk factors for causes of TBI and have inadequately prepared health systems (2). The major goals of anesthesia during craniotomy in patients with traumatic brain injury (TBI) are maintenance of hemodynamic stability, optimal cerebral perfusion pressure, lowering of ICP, and providing a relaxed brain (3). Although both inhalational and intravenous anesthetics are commonly employed, there is no clear consensus on which technique is better for the anesthetic management TBI (3). Oxidative stress is a disturbance in the balance between the production of reactive oxygen species (free radicals) and antioxidant defenses (4). Oxidative stress may contribute to many pathophysiological changes that occur after traumatic brain injury (4).

3688. Mohammadpour, M. and M. Soheilian (2005). "Concomitant optic nerve transection and chorioretinitis sclopetaria." BMC ophthalmology **5**: 29.

BACKGROUND: Optic nerve transection and chorioretinitis sclopetaria may occur following blunt ocular trauma. However, simultaneous occurrence has not yet been reported. We report the first case of concomitant optic nerve transection and chorioretinitis sclopetaria., CASE PRESENTATION: A 12-year-old boy with history of BB gun injury to his right eye was referred for loss of vision. His visual acuity was counting fingers at one meter in the right eye and with 3+ relative afferent pupillary defect (RAPD). On slit lamp examination, the right eye appeared normal except for 1+ vitreous reaction. Fundus examination of the right eye revealed a pale disc with superior retinal scar and diffuse submacular fibrosis compatible with chorioretinitis sclopetaria. Orbital CT-scans showed transection of the optic nerve by the BB gun pellet, which was lodged at the orbital apex., CONCLUSION: BB gun injury may cause concomitant optic nerve transection and chorioretinitis sclopetaria.

3689. Mohan, A. L., et al. (2005). "Knife wound to the posterior fossa in a child." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **21**(3): 255-258.

BACKGROUND: Knife wounds to the posterior fossa are a rare occurrence, especially in children. We report an 8-year-old girl who sustained a penetrating knife injury through the occipital bone into the posterior fossa. On presentation, the large knife blade was firmly embedded in her head., METHODS: Radiographic evaluation was limited to plain X-rays because of the large size and sharpness of the embedded blade. Innovative positioning was used during intubation and then the patient was positioned semi-prone on the operating room table. The blade was surgically removed and the dura was closed., CONCLUSIONS: Atypical penetrating cranial injuries in children may require the treatment team to take a creative approach to the evaluation and repair of the lesion in order to maximize patient safety and minimize the risk of neurological injury.

3690. Mohanty, S., et al. (1989). "Role of histamine in traumatic brain edema. An experimental study in the rat." Journal of the neurological sciences **90**(1): 87-97.

The possibility that histamine plays a role in the formation of traumatic brain edema was investigated in the rat. A 3 mm deep and 3 mm long stab injury was performed in the right parietal cortex under urethane anaesthesia. The brain water content and histamine levels in plasma and brain were measured at the end of 1, 2 and 5 h periods after trauma. There was a 3.46% increase in brain water content in the traumatized hemisphere from the value in the control

group at 5 h. The histamine content was increased by 107% in plasma and 51% in the traumatized brain hemisphere from the control value at this time period. The increased brain water content as well as the elevated plasma and brain histamine levels were prevented by prior treatment with the histamine H2-receptor antagonist cimetidine. Mepyramine (a histamine H1-receptor antagonist) failed to reduce the increased brain water content and the histamine levels in plasma and brain remained high. The results strongly indicate that histamine has a role in the formation of early traumatic brain edema and that this reaction can be influenced by pharmacological procedures.

3692. Molina, D. K., et al. (2013). "Gunshot wounds: a review of firearm type, range, and location as pertaining to manner of death." The American journal of forensic medicine and pathology **34**(4): 366-371.

Many studies have examined the characteristics of gunshot wounds by manner of death; however, no published study has directly compared these characteristics for the different types of firearms. This study was designed to address that deficiency. Existing data sets of nonaccidental deaths by handguns, shotguns, and rifles were reviewed. The victim data were analyzed by age and sex of the victims, wound location, range of fire, manner of death, and type of firearm. Handguns were the most common firearm used in both suicides and homicides, followed by rifles and then shotguns. For both homicides and suicides, there were significant differences between the firearm types for age of victims, range of fire, and wound locations. Possible reasons for those differences are discussed. It is concluded that information about the type of firearm is crucial to have when examining the nature of a firearm injury and determining the manner of death.

3693. Molina, D. K., et al. (2013). "Handgun wounds: a review of range and location as pertaining to manner of death." The American journal of forensic medicine and pathology **34**(4): 342-347.

Citizens of the United States own more firearms than those in any other country, and the majority of the firearms owned are handguns. Given such prevalence, surprisingly few studies have been published describing the characteristics of deaths due to handguns. To address this gap, nonaccidental handgun deaths examined at the Bexar County Medical Examiner's Office between 2000 and 2010 were reviewed. A total of 1450 cases were identified, including 797 suicides and 653 homicides. Age, range of fire, location of wound, and manner of death were analyzed. The average age of suicide victims (46.7 years) was found to be greater than that of homicides (34.3 years). Suicidal wounds tended to be contact wounds to the head; abdominal, extremity, back, and multiple wound locations were more common in homicides as were distant and intermediate wounds. Handgun wounds to the forehead, side of head, submental, and intraoral locations were significantly more common in suicide, whereas those to the face, apex of the head, and back of the head were more common in homicides. Where possible, likelihood ratios were calculated to determine relative likelihood of suicide or homicide for specific wound locations and ranges. While each death should be analyzed based on its unique circumstances and not solely its statistical probability, these data may help inform the pathologist's conclusions.

3694. Molina, D. K., et al. (2012). "The atypical entrance wound: differential diagnosis and discussion of an unusual cause." The American journal of forensic medicine and pathology **33**(3): 250-252.

The appearance of gunshot entrance wounds on the body depends upon many factors including, the type of firearm, the type of ammunition, the location of the wound on the body, and the circumstances of how a wound was sustained. Atypical gunshot entrance wounds are usually created when the bullet is destabilized prior to entering the body and consequently does not enter the body nose first but sideways or at an angle. The most common causes of an atypical entrance wound are bullet ricochet and interaction with an intermediate target. A case is presented in which the decedent sustained a gunshot wound with an atypical entrance. The cause of the atypical nature of the wound was determined to be increased yaw due to bullet instability caused by the condition of the firearm used, not a ricochet or intermediate target. The case emphasizes the importance of collaborative investigation between the different forensic agencies in gunshot cases.

3695. Moll, J., et al. (2018). "Altruistic decisions following penetrating traumatic brain injury." Brain : a journal of neurology **141**(5): 1558-1569.

The cerebral correlates of altruistic decisions have increasingly attracted the interest of neuroscientists. To date, investigations on the neural underpinnings of altruistic decisions have primarily been conducted in healthy adults undergoing functional neuroimaging as they engaged in decisions to punish third parties. The chief purpose of the present study was to investigate altruistic decisions following focal brain damage with a novel altruistic decision task. In contrast to studies that have focused either on altruistic punishment or donation, the Altruistic Decision Task allows players to anonymously punish or donate to 30 charitable organizations involved with salient societal issues such as abortion, nuclear energy and civil rights. Ninety-four Vietnam War veterans with variable patterns of penetrating traumatic brain injury and 28 healthy veterans who also served in combat participated in the study as normal controls. Participants were asked to invest $1 to punish or reward real societal organizations, or keep the money for themselves. Associations between lesion distribution and performance on the task were analysed with multivariate support vector regression, which enables the assessment of the joint contribution of multiple regions in the determination of a given behaviour of interest. Our main findings were: (i) bilateral dorsomedial prefrontal lesions increased altruistic punishment, whereas lesions of the right perisylvian region and left temporo-insular cortex decreased punishment; (ii) altruistic donations were increased by bilateral lesions of the dorsomedial parietal cortex, whereas lesions of the right posterior superior temporal sulcus and middle temporal gyri decreased donations; (iii) altruistic punishment and donation were only weakly correlated, emphasizing their dissociable neuroanatomical associations; and (iv) altruistic decisions were not related to post-traumatic personality changes. These findings indicate that altruistic punishment and donation are determined by largely non-overlapping cerebral regions, which have previously been implicated in social cognition and moral experience such as evaluations of intentionality and intuitions of justice and morality.10.1093/brain/awy064_video1awy064media15758316955001.

Maxillofacial gunshot injuries require proficiency to determine a suitable treatment plan and surgical intervention. In this paper, present 4 gunshot cases. Treatment in these patients is very challenging. Moreover, post-treatment infections are a serious problem in such cases. Thus, step-by-step surgery is essential to obtain a better result in these patients.

3698. Momjian, S., et al. (2003). "Occipital condyle fractures in children. Case report and review of the literature." Pediatric neurosurgery **38**(5): 265-270.

Occipital condyle fractures (OCF) are seldom described in children, with only 14 cases reported in the literature. We report the observation of a 13-year-old child in whom such a fracture was diagnosed. A review of the paediatric cases allowed us to identify the clinical features of OCF in children. The average age was found to be 10 years, and the causative traumatism was most often related to road traffic or sporting accidents with associated head injury. The level of consciousness was depressed in 67% of the cases, and in 53%, an injury to the cranial nerves, brain stem or high spinal cord was present. Neck pain with reduction of head mobility was reported in 27% of the cases. Treatment was generally conservative, i.e. a hard collar or halo vest for an average of 8 weeks. The course was favourable with respect to osseous consolidation, mobility and pain. On the other hand, the neurological deficits improved, but sequelae remained. Early diagnosis and treatment is mandatory since the secondary displacement of fractured fragments can injure the cranial nerves in a delayed fashion or even be fatal due to compression of the brain stem. 3699. Mommsen, P., et al. (2012). "Comparison of different thoracic trauma scoring systems in regards to prediction of post-traumatic complications and outcome in blunt chest trauma." The Journal of surgical research **176**(1): 239-247.

BACKGROUND: As accurate assessment of thoracic injury severity in the early phase after trauma is difficult, we compared different thoracic trauma scores regarding their predictive ability for the development of post-traumatic

complications and mortality., MATERIALS AND METHODS: Two hundred seventy-eight multiple trauma patients (ISS >= 16) age > 16 y with severe blunt chest trauma (AIS(chest) >= 3) admitted between 2000 and 2009 to Level I Trauma center were included. Exclusion criteria were severe traumatic brain injury (AIS(head) >= 3) and penetrating thoracic trauma. The association between AIS(chest), Pulmonary Contusion score (PCS), Wagner-score and Thoracic Trauma Severity score (TTS), and duration of ventilation, length of ICU stay, development of post-traumatic complications, and mortality was investigated. Statistical analysis was performed with chi(2)-test, ANOVA, logistic regression, and receiver operating characteristic (ROC) curve., RESULTS: Patients' mean age was 42.7 +/- 17.0 y, the mean injury severity score was 28.7 +/- 9.3 points. Overall, 60 patients (21.6%) developed ARDS, 143 patients (51.4%) SIRS, 110 patients (39.6%) sepsis, and 36 patients (13.0%) MODS. Twenty-two patients (7.9%) died. Among the examined thoracic trauma scores only the TTS was an independent predictor of mortality. With the TTS showing the best prediction power, the TTS, PCS, and Wagner-score were independent predictors of ventilation time, length of ICU stay, and the development of post-traumatic ARDS and MODS., CONCLUSIONS: Thoracic trauma scores combining anatomical and physiologic parameters like the TTS seem to be most suitable for severity assessment and prediction of outcome in multiple trauma patients with concomitant blunt chest trauma.

3700. Mondello, S., et al. (2013). "Characterization of TBI models and evaluation of the therapeutic efficacy of nicotinamide, erythropoietin and cyclosporine a using biochemical markers of brain injury: Results from operation brain trauma therapy." Journal of neurotrauma **30**(15): A167-A168.

Introduction To successfully develop compounds for clinical TBI, the multicenter consortium Operation Brain Trauma Therapy evaluates promising therapies in TBI models using the state-of-the-art behavioral, histological and immunohistochemical methods and circulating biomarkers. Here, we report model characterization using biomarker profiles and the effect of the first three therapies on biomarker concentrations. Methods Adult male Sprague-Dawley rats were subjected to controlled cortical impact (CCI), fluid percussion (FPI), or penetrating ballistic-like brain injury (PBBI) and treated with low or high dose of nicotinamide, erythropoietin [EPO] and Cyclosporine A [CsA], or with vehicle. Sham rats underwent all manipulations except trauma. The glial marker glial fibrillary acidic protein (GFAP) and the neuronal marker ubiquitin C-terminal hydrolase (UCH-L1) were measured by ELISA in serum at 4, 24 hours and 21 days after injury. Results Comparing across experiments no differences were found among sham groups and TBI + Veh groups in the same model, while UCH-L1 was significantly higher in CCI vs. FPI and PBBI ($P < 0.01$ and $P< 0.001$, respectively) and GFAP was significantly lower in PBBI vs. CCI and FPI ($P < 0.001$). Significant differences were also found comparing shams across the models, with higher UCH-L1 levels in CCI vs. FPI and PBBI ($P < 0.001$) and lower GFAP levels in FPI vs. CCI and PBBI ($P < 0.001$ and $P < 0.01$, respectively). Studies with nicotinamide showed that high dose treatment (500mg/kg) produced significant reductions of serum GFAP levels in PBBI and a trend toward a reduction in CCI at 24hrs postinjury (but not FPI). Nicotinamide had no impact on serum UCH-L1 levels. Studies with EPO showed that high dose treatment (10,000IU/kg) produced significant increases at 4hrs and significant reductions at 24hrs post-injury of serum UCH-L1 levels in CCI (but not PBBI and FPI). EPO had no impact on serum GFAP levels. Studies with CsA showed an initial dose-dependent trend of increase in GFAP at 4hrs in CCI and PBBI while in FPI there was a trend toward a reduction in the treated group vs. TBI + Veh. CsA had no impact on serum UCH-L1 levels. Conclusions We have characterized experimental TBI models using serum brain injury biomarkers and have shown that different models produced distinct biomarker profiles replicable across experiments. These findings provided robust evidence that biomarkers may be a valuable means for characterization, standardization and refinement of TBI animal models. Importantly, this study demonstrates that drugs differently affect distinct types of lesions as reflected by distinct biomarker pathways. Taken together, these findings strongly support the potential applications of biomarkers in TBI theranostics thereby holding promise for personalized medicine.

3701. Mondello, S., et al. (2012). "Differential effect of nicotinamide on serum damage marker profiles following controlled cortical impact, parasagittal fluid percussion, and penetrating ballistic-like brain injury: Results from operation brain trauma therapy." Journal of neurotrauma **29**(10): A48.

Introduction Preclinical models can help define TBI pathobiology and test new therapies. The multi-center, pre-clinical Operation Brain Trauma Therapy (OBTT) is evaluating drugs and biomarkers in three TBI models to prioritize for clinical translation. We evaluated the effect of nicotinamide across models on post-injury biomarker profiles and their neuropathological correlations. Methods Adult male Sprague-Dawley rats were subjected to controlled cortical impact (CCI), fluid percussion (FPI), or penetrating ballistic-like brain injury (PBBI) and treated with nicotinamide or vehicle at 15

min and 24 h post-injury. Sham rats in each model underwent all manipulations with the exception that they did not receivetrauma. In each model, animals were classified into 4 groups: (1): Sham, (2): TBI + Vehicle, (3): TBI + nicotinamide (50mg/kg), (4): TBI + nicotinamide (500mg/kg). At 21 days, rats were sacrificed and brain sections were assessed for lesion volume and either hemispheric or cortical tissue volume loss. The glial marker glial fibrillary acidic protein (GFAP) and the neuronal marker ubiquitin C-terminal hydrolase (UCH-L1) were measured by ELISA in serum at 4, 24 hours and 21 days after injury. Results At 4h post-injury, serum concentrations of UCH-L1 and GFAP were significantly increased compared to shams across all 3 TBI models. Initial GFAP levels were higher in CCI and PBBI model than in FPI model, whereas initial UCH-L1 concentration was highest after FPI. No significant treatment effect was detected in initial biomarker concentrations. At 24h post-injury, nicotinamide dose-dependently reduced serum GFAP levels in CCI and PBBI (but not FPI) with the greatest effect detected with the high dosage (500mg/kg). These findings were correlated with histological measures of lesion size and brain tissue loss. GFAP concentrations at 24h post-injury in CCI and PBBI strongly correlated with lesion volume ($R = 0.84$, $P < 0.0001$ and $R = 0.53$, $P < 0.0001$, respectively) and hemispheric tissue loss ($R = 0.87$, $P < 0.0001$ and $R= 0.59$, $P < 0.0001$). In FPI UCH-L1 concentrations at 4h post-injury correlated with lesion volume and hemispheric tissue loss ($R = 0.63$, $P < 0.0001$ and $R = 0.50$, $P = 0.002$, respectively). However, nicotinamide had no impact on serum UCHL1 levels. Conclusions Our results indicate that nicotinamide reduces GFAP levels following CCI and PBBI but not FPI, and that biomarker concentrations are predictive of lesion size and brain tissue loss. Differential effects of nicotinamide may be a reflection of the different animal models used and their associated type of injury. Our findings suggest the potential use of serum GFAP as a surrogate for volumetric analyses in preclinical therapeutic screening and the possibility that serum biomarker profiles may be useful in matching experimental models with patient subgroups in human TBI.

3702. Mondello, S., et al. (2011). "Analyses of brain damage biomarkers in patients with penetrating brain injury: A case series study." Critical care medicine **39**: 80.

Introduction: Penetrating brain injury (PBI) is a devastating insult associated to significant morbidity and mortality. To date, there are no therapies. In order to develop new therapeutic strategies, biomarkers represent a novel approach which may assess injury severity, provide objective and unique temporal information and insight into the pathophysiologic mechanisms following PBI. Hypothesis: We hypothesized that the magnitude of the increase in biomarker concentrations would reflect the severity of brain damage differentiating between mechanisms of injury, and that the time course of the biomarkers would mirror Blood-BrainBar-rier (BBB) dysfunction. Methods: Therefore, we evaluated concentration of Ubiquitin Carboxyl-Terminal Hydrolase-L1 (UCHL1) and glial fibrillary acidic protein (GFAP) in CSF and serum and compared their time course after PBI, closed head trauma and in uninjured controls. Samples were taken from each TBI patient at admission and every 6hrs up to 24hrs. Brain injury biomarkers were measured using absorbance-based ELISAassays. Results: CSF and serum levels of UCH-L1 and GFAP were significantly higher after PBI compared to closed head trauma and in uninjured controls. Initial and peak UCH-L1 and GFAP concentrations in CSF and serum were higher after PBI. Different temporal release patterns of biomarkers were observed. The temporal profile of CSF GFAP and UCH-L1 was more sustained in patients with PBI compared to patients with closed head trauma. Correlation between CSF and serum levels of both GFAP andUCH-L1 indicated an increased permeability of BBB in the first 12 hrs post-injury. Conclusions: Our findings including magnitude of the increase in biomarker concentrations and prolonged and elevated biomarker release suggest that the injury that occurs after PBI is particularly deleterious to the brain, and may explain the poor outcome in these patients. In addition, these preliminary results support the potential of brain biomarkers as monitoring parameters of BBB disruption following penetrating brain injury.

3703. Mondello, S., et al. (2014). "Comparison of TBI models using brain damage markers, and histological and behavioral outcomes in operation brain trauma therapy." Journal of neurotrauma **31**(12): A120.

Successful preclinical testing of neuroprotective drugs depends on the selection and characterization of appropriate animal models. Operation Brain Trauma Therapy (OBTT) is a multi-center pre-clinical drug screening consortium testing promising therapies for traumatic brain injury (TBI) in 3 well-established animal models (parasagittal fluid percussion injury [FPI], controlled cortical impact [CCI] and penetrating ballistic-like brain injury [PBBI]). Here, we characterize/ compare these models using circulating glial (glial fibrillary acidic protein [GFAP]) and neuronal (ubiquitin C-terminal hydrolase [UCHL1]) markers, behavior, and histology. At 4 h post-injury UCH-L1 was higher in CCI vs. FPI and PBBI ($P < 0.001$) and GFAP lower in PBBI vs. CCI and FPI ($P < 0.001$). Differences were also found comparing shams across models, with higher UCH-L1 levels in CCI vs. FPI and PBBI ($P < 0.001$) and lower GFAP levels in FPI vs. CCI and PBBI ($P <$

0.001 and P < 0.01, respectively). Increased cognitive deficits were observed in PBBI and CCI in the hidden platform task vs. FPI (P < 0.001) and in sham-CCI vs. sham-PBBI and sham-FPI (P < 0.001). Lesion volume was larger in PBBI vs. FPI and CCI (P < 0.001), while hemispheric volume loss was smaller in FPI vs. CCI and PBBI (P < 0.001). Average latency to find the hidden platform correlated with GFAP concentrations across models, but not with UCH-L1. Also, GFAP but not UCH-L1 correlated with lesion volume and hemispheric volume loss across models (P < 0.001). Experimental TBI models display major differences in biomarker profiles and functional and pathological consequences. Circulating GFAP levels best reflected behavioral and histological outcomes. Our data provide a unique characterization of TBI models that enlighten our understanding of the relationship between biomarkers and traditional TBI outcomes and could advance translational research.

3704. Mondello, S., et al. (2016). "Insight into Pre-Clinical Models of Traumatic Brain Injury Using Circulating Brain Damage Biomarkers: Operation Brain Trauma Therapy." Journal of neurotrauma **33**(6): 595-605.

Operation Brain Trauma Therapy (OBTT) is a multicenter pre-clinical drug screening consortium testing promising therapies for traumatic brain injury (TBI) in three well-established models of TBI in rats--namely, parasagittal fluid percussion injury (FPI), controlled cortical impact (CCI), and penetrating ballistic-like brain injury (PBBI). This article presents unique characterization of these models using histological and behavioral outcomes and novel candidate biomarkers from the first three treatment trials of OBTT. Adult rats underwent CCI, FPI, or PBBI and were treated with vehicle (VEH). Shams underwent all manipulations except trauma. The glial marker glial fibrillary acidic protein (GFAP) and the neuronal marker ubiquitin C-terminal hydrolase (UCH-L1) were measured by enzyme-linked immunosorbent assay in blood at 4 and 24 h, and their delta 24-4 h was calculated for each marker. Comparing sham groups across experiments, no differences were found in the same model. Similarly, comparing TBI + VEH groups across experiments, no differences were found in the same model. GFAP was acutely increased in injured rats in each model, with significant differences in levels and temporal patterns mirrored by significant differences in delta 24-4 h GFAP levels and neuropathological and behavioral outcomes. Circulating GFAP levels at 4 and 24 h were powerful predictors of 21 day contusion volume and tissue loss. UCH-L1 showed similar tendencies, albeit with less robust differences between sham and injury groups. Significant differences were also found comparing shams across the models. Our findings (1) demonstrate that TBI models display specific biomarker profiles, functional deficits, and pathological consequence; (2) support the concept that there are different cellular, molecular, and pathophysiological responses to TBI in each model; and (3) advance our understanding of TBI, providing opportunities for a successful translation and holding promise for theranostic applications. Based on our findings, additional studies in pre-clinical models should pursue assessment of GFAP as a surrogate histological and/or theranostic end-point.

3705. Mondello, S., et al. (2014). "Characterization of TBI models and evaluation of efficacy of nicotinamide, erythropoietin, and cyclosporin a using serum biomarkers: Results from operation brain trauma therapy." Journal of neurotrauma **31**(5): A35.

OBTT is a multicenter preclinical drug screening consortium for TBI. We measured serum glial fibrillary acidic protein (GFAP) and Ubiquitin C-terminal hydrolase (UCH-L1) in 3 rat models (parasagittal fluid percussion injury [FPI]), controlled cortical impact [CCI] and penetrating ballistic-like brain injury [PBBI]) treated with vehicle, or low or high doses of nicotinamide, erythropoietin [EPO] or Cyclosporin A [CsA]. At 4h after TBI UCH-L1 was significantly higher in CCI vs. FPI and PBBI, and GFAP lower in PBBI vs. CCI and FPI. Sham and TBI + Veh groups did not differ across experiments in the same model confirming intra-model reproducibility. But shams differed across models with highest UCHL1 levels in CCI and lowest GFAP in FPI. High-dose nicotinamide reduced GFAP but not UCH-L1 in PBBI at 24 h. High-dose EPO increased UCH-L1 at 4 h and reduced it at 24 h in CCI, but did not affect GFAP. CsA showed a dose-dependent increase in GFAP at 4 h in CCI and PBBI but a reduction trend in FPI vs. Veh. CsA had no impact on UCH-L1. Different models produced distinct biomarker profiles replicable across experiments supporting use of biomarkers to characterize, standardize and refine TBI animal models. Importantly, this study demonstrates that drugs differently affect distinct types of lesions as reflected by distinct biomarker pathways. Taken together, these findings provide robust evidence for a potential application of biomarkers in TBI theranostics thereby holding promise for personalized medicine.

3706. Mondello, S., et al. (2019). "Effects of glyburide on blood biomarker in three rat TBI models: Findings from OBTT." Journal of neurotrauma **36**(13): A33.

Glyburide (Gly) has shown promise in several studies of experimental traumatic brain injury (TBI) and the second highest scoring therapy tested in Operation Brain Trauma Therapy (OBTT). Although histological and functional measures remain central to assess therapeutic efficacy, there is interest in blood-based biomarkers to provide complementary, objective and efficient information. Here, we assess the effects of Gly on blood levels of neuronal and glial markers and their relationships with histopathological and behavioral outcomes across the OBTT consortium. Adult male rats subjected to controlled cortical impact (CCI), fluid percussion (FPI), or penetrating ballistic-like brain injury (PBBI) received a bolus 15min after-injury, followed by a continuous infusion for 7d. Serum glial fibrillary acidic protein (GFAP) and ubiquitin C-terminal hydrolase (UCH-L1) were measured at 4h and 24h after-injury. At 24h post-injury, GFAP was increased across models vs sham. At 24h, in CCI and PBBI, GFAP was lower in Gly-treated vs vehicle-treated, whereas there were no differences in UCH-L1 concentrations. Conversely, in FPI, Gly increased GFAP levels in treated rats at 4h and 24h, but attenuated neuronal injury as assessed by reduced UCHL1 at 4h. Contusion volume and hemispheric/cortical tissue loss were correlated with GFAP at both timepoints and with UCH-L1 at 4h across models; cognitive disfunction correlated with GFAP at 4h and 24h in CCI and at 24h in PBBI; no other correlations with behavioral outcomes were found. Overall, Gly produced distinct biomarker patterns and correlations across models. Greater understanding of the mechanisms underlying biomarker findings in TBI models may enhance their preclinical and clinical utility in TBI.

3707. Mono, J., et al. (1986). "Occult transorbital intracranial penetrating injuries." Annals of emergency medicine **15**(5): 589-591.

Emergency physicians who are confronted with orbital injuries must recognize that the transorbital route offers little resistance to intracranial penetration. Neither direct inspection of an orbital wound nor plain radiographs are sufficient to evaluate the extent of penetration beyond the orbital confines. A high index of suspicion is critical to the proper assessment and subsequent management of such injuries. We present two cases of penetrating injury. In the first, an arrow caused a hematoma in the superior cerebellar peduncle after passing through the medial orbit and superior orbital fissure. In the second, a wire entered the upper lid, fractured the orbital roof, and caused a frontal hematoma.

3708. Monson, D. O., et al. (1969). "Carotid vertebral trauma." The Journal of trauma **9**(12): 987-999.

3709. Monson, M. and A. Nations (2011). "Elevated intracranial pressure diagnosed by optic ultrasound in the setting of normal intraventricular catheter pressure measurements." Critical care medicine **39**: 17.

Case Report: One of the largest obstacles for physicians treating wounded service members is measuring intracranial pressure (ICP). Intraventricular catheters have long served as the «gold standard» of measuring, but are extremely invasive and difficult to maintain. Recent studies by Hansen HC, Blaivas M, Tayal V, Moretti R have shown that ultrasound measurement of the optic nerve sheath diameter can be used as a noninvasive way to gauge the ICP. We present the case of a wounded Marine who was diagnosed by ultrasound to have elevated ICP, in the setting of a normal intraventricular catheter pressure measurement. The patient is a 20 year old previously healthy male who was injured in an explosion causing multiple penetrating cranial wounds. Prior to arrival, he had undergone multiple surgeries, including a bifrontal craniectomy with intraventricular catheter placement for direct ICP monitoring. One week after arrival, the patient became acutely hypertensive and bradycardic, concerning for increasing ICP. The reading from the intraventricular catheter was discordant, however, showing a normal pressure. To assess help solve this diagnostic dilemma, a bedside ultrasound was performed of the orbit, which showed a markedly dilated optic nerve sheath diameter (6.9 mm with normal being less than 5.2 mm). The patient underwent a stat CT of the head, which showed a significant increase in size of a previously stable intracranial hemorrhage. He underwent arterial embolization, which he tolerated without complication. The intraventricular catheter did eventually show an elevated ICP, but not for another 2 hours. This case highlights the profound usefulness of the bedside ultrasound as a diagnostic modality in patients who have suffered traumatic brain injury. In this patient, whose vital signs and physical exam findings were conflicting, beside ultrasound of the optic nerve sheath was able to provide information leading to a definitive diagnosis prior to the «gold standard» of direct ICP measurement. We submit this case to bring to the attention of physicians the usefulness of a bedside ultrasound of the optic nerve sheath in evaluating for increased intracranial pressure.

3710. Montague, A. and B. Orozco (2017). "Systemic lead poisoning in an infant after gunshot injury to the spine and brain." Clinical Toxicology **55**(7): 790.

Background: Lead is a well-known toxic metal and developmental toxin in children. Cases of systemic absorption and toxicity from lead ingestion are common. Far more unusual is lead absorption and toxicity from non-ingested lead foreign bodies (LFBs), such as bullets. When this occurs, it is most likely because the LFB is in contact with circulating fluid, such as synovial fluid and possibly cerebrospinal fluid. We describe a case of lead poisoning in an infant after gunshot injury to the head and neck with LFBs in the central nervous system (CNS). Case report: The guardian of a 5-month-old female was attempting to fix a rifle when it discharged. The bullet ricocheted and struck the girl in her neck and thorax. She was stabilized at an outside hospital and transferred to a level one pediatric trauma center. Imaging revealed extensive soft tissue shrapnel in left neck, thorax, and occipital head. There were LFBs in the spinal canal at C4 and T2. LFB also tracked into the left cerebellum, penetrating to the midline brain near the cerebral aquaduct. Initial examination showed no movement in upper extremities and withdrawal to touch in bilateral lower extremities in a stable, intubated and sedated patient. Soft tissue was tattooed with black substance; LFBs and shrapnel were present. Debridement removed visible fragments. She had a C4-5 and T2-3 laminectomy with intradural LFB removal. Post-operative imaging revealed residual LFBs in the left cerebellar hemisphere, fourth ventricle, and occipital soft tissue. Two days after injury, a capillary blood lead level (BLL) was 27 mcg/dL. Thereafter, she was able to wean from the ventilator, smile, make eye contact and regain some extremity function. Constipation occurred that was attributed to medications and critical illness. Serial BLLs went up to 50 mcg/dL at 3 weeks post-injury. Succimer was started at standard dosing. BLLs initially decreased during succimer therapy, but quickly rebounded. Using a threshold of 45 mcg/dL for chelation, she required three courses of succimer in the 6 months since her injury. Highest BLL was 59 mcg/dL. She has not developed signs of neurotoxicity, hypertension, anemia or constipation. She is meeting appropriate language and social developmental milestones with motor limited as expected from her spinal injuries. Case discussion: Any symptoms of lead toxicity in this child are complicated by her young age and her co-occurring injuries. Her BLL may have risen rapidly secondary to initial high surface area exposure. Her ongoing source of lead is likely LFBs in contact with CSF. This type of exposure may result in chronic lead toxicity and potentially greater neurotoxicity. Unfortunately, the location of these LFBs also makes removal too risky to attempt. The role that potentially higher CSF lead burden may play is unstudied. The few pediatric reports of CNS LFB include no infants and no long-term outcomes. Conclusions: Elevated blood lead levels in an infant are complicated by retained lead foreign bodies in the CNS. For this rare scenario, no precedence was found in published cases to guide chelation therapy or predict long-term outcomes (Figure presented).

3711. Monterey, M., et al. (2019). "Open Surgery for Extraction of an Embolized Pellet in the Middle Cerebral Artery From a Shotgun Injury." Operative neurosurgery (Hagerstown, Md.) **17**(3): E119-E123.

BACKGROUND AND IMPORTANCE: Embolization of shotgun pellet from the peripheral vasculature to the cerebral vessels has been a known phenomenon that has been reported previously in the literature. However, there is no consensus on clinical indications for intervention, best modality of intervention or management upon leaving the hospital. We describe a case of a shotgun pellet in the neck that embolized to the middle cerebral artery that was treated with open surgery. Discussed is the initial management on presentation, timing of intervention from surgery and detailed surgical technique., CLINICAL PRESENTATION: A 20-yr-old man presented after being shot at close range with a shotgun. He was neurologically intact on exam. Initial screening computed tomography (CT) of the brain noted a shotgun pellet in the region of the sylvian fissure without intracranial hemorrhage. Computed tomography angiography again displayed pellet in the vicinity of the left middle cerebral artery. He was emergently taken for an awake cerebral angiogram and subsequent surgical extraction of the shotgun pellet., CONCLUSION: Missile embolization of a bullet fragment to the intracranial vasculature is rare and requires difficult decisions regarding management. Critical factors that are to be considered prior to treatment include neurological clinical presentation, timing of the trauma, and anatomic location of injury. Patients who are without neurological deficit that display compromised blood flow require immediate cerebral angiogram followed by surgical intervention depending on location.

3712. Montero-Menei, C. N., et al. (1996). "Early events of the inflammatory reaction induced in rat brain by lipopolysaccharide intracerebral injection: relative contribution of peripheral monocytes and activated microglia." Brain research **724**(1): 55-66.

We have previously demonstrated that lipopolysaccharide (LPS) intracerebral injection induced only minimal inflammatory reaction in rat brain, apart from an increased number of 'brain macrophages' observed 24 h after LPS administration [Montero-Menei et al., Brain Res., 653 (1994) 101-111]. However, the nature of these 'brain macrophages' in the inflammatory response is still unclear. The present study focused on the early time-points (from 5 h to 24 h) after LPS injection or stab-lesion, and was aimed at the identification of the peripheral (monocytes) or parenchymal (microglia) origin of these 'brain macrophages'. OX42- and ED1-labeling did not clearly discriminate between monocytes/macrophages and reactive microglia, both cell types being immunoreactive. In other experiments, rats were made aplasic by irradiation prior to lesioning. These experiments clearly demonstrated that LPS induces an intense monocyte recruitment and, to a lesser extent, microglial activation since about 80% of the cells present 24 h after LPS injection consisted of recruited monocytes not observed in aplasic rats. Interestingly, our data show that LPS exerts a sequential dual action by first inhibiting the monocyte recruitment observed 5 h after stab lesion and then enhancing it at 15 h and 24 h after injection. A possible involvement of cytokines, chemokines and adhesion molecules in the mechanisms occurring in the early events of brain inflammatory reaction is discussed.

3713. Montero-Menei, C. N., et al. (1994). "Lipopolysaccharide intracerebral administration induces minimal inflammatory reaction in rat brain." Brain research **653**(1-2): 101-111.

An inflammatory reaction, essential for defence against infection and for wound repair, may also induce irreversible tissue damage. It appears that the central nervous system has developed its own immunosuppressive strategy in order to limit the destructive effects of inflammation. To clarify this point, we have characterized in one unique model of inflammation induced in the rat by intracerebral lipopolysaccharide injection the kinetics of the inflammatory reaction, the participation of immunitary and glial cells and of three growth factors. Among these molecules, brain-derived neurotrophic factor mRNA expression was found decreased following LPS injection. No striking differences were observed in the brain parenchyma after stab lesion or inflammatory lesion apart from an increase in the number of monocytes/macrophages recruited early to the lesion area. Macrophages were later accumulated around the lesion when astroglia and microglia reactions occurred. Some of the macrophages and microglia expressed major histocompatibility complex class II antigens on their surface whereas no T or B lymphocytes were observed in the brain parenchyma. However, a subpopulation of CD3- and CD4-negative CD8-positive cells, likely natural killer cells, was observed around the lesion site; this recruitment was inhibited by the highest dose of LPS. This study therefore supports the hypothesis of a suppression of some aspects of cell-mediated immunity in the brain, mechanisms which need to be further characterized.

3714. Montgomery, S. P., et al. (2005). "The evaluation of casualties from Operation Iraqi Freedom on return to the continental United States from March to June 2003." Journal of the American College of Surgeons **201**(1): 7-3.

BACKGROUND: Most seriously wounded US Army casualties from the Iraqi theater of operations come through Walter Reed Army Medical Center on their return to the United States. General surgery and orthopaedic surgery services have developed a multidisciplinary team approach to triage and treatment of incoming casualties., STUDY DESIGN: Prospective database of returning casualties to Walter Reed Army Medical Center from Operation Iraqi Freedom (OIF) from March 1 to July 1, 2003., RESULTS: Of 294 casualties seen, 119 were triaged to inpatient status and treated within 1 hour of arrival; mean age 26.6 +/- 6.2 years (range 23 to 37). Time from original battlefield injury was a mean of 8 days (range 3 to 28 days). Forty-six (39%) sustained gunshot wounds, 37 (31%) sustained blast and shrapnel injuries, and 41 (34%) had blunt/motor vehicle collision mechanisms. There were a total of 184 wounded locations in these 119 casualties; of these, there were 29 head and neck, 25 chest, 20 abdomen, 74 lower extremity, and 36 upper extremity. Twenty-eight casualties (23%) required emergent surgical procedures on the night of arrival. Another 30 (25%) required an urgent surgical procedure within 48 hours of arrival., CONCLUSIONS: Followup surgical procedures were urgently or emergently required in 43% of admitted battlefield casualties from OIF on transfer to Level V care in the continental United States. The injury pattern of wounds from this engagement is described. The Walter Reed Army Medical Center system of incoming battlefield casualty evaluation using multidisciplinary teams is successful in expediting care and ensuring evaluation of the full range of potential injuries.

3715. Monticelli, F., et al. (2002). "Air rifle injury with an entrance through the nose: a case report and review of the literature." International journal of legal medicine **116**(5): 292-294.

A case of attempted homicide is reported where a 31-year-old woman was shot in the left nostril with a pellet from an air rifle. The projectile channel reconstruction showed penetration of the nasal septum, the maxillary and sphenoid cavities and the dura mater, with the pellet finally lodging in the anterior cranial fossa between the sinus cavernosus and the internal carotid artery. The patient was finally discharged from hospital in a good physical condition without any neurological symptoms. Although the muzzle velocity of the air rifle was within the legal limits, the present case demonstrates the potential lethality of air weapons considering the site of entrance of the pellet.

3716. Montiel, M. B. E., et al. (2018). "Renal allografts from brain dead donors following cerebral gunshot wounds." Transplantation **102**(7): S797.

Introduction: Severe brain injury following cerebral gunshot wounds may expose large amounts of tissue factor to the circulation and develop disseminated intravascular coagulation (DIC). DIC can lead to renal dysfunction. Objectives: Analyse the validity for transplantation of kidneys harvested from brain dead donors (BDD) following cerebral gunshot wounds and the outcome of the transplanted renal grafts. Methods: Retrospective descriptive study of renal allografts harvested from BDD following cerebral gunshot wounds, at a single center, between June 1, 2007 and May 31, 2017. Data on donors (patients' characteristics, blood tests, associated injuries) and recipients (graft survival, rejection) were collected. Results:We analysed data from six BDD following cerebral gunshot wounds (age 40.3 ± 9.6 years) without any cardiovascular risk factors, except one patient who had hypertension. All patients presented brain death in the first 24 hours of hospital admission. None of them had any associated injuries. One patient suffered a cardiopulmonary arrest (during 20 minutes) prior to ICU admission.One of the patients had elevated creatinine levels in the blood tests when he was admitted to the hospital. But, during the ICU length of stay, up to 50%of the patients presented acute renal failure. Fifty percent of the patients presented compatible or suggestive criteria for DIC. Four kidney grafts were not valid for transplantation because: acute renal failure (two kidney grafts), poor graft perfusion (one case) and complex vascular anomalies (one case). Eight kidney grafts (66.67%) were transplanted. Seven kidney grafts were transplanted in our center. One of them was explanted, in the first 24 hours after transplantation, due to cortical necrosis (pathology report: glomerular and vascular thrombotic microangiopathy lesions). Figure 1. The donor's contralateral kidney was not implanted due to poor perfusion. The pathology report of this kidney was: multiple fibrin trombi in glomerular capillaries and small-vessels (Figure 2). The remaining 6 grafts presented adequate function one year after the transplantation, except in one case which suffered underlying disease recurrence. Conclusion: An accurate evaluation of kidney grafts from BDD following cerebral gunshot wounds is required, because those patients are at risk for DIC and acute renal failure. Almost all transplanted renal allografts from BDD, following cerebral gunshot wounds, had good results in our study. Pre-transplant biopsy and, perhaps, the reduction of ischemia time may be indicated. Further studies with larger simple sizes are needed.

3717. Montoure, A., et al. (2016). "Neuro-critical care services can manage mild traumatic brain injury effectively without neurosurgical consultation." Neurocritical care. Conference: 14th annual meeting of the neurocritical care society. United states **25**(1 Supplement 1): S73.

Introduction: Mild traumatic brain injury (TBI) is a commonly seen pathology at trauma centers. Neurosurgical consultation is a routine practice; however, the vast majority do not require surgical intervention or invasive monitoring during the entirety of their hospital stay. In certain trauma centers, neurology-centered neurocritical care solely evaluate and manage mild TBI. We provide a retrospective analysis of this practice at our level 1 trauma center. Methods: A retrospective chart review was completed on TBI patients evaluated at a level 1 trauma center between September 2009 and December 2015. Inclusion criteria included; initial GCS 13-15, blunt head injury, available repeat imaging, and management by neurology-centered neuro-intensivists. Exclusion criteria included GCS <13, penetrating trauma, those that needed immediate surgery, those with neurosurgical consultation, and those without available imaging. A total of 87 patients were included in the final analysis. Results: Age was 48.8 +/- 21 years. There were 50 males and 37 females. The most common mechanism was falls (51.7%), followed by motor-vehicle collision (16.1%), motor-cycle accident (12.6%), bike-related (8.0%), assault (6.9%), and pedestrian-struck by automobile (4.6%). Polytrauma occurred in 8%, anticoagulation / antiplatelet (A/A) use in 23.0%, and skull fractures in 41.4%. On repeat CT head, 14.9% were better, 60.9% were stable, 24.1% were worse. Only 10 patients (11.5%) exhibited neuro-exam

changes, where 7 patients received repeat imaging which ultimately demonstrated stable findings. No patients required a neurosurgical procedure. Average hospital stay was 2.8 +/- 3.7 days. Conclusions: Neurology-centered neuro-intensivists can manage mild TBI appropriately without official neurosurgical consultation. This practice can streamline TBI management and potentially reduce hospital costs.

3718. Montoure, A., et al. (2016). "Routine repeat CT head is not necessary without neurological change for mild traumatic brain injury." Neurocritical care. Conference: 14th annual meeting of the neurocritical care society. United states **25**(1 Supplement 1): S61.

Introduction: Mild traumatic brain injury (mTBI) is defined as an initial Glasgow Coma Scale (GCS) 13-15. Current recommendations include a follow-up computed tomography (CT) scan of the head prior to discharge. Often, imaging and neurological exam remains stable, questioning the role of routine repeat imaging. Methods: A retrospective chart review was completed on TBI patients evaluated at a level 1 trauma center between August 2009 and December 2015. Inclusion criteria included: initial GCS 13-15, blunt head injury, and available repeat imaging. Exclusion criteria included GCS <13, penetrating trauma, those that required immediate surgery, or those without repeat imaging. A total of 198 patients were included in the analysis. Statistics were done with Mann-U Whitney or Chi-Square testing. Results: Age was 49.3+/-21 years. There were 123 males and 75 females. The most common mechanism was falls (43.9%), followed by motor-vehicle collision (22.7%), motor-cycle accident (12.6%), assault (9.1%), pedestrian-struck by automobile (6.1%), and bike-related (5.6%). Polytrauma occurred in 42.6%, anticoagulation / antiplatelet (A/A) use in 22.2%, and skull fractures in 50.5%. On repeat CT, 16.2% were better, 59.1% were stable, 24.7% were worse. Only 19 patients (19.6%) exhibited neuro-exam changes, where 16 patients received repeat imaging which ultimately demonstrated stable findings. Ultimately, only one patient required a neurosurgical procedure, an external ventricular drain, due to significant decline. Age, gender, mechanism, polytrauma, A/A use, and skull fractures did not significantly correlate with neuro-exam changes. On the other hand, neuro-exam changes significantly correlated with CT changes ($p = 0.01$). Conclusions: Repeat imaging tend to show worse findings when associated with neurological changes. On the other hand, results for repeat imaging were variable without neurological changes and generally did not alter treatment plans / patient outcomes. As CT imaging inflicts radiation exposure and hospital costs, repeat imaging is only warranted for neurological changes that may necessitate a neurosurgical procedure.

3719. Moon, J. H., et al. (2013). "Evaluation of probability of survival using trauma and injury severity score method in severe neurotrauma patients." Journal of Korean Neurosurgical Society **54**(1): 42-46.

Objective: Despite several limitations, the Trauma Injury Severity Score (TRISS) is normally used to evaluate trauma systems. The aim of this study was to evaluate the preventable trauma death rate using the TRISS method in severe trauma patients with traumatic brain injury using our emergency department data. Methods: The use of the TRISS formula has been suggested to consider definitively preventable death (DP); the deaths occurred with a probability of survival (Ps) higher than 0.50 and possible preventable death (PP); the deaths occurred with a Ps between 0.50 and 0.25. Deaths in patients with a calculated Ps of less than 0.25 is considered as non-preventable death (NP). A retrospective case review of deaths attributed to mechanical trauma occurring between January 1, 2011 and December 31, 2011 was conducted. Results: A total of 565 consecutive severe trauma patients with ISS>15 or Revised Trauma Score<7 were admitted in our institute. We excluded a total of 24 patients from our analysis: 22 patients younger than 15 years, and 2 patients with burned injury. Of these, 221 patients with head injury were analyzed in the final study. One hundred eighty-two patients were in DP, 13 in PP and 24 in NP. The calculated predicted mortality rates were 11.13%, 59.04%, and 90.09%. The actual mortality rates were 12.64%, 61.547%, and 91.67%, respectively. Conclusion: Although it needs to make some improvements, the present study showed that TRISS performed well in predicting survival of traumatic brain injured patients. Also, TRISS is relatively exact and acceptable compared with actual data, as a simple and time-saving method.

3720. Moore, D. F., et al. (2008). "Blast physics and central nervous system injury." Future neurology **3**(3): 243-250.

The effect of blast on biological tissue is well documented for particular organ systems such as the lung. This is not the case for the CNS, where the mechanism of CNS injury following a detonation and blast wave is unclear. The effect of blast on traumatic brain injury (TBI) has come into particular focus with the Global War on Terror and Operation Iraqi Freedom, and Operation Enduring Freedom where TBI has become known as the signature injury of

these conflicts. The reason for the prominence of TBI in these particular conflicts as opposed to others is unclear, but may result from the increased survivability of blast due to improvements in body armor. In this review, we trace the historical context of blast injury and develop current concepts from this framework, in addition to highlighting many remaining unsolved questions.

3721. Moore, H. B., et al. (2016). "Pediatric emergency department thoracotomy: A 40-year review." Journal of pediatric surgery **51**(2): 315-318.

BACKGROUND/PURPOSE: Emergency department thoracotomy (EDT) has been proposed to be futile in the pediatric patient population. This extreme procedure has survival rates of 0 to 26% in the nonadult population. When taking into consideration that the mechanism of injury is one of the strongest predictors of survival, we hypothesize that the low survival rate in pediatric patients is attributable to a higher rate of blunt trauma compared to their adolescent counterparts., METHODS: Prospective data collected from our level 1 trauma center from 1974 to 2014 on all patients undergoing EDT at our institution were evaluated for age 18years or younger. Patient predictor variables included injury mechanism, injury pattern, and detected cardiac activity in the field. Outcomes included successful resuscitation (reestablish of blood pressure and taken to operating room) and overall survival. Patients were dichotomized by age into pediatric (age<=15years) and adolescent (16-18years) categories., RESULTS: 1691 patients who underwent EDT were evaluated for age of 18years or less, which included 179 patents (11%). Overall survival in the adult population was 6.1%, compared to 3.4% in the nonadult population (p=0.157). Pediatric patients were more likely to sustain blunt injury than adolescents (72% vs 32%, p<0.001). This also corresponded to differences in anatomic injury patterns and more multisystem trauma (52% vs 44%, p=0.001). Adolescents had significantly higher survival rates than pediatric patients (5% vs 0%, p=0.036)., CONCLUSION: In nonadult patients undergoing EDT, adolescents have a higher survival rate than pediatric patients. The pediatric population had a significantly lower incidence of penetrating trauma and higher incidence of head injury. The discrepancy in survival between adolescent and pediatric patients appears to be attributable to differences in mechanism. Therefore, those pediatric patients with penetrating thoracic injuries may still benefit from EDT.

3722. Moore, H. B., et al. (2016). "Establishing Benchmarks for Resuscitation of Traumatic Circulatory Arrest: Success-to-Rescue and Survival among 1,708 Patients." Journal of the American College of Surgeons **223**(1): 42-50.

BACKGROUND: Attempts are made with emergency department thoracotomy (EDT) to salvage trauma patients who present to the hospital in extremis. The EDT allows for relief of cardiac tamponade, internal cardiac massage, and proximal hemorrhage control. Minimally invasive techniques, such as endovascular hemorrhage control (EHC) are available, but their noninferiority to EDT remains unproven. Before adopting EHC, it is important to evaluate the current outcomes of EDT. We hypothesized that EDT survival has improved during the last 4 decades, and outcomes stratified by pre-hospital CPR and injury patterns will provide benchmarks for success-to-rescue and survival outcomes for patients in extremis., STUDY DESIGN: Consecutive trauma patients undergoing EDT from 1975 to 2014 were prospectively observed as part of quality improvement. Predicted probabilities of survival were adjusted for pre-hospital CPR, mechanism of injury, injury pattern, patient demographics, and time period of EDT using logistic regression. Success-to-rescue was defined as return of spontaneous circulation with blood pressure permissive for transfer to the operating room., RESULTS: There were 1,708 EDTs included, with an overall 419 (24%) success-to-rescue patients and 106 survivors (6%), and 1,394 (79%) of these patients had pre-hospital CPR and 900 (54%) had penetrating wounds. The most common injury patterns were chest (29%), multisystem with head (27%), and multisystem without head (21%). Penetrating injury was associated with higher survival than blunt trauma (9% vs 3% p < 0.001). Success-to-rescue increased from 22% in 1975 to 1979 to 35% over the final 5 years (p < 0.001); survival increased from 5% to 14% (p < 0.001)., CONCLUSIONS: Outcomes of EDT have improved over the past 40 years. In the last 5 years, STR was 35% and overall survival was 14%. These prospective observational data provide benchmarks to define the role of EHC as an alternative approach for patients arriving in extremis.

3723. Moore, J. P., et al. (2009). "The corrected QT interval before and after heart transplantation." The American journal of cardiology **104**(4): 596-601.

Heart donor candidates have severe neurologic injuries that have been associated with significant prolongation of the corrected QT (QTc) interval. Screening for an underlying abnormality of cardiac repolarization such as the long-QT syndrome thus becomes difficult. The aims of this study were to establish normal values and determine factors associated with prolongation of pre- and post-transplantation QTc intervals in a large cohort of heart transplantation donors and recipients. The medical records of 179 donors and 112 recipients were reviewed for historical, electrocardiographic, and neuroimaging data. After linear regression analysis, gunshot wounds were associated with the shortest mean pre-transplantation QTc interval of 447 +/- 51 ms (p = 0.016), whereas all other mechanisms of brain injury were associated with markedly prolonged QTc intervals. Overall, the mean QTc interval decreased from 467 +/- 58 to 446 +/- 47 ms (p <0.001), the mean QRS duration increased from 87 +/- 16 to 98 +/- 21 ms (p <0.001), and the mean QT dispersion did not change significantly after transplantation. The only factor associated with a prolonged QTc interval in the post-transplantation period was hypokalemia, with a mean QTc of 468 +/- 37 ms (p = 0.047). In conclusion, the mechanism of donor brain injury is associated with alterations in the pre-transplantation QTc interval, with the shortest intervals related to gunshot wounds. Fewer than 5% of the donor population was found to have QTc interval > or =580 ms. For those afflicted by gunshot wounds, <5% had QTc intervals > or =550 ms. This information can be used in pre-transplantation donor assessment, and post-transplantation management can be tailored to avoid the occurrence of ventricular arrhythmia.

3724. Moore, N., et al. (2017). "Prevalence of ocular injuries in the setting of trauma: A 6-year retrospective analysis from a level-one trauma center." Investigative Ophthalmology and Visual Science **58**(8).

Purpose: To characterize ocular injuries in trauma patients requiring ophthalmic consultation. Methods: The American College of Surgeons (ACS) trauma registry was utilized to identify patients presenting to a level-one trauma center in the Midwest region who received ophthalmic evaluation for associated ocular injuries from January 1, 2006 to December 31, 2012. Data recorded from the registry included patient demographics, mechanism of injury, and the specific ocular injuries encountered. Descriptive analysis of the data was utilized. Results: 212 patients were identified as having ocular injuries related to major trauma requiring an ophthalmic evaluation. 161 patients were male (75.9%, median age 37) and 51 were female (24.1%, median age 44). Mechanisms of injury included: motor vehicle/motorcycle accidents (36%), assault (33%), fall (16%), gunshot injury (3.8%), and accidental or other cause of injury (11.2%). Of the total number of females, 72.5% (n=37) suffered a motor vehicle crash or a fall as a cause of their ocular injury, whereas 70% (n=113) of men suffered a motor vehicle crash or assault. Significant injuries included: open globe injury (24%, n=51), hyphema (16%, n=34), retrobulbar hemorrhage (14%, n=30), traumatic optic neuropathy (7%, n=15), vitreous hemorrhage (7%, n=15), optic nerve transection (2.4%, n=5), and retinal detachment (1.4%, n=3). Other common injuries included: orbital fracture (49%, n=104), eyelid laceration (32%, n=68), subconjunctival hemorrhage (24%, n=51), and corneal abrasions (14%, n=30). Orbital fractures were associated with simultaneous open globe injuries in 18 of the 51 patients (35%), traumatic optic neuropathy in 9 of the 15 patients (60%), and optic nerve transection in 3 of the 5 patients (60%). Seventy (33%) of all these patients required an ophthalmic procedural intervention. Conclusions: Patients presenting to the trauma service can also have significant ocular injuries. Young men are vulnerable to ocular injuries in the setting of trauma, especially with motor vehicle accidents and assaults. Women are more likely to suffer ocular injuries through a motor vehicle crash or fall. Orbital fractures were associated with significant sight threatening ocular injuries. Early ocular evaluation is important in the setting of major trauma, as one third of the patients in this analysis required an ophthalmologic procedural intervention.

3725. Moore, P. L., et al. (2003). "Gunshot injuries to the temporal bone." The Journal of laryngology and otology **117**(1): 71-74.

The current incidence of missile injury to the temporal bone (MITB) is very low in the United Kingdom. However, the increasing frequency of firearm violence in Britain suggests a greater risk of occurrence. This, along with the devastating potential sequelae of MITB (facial palsy, dead ear, intracranial damage, major vascular injury and cosmetic disfigurement), requires otolaryngologists to be conversant with all aspects of their management. The risk of major complications is much higher with MITB than with temporal bone injury following blunt trauma, and surgical management is, therefore, much more common. We present one such case, and review the literature outlining the pathogenesis, clinical features, and recommended management.

3726. Moore, R. A., et al. (2020). "Clinical utility of WAIS-IV 'excessive decline from premorbid functioning' scores to detect invalid test performance following traumatic brain injury." The Clinical neuropsychologist **34**(3): 512-528.

Objective: Excessive Decline from Premorbid Functioning (EDPF), an atypical discrepancy between demographically predicted and obtained Wechsler Adult Intelligence Scale-4th Edition (WAIS-IV) scores, has been recently proposed as a potential embedded performance validity test (PVT). This study examined the clinical utility of EDPF scores to detect invalid test performance following traumatic brain injury (TBI). Methods: Participants were 194 U.S. military service members who completed neuropsychological testing on average 2.4 years (SD = 4.0) following uncomplicated mild, complicated mild, moderate, severe, or penetrating TBI (Age: M = 34.0, SD = 9.9). Using TBI severity and PVT performance (i.e., PVT Pass/Fail), participants were classified into three groups: Uncomplicated Mild TBI-PVT Fail (MTBI-Fail; n = 21), Uncomplicated Mild TBI-PVT Pass (MTBI-Pass; n = 94), and Complicated Mild to Severe/Penetrating TBI-PVT Pass (CM/STBI-Pass; n = 79). Seven EDPF measures were calculated by subtracting WAIS-IV obtained index scores from the demographically predicted scores from the Test of Premorbid Functioning (TOPF). Cutoff scores to detect invalid test performance were examined for each EDPF measure separately. Results: The MTBI-Fail group had higher scores than the MTBI-Pass and CM/STBI-Pass groups on five of the seven EDPF measures ($p<.05$). Overall, the EDPF measure using the Processing Speed Index (EDPF-PSI) was the most useful score to detect invalid test performance. However, sensitivity was only low to moderate depending on the cutoff score used. Conclusions: These findings provide support for the use of EDPF as an embedded PVT to be considered along with other performance validity data when administering the WAIS-IV.

3728. Mora Rubio, J. and J. Mendoza-Vega (1971). "[Craniocerebral injuries. Epidemiology]." Traumatismos encefalocraneanos. Epidemiologia. **17**(2 Suppl): 199-212.

3729. Morais, B. A., et al. (2018). "Post-traumatic carotid-cavernous fistula in a pediatric patient: a case-based literature review." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **34**(3): 577-580.

BACKGROUND: Carotid-cavernous fistula (CCF) is a shunt between the carotid artery and the cavernous sinus. Traumatic CCFs are diagnosed in 0.2% of head traumas being only 4.6% of the pediatric population. Classified by Barrow in 1985, type A CCF is the most frequent, occurring in 75% of cases. Type A is characterized by direct and high-flow CCF that generally can occur as a result of traumatic injury or rupture of an intracavernous aneurysm., CASE PRESENTATION: The subject was an 8-year-old boy with penetrating trauma to his left eye. During the initial evaluation, a computed tomography (CT) scan was unremarkable, and after relief of symptoms, the patient was discharged. Seven days later, he developed grade I proptosis, conjunctival chemosis, ophthalmoplegia (III, IV, and VI cranial nerve palsies), and left-sided ptosis and mydriasis. Arteriography confirmed a post-traumatic CCF, and the patient was treated with an endovascular detachable balloon., CONCLUSION: CCF should be suspected in craniofacial traumas with ocular symptoms. The presence of a skull base fracture on CT is a poor predictor of CCF associated with head trauma. Early diagnosis and treatment can prevent permanent neurological deficits and unfavorable outcomes.

3730. Morales, C. H., et al. (2014). "Negative pleural suction in thoracic trauma patients: a randomized controlled trial." The journal of trauma and acute care surgery **77**(2): 251.

BACKGROUND: The study aimed to establish the benefits of using chest tubes with negative pleural suction against trapped water in patients with penetrating or blunt chest trauma who underwent tube thoracostomy, in terms of the incidence of complications, such as persistent air leak, clotted hemothorax, empyema, and duration of stay., METHODS: Patients who underwent tube thoracostomy because of traumatic pneumothorax, hemothorax, or hemopneumothorax were randomly assigned into one of two groups: in Group 1, the three-bottle drainage system was connected to a negative suction; in Group 2, no suction was given. Patients who required mechanical ventilation or emergency surgery (thoracotomy or thoracoscopy) either at the time of admission to the institution or immediately after the tube thoracostomy, patients who had histories of thoracic procedures or chronic pulmonary diseases (chronic

obstructive pulmonary disease, diffuse interstitial lung disease), and patients with multiple injuries with severe traumatic brain injury and a Glasgow Coma Scale (GCS) score less than 8 of 15 were excluded from the study. Hospital stay, duration of tube thoracostomy, prolonged fistula, and other clinical variables were compared., RESULTS: One hundred ten patients were included, 56 in the group with suction and 54 in the group without suction. There were no differences in the demographic characteristics of each group. There were no differences between the groups in terms of hospital stay (p = 0.22), duration of tube thoracostomy (p = 0.35) (3 days in each group), or complications. However, the probability of air leak presence in time was greater for the Group 1 patients with negative suction versus the Group 2 patients (p = 0.023)., CONCLUSION: The use of negative pleural suction did not demonstrate advantages over the three-bottle chest drainage system without suction in patients with uncomplicated traumatic pneumothorax, hemothorax, or hemopneumothorax., LEVEL OF EVIDENCE: Therapeutic study, level II.

3731. Morales, C. H., et al. (2014). "Negative pleural suction in thoracic trauma patients: A randomized controlled trial." The journal of trauma and acute care surgery **77**(2): 251-255.

BACKGROUND: The study aimed to establish the benefits of using chest tubes with negative pleural suction against trapped water in patients with penetrating or blunt chest trauma who underwent tube thoracostomy, in terms of the incidence of complications, such as persistent air leak, clotted hemothorax, empyema, and duration of stay., METHODS: Patients who underwent tube thoracostomy because of traumatic pneumothorax, hemothorax, or hemopneumothorax were randomly assigned into one of two groups: in Group 1, the three-bottle drainage system was connected to a negative suction; in Group 2, no suction was given. 3732. Morales, N. G., et al. (2021). "Eye injuries associated with nerf gun use in a pediatric population: a case series." Journal of AAPOS **25**(4): e41-e42.

Introduction: Nerf guns can cause vision-threatening injuries. We conducted a retrospective case series of patients evaluated during the acute management of Nerf gun-associated eye injuries to assess clinical outcomes and follow-up burden. Methods: An electronic medical record search was conducted for pediatric (age 1-19) patients seen at an academic pediatric ophthalmology clinic between 12/1/2017 and 3/31/2020. 445 patients were identified using ocular injury-related ICD codes. Thirteen patients met our inclusion criteria of injury with a Nerf gun, evaluation within 48 hours, and completion of follow-up appointments. Results: Mean patient age was 9.7 years old and most were male (69.2%). At presentation, only ∼1/3 had 20/20 near visual acuity and two had pressures >21 mm Hg. Hyphema, the most common injury, was documented in 11 patients (84.6%), and commotio retinae, the most severe injury, in one. Four patients (30.8%) required pressure lowering drops over an average of 15 days. Cumulative follow-up for all 13 cases amounted to 61 outpatient visits, with an average of 4.7 visits and 26-day follow-up windows per patient. Activity restriction averaged 15 days per patient, with ∼176 cumulative days of restriction for all patients. Although no severe complications were noted at discharge, both blunt trauma and hyphema confer an increased lifetime risk for angle-recession glaucoma, necessitating lifelong follow-up. Conclusion/Relevance: This case series highlights the ocular dangers and emphasizes the potential loss of productivity for children and their families resulting from Nerf gun injuries. The authors support formal recommendations for eye protection during the use of Nerf guns.

3734. Morariu, A. M., et al. (2008). "Early events in kidney donation: progression of endothelial activation, oxidative stress and tubular injury after brain death." American journal of transplantation : official journal of the American Society of Transplantation and the American Society of Transplant Surgeons **8**(5): 933-941.

Cerebral injury leading to brain death (BD) causes major physiologic derangements in potential organ donors, which may result in vascular-endothelial activation and affect posttransplant graft function. We investigated the kinetic of pro-coagulatory and pro-inflammatory endothelial activation and the subsequent oxidative stress and renal tubular injury, early after BD declaration. BD was induced by slowly inflating a balloon-catheter inserted in the extradural space over a period of 30 min. Rats (n = 30) were sacrificed 0.5, 1, 2 or 4 h after BD-induction and compared with sham-controls. This study demonstrates immediate pro-coagulatory and pro-inflammatory activation of vascular endothelium after BD in kidney donor rats, proportional with the duration of BD. E- and P-Selectins, Aalpha/Bbeta-fibrinogen mRNA were abruptly and progressively up-regulated from 0.5 h BD onwards; P-Selectin membrane protein expression was increased; fibrinogen was primarily visualized in the peritubular capillaries. Plasma von Willebrand factor was significantly higher after 2 h and 4 h BD. Urine heart-fatty-acid-binding-protein and N-acetyl-glucosaminidase, used as new specific and sensitive markers of proximal and distal tubular damage, were found significantly increased after 0.5 h, with a maximum at 4 h. Unexpectedly, oxidative stress was detectable only late, after the installation of tubular injury, suggesting only a secondary role for hypoxia in triggering these injuries.

3735. Morax, S., et al. (1980). "[Oculo-orbito-palpebral injuries by projectile]." Traumatismes oculo-orbito-palpebraux par projectile. **25**(4): 341-346.

3736. Moreira Filho, P. F. and M. R. Freitas (1986). "[Post-anoxic hemi-myoclonic encephalopathy: report of a case]." Encefalopatia hemi-mioclonica pos anoxica: registro de um caso. **44**(1): 67-72.

A case of a young man with myoclonus in his right side after cerebral hypoxia is reported. This patient had cerebral hypoxia caused by injury in his left common carotid artery. After a few hours he had generalized convulsive seizures of tonic-clonic type and also a septic shock. As consciousness was regained, he developed action and intention myoclonus in his right-side. The EEG showed diffuse typical myoclonus potentials. Clonazepan 8 mg daily was used with good results. This is the first reference in the medical literature of the unilateral localization in the Lance-Adams syndrome. The authors think that in this case two abnormalities contributed to the cerebral anoxia: the common carotid artery injury and the septic shock.

3737. Moreno, A., et al. (2009). "[Current treatment of pediatric penetrating traumas]." Tratamiento actual de los traumatismos penetrantes pediatricos. **22**(4): 193-196.

INTRODUCTION: The traditional management of pediatric penetrating trauma has been wide surgical examination. However, the selective nonoperative management is increasing thanks to the precise diagnosis obtained from radiologic studies as CT scan. The purpose of this study is reviewing our experience in the last eight years with a less invasive management., PATIENTS AND METHODS: We retrospectively reviewed (2000-2007) the patients with penetrating injuries of different parts of the body (excluding cranioencephalic traumatism) treated in our center and registered by the Clinical Documentation Unit. The variables collected and evaluated included age, mechanism of injury, kind of injury, diagnostic and therapeutic modalities and outcome., RESULTS: There were 17 patients (median 9.5 years, range 4-17) with penetrating trauma. According the localization of injury the patients were divided into 4 groups: abdominal (17.6%), thoracic (23.5%), cervical (17.6%) and extremities (41.2%). The most frequent kind of injuries were: skin and muscle (with or without penetrating peritoneal or chest cavity, 52.9%) vascular or neurological structures (29.4%). We would like to highlight one case of cardiac perforation and taponade, one traqueal lesion and one case of external iliac vein injury. The injuries caused by glass (35.3%) and sharp arms (29,4%) were the most frequent mechanism. Simple suture and observation was treatment enough in 47.1%. Three patients required neural and vascular micro suture. One patient followed a thoracotomy procedure and other one, a sternotomy. It wasn't necessary any laparotomy. No patient died and 88% of the patients have no sequelae., CONCLUSIONS: Most of the penetrating child traumas have good prognosis and are associated with few sequelae. Low energy thoracic and abdominal penetrating

traumas can be managed conservatively when the patient is hemodiynamically stable and CT scan shows no organ injury, avoiding unnecessary surgical examinations.

3738. Moreno, L., et al. (2013). "Ocular trauma from land mines among soldiers treated at a University Hospital in Medellin, Colombia." Colombia medica (Cali, Colombia) **44**(4): 218-223.

INTRODUCTION: Currently ocular combat injuries are complex and associated with poor visual outcomes. Our objective is to characterize the military population that suffer land mine combat ocular trauma in Colombia and identify the type of wound, treatment and visual outcomes., METHODS: Retrospectively review of medical history of soldiers evaluated in Pablo Tobon Uribe Hospital, whom had land mine trauma during January of 2004 and December 2012., RESULTS: 635 soldiers had land mine trauma, 153 of them had ocular trauma (226 eyes). Open ocular trauma was observed in 29.6%. The Ocular Trauma Score was calculated in 183 eyes, the initial visual acuity was not possible to be reported in the rest of them; the 45% of the eyes were classified in category 3. Three patients had no light perception in both eyes. 97.3% of the eyes received medical treatment and 49.1% had surgery also. Primary evisceration was made in 5.8% and enucleation in 1.8%. Intraocular foreign body was observed by ultrasonography in 11.1% and in 5.8% by orbital tomography. Eleven patients were legally blind at discharge., CONCLUSIONS: The ocular trauma related to a land mine is highly destructive at an ocular level. The treatments associated with better visual outcomes are primary closure of globe and systemic antibiotics; although the characteristics of the wound itself are the main prognostic factor. The Ocular trauma score is a useful tool for determining visual outcome in combat ocular trauma.

3739. Moreno, P., et al. (2013). "Early lung retrieval from traumatic brain-dead donors does not compromise outcomes following lung transplantation." European journal of cardio-thoracic surgery : official journal of the European Association for Cardio-thoracic Surgery **43**(6): e190-197.

OBJECTIVES: To determine whether lung retrieval from traumatic donors performed within 24 h of brain death has a negative impact on early graft function and survival after lung transplantation (LT), when compared with those retrieved after 24 h., METHODS: Review of lung transplants performed from traumatic donors over a 17-year period. Recipients were distributed into two groups: transplants from traumatic donor lungs retrieved within 24 h of brain death (Group A), and transplants from traumatic donor lungs retrieved after 24 h of brain death (Group B). Demographic data of donors and recipients, early graft function, perioperative complications and mortality were compared between both groups., RESULTS: Among 356 lung transplants performed at our institution, 132 were from traumatic donors (70% male, 30% female). Group A: 73 (55%); Group B: 59 (45%). There were 53 single, 77 double, and 2 combined LT. Indications were emphysema in 41 (31%), pulmonary fibrosis in 31 (23%), cystic fibrosis in 38 (29%), bronchiectasis in 9 (7%) and other indications in 13 patients (10%). Donor and recipient demographic data, need or cardiopulmonary bypass, postoperative complications and Intensive Care Unit and hospital stay did not differ between groups. Primary graft dysfunction (A vs B): 9 (16%) vs 13 (26%) P = 0.17. PaO2/FiO2 24 h post-transplant (A vs B): 303 mmHg vs 288 mmHg (P = 0.57). Number of acute rejection episodes (A vs B): 0.93 vs 1.49 (P = 0.01). Postoperative intubation time (A vs B): 99 vs 100 h (P = 0.99). 30-day mortality (A vs B): 7 (10%) vs 2 (3.5%) (P = 0.13). Freedom from bronchiolitis obliterans syndrome (A vs B): 82, 72, 37, 22 vs 78, 68, 42, 15%, at 3, 5, 10 and 15 years, respectively (P = 0.889). Survival (A vs B): 65, 54, 46, 42 and 27 vs 60, 50, 45, 43 and 29% at 3, 5, 7, 10 and 15 years, respectively (P = 0.937)., CONCLUSIONS: In our experience, early lung retrieval after brain death from traumatic donors does not adversely affect early and long-term outcomes after LT.

3740. Morentin, B. and B. Biritxinaga (2006). "Massive pulmonary embolization by cerebral tissue after head trauma in an adult male." The American journal of forensic medicine and pathology **27**(3): 268-270.

We report a case of an adult man who was run over by a car, suffering severe head trauma. After 3 hours in the hospital, he experienced sudden and severe hemodynamic deterioration, dying immediately. The autopsy showed massive cerebral tissue pulmonary embolization (CTPE), confirmed by immunohistochemistry. Multiple fractures of the skull, tear of the transverse sinus, and brain laceration of the occipital lobe were present. CTPE is very infrequent. In children and adults, it occurs as a complication of severe closed or penetrating head trauma. Although laceration of a large cerebral venous sinus is not always essential, in some cases (like in the present one) this laceration is the mechanism of entry of the cerebral tissue to the blood circulation. The clinical repercussion of CTPE is variable. In some cases, it could be an incidental finding of autopsy. In other cases, coagulation abnormalities and disseminated

intravascular coagulation have been reported. Finally, such as in the present case, the immediate cause of death is the sudden hemodynamic failure due to the massive CTPE.

3741. Moreschi, C., et al. (2019). "Medicolegal Investigations in Cases of Double Suicidal Gunshots to the Head Using 2 Different Handguns: A Report of an Unusual Case." The American journal of forensic medicine and pathology **40**(3): 266-268.

Suicides committed by firing 2 gunshots to the head are rare events and pose a significant challenge for coroners and forensic pathologists. The evaluation of the victim's ability to fire 2 shots simultaneously, or to act after a first gunshot, is crucial for the reconstruction of the death scene and to differentiate between homicide and suicide. We report an unusual case of suicide involving 2 gunshot wounds to the head. The medicolegal investigations hypothesized that the victim had either fired 2 shots near simultaneously or he suffered from rapid incapacitation after the first gunshot but was still able to fire a second consecutive and fatal shot to the head. This article focuses on the diagnostic difficulties involved, together with analysis of the death scene and autopsy findings, in cases where the courts demand confirmation that a double gunshot to the head is in fact a case of suicide.

3742. Morgan, K. S., et al. (1984). "Epikeratophakia in children." Ophthalmology **91**(7): 780-784.

Epikeratophakia was performed in 61 children for the correction of aphakia after the removal of unilateral congenital or traumatic cataracts; 51 patients (54 grafts) have more than 6 months follow-up. In the first 27 grafts, 8 (30%) failed, but in the last 27 grafts, only 2 (7%) failed, largely due to improved surgical and tissue handling techniques. The average increase in corneal refractive power for the early patients was 12.68 +/- 4.63 D with an average overrefraction of +0.45 +/- 5.60 D. The last half of the patients showed an average increase of 14.83 +/- 4.83 D, with an average overrefraction of -0.00 +/- 5.20 D. Visual acuity results in patients with traumatic cataracts have been the most satisfactory, with the majority of patients obtaining useful vision. It also appears that in patients with congenital cataracts, the younger the patient at the time of surgery, the greater the chance for a good visual result. Some improvement in vision has been seen in all of the children with successful grafts, even those beyond the age when amblyopia therapy would be considered to have some potential for therapeutic effect. By attaching the correction permanently on the eye, epikeratophakia facilitates the vigorous occlusion therapy required after cataract extraction in these children.

3743. Morita, T., et al. (2017). "External Ventricular Drainage Preceding the Removal of a Nail from the Intracranial Space as a Safe Management Strategy for Predicted Secondary Intraventricular Hemorrhage." World neurosurgery **106**: 1056.e1059-1056.e1013.

BACKGROUND: Intracranial nail gun injury is a rare traumatic event and can result from a suicide attempt. Cerebral angiography is essential in the evaluation of damage to the intracranial vessels, and surgical removal of nails is generally the optimal treatment. Intraventricular hemorrhage can happen after removal of intracranial nails. Endovascular surgery or intraoperative computed tomography has been reported to be useful for detection and treatment of intraventricular hemorrhage. After the surgical removal of nails, attention should be paid for complications such as pseudoaneurysm and infection., CASE DESCRIPTION: A 63-year-old man with a history of depression was transferred to our hospital in an unconscious state. Physical examination showed 2 nails puncturing his left thorax, and computed tomography revealed a nail puncturing the intracranial space. No damage to these intracranial vessels was observed on computed tomography angiography and venography. After drainage for potential intraventricular hemorrhage, the nails were removed. Postoperatively, prophylactic antibiotic therapy was administrated for secondary infection. Computed tomography angiography did not detect any postoperative pseudoaneurysms. The patient also underwent therapy from a psychiatrist and was transferred to another hospital., CONCLUSIONS: As for treatment of a case of intracranial nail gun injury, our case shows that preoperative cerebral angiography is not always needed in intracranial nail gun injury when there is no apparent damage to the intracranial vessels and emergent removal of nails is required. External ventricular drainage preceding the removal of a puncture object can be an effective management strategy for secondary intraventricular hemorrhage.

3744. Morris, C., et al. (2012). "Cervical spine injuries associated with mandibular trauma." Journal of oral and maxillofacial surgery **70**(9): e106-e107.

Introduction: Cervical spine fractures are a severe injury associated with high morbidity and mortality. Due to the tragic consequences of a missed cervical spine injury, maxillofacial surgeons must be acutely aware of the mechanisms most likely to result in cervical injury when evaluating patients with mandibular trauma.1 Past studies have investigated this association and reported a prevalence of 0.0 to 8.2%.2 This study examines the relationship between mandibular fractures and concomitant cervical spine injury at an urban trauma center. The importance of this study is to further isolate mechanismbased risk factors for cervical spine injuries presenting with mandibular fractures to provide data for when additional evaluation is necessary. Materials and Methods: The UT Southwestern Medical Center Institutional Review Board approved the study protocol and patient information was de-identified prior to analysis. Mandibular Fracture Data was collected from the Parkland Memorial Hospital trauma registry using ICD-9 codes (802.21-802.39). Additional information included fracture type, age, gender, mechanism of injury, and associated injuries. Methods of Data Analysis: Data was analyzed using a Microsoft excel spreadsheet. Results of Investigation: The Parkland Trauma Registry yielded 2288 patients presenting with mandible fractures to Parkland Memorial Hospital between 1993- 2007. These fractures were all managed by a single surgical service allowing a degree of consistency in coding and treatment. Of the 2288 patients presenting with mandibular fractures, 72 patients (3.1%) had associated cervical spine injuries. High velocity mechanisms resulted in 68 of the 72 c-spine injuries associated with mandibular fractures (94.4%). 12 (6.7%) of the cervical spine injuries associated with mandibular fractures were due to a high velocity penetrating mechanism (gunshot wounds). 56 of the 72 c-spine injuries (78% of the cervical spine injuries associated with mandibular fractures were due to high velocity blunt injury (motor vehicle, motor cycle, motor pedestrian collisions, or unspecified high velocity mechanisms). 5 patients had multiple c-spine injures; these were all the result of high velocity blunt mechanisms. In patients presenting with mandibular fractures and high velocity mechanisms (blunt and penetrating) the overall incidence of cervical spine injury was 12.1% (68/560). In high velocity blunt mechanisms the combined incidence was 11.9% (52/456). In patients presenting with mandibular fractures and low velocity mechanisms the overall incidence of cervical spine injury was 0.4% (4/986). Conclusion: Clinical examination should include an evaluation for recognized concomitant injuries including cervical spine involvement. The results of this investigation underscore the importance of association of high velocity mechanism with patients presenting with a mandibular fracture and cervical spine injury. Further investigation is needed to determine a cost-effective protocol to screen patients presenting with mandibular frac- tures caused by high velocity injuries for cervical spine injuries.

3745. Morris, C. D., et al. (2011). "Mandibular fractures: Epidemiology and patterns of injury in 4100 fractures." International journal of oral and maxillofacial surgery **40**(10): 1024.

Introduction: This study provides a large statistical sample to investigate patterns of mandibular injury in a major urban trauma center. The purpose of this study is to allow identification of population and mechanism-based risk factors and to isolate concomitant, potentially life-threatening injuries, presenting with fractures of the mandible. Methods: Data was collected from the Parkland Memorial Hospital Trauma Registry using ICD-9 codes. Information included fracture type, age, gender, mechanism of injury, and associated injuries. Results: 4143 mandibular fractures in 2828 patients were managed at Parkland Memorial Hospital between 1993 and 2010. The 3rd decade was the most prevalent age group; there was a male predominance of 83%. The injury distribution by site was: Condyle 9.2%, Subcondyle 10.6%, Coronoid 1.1%, Ramus 5.6%, Angle 29.18%, Symphysis 22.92%, Alveolar Border 3.2%, and Body 18.09%. Mechanism was generally subdivided for comparison of associated injuries. Subdivisions include high velocity penetrating (gunshot - 5%), low velocity penetrating (knife - 0.4%), high velocity blunt (MVC, MCC - 19.9%), Low velocity blunt (MPC, IPC, Falls, Sports - 46.85%) and other (NOS - 27.8%). Multiple fractures within the mandible were the predominant pattern representing 1426 of the 4143 fractures. 1402 fractures were limited to a single site. Fractures were more common in the summer months. Conclusion: This study provides a large statistical sample of mandible fracture patterns at a single institution. Future investigation of will provide greater insight into the patterns of injury and degree of severity of associated injuries based on mechanism of injury.

3746. Morrison, C. S., et al. (2013). "Utilization of intraoperative 3D navigation for delayed reconstruction of orbitozygomatic complex fractures." The Journal of craniofacial surgery **24**(3): e284-286.

Reconstructive goals for orbitozygomaticomaxillary complex fractures include restoration of orbital volume, facial projection, and facial width. Delayed reconstruction is made more difficult by malunion, nonunion, bony

absorption, loss of the soft tissue envelope, and scar. Three-dimensional intraoperative navigation, widely used in neurosurgery and sinus surgery, can improve the accuracy with which bony reduction is performed. This is particularly useful in the setting of bony absorption and comminution. We report a case of delayed reconstruction of an orbitozygomaticomaxillary complex fracture using intraoperative navigation and review this technology's utility in this setting.

3747. Morrow, J. D. (1994). "Prosthetic cranioplasty infection due to Sporobolomyces." Journal of the Tennessee Medical Association **87**(11): 466-467.

I have presented an unusual case of an infected prosthetic cranioplasty due to Sporobolomyces species found to be sensitive to amphotericin B in vitro. The infection was successfully treated with a combination of surgery and antifungal therapy.

3748. Morrow, K. D., et al. (2020). "Safety of MRI with Retained Civilian Bullets." Clinical neurosurgery **67**(SUPPL 1): 154.

INTRODUCTION: There is a concern for ballistic movement and radiofrequency induced heating causing damage to surrounding structures for patients who undergo MRIs with retained civilian bullets. METHODS: The prospectively maintained trauma database was queried for gun-shot wounds from 2016-2019. Charts from patients with retained bullets who subsequently underwent MRI were reviewed. RESULTS: 1,977 patients were evaluated for gun-shot wounds. 63 had retained bullets who subsequently underwent an MRI. A total of 67 MRIs were completed. 35 of the MRIs were performed within one month of the injury. 36 of the MRI images involved the same body part of the retained bullet. The majority of retained bullets were either near-complete projectile, fragmentation, or a combination of the two. 2 patients had retained intracranial bullets that underwent MRI Brain. 5 patients had retained intraspinal bullets/fragments that underwent an MRI spine. Following completion of MRIs, 17 patients had follow-up CTs that included imaging of the retained bullets. 11 of these 17 were performed within 1 month of the MRI. 3 bullets showed rotational movement; 1 bullet showed translational movement of .9 cm inferior. 13 patients did not have CT following the MRI but did have post-MRIs X-rays involving the retained bullet. There was no obvious bullet migration on these radiographs. There were no reported immediate complications as the result of an MRI. CONCLUSION: MRIs with retained civilian non-ferromagnetic ballistics produced in the United States are generally safe but each MRI should be completed on a case to case basis. Due to evidence of both rotational and translational movement, one should avoid MRIs for retained bullets near nerves or major blood vessels. There were no reported complications from undergoing MRI with retained projectiles.

3749. Morselli, C., et al. (2019). "Comparison between the different types of heterologous materials used in cranioplasty: a systematic review of the literature." Journal of neurosurgical sciences **63**(6): 723-736.

INTRODUCTION: The choice of heterologous materials for cranioplasty after decompressive craniectomy is still difficult. The aim of this study is to examine the association between material of choice and related complications to suggest the best treatment option., EVIDENCE ACQUISITION: A systematic review was performed for articles reporting cranioplasty comparing the following heterologous implants: titanium, poli-methyl-methacrylate (PMMA), polyetheretherketone (PEEK) and hydroxyapatite (HA). Extracted data included implant materials and incidence of the most frequent complications., EVIDENCE SYNTHESIS: The final selection resulted in 106 papers but according to our rules only 27 studies were included in the final analysis. Among a total of 1688 custom-made prosthesis implanted, 649 were titanium (38.49%), 298 PMMA (17.56%), 233 PEEK (13.82%), and 508 were HA (30.13%). A total of 348 complications were recorded out of 1688 reported patients (20.64%). In the titanium group, 139 complications were recorded (21.42%); in the PMMA group 57 (19.26%), in the PEEK group 49 (21.03%) and in the HA group 103 (20.3%). If we examine a summary of the reported complications clearly related to cranioplasty (postoperative infections, fractures and prosthesis displacement) versus type of material in multicentric and prospective studies we can see how HA group patients have less reported infections and cranioplasty explantation after infections than PMMA, PEEK and titanium. On the contrary HA patients seem to have a higher number of prosthesis displacement again if compared with the other materials. Since these data are not derived from a statistically correct analysis they should be used only to help to differentiate the properties of the various heterologous cranioplasties., CONCLUSIONS: The ideal material for all heterologous cranioplasty has not yet been identified. The choice of material should be based on the clinical data of

patients, such as the craniectomy size, presence of seizures, possibility of recovery, good long-term outcome associated with a cost analysis.

3750. Mortier, P., et al. (2013). "Is electroconvulsive therapy safe in the presence of an intracranial metallic object?: case report and review of the literature." The journal of ECT **29**(3): 231-238.

BACKGROUND: Little is known about the use of electroconvulsive therapy (ECT) in patients with intracranial metallic objects. Theoretically, electric current might cause heating of the metal and damage of the surrounding brain tissue. Moreover, intracranial foreign objects increase the risk for epileptic phenomena and could thus complicate the treatment course., METHODS: The case of a man with intracranial bullet fragments as a result of a headshot, treated with ECT for mania, is presented. We conducted a PubMed literature search for other relevant cases., RESULTS: In our patient, ECT was completed without complication. Electroconvulsive therapy was safely administered in 22 published cases of patients with intracranial metallic objects., CONCLUSION: After carefully weighing benefits and risks in each individual case, psychiatrists should not be reluctant to use ECT in patients with intracranial metallic objects. Apart from avoiding empirical dosage titration to minimize the exposure to current, positioning the electrodes to avoid the electric current of heating the metal, and continuing antiepileptic agents in high-risk patients, no precautions need to be considered.

3751. Moscote Salazar, L. R., et al. (2012). "[Transvaginal penetrating fetal head injury]." Traumatismo encefalocraneano fetal por via penetrante transvaginal. **110**(5): e99-e102.

In utero head traumas are extremely rare and are usually caused by penetrating injuries in the thoracic or abdominal wall that affect the uterine cavity. Transvaginal fetal head injuries have been reported in exceptional cases. This is a case-report of a fetus affected by penetrating head trauma with skull fracture and intra-ventricular hemorrhage after his mother's self-insertion of a blunt object, violently through the vagina. Trauma disrupted the integrity of intrauterine membranes and precipitated preterm labor. After birth, there was a debridement of the scalp and surgical management of the fracture was performed; nevertheless, the patient died four weeks later, due to neonatal sepsis. Management of these wounds must not only be focused on repairing the primary wound, but on preventing the infectious complications.

3752. Mosdal, C. (1985). "Cranio-cerebral injuries from Slaughterer's gun." Acta neurochirurgica **74**(1-2): 31-34.

3 patients attempted suicide by a powder-activated cattle skull impacting tool (Slauthterer's gun). While captive bolt pre-slaughter stunning in pigs and ruminants is safe, two of the patients remainded conscious after the shot and survived. Despite much lower impact velocity (less than 50 m/sec) these self-inflicted brain lesions are as serious as "low velocity" (less than 300 m/sec) penetrating gunshot wounds, mainly because of impaction of bone fragments and the dynamic energy possessed by the bolt.

3753. Mota, F., et al. (2021). "Noninvasive Assessment of Intralesional Antimicrobial Concentration-Time Profiles in Pulmonary and Central Nervous System Tuberculosis using Dynamic 18F-Pretomanid Positron Emission Tomography." Open forum infectious diseases **8**(SUPPL 1): S789-S790.

Background. Pretomanid is used in combination with bedaquiline and linezolid (BPaL regimen) in the treatment of multidrug-resistant tuberculosis (MDR-TB). However, the penetration of pretomanid in privileged sites remain unknown. Antimicrobial pharmacokinetic (PK) parameters are traditionally derived from clinical samples (blood and cerebrospinal fluid), which may not accurately represent the intralesional tissue PK, affected by drug properties, vascular supply, barrier permeability, and the microenvironment. Methods. We developed 18F-pretomanid (chemically identical to pretomanid) for in vivo multi-compartment PK by positron emission tomography (PET). Dynamic 18F-pretomanid PET was used to obtain cross species pretomanid concentration-time profiles in animal models of TB (mice and rabbits) to quantify penetration into pulmonary and brain lesions. A subset of animals underwent PET/CT imaging with 18F-py-albumin and 18F-FDG to assess vascular supply and inflammation. Postmortem 18F-pretomanid autoradiography (high-resolution) and mass spectrometry were performed in infected tissues. A mouse model of TB meningitis was used to evaluate the bactericidal activity of the BPaL regimen (Figure 1). Figure 1. Experimental schematics. (A) A new synthetic approach was developed to obtain radiofluorinated pretomanid (18F-pretomanid), which is chemically identical to

pretomanid and therefore undergoes identical PK and metabolism in vivo. Dynamic 18F-pretomanid PET/CT imaging was performed in validated preclinical models of tuberculosis following intravenous administration of 18F-pretomanid. (B) PET signal was quantified in multiple compartments to generate time activity curves (TACs) used to calculate area under the curve (AUC) over 0-60 minutes. A subset of animals also underwent PET/CT imaging of 18F-py-albumin to assess vascular supply to lung and brain lesions, and with 18FFDG to confirm the presence of neuroinflammation in the mouse and rabbit models of TB meningitis. Tissue resection post-mortem was used to visualize the intralesional retention of 18F-pretomanid using high-resolution (10 µm) autoradiography. The efficacy of the BPaL regimen in TB meningitis was compared to that of standard treatment with rifampin, isoniazid, and pyrazinamide in the mouse model. Mass spectrometry was performed following oral administration of BPaL to determine brain drug levels. (C) These data provide multicompartment PK analysis, intralesional levels of pretomanid, and insights into the mechanism that govern pretomanid tissue distribution. Results. 18F-Pretomanid PET provided detailed concentration-time profiles in infected tissues demonstrating excellent lung and brain tissue penetration (AUC ratio to plasma > 1) in both animal species, which was spatially compartmentalized, likely due to differential vascular supply (18F-py-albumin PET) (Figure 2). Brain lesions (identified by 18F-FDG PET) demonstrated localized leakiness on 18F-py-albumin PET. Autoradiography and mass spectrometry corroborated the imaging findings. The efficacy of the BPaL regimen in TB meningitis was substantially lower than standard TB treatment (Figure 3), likely due to restricted penetration of bedaquiline and linezolid into the brain parenchyma. Figure 2. Spatial heterogeneity of 18F-Pretomanid penetration and vascular supply to pulmonary TB lesions. (A) A novel synthetic was devised to obtain 18F-pretomanid, which is chemically identical to pretomanid. (B) Maximum intensity projection (MIP) of 18F-Pretomanid PET/CT in M.tb.-infected mice over 3 hrs shows hepatobiliary and renal excretion, high uptake into brown fat, brain, and lungs. (C) Resection of infected lungs 30 minutes post intravenous administration of 18F-pretomanid shows heterogenous distribution of 18F-pretomanid into the lungs visible by high resolution autoradiography. Areas of pneumonia are identifiable by hematoxylin and eosin (H&E) staining of the same tissue section used for autoradiography. (D) Time-activity curves of 18F-Pretomanid in infected mouse lung (0-3 hours) and derived area under the c rve (AUC) ratios to plasma (E) in infected mouse lung. Representative MIP of 18F-pretomanid (F) and 18F-py-albumin (H) PET/ CT in a rabbit with cavitary TB and quantification of the AUC ratios to plasma show reduced penetration into lung lesions and cavitary wall compared to areas of unaffected lung (G and I). Data are represented as median ± interquartile range, n=3-4 group. Figure 3. Exposure levels of 18/19F-pretomanid in models of TB meningitis. (A) Experimental timeline used to assess the penetration of pretomanid into infected mouse brain before and during treatment with antimicrobials bedaquiline (B), pretomanid (Pa), and linezolid (L), and corticosteroid dexamethasone (D). (B) Representative three-dimensional MIP of 18F-pretomanid PET/CT in the CNS-TB model, 10 min post-injection, and transverse section showing high and heterogeneous brain uptake. (C) High-resolution autoradiography was performed to confirm heterogeneous penetration of 18F-pretomanid into infected brain lesions in the mouse. (D). 8F-pretomanid AUC ratios of tissue to plasma in mouse brain before (day 0) and two weeks into treatment show a reduction in penetration at week 2. (E). Pretomanid concentrations (µg/mL) in mouse plasma and brain, at day 0 and two weeks into treatment, measured by mass spectrometry and derived concentration ratios of brain to plasma (F) suggest drug accumulation due to the long half-life. (G) While 18F-pyalbumin and 18F-FDG PET/CT show vascular leakage and neuroinflammation in the rabbit model of TB meningitis, the penetration of 18F-pretomanid is heterogeneous and reduced at the lesion site (indicated by white arrow). (H) Quantification of the PET signal shows variability within the same animal. Data are represented as median ± interquartile range, n=3-5 group. Figure 4. Evaluation of a pretomanid-containing regimen in TB meningitis. (A) Mice with experimentally induced TB meningitis were treated with Bedaquiline (25 mg/day), Pretomanid (100 mg/day), Linezolid (100 mg/day), and Dexamethasone (2 mg/day) or Rifampin (10 mg/day), Isoniazid (10 mg/day), Pyrazinamide (150 mg/ day) and Dexamethasone (2mg/day) for 8 weeks. Treatment efficacy was determined based on the brain bacterial burden after 2, 4, 6, and 8 weeks of treatment. (B) The penetration of 76Br-bedaquiline, 18F-linezolid, and 18F-pretomanid into the brain parenchyma was measured non-invasively by PET and revealed low penetration of 76Br-bedaquiline (AUC radio to plasma 0.15) and 18F-linezolid (AUC radio to plasma 0.3). (C) Mass spectrometry analysis was performed to confirm the brain penetration of bedaquiline, linezolid, and pretomanid following oral administration. Conclusion. Dynamic 18F-pretomanid PET provided holistic data on pretomanid exposures showing excellent penetration into infected lung and brain tissues. The BPaL regimen was inferior to standard TB treatment for TB meningitis. Thus, new pretomanid-containing regimens need to be developed for the treatment of MDR-TB meningitis.

3754. Motamedi, M. H. and H. Behnia (1999). "Experience with regional flaps in the comprehensive treatment of maxillofacial soft-tissue injuries in war victims." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **27**(4): 256-265.

This article presents our experience with regional flaps in the treatment of facial soft-tissue defects and deformities in 33 patients with various facial injuries from warfare during the period from 1986 to 1999. Thirty-two males and 1 female aged between 8 and 53 years (mean 24.18 years) were treated with facial soft-tissue injuries from high velocity projectiles and varying degrees of associated hard-tissue injuries. Bullets were the most common cause (70%), followed by injuries from shrapnel (21%), land mines (6%), and breech blocks (3%). The perioral region was involved in 15 cases (45%), the midface and cheeks were involved in 13 cases (39%), and the periorbital area was involved in 5 cases (15%). All soft-tissue injuries were treated primarily by debridement and primary closure and by combining, modifying, and tailoring standard regional flap techniques to fit the location of the injury and compensate for the extent of tissue loss. These procedures consisted basically of local-advancement or rotation-advancement flaps, used in conjunction with pedicled fat or subcutaneous supporting flaps, nasolabial, cheek, cervical, Dieffenbach, and Abbe-type flaps. Scar revision, tissue repositioning, and lengthening procedures, such as W, V-Y, Z, or multiple Z-plasty techniques were also used both primarily and secondarily. Revisions and secondary operations were done in 48% of the patients. Initial healing of the flaps was favourable in 76% of the patients. Postoperative discharge from the suture sites was seen in 24% of the patients, but this usually resolved within several weeks using daily irrigation, and these cases underwent scar revision subsequently. None of the soft-tissue flaps sloughed or developed necrosis. Form and function of the soft-tissue reconstructed regions usually recovered within one year postoperatively. The aesthetic results obtained were favourable. None required facial nerve grafting as only the terminal branches were injured in our cases and functional recovery was acceptable. Application of local tissue transfer procedures in our series of facial warfare injuries yielded acceptable tissue form, texture, and colour match, especially when these procedures were used in combination, and tailored to surgically fit the individual case. Moreover, application of these procedures is relatively easy and postoperative morbidity is limited, provided the general condition of the patient is stable, and the surgical techniques used have good indications and flap principles.

3755. Motamedi, M. H. K. (2003). "Primary management of maxillofacial hard and soft tissue gunshot and shrapnel injuries." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **61**(12): 1390-1398.

PURPOSE: A 10-year retrospective study was undertaken of all patients treated for facial gunshot and shrapnel wounds at our medical center to evaluate the outcomes and assess the results of simultaneous management to treat the hard and soft tissue injuries primarily., PATIENTS AND METHODS: A total of 44 patients were treated. Medical documentation of the patients was compiled. All maxillofacial gunshot, shrapnel, and warfare injuries were treated by the oral and maxillofacial surgeon. Other concomitant bodily injuries were treated by pertinent consultant specialists. Patients ranged in age from 8 to 53 years, with a mean age of 24.7 years. Maxillofacial hard and soft tissue injuries were treated definitively in the first operation except when gross contamination, infection, extensive comminution, or general condition precluded this., RESULTS: There were 2 shotgun, 28 bullet, 10 shrapnel, 3 land mine, and 1 breech block injuries. Overall postadmission mortality in this series was 2.2%. Of the 97.7% of the patients who had an injury to the underlying craniofacial skeleton, all required surgical intervention. The soft tissue and underlying bony injuries were addressed concomitantly (in a single stage at the time of primary surgical debridement) in 86.3% of the patients. Nine percent of the patients had a tracheostomy emergently for management of the airway, 6.8% had an intracranial injury, and 2.2% of them required neurosurgery. In the series, 4.5% of the patients had neck wounds that required exploration. Comprehensive treatment was rendered in 1 to 3 major operations (average, 1.5)., CONCLUSION: All patients in this series required surgical intervention for treatment of their facial gunshot wounds. Primary treatment of hard and soft tissue injuries of the face at the time of surgical debridement was possible in the majority of our patients. This minimized the number of admissions and did not bear a higher complication rate than other reported series that advocate multiple staged operations to treat such injuries despite the fact that, in our series, flaps were also mobilized for wound closure in the primary phase.

PURPOSE: To present a case of photorefractive keratectomy (PRK) after late traumatic LASIK flap loss., METHODS: The initial LASIK procedure was performed in 2003 with a Moria M2 microkeratome and NIDEK EC-5000 excimer laser using a 5.0/9.0-mm aspheric ablation pattern, resulting in 20/20(+) uncorrected distance visual acuity (UDVA) and plano refraction. Traumatic flap loss of the right eye occurred in 2007. The patient was treated for the trauma, and PRK for -5.00 -1.25 x 090degree was performed 2 months later., RESULTS: Posttraumatic flap loss UDVA was 20/200 in the right eye, with corrected distance visual acuity (CDVA) of 20/25(+2). After PRK with mitomycin C (MMC), UDVA was 20/15 2 months postoperatively and was maintained through the last postoperative follow-up in 2010 (approximately 3 years after PRK)., CONCLUSIONS: Treating a patient with traumatic LASIK flap loss can be done by careful, conservative treatment of the abrasion followed by correction of the refractive error using PRK with MMC. 3758. Mouawad, N. J., et al. (2020). "Blunt thoracic aortic injury - concepts and management." Journal of cardiothoracic surgery **15**(1): 62.

BACKGROUND: Blunt thoracic aortic injury, a life-threatening concern, remains the second most common cause of mortality among all non-penetrating traumatic injuries, second only to intracranial hemorrhage. Kinetic forces from the rapid deceleration are the impetus for the injury mechanism and are graded accordingly. Given the prevalence of trauma as a public health problem, contemporary management considerations are important., MAIN BODY: Blunt thoracic aortic injury may be fatal if not diagnosed and treated expeditiously. Endovascular options allow safe and effective management of these dangerous injuries. This paper describes the overview of blunt thoracic aortic trauma, the epidemiology, presentation, diagnosis, and treatment options with a focus on endovascular management., CONCLUSION: Blunt thoracic aortic injury requires a high index of suspicion based on mechanism of injury in the trauma population. Endovascular options have become the mainstay of blunt thoracic aortic injury treatment whenever feasible with satisfactory results and long-term outcomes.

3760. Mountney, A., et al. (2016). "Intravenous Administration of Simvastatin Improves Cognitive Outcome following Severe Traumatic Brain Injury in Rats." Journal of neurotrauma **33**(16): 1492-1500.

Simvastatin is a 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor commonly used to reduce serum cholesterol. The beneficial effects of oral simvastatin have been reported in pre-clinical models of traumatic brain injury (TBI). The current study was designed to evaluate the potential beneficial effects of simvastatin in a model of severe penetrating TBI using an intravenous (IV) route of administration. Rats were subjected to unilateral frontal penetrating ballistic-like brain injury (PBBI), and simvastatin was delivered intravenously at 30 min and 6 h post-injury and continued once daily for either 4 or 10 days post-PBBI. Motor function was assessed on the rotarod and cognitive performance was evaluated using the Morris water maze (MWM) task. Serum levels of inflammatory cytokines and the astrocytic biomarker, glial fibrillary acidic protein (GFAP), were quantified at 1 h, 4 h, and 24 h post-injury. Histopathological damage was assessed at the terminal end-point. Rotarod testing revealed significant motor deficits in all injury groups but no significant simvastatin-induced therapeutic benefits. All PBBI-injured animals showed cognitive impairment on the MWM test; however, 10-day simvastatin treatment mitigated these effects. Animals showed significantly improved latency to platform and retention scores, whereas the 4-day treatment regimen failed to produce any significant improvements. Biomarker and cytokine analysis showed that IV simvastatin significantly reduced GFAP, interleukin (IL)-1alpha, and IL-17 serum levels by 4.0-, 2.6-, and 7.0-fold, respectively, at 4 h post-injury. Collectively, our results demonstrate that IV simvastatin provides significant protection against injury-induced cognitive dysfunction and reduces TBI-specific biomarker levels. Further research is warranted to identify the optimal dose and therapeutic window for IV delivery of simvastatin in models of severe TBI.

3761. Mountney, A., et al. (2016). "Simvastatin Treatment in Traumatic Brain Injury: Operation Brain Trauma Therapy." Journal of neurotrauma **33**(6): 567-580.

Simvastatin, the fourth drug selected for testing by Operation Brain Trauma Therapy (OBTT), is a 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor used clinically to reduce serum cholesterol. In addition, simvastatin has demonstrated potent antineuroinflammatory and brain edema reducing effects and has shown promise in promoting functional recovery in pre-clinical models of traumatic brain injury (TBI). The purpose of this study was to assess the potential neuroprotective effects of oral administration of simvastatin on neurobehavioral, biomarker, and histopathological outcome measures compared across three pre-clinical TBI animal models. Adult male Sprague-Dawley rats were exposed to either moderate fluid percussion injury (FPI), controlled cortical impact injury (CCI), or penetrating ballistic-like brain injury (PBBI). Simvastatin (1 or 5 mg/kg) was delivered via oral gavage at 3 h post-injury and continued once daily out to 14 days post-injury. Results indicated an intermediate beneficial effect of simvastatin on motor performance on the gridwalk (FPI), balance beam (CCI), and rotarod tasks (PBBI). No significant therapeutic benefit was detected, however, on cognitive outcome across the OBTT TBI models. In fact, Morris water maze (MWM) performance was actually worsened by treatment in the FPI model and scored full negative points for low dose in the MWM latency and swim distance to locate the hidden platform. A detrimental effect on cortical tissue loss was also seen in the FPI model, and there were no benefits on histology across the other models. Simvastatin also produced negative effects on circulating glial fibrillary acidic protein biomarker outcomes that were evident in the FPI and PBBI models. Overall, the current findings do not support the beneficial effects of simvastatin administration over 2 weeks post-TBI using the oral route of administration and, as such, it will not be further pursued by OBTT.

3762. Mountney, A., et al. (2016). "Penetrating brain injury alters sleep-wake architecture in rodents." Journal of neurotrauma **33**: A41-A42.

Sleep disturbances are common following traumatic brain injury (TBI) and often exacerbate symptoms, impeding rehabilitation. This study provides a comprehensive profile of sleep architecture changes following severe penetrating ballistic-like brain injury (PBBI). Animals were randomly assigned to cohorts, implanted with bilateral electrodes and subjected to PBBI or sham. Electroencephalographic (EEG) recordings were scored into vigilance states and spectral analysis quantified relative power and frequency shifts during periods of wakefulness, slow-wave-activity (SWA), and rapid eye movement (REM) sleep. PBBI induced significant changes in bilateral sleep architecture. Sham animals displayed light-dependent rhythmic changes which oscillated between sleep-wake states, whereas, brain-injured rats showed irregular sleep patterns which deviated from baseline recordings. Following PBBI, rats showed rapid reductions in wakefulness (63%) and rapid eye movement (REM) sleep (67%) with concomitant increases in SWA (25%). Rats showed delayed REM onset, fewer sleep-stage transitions, and increased sleep disruptions. PBBI induced bioelectrical discordance-changes in REM and SWA were more prominent and persistent in the ipsilateral hemisphere. To discriminate SWA periods from TBI-induced delta slowing, SWA was further resolved into SWA-1 and SWA-2 according to the percentage of delta activity. PBBI-injured rats showed significant reductions in ipsilateral SWA-1 with increases in high-delta SWA-2. These rats showed rapid increases in delta activity (200% compared to baseline) and decreases in theta, alpha, beta, and gamma frequencies. Compared to baseline, post-injury sleep tracings showed acute peak frequency shifts and attenuation in EEG amplitude during SWS and REM. Overall, our results indicate that TBI produces significant effects on sleep architecture: altering wake, SWA, and REM periods compared to respective controls and indicate a decrease in restorative and quality sleep. Reduced REM sleep has been linked to decreases in memory consolidation, reduced reaction reflexes, increased risk of cardiovascular disease, and increased occurrence of mental health comorbidities. Furthermore, we report that slow-wave activity can be classified power into periods of slow-wave sleep and slow-wave delta activity which accompanies TBI.

3763. Mountney, A., et al. (2013). "Longitudinal assessment of gait abnormalities following penetrating ballistic-like brain injury in rats." Journal of neuroscience methods **212**(1): 1-16.

Traumatic brain injury (TBI) results in enduring motor and cognitive dysfunction. Although gait disturbances have been documented among TBI patients, few studies have profiled gait abnormalities in animal models of TBI. We sought to obtain a comprehensive longitudinal analysis of gait function following severe penetrating ballistic-like brain injury (PBBI) in rats. Rats were subjected to either unilateral frontal PBBI, probe insertion alone, or sham surgery. Sensorimotor performance was assessed using the CatWalk automated gait analysis system. Baseline measurements were taken 3 days prior to injury and detailed analysis of gait was performed at 1, 3, 7, 14, and 28 days post-injury. Both

PBBI and probe-inserted rats displayed altered static and dynamic gait parameters that were primarily evident during the early (<7 days) post-injury phase and were resolved by 1 month post-injury. PBBI produced more severe deficits compared to probe-alone which were reflected in the number, magnitude, and resolution time of abnormal gait parameters. While altered parameters were detected in all four paws, they were more apparent on the contralateral side. Gait parameters including paw pressure, print area, swing speed, and stride length were significantly decreased whereas stance, swing, and step cycle duration were increased compared to sham. Overall, altered gait patterns detected using the CatWalk system in the PBBI model were injury-severity dependent, resolved at later time points, and appeared similar to those reported in severe TBI patients. These results indicate that the CatWalk may be most useful for neuroprotection studies that focus on the acute/subacute recovery period after TBI. Copyright Published by Elsevier B.V.

3764. Mountney, A., et al. (2012). "Longitudinal profile of gait disturbances following penetrating ballistic-like brain injury using the CatWalk gait analysis system." Journal of neurotrauma **29**(10): A219.

Introduction Traumatic brain injury results in enduring motor and cognitive dysfunction. Although gait disturbances have been documented among TBI patients, few studies have profiled gait abnormalities in animal models of TBI. We sought to obtain a comprehensive longitudinal analysis of gait function following severe penetrating ballistic-like brain injury in rats. Methods Unilateral frontal PBBI (n = 10) was induced in the isoflurane anesthetized rat by stereotactically inserting a perforated steel probe through the right frontal cortex and rapidly inflating the elastic tubing of the probe tip into an elliptical shaped balloon with a volume equal to 10% of total rat brain volume. Control groups included insertion of the probe alone (probe control) or sham surgery (n = 10/group). Sensorimotor performance of sham, probe, and PBBI rats was assessed using the CatWalk automated gait analysis system. Baseline measurements were taken 3 days prior to injury and detailed analysis of gait was performed at 1, 3, 7, 14, and 28 days post-injury. Individual footprints were identified and processed using the CatWalk software, which generates comprehensive static and dynamic gait parameters. Mean changes of statistically significant gait abnormalities were analyzed between all groups. Results Our primary objective was to identify a longitudinal profile of gait abnormalities following PBBI using the CatWalk. Both PBBI and probe-inserted rats displayed altered static and dynamic gait parameters that were primarily evident during the acute (< 7 days) postinjury phase and were resolved by 1 month post-injury. As expected, PBBI produced more severe deficits compared to probe-alone which were reflected in the number, magnitude, and resolution time of abnormal gait parameters. In both PBBI and probe-inserted rats, altered parameters were detected in all four paws but were more apparent on the contralateral side. Gait parameters including paw pressure, print area, swing speed, and stride length were significantly decreased whereas stance, swing, and step cycle duration were increased compared to sham. Injured rats showed an altered distribution of limb support that appeared immediately following injury and resolved by two weeks. Conclusions Altered gait patterns detected using the CatWalk system in the PBBI model appear similar to those reported in severe TBI patients. However, significant motor recovery occurred by 1 week post-PBBI on the CatWalk task, whereas severe TBI patients show more enduring motor deficits. Collectively, these results indicate that the CatWalk may be useful for short-term neuroprotection studies focused on the acute post-injury recovery period after PBBI but not for chronic studies that require repeated testing at later time points.

3765. Mountney, A., et al. (2012). "Ethosuximide dose-dependently attenuated nonconvulsive seizures induced by penetrating ballistic-like brain injury in rats." Journal of neurotrauma **29**(10): A11-A12.

Introduction Traumatic brain injury can trigger non-convulsive seizures (NCS) that are detrimental to patients' prognosis. Identification of effective antiepileptic drugs against NCS remains crucial to improve neurological outcome. We evaluated the dose-response effects of ethosuximide (ETX) against NCS in a rat model of penetrating ballistic-like brain injury. Methods Unilateral frontal PBBI was produced in the right hemisphere of isoflurane anesthetized rats (10% injury severity level). Spontaneously occurring NCS were detected by continuous electroencephalograph (cEEG) monitoring and video-recording for 72 h post-injury. ETX (25, 125, 250, and 375 mg/kg, i.v., n ≥ 15/group) or vehicle was administered via a bolus injection 30 min post-injury followed by a maintenance dose (1/2 bolus dose) given twice daily thereafter. Animals were sacrificed 72 h post-injury and brain tissue was processed for histopathological assessment. The NCS were identified from offline review of the cEEG recordings and confirmed by investigators blind to treatment groups. ETX efficacy was evaluated on NCS parameters of incidence, frequency, episode duration, total seizure duration, and latency. Results ETX attenuated NCS seizures in a dose-dependent manner. In vehicletreated animals, 65% experienced NCS (averaging 9 NCS/rat) whereas ETX treatment at high doses (250 or 375 mg/kg) significantly reduced

NCS incidence to 27% and 13% ($p < 0.05$), and seizure frequency to 2.1 and 1.8 NCS/rat ($p < 0.05$), respectively. By comparison, effects of two low ETX doses (25 and 125 mg/kg) were relatively moderate (47% and 53% incidence, and 5.0 and 3.0 NCS/rat, respectively) and failed to achieve statistical significance. Except for the lowest doses tested, ETX treatment significantly shortened NCS total duration by 50-80% compared to the vehicle (261 sec), and delayed NCS onset from 29 h (vehicle group) to 57-68h (ETX groups) postinjury. Overall, the two highest doses exerted equivalent therapeutic efficacy, yet severe sedative effects were observed at only the highest dose tested.All ETX doses did not significantly alter lesion volumes compared to vehicle-treated animals. Conclusions Ethosuximide is an FDA-approved anti-epileptic drug commonly used to treat absence (petit mal) seizures. It has previously been shown to prevent post-ischemic NCS in a rat model of middle cerebral artery occlusion at the comparable doses tested in this study. For the first time we demonstrate here that ETX is effective against spontaneously occurring NCS following penetrating ballistic-like brain injury. These data taking together indicate that ETX may be considered as a drug option for treating post-traumatic/ischemic NCS and improve patient outcome. It is widely accepted that the effects of ETX on absence seizure is mediated by its modulation of calcium channels functions. In this regard, the mechanisms of ETX on post-traumatic/ischemic NCS remain to be elucidated.

3766. Mountney, A., et al. (2013). "Ethosuximide and phenytoin dose-dependently attenuate acute nonconvulsive seizures after traumatic brain injury in rats." Journal of neurotrauma **30**(23): 1973-1982.

Acute seizures frequently occur following severe traumatic brain injury (TBI) and have been associated with poor patient prognosis. Silent or nonconvulsive seizures (NCS) manifest in the absence of motor convulsion, can only be detected via continuous electroencephalographic (EEG) recordings, and are often unidentified and untreated. Identification of effective anti-epileptic drugs (AED) against post-traumatic NCS remains crucial to improve neurological outcome. Here, we assessed the anti-seizure profile of ethosuximide (ETX, 12.5-187.5 mg/kg) and phenytoin (PHT, 5-30 mg/kg) in a spontaneously occurring NCS model associated with penetrating ballistic-like brain injury (PBBI). Rats were divided between two drug cohorts, PHT or ETX, and randomly assigned to one of four doses or vehicle within each cohort. Following PBBI, NCS were detected by continuous EEG monitoring for 72 h post-injury. Drug efficacy was evaluated on NCS parameters of incidence, frequency, episode duration, total duration, and onset latency. Both PHT and ETX attenuated NCS in a dose-dependent manner. In vehicle-treated animals, 69-73% experienced NCS (averaging 9-10 episodes/rat) with average onset of NCS occurring at 30 h post-injury. Compared with control treatment, the two highest PHT and ETX doses significantly reduced NCS incidence to 13-40%, reduced NCS frequency (1.8-6.2 episodes/rat), and delayed seizure onset: <20% of treated animals exhibited NCS within the first 48 h. NCS durations were also dose-dependently mitigated. For the first time, we demonstrate that ETX and PHT are effective against spontaneously occurring NCS following PBBI, and suggest that these AEDs may be effective at treating post-traumatic NCS.

3767. Moussa, W. M. M. and M. Abbas (2016). "Management and outcome of low velocity penetrating head injury caused by impacted foreign bodies." Acta neurochirurgica **158**(5): 895-904.

BACKGROUND: Penetrating head injuries with impacted foreign bodies are rare, associated with a high incidence of morbidity and potentially life-threatening. In this study, we aimed at investigating the outcome of these cases as well as analyzing the factors affecting the prognosis., METHODS: A retrospective study in which the records of 16 patients who had penetrating head injuries caused by low-velocity impacted foreign bodies were revised. All patients were males with a mean age of 28.9 years (range, 18 to 50 years). The follow-up period ranged from 4 to 13 months with a mean of 8.1 months. Causes of injury were construction accidents in 6 (37.5 %) patients, assault in 6 (37.5 %) and road traffic accidents in 4 (25 %). The impacted objects included a bar of iron, a piece of wood, a nail, a sickle and a piece of glass. Diagnostic computerized tomography (CT) of the brain was carried out on admission in all patients. Thirteen (81.3 %) patients were submitted to surgery, and all had the appropriate management in the form of antibiotics and dehydrating measures as required. The primary outcome measure was the Glasgow Outcome Scale (GOS) at the end of follow-up., RESULTS: At the end of follow-up, ten (62.5 %) patients had a GOS score of 5, two (12.5 %) patients had a score of 4, and four (25 %) patients had a score of 1., CONCLUSIONS: Low-velocity penetrating head injuries are most common in young adult males. With the appropriate management, a majority of even the most severe cases can have a favorable outcome.

3768. Moxness, M. H. and B. Nedregaard (2001). "[Pneumocephalus as a complication to sinus surgery]." Pneumocephalus som komplikasjon til bihulekirurgi. **121**(2): 168-170.

BACKGROUND: Pneumocephalus is a rare complication of sinus surgery. The complications of sinus surgery are often classified as minor or major. Minor complications are seen as adhesions, scarring, bleeding, development of subcutaneous emphysema, penetration of the orbit without herniation and eyelid ecchymosis. The incidence of major complications is 0 to 3% and include haemorrhage, retrobulbar haematoma, injury to the optic nerve, CSF leaks, meningitis, intracranial penetration with development of tension pneumocephalus, and death., MATERIAL AND METHODS: We present a case of pneumocephalus after endonasal ethmoidectomy. The literature is reviewed., RESULTS: The patient had clinical findings consistent with non-tension pneumocephalus. Development of tension pneumocephalus is a distinct possibility and it is necessary to monitor these patients closely., INTERPRETATION: In order to reduce the risk of injury to the anterior skull base it is important to eliminate certain normal anatomic variations and to assess the individual anatomy thoroughly. This can be done with preoperative nasal endoscopy and CT imaging. This applies even more to patients who have previously undergone sinus surgery.

3769. Mrowka, R., et al. (1978). "Grave cranio-cerebral trauma 30 years ago as cause of the brain glioma at the locus of the trauma particulars of the case." Zentralblatt fur Neurochirurgie **39**(1): 57-64.

A glioblastoma multiforma developed 30 years after a penetrating craniocerebral injury in the left parietal region caused by fragments of an artillery projectile. The 3 cm large bone defect was located directly above the tumour. There were close scarry connections between dura, brain and tumour. Partial removal could not prevent the lethal exitus. Causal connection with the accident is assumed to exist.

3770. Muballe, K. D., et al. (2016). "Neurological findings in pediatric penetrating head injury at a university teaching hospital in Durban, South Africa: a 23-year retrospective study." Journal of neurosurgery. Pediatrics **18**(5): 550-557.

OBJECTIVES Penetrating traumatic brain injuries (TBIs) can be divided into gunshot wounds or stab wounds based on the mechanisms of injury. Pediatric penetrating TBIs are of major concern as many parental and social factors may be involved in the causation. The authors describe the penetrating cranial injuries in pediatric patient subgroups at risk and presenting to the Department of Neurosurgery at the University of KwaZulu-Natal, by assessment of the Glasgow Coma Scale (GCS) score and review of the common neurological manifestations including cranial nerve abnormalities. METHODS The authors performed a retrospective chart review of children who presented with penetrating TBIs between 1985 and 2007 at a university teaching hospital. Descriptive statistical analysis with univariate and multivariate logistic regression was used to assess the variables. RESULTS Out of 223 children aged 16 years and younger with penetrating TBIs seen during the study period, stab wounds were causal in 127 (57%) of the patients, while gunshot injuries were causal in 96 (43%). Eighty-four percent of the patients were male. Apart from abnormal GCS scores, other neurological abnormalities were noted in 109 (48.9%) of the patients, the most common being cranial nerve deficits (22.4%) and hemiparesis. There was a strong correlation between left-sided stab wounds and development of seizures. The mean age of patients with neurological abnormalities was 11.72 years whereas that of patients with no neurological abnormalities was 8.96 years. CONCLUSIONS Penetrating head injuries in children are not as uncommon as previously thought. There was no correlation between the age group of the patients and the mechanism of injury, which implies that stab or gunshot injuries could occur in any of our pediatric population with the same frequency. While gunshot injuries accounted for 56% of the patient population, stab injuries still accounted for 44%. Following penetrating head injuries, neurological abnormalities tend to occur in the older subgroup of the pediatric patients. The most common neurological abnormalities were hemiparesis followed by cranial nerve deficits. Facial nerve deficits were the most commonly seen cranial nerve abnormality. Immediate convulsions were a significant feature in patients with stab injuries to the head compared to those with gunshot injuries.

3771. Mucciarone, J. J., et al. (2006). "Tactical combat casualty care in the assault on Punta Paitilla Airfield." Military medicine **171**(8): 687-690.

Casualties incurred during the assault on Punta Paitilla Airfield during Operation Just Cause were evaluated through reviews of records and interviews with the participants. There were eight initial casualties. One-half of all subsequent casualties were wounded trying to move to these men while still under effective hostile fire. Consistent with other studies, the most common cause of death was internal hemorrhage; the second most common was catastrophic

brain injury. Rapid control of external exsanguination was the technique most likely to prevent death. Tourniquets were applied to three lower extremities for two casualties, without sequelae.

3772. Muckart, D. J. and S. Bhagwanjee (1997). "American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference definitions of the systemic inflammatory response syndrome and allied disorders in relation to critically injured patients." Critical care medicine **25**(11): 1789-1795.

OBJECTIVES: To determine the frequency of the proposed definitions for the systemic inflammatory response syndrome (SIRS), sepsis and septic shock, and to further define severe SIRS and sterile shock as determined at 24 hrs of admission to an intensive care unit (ICU) in critically ill trauma patients without head injury, and their relationships to mechanism of injury, Acute Physiology and Chronic Health Evaluation (APACHE) II score, risk of death, Injury Severity Score (ISS), number of organ failures, and mortality rate., DESIGN: Prospective, inception cohort analysis., SETTING: Sixteen-bed surgical ICU in a teaching hospital., PATIENTS: Four hundred fifty critically injured patients without associated head trauma. Penetrating trauma accounted for 70% (gunshot 202; stab 113) and nonpenetrating trauma for 30% (motor vehicle collision 103; blunt 32) of admissions. Three hundred ninety-four (88%) patients underwent surgical procedures., INTERVENTIONS: None., MEASUREMENTS AND MAIN RESULTS: Infective and noninfective insults were distinguished by the need for therapeutic or prophylactic antibiotics, respectively, based on an established antibiotic policy. Three hundred ninety-five (87.8%) patients fulfilled a definition of the SIRS criteria. The frequency of the definitive categories was SIRS 21.8%, sepsis 14.4%, severe SIRS 8.4%, severe sepsis 13.6%, sterile shock 9.3%, and septic shock 20.2%. Patients with penetrating trauma had a significantly higher frequency of sepsis, severe sepsis, and septic shock ($p < .01$). The APACHE II score, risk of death, and number of organ failures increased significantly in both infective and noninfective groups with increasing severity of the inflammatory response. Sterile shock was associated with a significantly higher APACHE II score ($p < .02$), risk of death ($p < .01$), and number of organ failures ($p = .03$) compared with septic shock. Only sterile shock was associated with a significantly higher ISS ($p < .01$). Organ system failure was significantly ($p < .001$) higher in nonsurvivors compared with survivors in all categories. The only significant ($p < .001$) difference in mortality rate was found between patients in shock and all other categories., CONCLUSIONS: The current definitions of SIRS, sepsis, and related disorders in critically injured patients without head trauma show a significant association with physiologic deterioration and increasing organ dysfunction. The only significant association with mortality, however, is the presence of shock. The definitions require refinement, with the possible inclusion of more objective gradations of organ system failure, if they are to be used for stratifying severity of illness in seriously injured patients.

3773. Mucke, T., et al. (2011). "Maxillary reconstruction using microvascular free flaps." Oral surgery, oral medicine, oral pathology, oral radiology, and endodontics **111**(1): 51-57.

OBJECTIVE: Loss of all or part of the maxilla as a result of tumor ablation has both functional and aesthetic consequences. Reconstruction of the maxilla remains a challenge despite the availability of several flaps and the skills of the prosthodontist. We have analyzed a series of maxillary resections that underwent flap reconstruction to guide planning of the rehabilitation of patients with such defects., STUDY DESIGN: The authors present 83 patients with various types of maxillary defects that were reconstructed with different microvascular free flaps. All clinical data, including data on the functional and aesthetic outcome, are analyzed., RESULTS: Flap transfer was successful in 80 of 83 patients who underwent maxillary reconstruction. Separation of the oral and nasal cavities was achieved in all cases. Flap compromise occurred in 6 cases, which made revision necessary. Three of these flaps were salvaged and 3 flaps failed. In 10 of 28 patients with transferred bone, osseointegrated implants were inserted and dentally rehabilitated with excellent functional and aesthetic results., CONCLUSION: Various types of maxillary defects can be reconstructed successfully using different microvascular free flaps. This procedure is challenging because of the anatomical site of reconstruction creating a steep learning curve. If the reconstruction is successful, both facial appearance and oral function can be improved. Microvascular flaps containing bone of the fibula, scapula, or iliac crest facilitate complete dental rehabilitation.

3774. Mudekereza, P. S., et al. (2021). "Factors associated with hospital outcomes of patients with penetrating craniocerebral injuries in armed conflict areas of the Democratic Republic of the Congo: a retrospective series." BMC emergency medicine **21**(1): 109.

INTRODUCTION: Penetrating craniocerebral injuries (PCCI) are types of open head injuries caused by sharp objects or missiles, resulting in communication between the cranial cavity and the external environment. This condition is deemed to be more prevalent in armed conflict regions where both civilians and military are frequently assaulted on the head, but paradoxically their hospital outcomes are under-reported. We aimed to identify factors associated with poor hospital outcomes of patients with PCCI., METHODS: This was a retrospective series of patients admitted at the Regional Hospital of Bukavu, DRC, from 2010 to 2020. We retrieved medical records of patients with PCCI operated in the surgical departments. A multivariate logistic regression model was performed to find associations between patients' admission clinico-radiological parameters and hospital outcomes. Poor outcome was defined as a Glasgow Outcomes Score below 4., RESULTS: The prevalence of PCCI was 9.1% (91/858 cases) among admitted TBI patients. More than one-third (36.2%) of patients were admitted with GCS < 13, and 40.6% of them were unstable hemodynamic. Hemiplegia was found in 23.1% on admission. Eight patients had an intracerebral hemorrhage. Among the 69 operated patients, complications, mainly infectious, occurred in half (50.7%) of patients. Poor hospital outcomes were observed in 30.4% and associated with an admission GCS < 13, hemodynamic instability, intracerebral hemorrhage, and hemiplegia ($p < 0.05$)., CONCLUSION: The hospital poor outcomes are observed when patients present with hemodynamic instability, an admission GCS < 13, intracerebral hemorrhage, and hemiplegia. There is a need for optimizing the initial care of patients with PCCI in armed conflict regions.

3775. Muehlschlegel, S., et al. (2016). "Predicting survival after acute civilian penetrating brain injuries: The SPIN score." Neurology **87**(21): 2244-2253.

OBJECTIVE: To identify predictors associated with survival in civilian penetrating traumatic brain injury (pTBI) utilizing a contemporary, large, diverse 2-center cohort, and to develop a parsimonious survival prediction score for pTBI., METHODS: Our cohort comprised 413 pTBI patients retrospectively identified from the local trauma registries at 2 US level 1 trauma centers, of which one was predominantly urban and the other predominantly rural. Predictors of in-hospital and 6-month survival identified in univariate and multivariable logistic regression were used to develop the simple Surviving Penetrating Injury to the Brain (SPIN) score., RESULTS: The mean age was 33 +/- 16 years and patients were predominantly male (87%). Survival at hospital discharge as well as 6 months post pTBI was 42.4%. Higher motor Glasgow Coma Scale subscore, pupillary reactivity, lack of self-inflicted injury, transfer from other hospital, female sex, lower Injury Severity Score, and lower international normalized ratio were independently associated with survival (all $p < 0.001$; model area under the curve 0.962). Important radiologic factors associated with survival were also identified but their addition to the full multivariable would have resulted in model overfitting without much gain in the area under the curve., CONCLUSIONS: The SPIN score, a logistic regression-based clinical risk stratification scale estimating survival after pTBI, was developed in this large, diverse 2-center cohort. While this preliminary clinical survival prediction tool does not include radiologic factors, it may support clinical decision-making after civilian pTBI if external validation confirms the probability estimates.

3776. Muehlschlegel, S., et al. (2016). "Predicting survival after acute civilian penetrating brain injuries: The spin score." Annals of neurology **80**: S54.

Objective: The aim of this study was to identify predictors associated with survival in a contemporary, large, diverse two-center penetrating traumatic brain injury (pTBI) cohort, and to develop a parsimonious survival prediction score for civilian pTBI. Methods: Our cohort comprised 415 pTBI patients retrospectively identified from the local trauma registries at two U.S. level-1 trauma centers, of which one was predominantly urban and the other predominantly rural. Predictors of inhospital and 6-month survival identified in univariate and multivariable logistic regression were used to develop the simple Surviving Penetrating Injury to the BraiN (SPIN) Score. Results: The mean age was 33±16 years and patients were predominantly male (87%) and black (58%). Survival at hospital discharge as well as 6-months post pTBI was 42.4%. Motor Glasgow Coma sub-score, pupillary reactivity, self-inflicted injury, transfer from other hospital, female sex, Injury Severity Score and INR were independently associated with survival (all $p<0.001$; model area-under-thecurve 0.962). Important radiological factors associated with survival were also identified but their addition to the full multivariable would have resulted in model overfitting without much gain in the area-under-the-curve. Interpretation: We developed the SPIN Score, a logistic regression-based risk stratification scale estimating survival after pTBI. While external validation is warranted, this clinical survival prediction tool may provide important information to guide families and physicians during intervention and goals-of-care decision-making after civilian pTBI.

3777. Muehlschlegel, S., et al. (2017). "Predicting survival after acute civilian penetrating brain injuries: the spin score." Journal of neurotrauma. Conference: 35th annual national neurotrauma symposium. United states **34**(13): A21.

Introduction: The predominant experience of penetrating traumatic brain injury (pTBI) derives from battlefield settings, but the civilian experience inWestern settings in patients treated after 2005 is limited to only small and single-center studies. As a result, outcome predictors of civilian pTBI in modern trauma and neurocritical care settings are poorly defined. The aim of this study was to identify predictors associated with survival in a contemporary, large, diverse two-center pTBI cohort, and to develop a parsimonious survival prediction score for civilian pTBI. Methods: Our cohort comprised 415 pTBI patients retrospectively identified from the local trauma registries at two U.S. level-1 trauma centers, of which one was predominantly urban and the other predominantly rural. Predictors of in-hospital and 6-month survival identified in univariate and multivariable logistic regression were used to develop the simple Surviving Penetrating Injury to the BraiN (SPIN) Score. Results: The mean age was 33- 16 years, and patients were predominantly male (87%) and black (58%). Survival at hospital discharge and 6-months post pTBI was 42.4%. Motor Glasgow Coma sub-score, pupillary reactivity, self-inflicted injury, transfer from other hospital, female sex, Injury Severity Score and INR were independently associated with survival (all $p < 0.001$; area-under-the-curve 0.962). Important radiological factors associated with survival were also identified but their addition to the full multivariable would have resulted in model overfitting without much gain in the area-under-the-curve. Conclusions: We developed the SPIN Score, a logistic regressionbased risk stratification scale estimating survival after pTBI. While external validation is warranted, this clinical survival prediction tool may provide important information to guide families and physicians during intervention-and goals-of-care decision-making after civilian pTBI.

3778. Muehlschlegel, S., et al. (2016). "Predicting survival after acute civilian penetrating brain injuries: the spin score." Neurocritical care. Conference: 14th annual meeting of the neurocritical care society. United states **25**(1 Supplement 1): S67.

Introduction: The predominant experience of penetrating traumatic brain injury (pTBI) derives from battlefield settings, but the civilian experience in Western settings in patients treated after 2005 is limited to only small and single-center studies. As a result, outcome predictors of civilian pTBI in modern trauma and neurocritical care settings are poorly defined. The aim of this study was to identify predictors associated with survival in a contemporary, large, diverse two-center pTBI cohort, and to develop a parsimonious survival prediction score for civilian pTBI. Methods: Our cohort comprised 415 pTBI patients retrospectively identified from the local trauma registries at two U.S. level-1 trauma centers, of which one was predominantly urban and the other predominantly rural. Predictors of in-hospital and 6-month survival identified in univariate and multivariable logistic regression were used to develop the simple Surviving Penetrating Injury to the BraiN (SPIN) Score. Results: The mean age was 33+/-16 years, and patients were predominantly male (87%) and black (58%). Survival at hospital discharge and 6-months post pTBI was 42.4%. Motor Glasgow Coma sub-score, pupillary reactivity, self-inflicted injury, transfer from other hospital, female sex, Injury Severity Score and INR were independently associated with survival (all $p<0.001$; area-under-the-curve 0.962). Important radiological factors associated with survival were also identified but their addition to the full multivariable would have resulted in model overfitting without much gain in the area-under-the-curve. Conclusions: We developed the SPIN Score, a logistic regression-based risk stratification scale estimating survival after pTBI. While external validation is warranted, this clinical survival prediction tool may provide important information to guide families and physicians during intervention-and goals-of-care decision-making after civilian pTBI.

3779. Muhammad Khyani, I. A., et al. (2008). "Endoscopic removal of bullet from orbital apex." Journal of the College of Physicians and Surgeons--Pakistan : JCPSP **18**(10): 646-648.

Penetrating injuries of face are not uncommon. Bullets or pallets may be lodged anywhere in the cavities of skull as a result of firearm injury. Lodgment of a bullet within the orbit through nose is uncommon. An eighteen 18 years old married woman sustained a bullet injury, which entered through lateral wall of the nose and lodged at left orbital apex area. The bullet was removed endoscopically via left nostril without any damage to the eye or disturbance in vision.

3780. Mukerji, S., et al. (2022). "Persistent coagulopathy after gunshot traumatic brain injury: the importance of INR and the SPIN score." European journal of trauma and emergency surgery : official publication of the European Trauma Society.

INTRODUCTION: Penetrating ballistic brain injury (gunshot traumatic brain injury or GTBI) is associated with a high mortality. Admission Glascow Coma Scale (GCS), injury severity score and neurological findings, cardiopulmonary instability, coagulopathy and radiological finding such as bullet trajectory and mass effect are shown to predict survival after GTBI. We aimed to examine the dynamics of the observed coagulopathy and its association with outcome., METHODS: In this single-centered retrospective cohort study, we examined 88 patients with GTBI between 2015 and 2021. Variables analyzed include patient age; temperature, hemodynamic and respiratory variables, admission Glasgow Coma Scale (GCS); injury severity score (ISS); head abbreviated injury scale (AIS); Marshall, Rotterdam, SPIN and Baylor scores, and laboratory data including PTT, INR and platelet count. Receiver operating characteristic analysis was conducted to evaluate the performance of the predictive models., RESULTS: The average age of our sample was 28.5 years and a majority were male subjects (92%). Fifty-four (62%) of the patients survived to discharge. The GCS score, as well as the motor, verbal, and eye-opening sub-scores were higher in survivors ($P < 0.001$). As was expected, radiologic findings including the Marshall and Rotterdam Scores were also associated with survival ($P < 0.001$). Although the ISS and Head AIS scores were higher ($P < 0.001$), extracranial injuries were not more prevalent in non-survivors ($P= 0.567$). Non-survivors had lower platelet counts and elevated PTT and INR ($P < 0.001$) on admission. PTT normalized within 24 h but INR continued to increase in non-survivors. SPIN score, which includes INR, was a better predictor for mortality than Rotterdam, Marshall, and Baylor etc. CONCLUSION : Progressively increasing INR after GTBI is associated with poor outcome and may indicate consumption coagulopathy from activation of the extrinsic pathway of coagulation and metabolic derangements that are triggered and sustained by the brain injury. The SPIN score, which incorporates INR as a major survival score component, outperforms other available prediction models for predicting outcome after GTBI.

3781. Mukherjee, S., et al. (2020). "Withanolide a penetrates brain via intra-nasal administration and exerts neuroprotection in cerebral ischemia reperfusion injury in mice." Xenobiotica; the fate of foreign compounds in biological systems **50**(8): 957-966.

1. Withanolide A (WA), a major constituent phytochemical of the Ayurvedic herb Withania somnifera reportedly combats neurodegeneration in Alzheimer's disease and Parkinson's disease. But no study has yet reported the ability of WA in crossing the blood-brain barrier (BBB). The present study analyses the brain penetration ability of WA after intra-nasal administration and assesses its neuroprotective ability in cerebral ischemia-reperfusion injury in adult mice model.2. Brain penetration of WA after intranasal administration in cortex and cerebellum was assessed using HPLC-UV. Three different doses (1 mg/kg, 5 mg/kg and 10 mg/kg) of the phytochemical were used to study the neuroprotective ability of WA by evaluating the brain damage, changes in cerebral neurotransmitter levels and brain tissue morphology.3. Intranasal administration of the phytochemical facilitates its penetration in the cortex and cerebellum. Post-treatment with WA significantly reduced cerebral infarction, restored BBB disruption and cerebral oedema. The WA post-treatment also lowered the ischemia-induced elevated neurotransmitter and biochemical levels in brain compartments. The highest dose (10 mg/kg) of WA also markedly reduced the morphological damages, apoptotic and necrotic cell death in brain tissue occurring due to cerebral ischemia pathophysiology.4. Intra-nasal administration enables brain penetration of WA and allows the phytochemical to exert neuroprotective ability in the global cerebral ischemia model.

3782. Mulazzani, M., et al. (2013). "Abdominal muscle contractions in brain death triggering the respirator: A case report." Journal of neurology **260**: S94.

Introduction: Brain death (BD) is the irreversible end of neuronal activity of the brain including the brainstem. Spontaneous as well as reflex-movements are present in 40-50 % of BDs. Preserved spinal reflex movements are not only challenging the diagnosing physician, but also leading to disconcertment among relatives and health personnel. In recent literature plantar withdrawal responses, muscle stretch reflexes, abdominal contractions and respiratory-like movements have been described before. Case presentation: A 23-year old man was admitted to a Viennese hospital after a self-induced penetration of the skull using a crossbow in the attempt of suicide. The initial cranial computer tomography (CCT) showed a massive cerebral trauma at the entry point (left frontal lobe) with cerebral edema and cerebral prolapse through the right temporal bone. After transfer to the Medical University Hospital of Vienna, the

clinical assessment by two neurologists fulfilled the criteria for brain death (coma, hypotonic quadriplegia, absent brainstem reflexes, negative atropine-test and apnoea-test, and no exclusion criterion found). An electroencephalography (EEG) showed complete cessation of cortical electrical activity. Thereafter, while repositioning the patient, abdominal muscle contractions activated the respirator (see enclosed video). Passive flexion of the cervical spine led to reflex movements and persistent spontaneous contractions of the abdominal muscles. Nevertheless, repeated EEGs confirmed the isoelectric finding. Because of the open skull trauma and concomitant decompression, magnetic resonance imaging (MRI) and CCT-Angiography failed to show a complete loss of perfusion. Transcranial Doppler indicated minimal residual perfusion. Seven days after the suicide, electromyographic studies of abdominal muscles and the lower extremities documented spinal reflex activity as the cause for the triggered respirator. A positron emission tomography scan demonstrated no cerebral glucose uptake, and brain death was therefore confirmed. Conclusion: Mechanically induced movements through passive neck flexion are often present in BD during the first 24 h. Sometimes, as seen in this case, prolonged presence of spinal reflexes as well as spontaneous abdominal contractions can persist. Physicians and health personnel caring for BDs should be aware of these phenomena and of the fact that spinal reflex movements do not preclude the diagnosis of brain death or organ transplantation.

3784. Mulholland, N. and S. Connor (2004). "A summer trip." The British journal of radiology **77**(913): 77-78.

3785. Mulla, M., et al. (2017). "Civilian Occult Orbitocranial Penetrating Injury Presenting with Cerebral Abscess in Elderly Patient." Indian Journal of Neurotrauma **14**(2-3): 145-148.

Orbital penetrating injuries are uncommon and occur following accidental entry of objects through orbit. The authors report an interesting case of right frontal abscess resulting from orbitocranial penetrating injury due to accidental penetration of wooden stick into the right eye, which remained undiagnosed. A 70-year-man presented with complaints of headache and vomiting for few days. His computed tomographic (CT) scan of the brain revealed peripheral rim-enhancing cystic lesion in the right frontal lobe with perilesional edema, mass effect, and midline shift. Orbital CT scan revealed hyperdense lesion just lateral to medial orbital wall. Magnetic resonance imaging of the brain showed cystic peripheral rim-enhancing lesion that was homogenous hypointense on T1-weighted images and homogenous hyperintense on T2-weighted images. The patient underwent right frontal craniotomy. Pus was drained out, and abscess wall was excised. Foreign bodies protruding through fractured orbital roof were found and removed. He made good clinical recovery. He has received intravenous antibiotics for 2 weeks followed by 4 weeks of oral antibiotics. He had no visual symptoms. The authors report the case, review the literature, and highlight need for imaging in every case of orbital penetrating injury to prevent the life-threatening cerebral parenchymal complications.

3786. Müller-Vahl, H. (2015). "Traumatic nerve damage: Causes, approaches and prognosis." Nervenarzt **86**(2): 142-150.

Whereas minor injuries to peripheral nerves merely lead to a circumscribed damage of the myelin sheath which is completely healed within 3 months, penetrating injuries lead to degeneration of the distal axonal fragment (Waller degeneration) and simultaneously to time-dependent alterations in the effector organs, in the perikarya in the medulla and spinal ganglia as well as in the brain. Animal experimental studies and also findings in humans confirm that the conditions for regeneration of nerve fibers are most favorable in the first days and weeks following injury. Therefore, for optimal therapy it should be clarified as early as possible whether there is a chance for reinnervation using exclusively conservative therapy or whether an operative reconstruction is necessary due to the severity of structural damage. Imaging investigation procedures, such as neurosonography and magnetic resonance (MR) neurography can provide decisive information on this aspect. As a rule, the decision on the indications for a nerve operation should be made within the first 3 months. Even with optimal therapy the healing process of severe neural injuries is often unsatisfactory. For some years novel procedures for improvement of nerve regeneration have been tested in animal experiments which involve totally different points in the healing process. It is hoped that with these approaches procedures for improvement in the treatment of nerve injuries in humans can be developed in the near future.

3787. Mullins, R. J., et al. (2002). "Survival of seriously injured patients first treated in rural hospitals." The Journal of trauma **52**(6): 1019-1029.

BACKGROUND: Patients injured in rural counties are hypothesized to have improved survival if local hospitals are categorized as Level III, Level IV, and Level V trauma centers., METHODS: Data were abstracted on patients with brain, liver, or spleen injuries who were first treated in 16 rural hospitals in Oregon (with categorized trauma centers) and 16 hospitals in Washington (without categorized trauma centers). Logistic regression models evaluated survival up to 30 days after hospital discharge., RESULTS: Among Oregon's 642 study patients, 63% were transferred to another hospital. Among Washington's 624 patients, a higher proportion, 70%, were transferred. Risk-adjusted odds of death for Washington patients (reference odds, 1) were the same as for Oregon patients (odds ratio, 0.82; 95% confidence interval, 0.53-1.28). Most patients died after transfer to another hospital., CONCLUSION: In states with a prevailing practice of promptly transferring brain-injured patients, survival of these patients may not be enhanced by categorization of hospitals as rural trauma centers. To further improve the outcome of these patients, policy makers should adjust statewide trauma system guidelines to enhance integration and to perfect coordination among sequential decision makers.

3788. Mulvey, J. M., et al. (2008). "Profile of injuries arising from the 2005 Kashmir earthquake: the first 72 h." Injury **39**(5): 554-560.

BACKGROUND: The Kashmir Earthquake of October 8, 2005 had widespread destructive effects with in excess of 86,000 people killed and over 80,000 severely injured. Most hospitals were destroyed and limited facilities were available for medical service in the immediate aftermath. A small military hospital in Forward Kahuta, Pakistan, remained functional and was inundated with severely injured patients over 72h., METHODS: A retrospective review of medical records to document the injury patterns, subsequent treatment, infections and logistical requirements that occurred following this earthquake., RESULTS: One thousand five hundred and two patients were triaged over 72h. Four hundred and sixty eight (31.1%) patients required admission. Three hundred and nineteen (68.2%) patients were managed non-operatively and 149 (31.8%) required a procedure under general anaesthesia. The most common type of injuries were: superficial lacerations (64.9%); fractures (22.2%); and soft tissue contusions/sprains (5.9%). There were 266 major injuries to the extremities (40.1% upper limb; 59.9% lower limb). Six patients had significant abdominal injuries, 66.6% of these required urgent laparotomy. 14.8% had clinically relevant infections at follow-up requiring surgical debridement or antibiotic therapy., CONCLUSIONS: Disaster response in the early phase of earthquake relief is complex, with local facilities often overwhelmed and damaged. Limb injuries are most likely; however facilities should have clear plans to deal with severe trauma including head injuries and penetrating abdominal trauma. Coordinated effort is required for success, with lessons learnt to improve future disaster management.

3790. Muneza, S., et al. (2015). "Incidentally detected intracranial sewing needle in a child - A case report." Interdisciplinary Neurosurgery: Advanced Techniques and Case Management **2**(2): 95-97.

A 4-year-old boy with normal physical and mental development presented to the emergency room with minor head injury and skin laceration on the right frontal region following an accidental fall in a ditch while playing with other kids. At presentation, he had normal neurologic examination. The skull X-ray showed a 4.5 cm long sewing needle-like foreign body, which was later confirmed by cranial computed tomography scanning. There was no suspected entry at the corresponding location to suggest an acute penetrating injury. This object may have penetrated during early infanthood before closure of anterior fontanelle. A nonsurgical management was opted because there were no neurological complaints, even after a three-year follow-up.

3791. Munoz Pareja, J. C., et al. (2022). "Biomarkers in Moderate to Severe Pediatric Traumatic Brain Injury: A Review of the Literature." Pediatric neurology **130**: 60-68.

BACKGROUND: Despite decades of research, outcomes in pediatric traumatic brain injury (pTBI) remain highly variable. Brain biofluid-specific biomarkers from pTBI patients may allow us to diagnose and prognosticate earlier and with a greater degree of accuracy than conventional methods. This manuscript reviews the evidence surrounding current brain-specific biomarkers in pTBI and assesses the temporal relationship between the natural history of the traumatic brain injury (TBI) and measured biomarker levels., METHODS: A literature search was conducted in the Ovid, PubMed, MEDLINE, and Cochrane databases seeking relevant publications. The study selection and screening process were documented in a Preferred Reporting Items for Systematic Reviews and Meta-Analyses flow diagram. Extraction forms included developmental stages of patients, type and biofluid source of biomarkers, brain injury type, and other relevant data., RESULTS: The search strategy identified 443 articles, of which 150 examining the biomarkers of our interest were included. The references retrieved were examined thoroughly and discussed at length with a pediatric neurocritical care intensivist specializing in pTBI and a Ph.D. scientist with a high degree of involvement in TBI biomarker research, authoring a vast amount of literature in this field., CONCLUSIONS: TBI biomarkers might serve as valuable tools in the diagnosis and prognosis of pTBI. However, while each biomarker has its advantages, they are not without limitations, and therefore, further research is critical in pTBI biomarkers.

3792. Murabito, M. and H. Seitz (2002). "Craniocerebral gunshot wound: Report of an attempted murder." Chirurgia **15**(3): 125-129.

An interesting and unusual case of gunshot wound to the head with severe brain injury that survived the bullet wound, as well as the delicate operation and a not wished cerebrospinal fluid leak complication are reported. Certainly an early and aggressive surgical and perioperative management seem to improve the outcome of such patients, even if many factors should be evaluated before surgery. Our patient showed only minor neurological deficits on discharge thus confirming that the outcome, according to the Glasgow outcome Scale, strongly correlated with the conditions upon admission, as determined by the Glasgow Coma Scale. Intracranial gunshot wounds can result in a wide variety of immediate severe, life threatening injuries. These patients need to be rapidly and thoroughly evaluated in a rational and systematic manner to minimize mortality and long-term morbidity.

3793. Murabito, M. and H. Seitz (2004). "Gunshot to the head with brain injury: Report of an attempted murder." European Surgery - Acta Chirurgica Austriaca **36**(4): 257-261.

Background: We present an interesting and unusual case of a gunshot wound to the head with severe brain injury. The patient survived and presented only minor neurological deficits upon discharge. Methods: An early and aggressive surgical and perioperative management. Results: Our patient confirms that the outcome as measured by the Glasgow Outcome Scale strongly correlates with the condition upon admission, as determined by the Glasgow Coma Scale. Conclusions: Intracranial gunshot wounds need to be rapidly and thoroughly evaluated in a rational and systematic manner to minimize mortality and long-term morbidity.

3794. Murakami, Y., et al. (2009). "Reduction of brain oxygen tension following penetrating ballistic-like brain injury in rats." Journal of neurotrauma **26**(8): A22.

Clinically, brain tissue oxygen tension (PbtO2) is one of the most important parameters for evaluating severity of injury and the outcome of therapeutic intervention in patients having sustained a traumatic brain injury. To determine the status of cerebral oxygen level following a penetrating injury, we measured PbtO2 levels in an experimental model of penetrating ballistic-like brain injury (PBBI). Rats were anesthetized with isoflurane (2%) mixed in oxygen and air. The inhalational oxygen was maintained at 25-26% to minimize its interference on PbtO2. An oxygen probe was implanted along with a temperature probe into the brain near the core region of the injury (~ 2 mm lateral; 2.5 mm posterior to bregma and ~6 mm in depth) to record PbtO2 and brain temperature. The mean arterial blood pressure (MABP) was monitored by a femoral artery catheter and the body temperature was maintained at 37°C. Rats were subjected to a right frontal PBBI or sham surgery. All parameters were monitored continuously beginning at 15 min (baseline) prior to PBBI and ending at 150-min post PBBI. Within 5 min post injury, PbtO2was significantly reduced by ~40% in PBBI rats (16.9 mmHg±4.0) as compared to sham rats (28.6 mmHg ± 6.2; mean±SD, $p<0.05$). This reduced PbtO2 was sustained for at least 150 min post PBBI. No significant differences in other physiological parameters, i.e. MABP, body or brain temperatures, were observed between PBBI and sham rats. In summary, our observations provide direct evidence of

acute decreases in PbtO2 immediately after PBBI, indicating a metabolic disturbance in the peri-lesion regions of the injury. Further studies are underway to evaluate the time course of PbtO2 reduction and its effect on the surrounding brain areas. Collectively, these data will provide important information on the development of secondary injury associated with PBBI and help to further define a rationale therapeutic strategy to prevent PBBI induced reductions in PbtO2 and improve brain metabolic dysfunction.

3795. Murano, T., et al. (2005). "Civilian craniocerebral gunshot wounds: an update in predicting outcomes." The American surgeon **71**(12): 1009-1014.

Given the high mortality in patients sustaining intracranial injury secondary to gunshot wounds (GSWs), predictors to identify patients at increased risk of death are needed to assist clinicians early in determining optimal treatment. There have been few recent studies involving penetrating craniocerebral injuries, and most studies have been restricted to small numbers of patients, which do not allow for adequate prediction of mortality. A retrospective chart review of 298 patients who sustained GSWs to the head between 1992 and 2003 was conducted at a level 1 trauma center. Demographics, bullet trajectory, admitting Glasgow Coma Scale (GCS), head Abbreviated Injury Score (AIS), as well as admission blood pressure and respiratory rate were evaluated. Univariate testing followed by multivariate logistic regression was performed to identify independent predictors of death. In-hospital mortality for patients with intracranial injury secondary to GSW was 51 per cent. A GCS <5 on admission and a high Injury Severity Score (ISS >25) was associated with mortality as compared with survivors ($P < 0.05$). Of those patients presenting with a GCS of 3, there were seven survivors to discharge. Logistic regression identified the following variables as predictors of death: respiratory arrest on admission, hypotension on admission, transhemispheric and transventricular GSW. Identification of those patients at the highest risk of death secondary to a craniocerebral GSW allows clinicians to better predict outcome and prognosis. This is not only important in determining treatment algorithms for physicians but also for appropriate counseling of family members to educate them with regard to patients' outcomes.

3796. Murashkin, S. V., et al. (1996). "[The intra-aortic antibacterial therapy of wounded patients with gunshot meningoencephalitis]." Vnutriaortal'naia antibakterial'naia terapiia ranenykh s ognestrel'nym meningoentsefalitom. **317**(12): 21-80.

The original decision of permanent introduction of antibacterial means to tissues of brain at gunshot meningoencephalitis is offered. For antibacterial therapy the intra-aortal catheter with diameter of 2,5 mm (through a.femoralis) was introduced. After washing the catheter by solution of crystalloid with heparin the various combinations of preparations in 5% solution of glucose were introduced: cephalosporin--8 g/day; hentamicin and brumacilin--240 mg/day accordingly, amicacin--1500 mg/day. Speed of introduction--20-50 mg/h, total volume--500 ml. The catheter was in aorta not more than 10 days, maximum--14 days. A described technique was applied in Burdenko Main Military Clinical Hospital on 34 wounded in head. At computer tomography of brain of all wounded intracranially the splinters and bullets were revealed, clinically--meningoencephalitis. Foreign bodies have been extracted after cupping of clinical and laboratory signs of meningoencephalitis. The authors consider, that the technique is effective not only at wounds of brain, but also at suppurative meningoencephalitis of other etiology.

3797. Muresanu, D., et al. (2017). "Traumatic brain injury in diabetic and hypertensive rats exacerbates brain pathology and functional outcome-role of neurotrophic factors and nanomedicine." Brain injury **31**(6-7): 842.

Piercing traumatic brain injury (pTBI) cuts neuronal connections by direct physical tissue damage, microhaemorrhages and lacerations. Damage to the brain centres controlling movements; speech, cognitive functions as well as sensory motor disturbances lead to irreparable functional disturbances. However, if pTBI occurs in victims having hypertension, diabetes or a combination, the magnitude and intensity of brain damage intensify. In such cases, axonal regenerations, bridging tissue loss and making new connections by enhancing neuroplasticity is the need of the hour. There are reasons to believe that select combination of neurotrophins could help in pTBI cases complicated with additional comorbidity factors. In addition, use of nanotechnology to deliver neurotrophic drugs in these pTBI cases may further enhance their therapeutic efficacy in neurorepair. Our laboratory has initiated a series of investigations on TBI associated with comorbidity factors and showed that TBI inflicted in either hypertensive or diabetes rats caused greater damages on functional and pathological outcome as compared to TBI alone in healthy animals. However, the effects of TBI in hypertensive and diabetic animals are not well evaluated. In this investigation, we examined the effects of pTBI in

diabetic and hypertensive (DBHY) rats on brain pathology and functional outcome after 24 and 38 hours of the basic insult. We also evaluated a combination of neurotrophic drugs with active peptide fragments e.g., cerebrolysin treatment with or without nanodelivery to achieve better neuroprotection and functional recovery. pTBI was inflicted in rats under anaesthesia by opening of the right parietal cortex (4 mmb) and a longitudinal cortical incision was made (3 mm deep and 5 mm long) using stereotaxic guidance with a sterile scalpel blade. pTBI was also inflicted in separate group of rats made hypertensive by 2-kidneys-1-clip (2K1C) method. 2K1C was also applied in a group of rats that were made diabetic by streptozotocin (60 mg/kg, i. p. for 3 days). These DBHY rats were subjected to identical pTBI and allowed to survive for 24 hours after the insult. Our observations showed that pTBI in DBHY rats resulted in breakdown of the blood-brain barrier (BBB) to proteins, oedema formation and cell injuries that were 4-6 times higher than the identical pTBI in healthy rats. In these rats, cerebrolysin (2.5 or 5 ml/kg, i.v.) was able to reduce some of the pathological changes without having a significant effect on functional parameters such as Rotarod performance and grid waking. However, when TiO2 nanodelivery of cerebrolysin was done (5 ml/kg, i.v.), significant improvement on function parameters and pathological outcome was seen in pTBI in DBHY animals. These observations suggest that pTBI associated with comorbidity factors require nanodelivery of cerebrolysin to achieve good neuroprotection, not reported earlier.

3799. Murillo-Ponce, C., et al. (2018). "Orbital aerocele: Case report." Journal of Neurological Surgery, Part B: Skull Base **79**.

Objective: We present a 26-year-old man with an orbital aerocele following roof and medial orbital wall fracture due to facial trauma for gunshot wound, managed with open surgery with orbital reconstruction. (Figure Presented) Methods: A case report and a review of the world literature concerning the etiology, clinical features, and management of orbital fractures are presented. Results: Our patient presented with a delayed posttraumatic orbital aerocele related to facial trauma by gunshot wound 4 years ago, and exacerbated by air travel and nose blowing. CT scan revealed a fracture of the ethmoid bone, deformed orbital roof, and orbital aerocele causing proptosis and stretching of the ophthalmic nerve and extraocular muscles. Management with a fronto-orbital approach, with reconstruction of the roof and medial orbital wall produced excellent results, with decompression achieved and immediate and sustained improvement in visual acuity and ocular movements. (Figure Presented) Conclusion: A search of the world literature revealed no documented cases of orbital aerocele as a delayed complication of roof and medial orbital wall fractures due to gunshot wound. Also, we take in consideration the open surgery with orbital reconstruction and its advantages over other procedures.

3803. Murray, L. (2021). "Craniocerebral nail gun injuries: a definitive review of the literature." Brain injury **35**(2): 164-172.

AIM: Nail guns are important time saving devices but are associated with morbidity and mortality. Specifically, craniocerebral injuries have been reported in the literature since 1963 and have increased in frequency as the use of these tools has become commonplace. There remains a paucity of literature comprehensively assessing nail gun injuries, as compared with other penetrating craniocerebral injuries like those from firearms., METHOD: A literature review of PubMed, Medline (Ovid), Cochrane library, and Google Scholar for articles published between 1960 and 2018 reporting

craniocerebral nail gun injuries., RESULTS: In total, 96 individual cases were identified, with 80 meeting inclusion criteria. These were categorized as accidental and intentional injuries. The demographic was overwhelmingly young males (97.5%), and intentional self-inflicted injuries (54%) was the most frequent mechanism of injury. Overall mortality was 10%. Mortality was more common in patients with intentional injuries, but morbidity rates were similar between the accidental and intentional injury cohorts. Post-operative complications rate was 23.8%., CONCLUSION: Craniocerebral nail gun injuries are associated with lower rates of both mortality and residual neurological deficits than craniocerebral firearms injuries. There is limited data to inform clinical prognostication about long-term neurological impairments and the time to recovery which should be addressed in future studies.

3805. Musat, O., et al. (2012). "[Penetrating ocular trauma with intraocular foreign body]." Traumatism ocular penetrant cu retentie de corp strain. **56**(1): 64-68.

We present the case of a 65 years old pacient which was admitted for the sudden decrease of visual acuity in the left eye, accompanied by ocular pain and conjunctival hiperemia, simptoms appeared after an ocular trauma. After the clinical and paraclinical examination we determined the diagnosis of OS: Penetrating ocular trauma with retention of a foreign body; posttraumatic cataract. Surgical treatement was warrented and we performed OS : Facoemulsification + PFK implant in sulcus + 23 Ga posterior vitrectomy + peeling of the posterior hyaloid membrane + extraction of the foreign body + LASER endofotocoagulation + transscleral cryotherapy + SF6 gas injection. The post-operatory evolution was favorable.

3806. Musker, P. and G. Musker (2011). "Pneumocephalus and Brown-Sequard syndrome caused by a stab wound to the back." Emergency medicine Australasia : EMA **23**(2): 217-219.

This report describes a case of Brown-Sequard syndrome in a man who presented to the ED after a stabbing to the left scapula region. The incidental finding of pneumocephalus found on CT scan during workup lead to cervical MRI that revealed the spinal cord pathology associated with Brown-Sequard syndrome.

3807. Musyaju, S., et al. (2022). "POST-INJURY TIME-COURSE OF MITOCHONDRIAL OXIDATIVE STRESS AND ANTIOXIDANTS MARKERS FOLLOWING SEVERE PENETRATING TBI." Journal of neurotrauma **39**(11-12): A55.

Oxidative stress is a pathological state when free radicals generation outbalances elimination of these radicals through innate antioxidants system. The injured brain is susceptible to oxidative stress due to its high metabolic demand, and contains high polyunsaturated fatty acids and redox transition metals making it an ideal target for free radicals attack. In the interest of future evaluation ofmitochondria targeted neuroprotection drugs, we conducted a time-course evaluation of oxidative stress and antioxidantmarkers following penetrating traumatic brain injury (PTBI). Anesthetized adult male Sprague-Dawley rats (280-350 g) were subjected to either 10% unilateral PTBI or Sham craniectomy, followed by excitotoxic responses evaluated at 30min, 3h, 6h, 24h, 3d, 7d and 14d (n = 6-10 animals/group X 7 time-points). At each-time point, animals were euthanized and mitochondria isolated fromipsilateral frontal cortex and striatum areas. Both 3-nitrotyrosine (3-NT) and protein carbonyl (PC), the hallmarks of free radicals mediated protein modification during oxidative stress resulted in significantly increased expression (14-53%, vs. Sham) during first 3d time-points following PTBI. In general, all antioxidants such as glutathione (GSH), peroxiredoxins (PRX-3), thioredoxins (TRX), nicotinamide adenine dinucleotide phosphate (NADPH) and superoxide dismutase (SOD) expression/level were significantly decreased (20-80%, vs. Sham), whereas the catalase (CAT) exhibited increased (45-75%, vs. Sham) expression during first 7d post-injury period. Overall, we observed a maximum imbalance of oxidative stress and antioxidant markers during the first week following PTBI. The mitochondria-targeted acute pathophysiological secondary injury responses should be mitigated by targeted mitochondrial antioxidant therapeutics following PTBI.

3809. Muthe, M. M., et al. (2021). "Imaging findings in transorbital intracranial penetrating injury with an ice pick." BMJ case reports **14**(8).

3810. Mutlukan, E., et al. (1991). "Case of penetrating orbitocranial injury caused by wood." The British journal of ophthalmology **75**(6): 374-376.

A case of retained intraorbital and intracerebral wooden foreign body following an orbitocranial penetrating injury through the lower lid of an adult is described. Initial failure to recognise the true nature of the injury led to intracerebral abscess formation and monocular blindness. Diagnosis and management of such cases are discussed.

3811. Mutyala, A., et al. (2012). "Anton syndrome after gun shot wound to head: A case report." PM and R **4**(10): S194-S195.

Results or Clinical Course: 23-year-old man sustained a gun shot wound to the left occipital lobe. His initial GCS was 7T, and was found to have a left occipital entry point with ricochet off left temporal inner table, with fragments projecting into the right anterior cranial fossa. He sustained hemorrhages to the right occipital and temporal regions, right subdural hematoma, bilateral subarachnoid hemorrhages, midline shift with subfalcine herniation, and cerebellar tonsillar herniation. He underwent emergent craniectomy and right anterior temporoparietal lobectomy. On POD 5, he was found to have intact EOMs and pupillary reflex, intact light perception, but he was unable to visually track or identify objects. At this time he denied vision loss, and was found to be confabulating parts of the visual examination, and was diagnosed with Anton Syndrome. The remainder of his examination was intact for strength, sensation, and cranial nerves, and he was classified as a Ranchos los Amigos level IV. He was transferred to an acute inpatient rehabilitation setting with Ranchos level VI on POD 17. At this time he was only able to identify shadows. On POD 18 he was able to distinguish outline of shapes; by POD 21 he was able to identify colors and track objects. At this time it was apparent that the patient was recovering some vision but was demonstrating visual object agnosia and prosopagnosia in that he was unable to recognize details of objects or his own face. He also demonstrated alexia without agraphia. Therapies focused on tactile kinesthetic input to facilitate object recognition and initiation of eye movements. By discharge on POD 31 he was able to identify objects and characteristics of faces, read large letters and numbers, with MME of 28/30 on discharge. Conclusions: Cortical blindness (Anton Syndrome) is a rare symptom of brain damage occurring in the bilateral occipital lobes, with preservation of pupillary reaction, optic nerve function, with denial of visual loss and confabulation. This patient had Anton syndrome secondary to TBI resulting from GSW. Resolving cortical edema resolved the Anton Sydrome, but revealed agnosia, prosopagnosia, and alexia without agraphia. Patient participated in Speech therapy, PT, and OT with improvement in ambulation, cognition and ADLs.

3813. Muzumdar, D., et al. (2006). "Intrauterine penetrating direct fetal head trauma following gunshot injury: a case report and review of the literature." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **22**(4): 398-402.

CASE REPORT: An unusual case of an intrauterine penetrating head injury due to a pellet from an airgun is described. A 28-year-old pregnant woman, at term, shot herself intravaginally with a toy BB gun. Following a spontaneous precipitous vaginal delivery, the neonate presented with persistent seizure disorder, meningitis, cerebritis, and a right parietal region scalp swelling. Imaging studies revealed intracranial hemorrhage, and the metallic pellet was adjacent to the right lateral ventricle, which was removed through a parietal craniotomy. Computed tomography of the brain after 1 week demonstrated early abscess formation in the left frontal operculum and a subdural empyema in the posterior fossa. The abscesses were evacuated, and the meningitis was treated vigorously with broad-spectrum antibiotics. Although well for the past 6 years, the child demonstrates significant mental handicap and developmental

delay., DISCUSSION: The pathogenesis, management, and medicolegal issues pertaining to the above case are discussed, and the relevant literature is briefly reviewed.

3814. Mwipatayi, B. P., et al. (2004). "Management of extra-cranial vertebral artery injuries." European journal of vascular and endovascular surgery : the official journal of the European Society for Vascular Surgery **27**(2): 157-162.

OBJECTIVES: To review the management of vertebral artery injuries, and the impact of pre-operative angiography., MATERIALS AND METHODS: A retrospective review was conducted of all patients with vertebral artery (VA) injuries admitted to Groote Schuur Hospital, Cape Town between January 1987 and December 2002. Patients presenting with uncontrolled active bleeding or haemodynamic instability with a poor response to resuscitation were taken immediately to surgery. Stable patients, including those who stabilised after simple resuscitation, with evidence of a vascular injury (a bruit or a large haematoma) or trans-cervical gunshot wounds, underwent routine aortic arch and selective angiography., RESULTS: One hundred and one patients with vertebral artery injuries were included in the study. Ninety-two patients sustained penetrating injuries (41 gunshot, 51 stab), three were iatrogenic and six due to blunt trauma. Angiography was performed as the primary investigation in 88 patients, while seven patients had angiography following surgery. Thirty-nine vertebral artery occlusions, 11 arteriovenous fistulae, two intimal injuries and 36 false aneurysms were identified. Thirty-three radiological interventions were performed. There were 22 associated vascular injuries in 16 patients, 27 nerve injuries in 25 patients, 11 osseous injuries in nine patients and eight aerodigestive injuries. Seven patients died., CONCLUSIONS: Angiography and intervention is of great benefit in the diagnosis and management of traumatic vertebral artery injuries. Angiography often avoids unnecessary exploration and permits endovascular treatment.

3815. Myers, J. C., et al. (1999). "Three-dimensional (3-D) imaging in post-mortem examinations: elucidation and identification of cranial and facial fractures in victims of homicide utilizing 3-D computerized imaging reconstruction techniques." International journal of legal medicine **113**(1): 33-37.

The analysis of cranial and facial fractures in skeletal remains of homicidal victims can prove challenging for forensic anthropologists and forensic pathologists in postmortem examination. In such cases, the use of 3-D computerized imaging to elucidate the fractures and patterns of injuries can provide strong medical evidence that is very useful during litigation and at trial. The authors describe 3-D reconstructions of the skull performed as part of forensic postmortem examination in a recent victim of homicide.

3816. Myers, K., et al. (2017). "Adherence to the pediatric emergency care applied research network head CT rule: 2013 to 2015." Annals of emergency medicine **70**(4): S88.

Study Objectives: Pediatric head injury is common and accounts for approximately 600,000 emergency department visits and over 7,600 deaths in the United States annually. Although the vast majority of children have minor injuries, a small number, even among well-appearing children, have serious injuries with the potential for deterioration and significant sequelae. The Pediatric Emergency Care Applied Research Network (PECARN) performed a large multicenter prospective cohort study and identified seven criteria that correlate with increased risk of clinically important traumatic brain injury (ciTBI). This study was conducted to determine whether the emergency department at the author's institution (17k annual pediatric visits in 2015) is following the PECARN guidelines for head CT scans in children with minor head injury. Methods: A retrospective review was performed of all pediatric head injury presenting to the emergency department in July-December 2013 and January-December 2015.The EMR database was accessed to obtain all emergency department visits for patients < 18 years old with documentation of “head injury.” Patient were excluded if they did not have blunt head trauma or if their GCS was <14. Adherence to the PECARN rule was determined based on documentation of the history and physical exam, and whether the patient obtained a head CT. Secondary analysis was conducted to see if there was any improvement in adherence between 2013 and 2015 after implementation of department-wide education regarding the utilization of the PECARN rule. Results: Of the 627 charts reviewed (2013: 228, 2015: 399), 47 encounters were excluded for not meeting inclusion criteria (9 penetrating injuries, 17 without head trauma, and 21 with GCS<14). Among the remaining 580 encounters (2013: 207, 2015: 373) and based on the PECARN criteria, 108 (18%) were considered “high risk” for ciTBI (2013: 40, 2015: 68), 220 (38%) were “low risk” (2013: 74, 2015: 146), and 252 (43%) were “very low risk” (2013: 93, 2015: 159). Head CT is recommended in the “high risk” category, and among these patients, 93 (86%) were scanned (2013: 31/40-77.5%, 2015: 62/68-91.2%). Among the

“low risk” patients, 162 (73.6%) were scanned (2013: 64/74-86.5%, 2015: 98/146-67.1%). Among the “very low risk” patients, 30 (11.9%) received a head CT (2013: 17/93-18.3%, 2015: 13/159-8.2%). The overall adherence to the PECARN rule in 2013 was 87.4%, and the overall adherence in 2015 was 94.9%. This indicates a relative improvement in PECARN adherence by 60% between 2013 and 2015. Conclusions: Overall adherence to the PECARN rule for head CT in patients with mild TBI improved by 60% between 2013 and 2015 to an absolute adherence rate of nearly 95% in 2015. Notably, there was also a decline in number of head CTs performed among the patients who met “low risk” criteria, in which cases clinical judgement is recommended (87% in 2013 to 67% in 2015). Over the course of 1 year and after implementation of department-wide education regarding head CT in children with head injury, we have made significant improvement in adherence to the PECARN rule, leading to fewer unnecessary scans and better clinical decisionmaking.

3817. Mzimbiri, J. M., et al. (2016). "Orbitocranial Low-Velocity Penetrating Injury: A Personal Experience, Case Series, Review of the literature, and Proposed Management Plan." World neurosurgery **87**: 26-34.

BACKGROUND: Orbitocranial penetrating injuries (OPI) are an unfamiliar subset of head injury and are particularly rare in clinical practice. They are usually the result of falls or motor vehicle collisions and occur more commonly in children, who are prone to trauma while playing games improperly., METHODS: We present a retrospective review of 5 cases of OPI treated in the Neurotrauma Department at Xiangya Hospital of Central South University in the last 5 years. Also, we performed comprehensive literature searches using Web of Science and the terms "orbitocranial injury," "penetrating ocular trauma," "penetrating orbital trauma," and "transorbital chopstick penetrating injury" to search for presentation, mechanism of injury, and management of transorbital penetrating injury., RESULTS: In 2 patients, there was right internal carotid artery occlusion while in other 2 patients, the penetrating objects reached the brainstem through the cavernous sinus, resulting in orbital apex syndrome. All patients underwent a thorough physical examination followed by diagnostic imaging. The cases were successfully managed surgically by removing the foreign bodies through their trajectories., CONCLUSIONS: Computed tomography, magnetic resonance imaging, and computed tomography angiography are key imaging modalities that are frequently used to determine the course of the foreign object and the extent of brain tissue injury as well as to rule out vascular injury in these types of cases. Early surgical exploration by a multidisciplinary team approach is essential to attain good recovery and a favorable outcome.

3818. Mzimbiri, J. M., et al. (2016). "Surviving Penetrating Brainstem Injury by Bamboo Sticks: Rare Case Reports and a Brief Review of Literature." Neurosurgery **78**(5): E753-760.

BACKGROUND AND IMPORTANCE: Chopsticks are common utensils used in many Asian cultures. However, they sometimes can be used as weapons or can cause accidents, particularly in children. Penetrating transorbital/transpharyngeal intracranial injuries with bamboo sticks are peculiar accidents and are relatively rare. Because of their rarity, the management of such injuries is often complex. We discuss 3 cases of penetration of the brainstem by bamboo sticks, 1 case through the foramen magnum, which, to the best of our knowledge, is the first reported case of such an injury., CLINICAL PRESENTATION: The case of a 50-year-old man who was stabbed with a pair of chopsticks in his left eye is presented. The chopsticks passed through the cavernous sinus, and the patient sustained superior orbital fissure syndrome. The other 2 cases were those of a 4-year-old girl having a similar pattern but different mechanism of injury and a 2-year-old boy who sustained transpharyngeal intracranial injury via the foramen magnum. Computed tomography, magnetic resonance imaging, and computed tomographic angiography (CTA) are the key imaging modalities frequently used to determine the course and extent of brain injury., CONCLUSION: Early surgical exploration by a multidisciplinary team approach is essential for attaining a favorable outcome. All cases demonstrated good postoperative recovery and were successfully managed by removing the foreign body through its trajectory. We discuss and briefly review the literature on patterns, complications, and management issues of these less common injuries.

3819. Nadalo, L. A., et al. (1991). "The neuroradiology of visual disturbances." Neurologic clinics **9**(1): 1-33.

The neuroradiology of visual deficits has advanced dramatically in recent years. Plain film evaluation of the orbit and face remains useful in the emergency room for the evaluation of trauma. High-resolution coronal CT remains the method of choice in the assessment of serious injury to the orbit and in cases of penetrating metallic foreign body. The contrast-enhanced orbital CT provides useful information in cases of tumor and infection and when the bones of the

face or skull are involved. MRI has largely replaced CT in the search for brain infarct, brain tumor, and cerebral inflammatory and demyelinating processes. MRI is the study of choice in all cases of sellar and parasellar disease. It offers high-resolution images in any plane. GTPA enhancement has provided additional information from MRI without significant risk. The final selection of an imaging modality should be based upon the clinical presentation and any physical limitations of the patient.

3820. Nader, M. A., et al. (2000). "Neglected craniocerebral gunshot wound resulting in an encephalocele: case report." Surgical neurology **54**(5): 397-400.

3821. Nadezhdina, M. V. (1990). "[Comparative dynamics of the epileptic syndrome in patients with open and closed war-time head injuries in the late period]." Sravnitel'naia dinamika epilepticheskogo sindroma u bol'nykh s otkrytoi i zakrytoi voennoi travmoi cherepa v otdalennom periode. **90**(6): 72-77.

The dynamics of the epileptic syndrome was studied in 55 patients with penetrating cranial wound and in 65 patients with closed cranial injury. Account was taken of the anamnesis, all-round clinical examination data, EEG and computer-aided tomography readings. The patients had been followed up over 40 years. Among the patients with fighting cranial injury, the incidence of the epileptic syndrome amounted to 14.01%. The epileptic syndrome was established to occur most frequently during the first year after injury, with that time (in patients with penetrating cranial wound) being the less the graver injury and longer consciousness loss. At the same time the later was the onset of epileptic attacks in patients with closed cranial injury the rarer was their incidence and more pronounced were mental disorders. In patients with penetrating cranial wound, focal and secondary-generalized attacks dominated in the structure of the epileptic syndrome, whereas in patients with closed cranial injury, convulsions and psychomotor fits ranked the first. With age the rate of epileptic attacks declined along with reduction and disappearance of epileptic activity on the EEG, augmentation of mental disorders and atrophy of substantia medullaris.

3822. Nagahiro, S., et al. (1981). "[Penetrating craniocerebral injuries - report of two unusual cases and review of literature (author's transl)]." No shinkei geka. Neurological surgery **9**(11): 1313-1318.

3823. Nagata, I. (2002). "How to avoid perforator injury when operating on anterior communicating aneurysms: A technical note." Japanese Journal of Neurosurgery **11**(11): 714-718.

A wide operative field and an approach which permits direct visualization of the whole ACOM complex may help avoid perforator injuries in operation for ACOM aneurysms. Sewering of the bridging veins while preserving the collateral channels allows good operative field. How to use retractors and clips are also indicated.

3824. Nagel, M., et al. (1991). "[Injuries of the small and large intestine in the traumatized abdomen]." Verletzungen von Dunn- und Dickdarm beim traumatisierten Abdomen. **94**(3): 105-109.

Between 1973 and 1989 a total of 388 patients underwent laparotomy because of abdominal trauma. In 98 cases, injuries of the small bowel, the colon or the mesentery were found. The injuries were caused by motor vehicle accidents in 55 patients; 12 had gunshot or stab wounds and 12 committed suicide. There were 78 patients who had sustained a blunt abdominal trauma and 20 patients with a penetrating trauma. Only 21 patients had suffered a solitary injury of the gastrointestinal tract. In 41 patients there were also lesions to other intraabdominal organs, in 11 patients, thoracic injuries and in 24 patients, a craniocerebral trauma. Combined injuries of skull, thorax and abdomen were present in 24 patients. Neither ultrasound nor peritoneal lavage allows reliable prediction of injuries of the gastrointestinal tract. In 51 cases a defect of the mesentery or serosa was repaired. In 54 patients there was a rupture of the small or large intestine: in 20 of these cases primary repair without resection was performed and in 34, resection and anastomosis. Ileostomy or colostomy was done in only 8 patients. An anastomotic leak developed in 2 patients. Lethality is correlated to the extent of concomitant injuries. Solitary injury of the small bowel or colon was followed by lethality of only 4.1%, increasing to 50% in patients with combined injuries of skull, thorax and abdomen.

3825. Nagele, D. (2018). "Screening for brain injury: Can we decrease disability by getting more people to brain injury services and supports?" Journal of Head Trauma Rehabilitation **33**(3): E78.

The literature is beginning to abound with examples of people who have brain injury, but who do not know that they have a brain injury. How does this occur, one might ask? Certainly, public awareness about brain injury has increased, due to publicity about brain injury in athletes as a result of sports injuries (collisions with other players/goal-post/ground, and now Chronic Traumatic Encephalopathy), as well as brain injury in soldiers involved in war-related injuries (gunshot wounds/blast-related injuries/motor vehicle crashes). What is being found is that multiple, mild brain injuries have a cumulative effect, and yet each one, on its own, may not result in a diagnosis of brain injury. Without a diagnosis of brain injury, it is unlikely that one will be treated for brain injury. If there are residual cognitive or physical sequelae of mild brain injury, but no brain injury diagnosis, then the root cause of these problems is either overlooked or attributed to psychological problems, and consequently people do not get the benefit of brain injury treatment and supports that are available and validated as efficacious. A growing list of 'at-risk' populations are coming to the attention of brain injury professionals. In addition to athletes and military personnel, people who are homeless, victims of domestic violence, and people in juvenile justice or adult corrections may in fact have a lifetime history of brain injury, but not be aware of it, and may never have received treatment for it. In addition, there may be an over-representation of a lifetime history of brain injury among people presenting for vocational rehabilitation services, mental health services, drug and alcohol services, and psychiatric hospitalizations. The issue for these populations is that brain injury, left untreated, can result in any number of mood, behavior, substance use disorders, that then become the focus of treatment. Without an understanding of the root cause of the person's difficulties, and how they developed into mood, behavior, or substance use disorders, the traditional treatments for those disorders are likely to be less effective. The reason has to do with cognitive impairments that can undermine new learning and applying that learning, which is essential for change when dealing with mood, behavior, and substance-use disorders. This presentation will highlight recent research done in several 'at-risk' populations, including corrections and juvenile justice, to get at the prevalence of previously undiagnosed brain injury. In a backward chaining fashion, we will make the public policy argument for annual screening for brain injury in children, much as is currently done for developmental disorders, or visual/auditory impairments, so that we can more easily identify who could benefit from brain injury interventions and supports, and break the cycle of mild brain injury masquerading as other disorders.

3826. Nagib, M. G., et al. (1986). "Civilian gunshot wounds to the brain: prognosis and management." Neurosurgery **18**(5): 533-537.

The extent of treatment for the victims of gunshot wounds to the brain remains quite controversial, particularly when these patients present with extensive neurological dysfunction. We propose guidelines regarding the degree and aggressiveness of therapy. The factors that seem to have a significant impact on the patient's final outcome are the neurological examination at the time of admission, the radiological findings, and the motivation for the shooting. Thus, the authors propose a nonsurgical line of therapy for comatose patients with unilateral or bilateral cerebral gunshot wounds where bone or metal fragments are visualized away from the bullet path on computed tomography scan, particularly when these individuals are suicide victims.

3827. Nagoria, R., et al. (2013). "A rare case of fusarium meningitis." Indian Journal of Critical Care Medicine **17**: 39.

Introduction: Fungal meningitis is very uncommon in immunecompetent patients. Here we are reporting case of fusarium meningitis, in an agriculture worker after she had a penetrating injury. 53 yrs old female was apparently well till 2 months back when she had giddiness and fall while watering the plants following she was unconscious for a brief period. After regaining consciousness she noticed weakness of left side of body. she was diagnosed to have cervical fractures which was managed conservatively. For last 1 week patient attenders noticed that she was sleeping a lot although she was oriented and talking sense. Patient drowsy but arousable, Oriented to place, person and time. Power was left upper and lower limb: 3/5. Findings of CT Brain was asymmetrically dilated lateral ventricles and MRI Brain was showing asymmetrical ventricles with no other space occupying lesion. CT C Spine was showing C5/C6 cervical cord contusion.patient underwent endoscopic septostomy. Findings was multiple clumsy tissue strands present in right lateral ventricle blocking Foramen of Monro. Septostomy was done. Tissue was sent for biopsy, staining and culture. Immediately after surgery patient sensorium improved. Tuberculosis was suspected and she was started emperically on ATT. Culture showed a growth of filamentous fungus initially, so amphoterecin was started with proper monitoring of potassium and creatinine. After 3-4 days, patient was again drowsy. CT scan of brain was done which showed bilaterally

asymmetrically enlarged ventricles. In view of her clinical condition and ventriculomegaly right V-P shunt was performed. Patient sensorium improved after the surgery. Her final culture growth was suggestive of fusarium species. Conclusion: CNS fungal infection are commonly seen in immunecompromised patients. But rarely we can seen the infection immune-competent patient after CNS trauma or device placement.

3831. Nahum, Y., et al. (2016). "Visual Outcomes of Repeat Versus Primary Descemet Stripping Automated Endothelial Keratoplasty-A Paired Comparison." Cornea **35**(5): 592-595.

PURPOSE: To compare the results of repeat Descemet stripping automated endothelial keratoplasty (DSAEK) with those of primary DSAEK., MATERIALS AND METHODS: This retrospective study consisted of all consecutive eyes that underwent one or more repeat DSAEK surgeries after primary DSAEK performed at Villa Serena-Villa Igea Private Hospitals (Forli, Italy) between January 2005 and June 2015. A paired comparison between the outcomes of primary and the second DSAEK was performed. Main outcome measures included best recorded best spectacle-corrected visual acuity (BSCVA), postoperative endothelial cell loss (ECL), and refractive error., RESULTS: Of 1413 procedures, 51 eyes were included in the final analysis. Indications for primary DSAEK included pseudophakic bullous keratopathy (n = 21), Fuchs endothelial dystrophy (n = 20), failed penetrating keratoplasty (n = 9), and trauma (n = 1). Indications for repeat DSAEK were slowly progressive ECL (n = 35), endothelial rejection (n = 15), and host-graft interface abnormalities (n = 1). Preoperative BSCVA (logarithm of the minimum angle of resolution 1.23 +/- 0.8 vs. 1.38 +/- 0.6, P = 0.29) and best postoperative BSCVA (logarithm of the minimum angle of resolution 0.32 +/- 0.44 vs. 0.34 +/- 0.49, P = 0.70) did not differ significantly between the 2 groups. ECLs for primary and repeat DSAEK at 1 (46% +/- 16% vs. 40% +/- 18%, P = 0.22) and 2 years (50% +/- 18% vs. 44% +/- 2%, P = 0.33) were also similar. The mean postoperative spherical equivalent did not differ significantly between the 2 groups (-0.01 +/- 1.9 vs. -0.5 +/- 1.6, P = 0.08) nor did the absolute astigmatic error (1.6 +/- 1 vs. 1.8 +/- 1.2, respectively, P = 0.17)., CONCLUSIONS: After the failure of a primary DSAEK graft, a subsequent DSAEK can yield visual outcomes and ECL rates that are comparable with those of primary DSAEK.

3832. Naidoo, S. and A. B. Van As (2011). "Vulnerability of children to gunshot trauma in violence-prone environment: the case of South Africa." African journal of paediatric surgery : AJPS **8**(1): 101-104.

South Africa has a high level of violence, as more people are killed by gunfire each year than in motor vehicle accidents, and the numbers are increasing. Regrettably, children are affected most by this epidemic. During 1997, a total of 142 children aged less than 14 years died from gunshot injuries while many more were injured. Here we present the case of an 11-year-old male street child who sustained a gunshot to the face, and illustrate the magnitude of the problem. The escalating epidemic of firearm-related injuries and deaths among children and adolescents in Cape Town, like in many other parts of the world, calls for concern. Further research is needed to understand firearm-related injuries among children and adolescents in South Africa, and to develop policies and programmes for effective prevention of situations such as this.

3833. Naidu, K. (2006). "The injured eye - Practical management guidelines and referral criteria for the rural doctor." South African Family Practice **48**(7): 39-45.

Ocular trauma encompasses a wide spectrum of mechanisms and presentations, affecting the orbit, globe of the eye, optic nerve and adnexae. The causative injuries range from the relatively superficial to those that threaten sight. The rural doctor plays a vital role in the initial management of patients with ocular trauma and his/her decisions and treatment can influence the patient's final visual outcome. This article serves to classify ocular trauma and to provide management guidelines for treating minor trauma and initiating proper care for injuries that require referral to specialist ophthalmologists.

3834. Naik, M. N., et al. (2011). "An extraordinary orbital foreign body." Ophthalmic plastic and reconstructive surgery **27**(6): e149-152.

The authors report a unique case of a broken motorbike handle that presented as a bilateral orbital foreign body. A 30-year-old male sustained an injury to the right side of his face when he skidded from his motorbike while riding. He had bilateral sudden loss of vision and presented to emergency services with bilateral proptosis, motility restriction, and a right lower eyelid laceration. CT scan revealed a 7-cm-long motorbike handle lodged in the retrobulbar space of both orbits, close to the cribriform plate. Left lateral orbitotomy was performed to remove the foreign body; the right eye regained normal vision and function. The unique features of this case include the nature of the foreign body, its bilateral location, its proximity to the optic nerve and cribriform plate, and the challenges in its removal. The clinical presentation and management is presented, along with the surgical video.

3835. Naik, P. M. and L. F. Angel (2011). "Special issues in the management and selection of the donor for lung transplantation." Seminars in immunopathology **33**(2): 201-210.

Lung transplantation is a viable treatment option for select patients with end-stage lung disease. Two issues hamper progress in transplantation: first, donor shortage is a major limitation to increasing the number of transplants performed. Secondly, recipient outcomes remain disappointing when compared with other solid organ transplant results. Outcomes are limited by primary graft dysfunction (PGD), the posttransplant acute lung injury that increases both short-and long-term mortality. Attempts to overcome donor shortage have included aggressively managing solid organ donors to increase the number of donor lungs suitable for transplantation. Yet, the quality of the lung donor is likely to be related to the probability of the recipient experiencing PGD. PGD is the culmination of a series of insults, hemodynamic, metabolic, and inflammatory, that begin with the brain dead donor and result in poor recipient outcomes. Understanding the mechanism of donor lung injury resulting from brain death and the possible treatment strategies for its inhibition could help to increase the number of usable lungs and decrease the rate of PGD in the recipient. Here we present a review of the key pathways which result in donor lung injury, and follow this with a brief review of recent biomarkers that are proving to be instrumental to our ability to predict truly unsuitable lungs, and our ability to predict and hopefully prevent or treat recipients with subsequent lung injury.

3836. Naik, S. K., et al. (2014). "Infantry rifle contact wound mimicking multiple gun shot entrywounds." Journal of Forensic Medicine and Toxicology **31**(1): 18-21.

When a contact or near contact shot is fired from a rifled firearm, apart from the muzzle imprint other constructional parts like front sight and/or the recoil spring guide of semiautomatic pistols may surround the bullet entry wound. But when a rifle fitted with a flash suppressor is fired, the emerging soot-laden gas in the barrel escapes from the slits of the flash suppressor. If the shot is contact or near contact, the flash suppressor will produce a characteristic “flower-like” pattern of blackened zones around the entrance, or rarely may produce deep burns mimicking “grouping of gun-shot entry wounds”. We present a case where due to deep dermal burns resulting from escaping hot soot-laden gases through the slits/ openings of a flash suppressor of an infantry rifle in a contact shot mimicked multiple entry wounds.

3838. Naimer, S. A., et al. (2004). "Control of massive bleeding from facial gunshot wound with a compact elastic adhesive compression dressing." The American journal of emergency medicine **22**(7): 586-588.

The issue of immediate control of acute external traumatic hemorrhage is poorly dealt with in the medical literature. A compact unit incorporating the desired components capable of applying significant compression over diverse body areas has been suggested in the past but not formally demonstrated effective in practice. In this report we describe the treatment of a young man presenting with a very large, complex, profusely bleeding facial gunshot wound. The calvarium remained intact. The upper airway was diverted and secured by performing a cricothyroidotomy. A transparent elastic adhesive dressing was then applied by covering the anterior aspect of the face by a contact pad followed by sequential wrapping of the roll covering all structures between the forehead and the neck. This procedure successfully controlled the hemorrhage and maintained the victim's condition hemodynamically stable until definitive surgical intervention at the level 1 medical center. We attribute the survival of this victim to the innovative dressing technique and excellent cooperation between the trauma team and hospital staff. This case demonstrates the contribution of elastic adhesive compression dressing towards saving the lives of those inflicted by severely challenging bleeding wounds. We suggest this technique be considered by Emergency personnel working in the prehospital arena in selected cases.

3839. Najenson, T., et al. (1974). "Rehabilitation after severe head injury." Scandinavian journal of rehabilitation medicine **6**(1): 5-14.

3840. Nakagawa, A., et al. (2002). "[A temporal head injury involving intracranial penetration by glass]." No shinkei geka. Neurological surgery **30**(5): 529-533.

The authors report a rare case of intracranial glass injury due to a temporal head injury. This 72-year-old man slipped on a bathroom floor, impacting a glass door with his head and right shoulder. His right temporal scalp and right shoulder were cut by the broken glass. He visited our emergency unit four hours after sustaining the injury. Physical and neurological examinations showed no abnormalities except for two lacerated wounds on both the right temporal scalp (1.5 cm) and the right shoulder skin (10 cm). Foreign bodies were not palpable around the lacerated wounds. Skull X-ray and CT studies disclosed a single, 5-cm long, radiopaque foreign body penetrating the temporal skull bone into the right temporal lobe, but no evidence of intracranial bleeding was found. Under the diagnosis of intracranial glass injury, total removal of the foreign body with dural repair was carried out. On surgical exploration, glass penetrating the skull bone 5-mm distant anteriorly to the scalp laceration was observed. Postoperative angiography showed no vascular lesions, and one-week later he was discharged with no complications. According to the literature, most of the intracranial foreign bodies occur around the orbital, the frontal sinus, and the nasal areas. To our knowledge, this is the first report of an intracranial glass penetrating injury to the temporal lobe. Since the clinical manifestations occasionally do not correspond to the appearance of the laceration after glass penetrating injuries, serious caution concerning patients with intracranial glass penetrating injuries is important.

3841. Nakaji, P. (2010). "Comments." Neurosurgical review **33**(4): 504.

3842. Nakamura, N., et al. (2017). "[A Case of Transoral Penetrating Head Injury from a Crossbow-Fired Arrow]." No shinkei geka. Neurological surgery **45**(9): 799-804.

Penetrating head injuries are extremely rare in Japan. The authors describe a case involving a penetrating head injury from an arrow fired from a crossbow. A 52-year-old man who had shot himself transorally in a suicide attempt was admitted to the authors' hospital. On admission, he was conscious and exhibited no neurological deficits. The end of the arrow was visible inside his oral cavity. Computed tomography revealed the arrow had penetrated the right cerebellum and occipital lobe, resulting in a very small hematoma. Digital subtraction angiography revealed no significant vascular injuries. After considering these findings and the nature of the object, the authors decided to remove the arrow from the cranium by pulling it from the patient's oral cavity. To remove the arrow, surgery was performed with several devices, including intraoperative X-ray, endoscopy, and intraoperative angiography. The authors were able to completely remove the arrow, and the patient experienced no new deficits, except mild ataxia and mild dysphasia, and no signs of cerebral infection or cerebrospinal fluid leakage after the surgery. Although most cases of penetrating

head injuries require craniotomies, the authors were able to safely remove the foreign object in this case without performing a craniotomy. Because guidelines for the treatment of penetrating head injuries have not been established, the treatment of each case must be modified according to the nature of the foreign object and the findings of preoperative imaging techniques.

3843. Nakamura, T., et al. (2004). "[Multiple cerebral white matter lesions following head trauma with eyeball contusion]." Rinsho shinkeigaku = Clinical neurology **44**(2): 108-110.

We reported a 36-year-old man with multiple cerebral white matter lesions following head trauma with eyeball contusion. He had suffered from optic neuritis on non-injured side after one and half months from the head trauma. Brain MRI revealed multiple cerebral white matter lesions and lumbar puncture disclosed an elevated level of protein of the cerebrospinal fluid after two and half months from the head trauma. He was treated with steroid pulse therapy and resulted in an improvement of his visual acuity and a remarkable decrease of multiple cerebral white matter lesions. There has been a controversy concerning the causal relationship between trauma and multiple sclerosis (MS). In this case, MS-like multiple cerebral white matter lesions are considered to be relevant to the head trauma.

3844. Nakayama, D. K. (2019). "Vesalius: Surgeon to monarchs." American Surgeon **86**(3): 173-175.

3845. Nakayama, Y., et al. (1995). "[Penetrating head injury caused by weed--case report]." No to shinkei = Brain and nerve **47**(12): 1192-1194.

A case of penetrating head injury caused by weed was reported. A 69-year-old man fell from a bicycle and was stuck by the hard stalk of weed through the right nasal cavity. On admission the patient was fully alert and with no neurological deficits. The weed was pulled out at an out-patient department and then he became semicomatose and hemiplegic on the left side together with an occurrence of nasal bleeding. Subsequent computed tomographic (CT) scan showed an intracerebral hematoma in the right frontal lobe. The hematoma was immediately evacuated and the dural defect, lateral to the cribriform plate, was closed. It is stressed that neuroradiological evaluation with CT scan and/or magnetic resonance imaging (MRI) is mandatory because an information about an anatomical location of penetrating objects and intracranial complications are essential to a decision-making of surgical strategy. The objects should be urgently removed in a surgical exposure of the intracranial lesion and the contused brain should be debrided with a repair of the lacerated dura mater.

3846. Nam, J. and W. Kelly (2020). "PNEUMOMEDIASTINUM FROM PNEUMATIC NAIL GUN INJURY TO THE HAND." Chest **158**(4): A736.

SESSION TITLE: Fellows Critical Care Posters SESSION TYPE: Fellow Case Report Posters PRESENTED ON: October 18-21, 2020 INTRODUCTION: Pneumatic nail guns are important in manufacturing and construction due to increased production rates. These tools use a great deal of energy to make a nail into a projectile. Most nail gun injuries are superficial1 and tend to affect extremities, but there are documented cases affected brain, eyes, neck, heart, thorax, spinal cord, bowel, and liver.2 We report a case of pneumomediastinum from nail gun injury to the hand. CASE PRESENTATION: 40-year-old male presented from a construction site with nail extending from his left thumb to his left middle finger. He was alert and oriented with pain in his left arm and mildly dyspneic. On exam, a nail had pierced the pneumatic tube with a section of tubing in between his two digits pinned by the nail. There was noticeable crepitus and subcutaneous emphysema in his left hand extending to his shoulder and decreased breath sounds on right lung. While being evaluated in the Emergency Department, he became progressively dyspneic. He described a sensation of fullness in his throat. Due to worsening hypoxia the patient underwent rapid sequence intubation. Imaging showed extensive subcutaneous emphysema in chest, pneumomediastinum, pneumopericardium, and a small right pneumothorax. Right thoracostomy tube was placed and the nail and pneumatic tubing were successfully removed, with extubation and discharge after several days. DISCUSSION: The construction industry first used pneumatic nail guns in 1959. There have been increasing numbers of accidents related to these devices as they become more popular.2 Injuries often occur when the operator misses the intended surface, the tool becomes accidentally activated, or the hose becomes disconnected from the tool. There have been 151,000 nail gun injuries in US Emergency Departments from 2006 to 2011. Although 90% of patients were treated and released, there have been case reports involving paralytic spinal cord transection,

bowel perforation, long bone fracture, liver laceration, hemo-pneumothorax, blindness, cerebral damage, and fatalities.3 CONCLUSIONS: We believe this to be the first case of pneumomediastinum from a distal hand nail gun injury, caused by air insufflation from the nail passing through the tubing, which can be added to the list of hazards as pneumatic tools become increasingly prevalent at both work sites and in homes. 3847. Nan, B., et al. (2011). "A clinical investigation of the mechanism of growing skull fractures in children." Journal of neurotrauma **28**(5): A39-A40.

Background: Many theories have been offered to explain growing skull fractures (GSFs), such as dural tears, arachnoid herniation, increased intracranial pressure, bone absorption due to ischemia of the fracture line, and delayed or ceased bone growth. These theories, however, are limited by certain inadequacies. In this prospective study, we sought to uncover the mechanisms of GSFs, and their treatment methods in children. Methods: Ten patients with GSFs who received treatment at our hospital between November 2000 and October 2009 were retrospectively analyzed. The age at injury, duration from the time of injury to the appearance of the GSF, fracture width, and imaging characteristics were analyzed. Cranioplasty was carried out, while duraplasty was not performed. Results: The age at injury ranged from 7-21 months, and the age at surgery ranged from3-5 years. The injuries included 4 fall injuries and 6 automobile collision injuries. All were linear skull fractures. The duration from the time of injury to the appearance of a GSF was <1month in 4 cases and<2 months in 6 cases. Six patients had frontal bone fractures, 2 had parietal bone fractures, and 2 had occipital bone fractures. The fracture width ranged from 1.5-3.0 cm. The growing fractures became stationary just after onset, without further progression. CT revealed 4 cases of encephalocele underneath the fracture, and 6 cases of encephalomalacia due to brain contusion. Follow-up ranged from6 months to 7 years. Titanium plate fixation was stable, without loosening or displacement. There were no skull deformities in any patient. Conclusion: GSFs usually occur in young children. The rapid growth of the brain in young children produces an outward expansion force, which plays a crucial role in GSF development. It is possible that the current theories such as dural tear, arachnoid herniation, increased intracranial pressure, bone absorption due to ischemia of the fracture line, and delayed or ceased bone growth, only constitute secondary causes.

3848. Nance, M. L., et al. (2003). "Nonintracranial fatal firearm injuries in children: implications for treatment." The Journal of trauma **55**(4): 631-635.

BACKGROUND: Understanding the injury characteristics of nonintracranial fatal (NIF) gunshot wounds in children treated in a statewide trauma system will help guide effective treatment strategies., METHODS: This study was a retrospective analysis of children fatally injured with firearms. The review included demographic information, firearm injury characteristics, and outcome. The setting included trauma centers participating in a statewide trauma registry. Patients were all children (age < 18 years) treated in trauma centers for NIF gunshot wounds from January 1988 through December 2000. The main outcome measures were characteristics of fatal firearm injuries in children., RESULTS: Over the 13-year period, there were 1,954 children with firearm injuries including 368 (18.8%) children with fatal wounds. Of the fatally wounded children, 177 (48.1%) had no intracranial injury. The NIF injury population was 90.4% male, with a mean age of 14.9 years (range, <1-17 years) and an Injury Severity Score of 38.2 (range, 9-75). Over 95% of deaths in this group occurred within 24 hours of admission. Although injuries to the thorax were most common (78.5%), 48.6% of the NIF cohort had injuries to multiple body regions, including 31% with injuries in both the abdomen and thorax. Compared with all children wounded by firearms, NIF firearm injury patients had, on average, more body regions injured (1.6 vs. 1.1, $p < 0.001$) and a greater total number of injuries (6.0 vs. 3.5, $p < 0.001$). Patients with an NIF injury were more likely to suffer a major vascular injury (54.8% vs. 13.8%, $p < 0.001$), lung injury (56.5% vs. 12.9%, $p < 0.001$), or cardiac injury (44.6% vs. 4.6%, $p < 0.001$) than all children with a firearm injury., CONCLUSION: Most children who arrive at trauma centers alive and subsequently die from NIF firearm injuries do so rapidly from major vascular and thoracic injury. Almost half of these children have injuries to multiple body regions, further complicating management. Innovative, aggressive treatment approaches should be sought to improve survival in this extremely injured cohort of children.

3849. Nandra, B., et al. (2017). "Free Bone Grafts for Mandibular Reconstruction in Patients Who Have Not Received Radiotherapy: The 6-cm Rule-Myth or Reality?" Craniomaxillofacial Trauma and Reconstruction **10**(2): 117-122.

Bony reconstruction of the mandible after surgical resection results in improved rehabilitation and aesthetics. Composite tissue transfer has transformed reconstruction, particularly in patients who have received radiotherapy. However, there is morbidity related to free tissue transfer. Free nonvascularized bone grafts have much lower morbidity. Surgeons believe that free bone grafts greater than 6.0 cm are prone to failure. The aims of this study was to assess whether bone grafts greater than 6.0 cm in length have a high risk of failure. A retrospective study was performed on all patients who had free bone grafts greater than 6.0 cm in length at Birmingham, UK, and Florida, the United States. None of the patients received radiotherapy. A total of 14 patients had undergone bone grafts for mandibular defects greater than 6.0 cm in length; 13 of the bone grafts were successful. Of these 13, none were infected and there was radiographic evidence of bony union. Some of the patients have been dentally rehabilitated with implants. Contrary to much of the literature and many surgeons belief, our study has shown that long mandibular defects (>6.0 cm) are not a contraindication to the use of free bone grafts. Key principles to achieve success are discussed in this article.

The case of a horse affected with frontal sinusitis, in which neurological complications occurred following trepanation, is reported. The previous history of the animal as well as the clinical, radiological and pathological findings are discussed.

3851. Naresh, P. K. and P. Veneet (2001). "Penetrating foreign body presenting as an aural polyp." Indian Journal of Otology **6**(4): 33-34.

A case of penetrating foreign body [Gunshot pellets] presenting as aural polyp is described. In any case of recurrent aural polyp not responding to standard therapeutic measures, a foreign body should be suspected which may be lying outside the external auditory canal or in middle ear.

3852. Narotam, P. K., et al. (1994). "Operative sepsis in neurosurgery: a method of classifying surgical cases." Neurosurgery **34**(3): 409-406.

Neurosurgical operations have traditionally been classified along the lines of general surgical procedures. A prospective study, during an 18-month period, was undertaken in 2249 patients undergoing neurosurgical procedures to establish and evaluate a method of classifying surgical cases by the use of specific neurosurgical criteria. Patients were placed in one of five categories according to the level and type of contamination at the time of surgery. Infection included all abnormal wounds and was documented as deep when infection occurred beneath the galea (subgaleal pus, osteitis, abscess/empyema, ventriculomeningitis) and as superficial if only the scalp (including wound erythema) was involved. A statistically significant difference in the sepsis rate was found in the different categories ($P < 0.0001$). Of the 342 "dirty cases," 9.1% of patients developed further wound sepsis. Concomitant cerebrospinal fluid fistulae (44%), second operations (11.8%), and patients with penetrating injuries (9.2%) were the major factors implicated in sepsis in the "contaminated" category (9.7%). In the "clean contaminated" category, a sepsis rate of 6.8% was found. Prolonged surgery (longer than 4 hours) was also implicated in higher infection rates (13.4%). This study strongly supports the separation of patients who have foreign materials implanted (sepsis rate = 6.0%) from "clean" patients, essentially cases categorized as having no known risk factors that may affect sepsis, in whom a sepsis rate of 0.8% was found ($P < 0.001$). Importantly, surgery for the repair of so-called "clean" neural tube defects in neonates requires separate consideration. An infection rate of 14.8% existed in this subgroup. A uniform system of reporting wound abnormalities is also proposed.

3853. Naseem, M., et al. (1986). "Traumatic pneumocephalus caused by stab wound to the neck." AJNR. American journal of neuroradiology **7**(1): 174-175.

3854. Nashed, A., et al. (2011). "The outcome of early surgical repair with vitrectomy and silicone oil in open-globe injuries with retinal detachment." American journal of ophthalmology **151**(3): 522-528.

PURPOSE: To determine the functional and anatomic outcome of early surgical repair with vitrectomy and silicone oil in open-globe injuries with retinal detachment (RD)., DESIGN: Retrospective consecutive interventional case series., METHODS: All patients with open-globe injuries with RD treated between 1997 and 2007 underwent primary repair including vitrectomy with silicone oil within 8 hours after presentation. For data analysis, patients were divided into 3 groups according to the BETT classification: Group 1, intraocular foreign body; Group 2, penetrating injury; Group 3, globe rupture. Outcome measures were final reading visual acuity (0.4 logMAR or better), final ambulatory visual acuity (1.6 logMAR or better), endophthalmitis, and postoperative proliferative vitreoretinopathy (PVR)., RESULTS: Eighty-eight patients were included (Group 1, n = 13; Group 2, n = 36; Group 3, n = 39). Mean follow-up was 22 months (standard deviation [SD] = 23, range 6-107 months). Eight percent of patients retained reading vision without significant difference between the 3 groups. Fewer patients in Group 3 than in Group 1 or 2 retained ambulatory visual acuity (Group 1, 62%; Group 2, 64%; Group 3, 33%, P = .024). Endophthalmitis occurred in 3.4% of eyes (1 eye in each group). PVR grade B-C, type 1-3 developed in 44% of patients without significant difference between the 3 groups. Re-RD occurred in 38% of eyes., CONCLUSIONS: Few patients achieved reading vision while 50% of patients retained ambulatory visual acuity. Final visual outcome is related to the severity of the injury. The frequency of postoperative endophthalmitis is low. Postoperative development of advanced PVR is avoided in most patients.

3855. Nasr, A. M., et al. (1999). "Penetrating orbital injury with organic foreign bodies." Ophthalmology **106**(3): 523-532.

OBJECTIVE: The authors reviewed the clinical features, diagnostic workup, and management of patients of penetrating orbital injuries with retained organic foreign bodies., DESIGN: Retrospective, noncomparative case series., PARTICIPANTS: Nineteen patients (15 males, 4 females) with penetrating orbital injuries due to organic foreign bodies., RESULTS: The series included 15 (78.9%) males and 4 (21.1%) females who ranged in age from 6 months to 40 years (mean = 14.6 years); 12 (63.2%) patients were younger than 12 years of age. Twelve (63.2%) right and 7 (36.8%) left orbits were involved. Time between injury and presentation varied from a few hours to 9 months. Most common injury site was the superior orbit in 11 (57.9%) patients leading to abnormal extraocular motility (84.2%), proptosis (68.4%), and upper lid ptosis (47.4%). Associated pathologies also included acute cellulitis in 11, orbitocutaneous fistula in 5, and osteomyelitis in 2 patients. Preoperative computed tomography (CT) and magnetic resonance imaging (MRI) identified the foreign bodies in 42% and 57% of the patients, respectively., CONCLUSION: Preoperative identification of the foreign material in the orbit was found to be very helpful for patient management but was only possible in approximately 50% of our cases with the use of CT and MRI. The vision in our patients usually improved shortly after treatment; the long-term complications more often included extraocular muscle and eyelid motility problems and periorbital scarring.

3856. Nasr, M. M. (2015). "Bilateral external carotid artery ligation: A life saving procedure in severe maxillofacial trauma." International journal of surgery case reports **8**: 81-83.

Introduction Bilateral external carotid arteries ligation is a rare practice in cases of extensive maxilla-facial injuries. Defining indication criteria in the management of such cases is highly demanded in emergency surgery. Case presentation Reported case presents a male patient 67 years old man with a gunshot to the face. The whole face was macerated. Patient was operated surgically performing bilateral external carotid artery ligation, tracheostomy, pharyngostomy, gastrostomy and pressure dressing to face and head. Conclusion The procedure of bilateral external carotid artery ligation has no defined role in the management of maxillofacial trauma. The current status of such procedure in maxillofacial trauma needs revision.

3857. Nasser, R., et al. (2016). "Penetrating thoracic spinal cord injury with ice pick extending into the aorta. A technical note and review of the literature." Surgical neurology international **7**(29): S763-S766.

Background: Penetrating spinal cord injuries pose a great challenge to both patients and the treating physicians. Although the overall incidence of penetrating spinal cord injury is the highest in the military, the ubiquity of guns in our society continues to make penetrating spinal cord injury prevalent in the civilian population. These types of injuries are particularly complicated because, beyond the trauma to the neural elements and supporting structures, other organs

can be affected and a team approach is required for successful treatment. Case Description: In this report, the authors present a unique case of an ice pick penetrating posteriorly through the spinal canal into the aorta. The described surgical management involved careful consideration and planning to prevent worsening vascular and neurological compromise. Among the challenges faced are neurological compromise, vascular injury, spinal instability, and cerebrospinal fluid leak. Conclusion: To the author's knowledge, this challenging case represents the first description of a successful removal of a penetrating thoracic spinal foreign body that terminated within the lumen of the thoracic aorta.

3858. Nassiri, N., et al. (2009). "Is cranial reconstruction with a hard-tissue replacement patient-matched implant as safe as previously reported? A 3-year experience and review of the literature." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **67**(2): 323-327.

PURPOSE: This study aimed to verify the low complication rates (0% to 11%) previously reported in cranial reconstruction using hard-tissue replacement patient-matched implant (HTR-PMI)., PATIENTS AND METHODS: A 3-year multidisciplinary experience involving 21 patients undergoing HTR-PMI reconstruction of large cranial defects was reviewed. Complications were defined as implant exposure, implant infection, or soft-tissue infection., RESULTS: A statistically higher rate of complications was observed, compared with previous series (P= .043). We also determined whether previous bone infection, a history of diabetes, or smoking were risk factors for the development of complications. Diabetes, smoking, and pre-existing bone/implant infections were not significant risk factors for HTR-PMI failure. The higher rate of complications can be partially attributed to a diverse and complicated patient population, with multiple comorbid conditions and various indications for HTR-PMI reconstruction. In particular, decompressive craniectomies in trauma patients can be risky indications for the use of HTR-PMI., CONCLUSION: Larger studies are suggested to verify our findings.

3859. Nassuphis, P. (1968). "[Cholesteatoma of the ear and brain abscess following gunshot injury]." Cholesteatom des Ohres und Hirnabscess nach Schussverletzung. **191**(2): 652-658.

3860. Nast-Kolb, D., et al. (1998). "[Abdominal trauma]." Abdominaltrauma. **101**(2): 82-91.

While a great part of the Anglo-American medical literature addresses the topic of penetrating trauma the German speaking countries rather publish on blunt abdominal injury. The presented paper discusses the strategic principles of acute clinical management of abdominal trauma on the combined basis of own research results and a comprehensive review of the literature. Blunt abdominal injuries in most cases from a part in the pattern of multiple trauma. The early, first-hours mortality is most often caused by severe traumatic brain injury or abdominal trauma with massive hemorrhage. The prehospital management of penetrating injuries is characterized rather by the concept of 'load and go', whereas the onscene stabilization of the patient with blunt abdominal injury should precede transport to the adequate hospital. On arrival in the accident and emergency room an immediate blood transfusion is recommended for hemodynamically unstable patients. If then a stabilization is not achieved, an emergency laparotomy should follow. Abdominal stab injuries should be explored by laparoscopy if an intraperitoneal lesion is suspected. If then the possibility of an intestinal lesion is present a laparotomy should be performed directly thereafter. Firearm injuries require open revision in almost all cases. The standard diagnostic technique in blunt abdominal trauma is sonography, assisted by computed tomography and, if indicated, angiography in hemodynamically stable patients. Isolated abdominal injuries without hemodynamic or coagulation disorders allow conservative treatment in the intensive care setting. In severe multiple trauma as well as in manifest shock even the smallest fluid detection should lead to laparotomy. The surgical treatment of splenic rupture is still a matter of discussion. Splenectomy is indicated in patients with severe concomitating injuries or shock whereas in the remainder of cases the total or partial preservation of the spleen should be pursued. Hepatic injuries offer a broad spectrum of operative interventions, ranging from superficial hemostatic measures over compression techniques like 'packing' and 'mesh-wrapping' to atypical and anatomical resections and to liver transplantation in exceptional cases. Lesions of tubular organs and the pancreas pose especially difficult diagnostical problems but regularly allow a rather easy operative treatment.

3861. Nath, F. P., et al. (1984). "Penetrating injury of the tuberculum sellae." Neurosurgery **14**(5): 598-600.

An unusual case of perforation of the tuberculum sellae and right ethmoid bone by a 10-in. serrated bread knife is described. The patient survived with no neurological or endocrine deficit. The importance of preoperative angiography and control of the proximal and distal vasculature is stressed.

3862. Nathoo, N., et al. (2000). "Transcranial brainstem stab injuries: a retrospective analysis of 17 patients." Neurosurgery **47**(5): 1117-1123.

OBJECTIVE: Transcranial stab injuries remain a frequent cause of emergent neurosurgical admissions to neurosurgical units in South Africa. Brainstem stabs are an uncommon, yet often fatal, form of brain injury., METHODS: A retrospective audit of 597 patients with transcranial stab injuries admitted to our unit over a 12-year period (January 1987 to December 1998) identified 17 patients (2.85%) with brainstem stab injuries. The computed tomographic scans of all patients were analyzed, and a detailed autopsy examination of the skull and its contents was performed in all patients who died. Stepwise linear regression analysis was used to formulate a predictive model of outcome for the entire series of 597 patients., RESULTS: The majority of the patients were males (16 patients), and the study group had a mean age of 28.65 +/- 9.59 years and a mean Glasgow Coma Scale score of 8.59 +/- 2.76. Knives (82%) were the most common instruments of penetration. Cerebral angiography identified 3 patients with vascular abnormalities, and autopsy revealed an additional 4 patients with vascular injury. Emergency ventriculostomy was performed in 10 patients for obstructive hydrocephalus. Four of the 17 patients survived (76.5% mortality). Factors significantly predictive of outcome in patients with transcranial stab injuries were the Glasgow Coma Scale score (F = 43.7), the occurrence of intraventricular hemorrhage (F = 22.8), the type of associated lesion (intracranial bleed, vascular abnormality, or brain abscess) (F = 5.9), and the number of operations (F = 3.2)., CONCLUSION: The Glasgow Coma Scale score is the most significant predictor of outcome in low-velocity transcranial stab injuries. Brainstem stab injuries have a great propensity for vascular damage. Survivors are incapacitated by severe, fixed neurological deficits.

3863. Nathoo, N., et al. (2002). "Civilian infratentorial gunshot injuries: outcome analysis of 26 patients." Surgical neurology **58**(3-4): 225-223.

BACKGROUND: Craniocerebral missile injuries have steadily increased to become the most common form of penetrating neurotrauma in our environment resulting in continued morbidity and neuropsychological sequelae. Civilian infratentorial gunshot injuries are uncommon but generally regarded as fatal injuries, with many patients dying before reaching hospital., METHODS: A retrospective analysis of 1,069 patients with civilian gunshot wounds (GSW), admitted to our unit over a 14-year period (1986-2000), identified 26 patients with infratentorial gunshot injuries (2.4%). A detailed analysis of these patients was carried out, which included demographic factors, clinical and anatomic correlation, computed tomography scans, surgical management, and outcome., RESULTS: All patients were male. The mean age was 26.5 +/- 11.5 years and the mean admission Glasgow Coma Score 11.8 +/- 2.7. Twenty-four of 26 patients required cerebrospinal fluid (CSF) diversion to control secondary hydrocephalus. The second commonest surgical procedure was posterior fossa decompression. Five of 26 patients died (19.2%). Severe morbidity was noted in 9 of 21 surviving patients (42.8%). Significant predictors: good outcome was associated with primary missile entry of the infratentorial compartment ($p = 0.005$), while patients with supratentorial to infratentorial missile trajectory were noted to have a poorer outcome ($p = 0.041$). Location of cerebellar injury (lateral or medial) and missile caliber had no significant influence on patient outcome., CONCLUSION: Early control of incipient or established hydrocephalus and aggressive surgical management where appropriate, with careful postoperative monitoring, is necessary for good outcome in patients with civilian infratentorial missile injuries.

3864. Nathoo, N. and S. S. Nadvi (1999). "Intracranial malposition of a nasogastric tube following repair of choanal atresia." British journal of neurosurgery **13**(4): 409-410.

Intracranial penetration during attempted nasogastric intubation is a rare, often lethal occurrence. We report the inadvertent introduction of a nasogastric tube intracranially in a neonate following repair of unilateral choanal atresia. Following manual removal of the tube, the patient made a good recovery.

3865. Nathoo, N. and S. S. Nadvi (1999). "Traumatic intracranial aneurysms following penetrating stab wounds to the head: two unusual cases and review of the literature." The Central African journal of medicine **45**(8): 213-217.

Two patients with rare complications of traumatic intracranial aneurysms following penetrating cranial stab wounds are described. One patient had a good outcome despite a secondary rupture of a traumatic proximal middle cerebral artery aneurysm, while the second patient had a traumatic basilar bifurcation artery aneurysm. To our knowledge neither the survival from a secondary rupture of a traumatic intracranial aneurysm, nor the development of a basilar bifurcation aneurysm secondary to a transcranial stab wound has been described previously. Furthermore, this is the first report of the technique of deep hypothermic cardiac arrest utilized to treat a traumatic false aneurysm. Traumatic intracranial aneurysms are a rare clinical entity, most often diagnosed after rupture and often resulting in fatal haemorrhage. A high index of suspicion needs to be maintained when managing patients with transcranial stab wounds. Early surgical intervention improves outcome by preventing initial aneurysmal rupture or rebleeding.

3866. Nathoo, N., et al. (2011). "Brain abscess: management and outcome analysis of a computed tomography era experience with 973 patients." World neurosurgery **75**(5-6): 716-717.

OBJECTIVE: Brain abscess (BA) is a neurosurgical emergency and despite significant medical advances, it remains a surgical challenge. A single institution's two decade computed tomography era management experience with BA is reported., METHODS: A retrospective analysis of patients with BA, admitted to the Department of Neurosurgery, Wentworth Hospital, Durban, KwaZulu-Natal, South Africa, was performed. The medical records were analyzed for demographic, clinical, neuroimaging, neurosurgical and otolaryngology management, microbiological characteristics, and their relationship to outcome., RESULTS: During a 20-year period (1983-2002), 973 patients were treated. The mean age was 24.36 +/- 15.1 years (range: 0.17-72 years) and 74.2% (n = 722) were men. The mean admission Glasgow Coma Score was 12.5 +/- 2.83. The majority of BAs were supratentorial (n = 872, 89.6%). The causes were otorhinogenic (38.6%), traumatic (32.8%), pulmonary (7%), cryptogenic (4.6%), postsurgical (3.2%), meningitis (2.8%), cardiac (2.7%), and "other" (8.6%). Surgical drainage was performed in 97.1%, whereas 19 patients had nonoperative management. The incidence of BA decreased during the study period. Patient outcomes were good in 81.3% (n = 791), poor in 5.3% (n = 52), and death (13.4%, n = 130) at discharge. The management morbidity, which included postoperative seizures, was 24.9%. Predictors of mortality were cerebral infarction (odds ratio [OR] 31.1), ventriculitis (OR 12.9), coma (OR 6.8), hydrocephalus (OR 5.1), dilated pupils (OR 4.8), bilateral abscesses (OR 3.8), multiple abscesses (OR 3.4), HIV co-infection (OR 3.2), papilledema (OR 2.6), neurological deterioration (OR 2.4), and fever (OR 1.7)., CONCLUSIONS: Optimal management of BA involves surgical drainage for medium-to-large abscesses (>=2.5 cm) with simultaneous eradication of the primary source, treatment of associated hydrocephalus, and administration of high doses of intravenous antibiotics. The incidence of BA is directly related to poor socioeconomic conditions and therefore, still poses a public health challenge in developing countries.

3867. Natrella, M., et al. (2012). "Treatment of a transorbital penetrating injury: a particular endovascular approach." Interventional neuroradiology : journal of peritherapeutic neuroradiology, surgical procedures and related neurosciences **18**(2): 191-194.

The management of craniocerebral penetrating injury currently represents a challenge for neurosurgeons and neuroradiologists and requires innovative planning. This report describes the case of a worker admitted to hospital with an intracranial piece of concrete-cutting saw stuck through the right eye. At the time of admission the patient was conscious and this fact influenced the choice of a particular approach. This patient escaped without neurological deficit or complications, except for the inevitable removal of an eye.

3868. Natung, T., et al. (2018). "A challenging case of a large intraorbital foreign body perforating the nasal septum in a child." Indian journal of ophthalmology **66**(10): 1511-1513.

A 5 year old boy with a history of fall from a height of about 4 feet, presented after one week with swelling, watering and discharge of the right eye. He had severe conjunctival chemosis with superior displacement of the globe. Computed Tomography (CT) showed a linear low attenuation tract in the right orbit extending from the inferolateral wall up to the left uncinate process of the ethmoid bone with increasing Hounsfield unit after 10 days. The parents did not agree for early exploration. After 10 days an exploration was done and a large linear and irregular wooden foreign body (FB) measuring 4.5 x 1.5 cm2 was removed from the right orbit and a smaller one from the nasal cavity. Four weeks post surgery, his vision was 6/9 in the right eye with the eyeball in the normal position. This case was challenging because of

the late presentation, parents not agreeing for early exploration, difficulty in diagnosing by CT and a large and very deep penetrating FB.

3869. Navaneetham, A., et al. (2010). "Submental intubation: our experience." Journal of maxillofacial and oral surgery **9**(1): 64-67.

INTRODUCTION: Airway management for patients who suffered midfacial fractures is complicated. In maxillofacial injuries, a choice has often to be made between different ways of intubation when surgical access to both the nasal and oral cavities is necessary. Submental intubation technique is an alternative to nasoendotracheal intubation and tracheostomy in the management of patients with severe midfacial fractures. This procedure is simple to do and has a low morbidity., MATERIAL: Submental intubation-paramedian technique has been used in 15 cases from May 2005-April 2007 in Hosmat Hospital, Bangalore. All patients had fractures disturbing the dental occlusion plus either an associated fracture of the skull base or a displaced nasal fracture., RESULTS: Average duration of procedure was 7 minutes. Average duration of tube in vitro after surgery was 20 hours. There were 2 postoperative complications of tube obstruction which were successfully managed., CONCLUSION: Submental intubation demands certain technical skills but it is simple, rapid and may avoid tracheostomy in selected patients.

3870. Navarro Artiles, G. and V. Crespo-Lopez (1970). "[Surgical indications in skull and brain injuries and bone collapse]." Indicaciones quirurgicas en las heridas craneocerebrales y en los hundimientos oseos. **116**(2): 151-154.

3871. Navarro León, D., et al. (2020). "Low-cost mandibular reconstruction workflow." Oral and Maxillofacial Surgery Cases **6**(2).

Introduction: The utility of CAD/CAM technology in the treatment of mandibular defects has been demonstrated, allowing effective analysis, diagnosis and treatment for bone defects, however the high cost and sometimes the difficult access to this technology limits its use. Materials and methods: observational descriptive cross-sectional study in which craniofacial bone defects were analyzed with emphasis at the mandibular level, with free 3D reconstruction software, determining characteristics of the population and bone defect. A management workflow is proposed and some cases analyzed are presented. Results: 50 patients with craniofacial bone defects were collected over a one year period. Mandibular defects account for 44% of the total sample, the majority of cases involving more than one mandibular area; the most affected areas were the body and parasymphysis; the average bone defect size was 36mmx56 mm × 15 mm. The proposed low cost workflow allows multidisciplinary work with industrial design teams to ensure the best treatment for the patient. Conclusions: It is possible to implement low-cost management of mandibular defects. The multidisciplinary work between reconstructive surgeons, industrial design and biomedical engineering is useful for the treatment of patients.

3872. Navarro Suay, R., et al. (2012). "Gunshot and improvised explosive casualties: a report from the Spanish Role 2 medical facility in Herat, Afghanistan." Military medicine **177**(3): 326-332.

OBJECTIVE: To provide an analysis of casualties treated during medical evacuation (MEDEVAC) or/and at the Spanish Role 2 in Herat, Afghanistan, including type of weapon, injuries, and effects of protective measures., METHOD: A retrospective analysis was carried out concerning patients who had suffered injuries from either gunshot or explosive devices treated during MEDEVAC or/and at this facility during the period 2005-2008., RESULTS: The total number of cases analyzed was 256. The majority of the casualties were produced by explosive devices (71%). The anatomical regions most affected were the lower limbs (48%). There was a higher New Injury Severity Score in casualties wounded by gunshot (14 +/- 1) than in those wounded by explosive devices (8.5 +/- 1.5) ($p < 0.001$). Surgical procedures for injuries caused by gunshots were 1.7 times more likely than for those due to explosive devices (95% confidence interval: 1.4 to 2.1). Protective devices were used only by 25% of casualties., CONCLUSIONS: The injury score indices of firearm casualties were higher than the explosive device casualties' injury score indices. The possible reasons for this finding are discussed.

3873. Navarro Suay, R., et al. (2015). "Perioperative pain treatment in combat casualty: Experience from the Spanish Military Hospital in Herat (Afghanistan)." Revista de la Sociedad Espanola del Dolor **22**(3): 112-115.

Analgesia has been considered always a vital role in the casualty medical assistant. This opinion is present in Irak and Afghanistan conflicts, too. Since 2005, Spanish military corps has been deployed in the Spanish Military Hospital in Herat (Afghanistan). In this medical facility 30.000 patients (some of them casualties) have been treated, kept an important experience in the treatment of this kind of politrauma. We show a medical report about a military, who is injured by an gunshot and explosive attack suffering traumatic brain injury, ocular lesion, abdominal and leg trauma. Perioperative painkiller treatment is described in this casualty.

3874. Navarro-Suay, R., et al. (2016). "Retrospective study about 211 combat casualties with traumatic brain injury by gunshot or improvised explosive devices treated in the spanish military hospital deployed in herat (afghanistan) from 2006 to 2014." Journal of neurosurgical anesthesiology **28**(2): S18.

Background: Over the last 10 years, conflicts in Afghanistan and Iraq have resulted in a high numbers of casualties, some of them with blunt or penetrating brain injuries. The aim of this study is to analyze casualties who suffered gunshots wounds (GSW) and explosive device injuries (IED) and were treated in the Spanish Military Hospital from 2006 to 2014. Methods: We carried out a retrospective study of patients seen from January 1, 2006 to December 31, 2014. The population chosen for the study was all patients who were wounded by gunshots or by explosive devices and who were treated at Spanish Military Hospital in Herat (Afghanistan). This study was approved by Spanish Medical Authorities, with NATO medical study policies. Results and Discussion: During the period studied, 738 combat casualties were treated at our medical facility (211 combat casualties with head and/or neck trauma). In total, 199 (94.3%) were male and 12 (5.7%) were female. A total of 89 (42.1%) were Afghan soldiers, 80 (37.9%) were NATO members, and 42 (20%) were civilian. In total, 185 (87.6%) were evacuated by helicopter to military hospital and the rest (26, 12.4%) were transferred by ground ambulance. The majority were wounded by explosive devices (74.4%), and the rest had GSW (25.6%). We did not see any casualties who were injured by both gunshots and explosives. In total, 32.2% of the casualties were 25 to 29 years old. The mortality of the casualties treated was 4.2% (N=9 to 7 by IED and 2 by GSW). In total, 52 (24.6%) casualties were evacuated to another military hospital. A total of 138 (65.4%) casualties needed a surgical procedure. A total of 108 (51.1%) casualties were admitted into the intensive care unit. Applying the NISS, 146 (69.3%) of casualties were categorized as minor injuries, 37 (17.5%) suffered mild injuries, and 28 (13.2%) suffered severe injuries (25% to 89.2% by improvised explosive device and 3% to 10.8% by gunshot). Conclusions: During the period studied, 211 combat casualties with head and/or neck trauma were treated in the Spanish Military Hospital deployed in Herat (Afghanistan). The majority (74.4%) were wounded by explosive devices and the rest by gunshot. In total, 69.3% were categorized by NISS like minor injuries, 13.2% like mild injuries, and 13.2% like severe injuries (89.2% of this grade by improvised explosive devices).

3875. Naveed, S., et al. (2019). "Weaponry pattern of homicidal deaths in district Peshawar." Journal of Medical Sciences (Peshawar) **27**(3): 194-197.

Objective: To determine the weaponry pattern due to homicidal deaths in tertiary case setup. Materials & Methods: The cross-sectional descriptive study was held in Forensic Medicine Department, Khyber Medical College, Peshawar from Jan 2016 - June 2016. Out of total 537 autopsies in this department, 377 samples of homicidal deaths were taken and studied in detail. A pre-designed questionnaire with demographic details was used as research tool. SPPS v 25.0 was used as analytical tool, categorical variables were presented/tabulated in the form of frequency and percentages while numerical variables were presented in the form mean ± S.D. Results: Out of 377 autopsies, in 86.7% cases cause of death was due to firearm injury followed by sharp cutting object 6.1%, bomb blast and ligature related deaths were 3.2% and blunt trauma had only 0.8% cases. The male to female preponderance of homicidal cases is not unique one with male more dominant with 87.5% and only 12.5% female cases. The cause of death in these cases shows that maximum died due to injury to brain with 38.5% followed by Heart/Lung injury 93 (24.7%) and then injuries to other organs. Conclusion: This study concludes that homicide was the most common manner of death in Peshawar. Out of the total unnatural deaths, firearms were used in the maximum number of cases.

3876. Nawaz, K., et al. (2017). "Case report acute necrotizing pancreatitis following percutaneous transhepatic biliary drainage in post Liver transplant patient: A rare and serious complication." Hepatology International **11**(1): S599-S600.

Background: The percutaneous transhepatic approach to the biliary tree plays an important role in the management of biliary obstruction. ERCP is preferred over percutaneous transhepatic cholangiography (PTC) in patients with hilar biliary obstruction as it is less invasive. Studies indicate that percutaneous drainage or stent insertion carries a small risk of severe bleeding (0.5-4.1%), bile leak (0.5-1.6%) and subsequent sepsis (0.5-1.9%) with an overall rate of complications of 3-10% and procedure related mortality of 0.1-0.8%. These risks are comparable to those of the endoscopic approach, which has a complication rate of 3.6-14% and a mortality rate of 0.5%2. Pancreatitis is a rare but recognized complication of PTBD and necrotizing pancreatitis is even rarer and may preferably be explained in routine as a possible complication of the procedure while taking consent. Methods: Case History: 55 year old male status post LDLT was admitted for PTBD and CBD stent placement for anastomotic stricture six months ago. The patient underwent PTBI and ballooning the stricture without any intra-procedural complications. Next day patient had complaints of abdominal pain, radiating to back and vomiting. O/E abdomen was tender. Diagnosis of acute pancreatitis was made. CT showed peri-pancreatic inflammatory changes with necrosis along with peri-pancreatic fluid collection. The patient was kept npo and managed with i/v fluids, analgesia and antibiotics. A drain was placed for peri-pancreatic fluid collection & Fluid amylase was checked which was>20,000 IU. Fluid was large in amount>1000 ml per day and there was suspicion of pancreatic fistula. ERCP confirmed it for which pancreatic stent was placed. Drain output decreased gradually. Initially it was 1000 ml per day to <50 ml per day in 6-7 days. Improvements were followed by the normalization of transaminases. He was discharged and follow up visit patient was unremarkable and Abdominal drain was removed. Result: Necrotizing pancreatitis is a very rare complication of PTBI for anastomotic stricture in liver transplant recipients, ion. Endoscopic retrograde route is preferred over PTBD in patients with hilar obstruction. My patient developed the rare complication of necrotizing pancreatitis. Similar pattern has been observed before by Al- Bahrani AZ et al. who reported cases of pancreatitis as a complication percutaneous transhepatic intervention (PTBI) and documented five patients with pancreatitis following PTBI7. Another observation was a risk of pancreatitis comparable to ERCP. This risk was greater with distal biliary intervention than with proximal. Similarly in our patient. Conclusion: Although pancreatitis is being reported with PTBI but necrotizing pancreatitis is not a usual occurrence as known by literature till date. So it is important to keep this complication in consideration while taking consent for PTBI. (Figure presented).

3877. Nayak, G. H. and P. Muthamizh Selvan (2017). "Pattern of craniocerebral injuries among homicidal deaths in Hubballi Dharwad region - One year retrospective study." Medico-Legal Update **17**(2): 56-59.

Inflicting injury to the head is one of the most effective methods of homicide. The aim of the present study was to evaluate the pattern of head injury among homicidal death victims. In present study, out of 45 homicidal deaths, 23 cases of homicide infliction over the head were studied in one year period from 1st January 2015 till 31st December 2015. Majority of cases were in 21-40 years of age comprising of 12 cases (52.17%). Injuries were inflicted by blunt weapons in significant number of cases; 13 cases (56.5%) which were followed by injuries by sharp weapons in 9 cases (39.1%) and firearm in 1 case (04.34%). The skull was fractured in 21 cases (91.30%) of victims and 2 cases (08.69%) of deceased presented without skull fracture. Most common intracranial hemorrhage observed was combination of subdural hemorrhage and subarachnoid hemorrhage(73.91%).

3878. Naylor, K. L., et al. (2016). "Fracture Incidence in Adult Kidney Transplant Recipients." Transplantation **100**(1): 167-175.

BACKGROUND: It remains uncertain whether kidney transplant recipients are a high-risk group for fracture., METHODS: We conducted a cohort study using Ontario, Canada health care databases to estimate the 3-, 5- and 10-year cumulative incidence of nonvertebral fracture (proximal humerus, forearm, hip) in adult kidney transplant recipients between 1994 and 2009, stratifying by sex and age (<50 versus >=50 years) at transplant. We also assessed the 3-year cumulative incidence of all fracture locations (excluding skull, toes, and fingers) and falls, 10-year cumulative incidence of hip fracture alone, and nonvertebral fracture incidence in recipients compared to nontransplant reference groups matched on age, sex, and cohort entry year. We studied 4821 recipients (median age, 50 years)., RESULTS: Among the age and sex strata, female recipients aged 50 years or older had the highest 3-year cumulative incidence of nonvertebral fracture (3.1%; 95% confidence interval [95% CI], 2.1-4.4%). Recipients had a higher 3-year cumulative incidence of nonvertebral fracture (1.6%; 95% CI, 1.3-2.0%) compared to the general population with no previous nonvertebral fracture (0.5%; 95% CI, 0.4-0.6%; P < 0.0001) and nondialysis chronic kidney disease (1.1%; 95% CI, 0.9-1.2%; P = 0.03), but a lower fracture incidence than the general population with a previous nonvertebral fracture (2.3%; 95% CI, 1.9-2.8%; P = 0.007). The 10-year cumulative incidence of hip fracture in all recipients was 1.7% (>=3% defined as high risk in

clinical guidelines)., CONCLUSIONS: Kidney transplant recipients may have a lower fracture risk than previously suggested in the literature. Results inform our understanding of fracture incidence after kidney transplantation and how it compares to nontransplant populations.

3879. Nazarali, S., et al. (2017). "A rare case of perfluoro-n-octane in the orbit following vitreoretinal surgery." Canadian journal of ophthalmology. Journal canadien d'ophtalmologie **52**(3): e113-e115.

3880. Ndhlovu, L. C., et al. (2017). "CSF S100B and CX3CR1 monocytes in acute HIV infection predict putamen atrophy." Topics in Antiviral Medicine **25**(1): 155s.

Background: We previously reported decreases in brain regional gray matter (GM) volumes over 24 months in individuals who initiated combination antiretroviral therapy (cART) during acute HIV infection (AHI). Here we examined relationships of caudate, putamen, pallidum and total subcortical GM volumetric reductions to peripheral immune activation/inflammation (sCD163, sCD14, IL-6, TNF-α, MCP-1) and neuronal (S100B and neurofilament light protein) markers and to monocyte phenotypes implicated in HIV neuropathogenesis. Methods: We prospectively enrolled individuals with AHI (Fiebig stages I-IV) who underwent brain magnetic resonance imaging (MRI) at 1.5T and then immediately initiated cART. MRI was repeated at 24 months. Biomarkers in cerebrospinal fluid (CSF) were assayed by ELISA or Luminex. Peripheral blood mononuclear cells were assayed by flow cytometry to measure monocyte frequencies based on CD14, CD16, CCR5, CCR2 and CX3CR1 expression. Nonparametric statistics were used. Results: Biomarkers and monocyte frequency data at baseline prior to cART and at 24 months were obtained for 15 participants [14 male; baseline median (range) age=28.0 (19-45) years; exposure time=15 (8-28) days; CD4 count=339 (132-740) cells/mm3; plasma HIV RNA=5.53 (2.78-7.56) log10 copies/mL]. Regional volumes at both timepoints were available for 13 individuals. S100B increased from 966 (540-1493) pg/mL at baseline to 1024 (649-1590) pg/mL at 24 months post-ART initiation (p=0.009). At baseline, higher S100B correlated with higher frequencies (%) of non-classical (patrolling/inflammatory) monocytes (ρ=0.56, p=0.029), and on a per cell basis for non-classical monocytes expressing CX3CR1, a receptor that facilitates monocyte migration and survival (ρ=0.64, p=0.010). % decrease in putamen volume from baseline to 24 months post-cART correlated positively with baseline S100B (ρ=0.58, p=0.002) and with baseline % CX3CR1+ monocytes (ρ=0.76, p=0.004). Conclusion: S100B, serves as a marker of brain damage and AHI participants exhibited an increase in CSF S100B over 24 months despite immediate initiation of cART. CSF S100B in AHI may predict atrophy of the putamen, a region which has been suggested to be preferentially susceptible to early HIV-related damage (Wright et al, 2016). CX3CR1 monocytes may penetrate the brain and be involved in neuronal-microglial interactions that contribute to brain volumetric changes ultimately reflected by elevated CSF S100B. (Figure Presented).

3881. Ndung'u, A., et al. (2019). "Patterns and outcomes of paediatric trauma at a tertiary teaching hospital in Kenya." African Journal of Emergency Medicine **9**: S47-S51.

Introduction: Trauma continues to be a major cause of morbidity and mortality especially in the paediatric population of low- and middle-income countries such as Kenya. The aim of this study was to establish the profile and outcomes of admitted paediatric trauma cases at the Aga Khan University Hospital, Nairobi. Methods: This retrospective, descriptive study involved a 12-month chart review (January 2016–December 2016). A total of 218 records were identified of which 144 were reviewed. Results: Most injuries were amongst boys (65.3%) and the very young (mean age 6), occurred in private residences (42.4% homes, 25.7% residential institutions), were typically caused by falls (56.3%) or penetrating trauma (13.2%), mostly resulted in extremity fractures (45.8% closed, 4.9% open) and burn or head injuries (in infants and small children), and got very little or no pre-hospital care (51.4% no care). Additionally, children with burns, brain injuries, or poly-trauma had the longest hospital stays and highest rates of mortality. A more detailed description of the patterns and outcomes seen are included in the study. Discussion: Paediatric injuries remain a major public health problem and contribute a substantial proportion of all paediatric surgical admissions at the Aga Khan University Hospital in Nairobi. Based on the patterns and outcomes seen in this study, we therefore recommend for Nairobi (and possibly Kenya) to establish greater supervision and safety measures for children; targeting safety interventions at all children but particularly at boys, the very young, at home and in residential buildings; building pre-hospital emergency care that can accommodate children; and equipping paediatric trauma hospitals to especially handle bony fractures, burns, head injuries, and poly-traumas. A bespoke trauma registry would benefit the hospital, and likely the country as a whole.

3882. Neal, C. J., et al. (2007). "Effect of penetrating brain injury on aquaporin-4 expression using a rat model." Journal of neurotrauma **24**(10): 1609-1617.

Cerebral edema (CE) is a frequent and potentially lethal consequence of various neurotraumas, including penetrating brain injury (PBI). Aquaporin-4 (AQP4) water channel is predominantly expressed by astrocytes and plays an important role in regulating water balance in the normal and injured brain. Using a rat model of PBI, we show that AQP4 immunoreactivity was substantially increased in the peri-injury area at both 24 and 72 h after PBI. The increase in AQP4 expression was paralleled by increased GFAP expression. The two proteins were co-expressed by peri-vascular astrocytes, whereas reactive astroglia identified by their stellar morphology did not express AQP4 at either time points after injury. Western analysis confirmed the increase in AQP4 immunoreactivity observed in the injured tissue. The apparent increase in AQP4 immunoreactivity was likely due to de novo AQP4 protein synthesis, as most of the increased AQP4 immunoreactivity was found in the soluble (cytosolic) fraction. Our results demonstrate dynamic spatial and temporal changes in AQP4 expression that contribute to the molecular pathophysiology of PBI.

3883. Neal, G. and E. F. Downing (1996). "Clostridial meningitis as a result of craniocerebral arrow injury." The Journal of trauma **40**(3): 476-480.

We report a case of a 6-year-old girl who presented with an arrow lodged in the temporal lobe and carotid sinus. Her postoperative recovery was complicated by a rare penicillin-resistant clostridial meningitis. A review of the literature reveals no other cases of this nature in the pediatric population.

3884. Neal, M. D., et al. (2011). "Over reliance on computed tomography imaging in patients with severe abdominal injury: is the delay worth the risk?" The Journal of trauma **70**(2): 278-284.

BACKGROUND: Computed tomography (CT) has a high sensitivity and specificity for detecting abdominal injuries. Expeditious abdominal imaging in "quasi-stable" patients may prevent negative laparotomy. However, the significance of potential delay to laparotomy secondary to abdominal imaging remains unknown. We sought to analyze whether the use of abdominal CT (ABD CT) in patients with abdominal injury requiring laparotomy results in a significant delay and a higher risk of poor outcome., METHODS: A retrospective analysis of data from the National Trauma Data Bank (version 7.1) was performed. Inclusion criteria were adult patients (age>14 years), a scene admission (nontransfer), hypotension on arrival (emergency department systolic blood pressure<90 mm Hg), an abdominal Abbreviated Injury Scale (AIS) score>3, and undergoing a laparotomy within 90 minutes of arrival. Patients with severe brain injury (head AIS score>3) were excluded. The independent mortality risk associated with a preoperative ABD CT was determined using logistic regression after controlling important confounders., RESULTS: This cohort of patients (n=3,218) was significantly injured with a median Injury Severity Score of 25 ([interquartile range, 16-34]). Patients who underwent ABD CT had similar Glasgow Coma Scale scores, a lower head AIS, longer time delays to the operating room, and a higher crude mortality (45% vs. 30%; p=0.001). Logistic regression revealed that ABD CT was independently associated with more than a 70% higher risk of mortality (odds ratios, 1.71; 95% CI, 1.2-2.2; p<0.001). When stratified by injury mechanism, intubation status and whether or not a head CT was performed, the mortality risk remained significantly increased for each subgroup. When the laparotomy was able to occur within 30 minutes of arrival, an ABD CT was independently associated with more than a sevenfold higher risk of mortality (odds ratios, 7.6; p=0.038)., CONCLUSION: Delay secondary to abdominal imaging in patients who require operative intervention results in an independent higher risk of mortality. ABD CT imaging is an important and useful tool after injury; however, these results suggest that delay caused by overreliance on ABD CT may result in poor outcome in specific patients. Clinicians who take care of critically injured patients should be aware of and understand these potential risks.

3885. Nedugov, G. V. (2011). "[Morphometric diagnostics of the age of encapsulated subdural hematomas]." Sudebno-meditsinskaia ekspertiza **54**(3): 19-22.

The present morphometric investigation was carried out using dura matter preparations, capsules, and contents of 94 encapsulated subdural hematomas obtained from the corpses of subjects with a non-penetrating craniocerebral injury and the duration of the post-traumatic period ranging from 8 days to 2.5 years. The correlation analysis confirmed the necessity of differentiation between resorbed and unresorbed encapsulated subdural hematomas. The data

obtained were used to construct 5 regression models for the estimation of the age of unresorbed encapsulated subdural hematomas and 1 regression model for the identification of the age of resorbed encapsulated subdural hematomas. The regression models included different combinations of three morphometric characteristics of the hematoma capsule as the independent variables, viz. maximum thickness, relative extent of hemosiderosis, and relative amount of macrophages in the cellular infiltrate. The amount of variability in the age of encapsulated subdural hematomas accounted for by the regression models is 62%. It is concluded that the results of the study can be used in the practical work of forensic medical experts.

3886. Nedugov, G. V. (2011). "[Qualitative histological diagnostics of the remoteness of traumatic subdural hematomas]." Sudebno-meditsinskaia ekspertiza **54**(2): 19-22.

The present histological study was based on the examination of dura mater, capsules, and contents of 200 subdural hematomas (SDH) obtained from the corpses of subjects with a non-penetrating craniocerebral injury within a period from 1 hour to 2.5 years after the trauma. A total of 14 well-reproducible qualitative morphological criteria have been identified for diagnostics of the prescription of subdural hematomas; the probability and the exact earliest and latest times of their manifestation at different dates of the posttraumatic period were calculated. Sensitivity, specificity, and prognostic value of the proposed qualitative morphological criteria for the prescription of traumatic subdural hematomas were evaluated. The results of the study can be used in the practical work of forensic medical experts.

3887. Nee, R., et al. (2012). "A near fatal miss in a penetrating neck injury." Irish journal of medical science **181**: S38-S39.

A 25 year old male presented to the Emergency Department with a stab wound to the right mandible. Bleeding was managed by pressure applied to the area. Patient was awake but confused. Patient was intubated to allow proper examination of the wound. On intubation a small amount of blood was noted and the tongue was bitten. There was a 3 cm wound to the depth of the mandibular bone. ENT examination inside the mouth did not reveal any abnormalities. The next morning he was extubated. Approximately 15 min later the patient began perfusley bleeding. He was taken to theatre and intubated. Post induction he had a PEA arrest. CPR was commensed, adrenaline was given, cardiac output was restored. He was stablised and blood products commensed. ENT assessment found that bleeding had stopped and a small penetrating injury to the left palate/pharynx was noted and sutured. The patient recovered well. Pentrating neck injuries offer particular challenges. Due to the presence of many vital structures in a small area the risk of fatal injury is high. It also poses problems for anaesthesia as there is risk of airway compromise. This case raises many important points such a the importance of extubating these patients when senior staff are present, the imporatnce of thorough examination and imagining in neck penetrating injuries and the need for rapid action and resuscition.

3888. Neff, L. L., et al. (2008). "Transoral endoscopic removal of a bullet from the infratemporal fossa." Otolaryngology--head and neck surgery : official journal of American Academy of Otolaryngology-Head and Neck Surgery **138**(1): 113-114.

3889. Nehme, A. E. (1980). "Intracranial bullet migrating to pulmonary artery." The Journal of trauma **20**(4): 344-346.

A young male patient with a gunshot wound to the head is presented. The .22-caliber bullet initially lodged in the superior sagittal sinus migrated to the chest and permanently embolized in a branch of the left pulmonary artery. The patient is asymptomatic except for focal epilepsy.

3890. Neidlinger, N. A., et al. (2004). "Cardiac thromboemboli complicating a stab wound to the heart." Cardiovascular pathology : the official journal of the Society for Cardiovascular Pathology **13**(1): 56-58.

A 27-year-old man was noted to have neurologic deficit 4 days following cardiorrhaphy to repair a penetrating cardiac injury. Cerebral computed tomography scan showed multiple embolic infarcts and two-dimensional echocardiography revealed the source as thrombus in the left ventricle. Although this entity has been described following blunt chest trauma and cardiac contusion, it has not been noted in association with penetrating injury. Intracardiac thrombus with systemic emboli should be considered as a possible complication following cardiorrhaphy for penetrating trauma.

3892. Nelson, T. J., et al. (2006). "Predictors of mortality in close proximity blast injuries during Operation Iraqi Freedom." Journal of the American College of Surgeons **202**(3): 418-422.

BACKGROUND: Blast injury is an increasingly common problem faced by military surgeons in the field. Because of urban terrorism worldwide, blast injury is becoming more common in the civilian sector as well. Blast injuries are often devastating and can overwhelm medical resources. We sought to determine whether simple factors easily obtained from the clinical history and primary survey could be used to triage patients more effectively., STUDY DESIGN: A retrospective review of 18 consecutive close-proximity blast injury patients presenting to a forward deployed surgical unit in Iraq was performed. Patients' injuries and outcomes were recorded. We compared the presence of sustained hypotension, penetrating head injury, multiple (three or more) long-bone fractures, and associated fatalities (whether another patient involved in the same explosion died) between nonsurvivors and survivors using Fisher's exact test., RESULTS: All patients who presented alive but exhibited sustained hypotension (n = 5) died, versus 0% who did not exhibit sustained hypotension (n = 9, p < 0.01). There was no marked increase in mortality with presence of multiple long-bone fractures, penetrating head injury, or associated fatalities individually. Having two or more of these factors was associated with a mortality of 86% (6 of 7) versus 20% (2 of 10, p = 0.015) in those who had less than two factors., CONCLUSIONS: Blast injury can overwhelm military and civilian trauma systems alike. Sustained hypotension and presence of two or more easily determined factors, including three or more long-bone fractures, penetrating head injury, and associated fatalities, are associated with increased mortality and can potentially help triage patients and allocate scarce resources more efficiently.

3893. Nemec, P., et al. (2010). "Successful re-use of the transplanted heart." The Annals of thoracic surgery **90**(4): 1337-1338.

The case of re-use of a previously transplanted heart after brain death of the first recipient is reported. The second recipient was a 60-year-old man who suffered end-stage ischemic heart disease. The operative and postoperative course was uneventful, with the exception of secondary diabetes. The patient is post-transplantation by more than 10 months and is now in New York Heart Association functional class I. This case confirms the possibility of using this procedure, particularly in the situation when there is a shortage of organ donors.

3894. Nemkova, S. A., et al. (2002). "[New possibilities of the use of space technologies in the treatment of children with injuries of the central nervous system]." Novye vozmozhnosti ispol'zovaniia kosmichskikh tekhnologii v lechenii detei s travmaticheskimi porazheniiami tsentral'noi nervnoi sistemy. **36**(3): 55-58.

The computerized stabilography was used to study the role of the visual analyzer (VA) in vertical posture acquisition and specifics of posture implementation by patients with craniocerebral injury (CCI) wearing suit Adele for dynamic proprioception correction (SDPC). Results of the investigation revealed a decreased vertical stability (VS) of CCI patients and a greater reliance on VA, which may be a compensatory instrument. Following the SDPC course, vertical stability was improved and the VA role in posture acquisition normalized suggesting alteration of the interanalyzer interaction in CCI patients owing to the treatment of proprioception impulsation.

3895. Nemzek, W. R., et al. (1996). "Prediction of major vascular injury in patients with gunshot wounds to the neck." AJNR. American journal of neuroradiology **17**(1): 161-167.

PURPOSE: To determine whether plain film and CT findings help predict the presence and severity of vascular trauma., METHODS: The records of 65 patients with gunshot wounds of the neck were reviewed. There were 58 men and 7 women ranging in age from 2 to 72 years. All had angiography of the cervical vessels; in addition, 64 had plain radiography, 22 had CT, and 14 had a barium swallow. The results of plain films, barium swallow, and CT scans were correlated., RESULTS: Eighteen patients (28%) had major vascular injury, which included 10 pseudoaneurysms, six vascular occlusions, four intimal injuries, and one arteriovenous fistula. Ten patients had prevertebral soft-tissue

swelling (sensitivity, 59%; specificity, 77%), 14 had a bullet fragment close to a vessel (sensitivity, 78%; specificity, 36%), and 13 had missile fragmentation (sensitivity, 72%; specificity, 45%)., CONCLUSION: Prevertebral soft-tissue swelling, missile fragmentation, and missiles adjacent to major vessels are useful but nonspecific radiographic signs and are present in many patients with normal angiographic findings. A knowledge of the physical findings, including the entry and exit wounds, plus the results of plain radiography and CT can help define bullet trajectories and guide angiographic evaluation.

3896. Nerobeev, A. I., et al. (1997). "[A clinical x-ray analysis of the results of using titanium mandibular endoprostheses]." Kliniko-rentgenologicheskii analiz rezul'tatov ispol'zovaniia titanovykh endoprotezov nizhnei cheliusti. **76**(4): 40-42.

Late results of repair surgery are analyzed in 40 patients with segmented mandibular defects of different origin. Titanium constructions were used for repair of defects in 21 patients and in 19 others combined endoprostheses were used, consisting of the crest of the patient's iliac bone and a titanium carcass. Check-ups 1.5-2 years after repair showed a higher reliability of combined endoprostheses.

3897. Nesbitt, K. M., et al. (2013). "Pharmacological mitigation of tissue damage during brain microdialysis." Analytical chemistry **85**(17): 8173-8179.

Microdialysis sampling in the brain is employed frequently in the chemical analysis of neurological function and disease, but implanting the probes, which are substantially larger than the size and spacing of brain cells and blood vessels, is injurious and triggers ischemia, gliosis, and cell death at the sampling site. The nature of the interface between the brain and the microdialysis probe is critical to the use of microdialysis as a neurochemical analysis technique. The objective of the work reported here was to investigate the potential of two compounds, dexamethasone, a glucocorticoid anti-inflammatory agent, and XJB-5-131, a mitochondrially targeted reactive oxygen species scavenger, to mitigate the penetration injury. Measurements were performed in the rat brain striatum, which is densely innervated by axons that release dopamine, an electroactive neurotransmitter. We used voltammetry to measure electrically evoked dopamine release next to microdialysis probes during the retrodialysis of dexamethasone or XJB-5-131. After the in vivo measurements, the brain tissue containing the microdialysis probe tracks was examined by fluorescence microscopy using markers for ischemia, neuronal nuclei, macrophages, and dopamine axons and terminals. Dexamethasone and XJB-5-131 each diminished the loss of evoked dopamine activity, diminished ischemia, diminished the loss of neuronal nuclei, diminished the appearance of extravasated macrophages, and diminished the loss of dopamine axons and terminals next to the probes. Our findings confirm the ability of dexamethasone and XJB-5-131 to mitigate, but not eliminate, the effects of the penetration injury caused by implanting microdialysis probes into brain tissue.

3898. Neto, A. S., et al. (2020). "Moral distress in pediatric neurosurgery: Discussing the withdrawal of a shunt in the context of severe traumatic brain injury." Child's Nervous System **36**: 2130.

Introduction: The decision to operate or not a child with a severe neurological disease can generate moral distress in pediatric neurosurgery routines. One of the most frequent situations is shunting or not a seriously compromised young patient. Methods: Case report: An 11 years-old girl was admitted to the hospital with a history of traumatic brain injury by a gunshot over the right parietal bone. Initial Glasgow coma Scale(GCS) was 6, with orotraqueal ventilation, StO2 of 98%and blood pressure of 150x80mmHg. Both pupils react to the light.A Computed tomography of skull revealed the trajectory of the bullet crossing themidline at the level of splenius of corpus callosum. There was evidence of moderate brain swelling and the patient was moved to operate room for treatment of entry site injury, with cleaning of trashes, craniectomy and local duroplasty. Results: The patient remained 03 months in intensive care unit(ICU) where after withdrawal of sedative drugs mainteined GCS of 4. Serials CT scans showed progressive dilation of ventricular system and bulging of craniectomy site. The multi-professional team of ICU brought up questions concerning about the patient age, media pressure(involviment with drug traffiking) and neurological prognosis. Initially an External ventricular derivation(EVD) was inserted with no changes at GCS score. After an opportunity of clear communication with the parents the team decided for remove the EVD. The patient died after 04 days. Conclusion: In cases with ethical dillema the choice of the best therapeutic option can raise a moral suffering for the health practitioners. Avoid put a shunt in a young patient with poor neurological prognosis is a difficult decision . Paliattive care education, multi-

professional discussion and better communicattion process are helpful to overcome those problems and facilitate the decision-making process.

3899. Neto, T., et al. (2013). "A 10-year (2002-2011) retrospective review of 1786 patients and 2212 maxillofacial fractures treated surgically at Coimbra University Hospital, Portugal." International journal of oral and maxillofacial surgery **42**(10): 1230.

The aim of the present study was to analyse the patterns and treatment modalities of maxillofacial fractures treated surgically during the last decade at the Department of Maxillofacial Surgery of University Hospital Center of Coimbra, Portugal. The medical records of 1786 patients, and 2212 maxillofacial fractures treated surgically between 1 January 2002 and 31 December 2011 were analysed retrospectively. Age, sex, type of fracture, association of fractures and methods of treatment were studied. From the 2212 fractures operated in the last 10 years, 77.55% were in male patients, predominantly in young adults, between 19 and 30 years. Pediatric fractures accounted for 12% of cases. The most common fractures were jaw (35%), malar (22%), nasal (21%), LeFort (7%), zygomatic arch (5%) and orbital floor (5%). Submental intubation was used in 1.51% and tracheostomy in 0.83% of patients. The challenging ballistic trauma facial fractures corresponded to 1.06% of cases. Open surgery with internal stable fixation was indicated for most of the patients. There was a progressive decrease in maxillofacial fracture cases in the last decade. This large 10 years review study could improve our understanding of the pattern and treatment of maxillofacial fractures in Portugal. Maxillofacial, facial, fracture, trauma, retrospective.

3900. Neubauer, D. C., et al. (2022). "The new face of war: Craniofacial injuries from Operation Inherent Resolve." The journal of trauma and acute care surgery **93**(2S Suppl 1): S49-S55.

BACKGROUND: During the last 20 years of conflict in the Middle East, improvements in body armor and the use of improvised explosive devices have resulted in an increased incidence of complex craniofacial trauma (CFT). Currently, CFT comprises up to 40% of all casualties. We present new data from the recent conflict in Iraq and Syria during Operation Inherent Resolve., METHODS: Data were collected for patients treated at role 1, role 2, and role 3 facilities in Iraq and Syria over a 1-year period. During this time, a specialized head & neck surgical augmentation team was deployed and colocated with the central role 3 facility. Data included for this cross-sectional study are as follows: injury type and mechanism, triage category, initial managing facility and subsequent levels of care, and procedures performed., RESULTS: Ninety-six patients sustained CFT over the study period. The most common injuries were soft tissue (57%), followed by cranial (44%) and orbital/facial (31%). Associated truncal and/or extremity injuries were seen in 46 patients (48%). There were marked differences in incidence and pattern of injuries between mechanisms (all $p < 0.05$). While improvised explosive devices had the highest rate of cranial and truncal injuries, gunshot wounds and blunt mechanisms had higher incidences of orbital/facial and neck injuries. Overall, 45% required operative interventions including complex facial reconstruction, craniotomy, and open globe repair. Mortality was 6% with 83% due to associated severe brain injury. Most patients were local nationals (70%) who required discharge or transfer to the local health care system., CONCLUSION: Complex craniofacial trauma is increasingly seen by deployed surgeons, regardless of subspecialty training or location. Deployment of a centrally located head and neck team greatly enhances the capabilities for forward deployed management of CFT, with excellent outcomes for both US and local national patients., LEVEL OF EVIDENCE: Therapeutic/care management; Level V.

3901. Neubauer, D. C., et al. (2021). "Craniofacial Trauma on the Modern Battlefield: Initial Management and Techniques." Current Trauma Reports **7**(2): 44-51.

Purpose of Review: This review focuses on the literature from the recent conflicts in Iraq/Syria and Afghanistan as well as techniques for addressing combat related craniofacial trauma. This review also includes practical lessons, techniques, tips, and “pearls” from several military experts with operational deployment experience. Recent Findings: Craniofacial trauma is increasing in incidence in modern conflicts due to improved body armor and the use of IEDs. The most common injuries are soft tissue defects, midface fractures, and mandible fractures. Recent data from Operation Inherent Resolve shows that these injuries are increasing in their complexity with many patients having injury to

multiple sites on the head and neck. Many of these injuries can be safely and effectively addressed in theater through debridement, immediate reduction and repair of the fractures, and closure of the soft tissue. Summary: Craniofacial injuries are an increasing proportion of the surgical care provided by deployed surgeons and all military surgeons should be familiar with their basic management.

3903. Neupert, E. A., 3rd and S. B. Boyd (1991). "Retrospective analysis of low-velocity gunshot wounds to the mandible." Oral surgery, oral medicine, and oral pathology **72**(4): 383-387.

A retrospective study was conducted of 32 patients with mandibular fractures resulting from low-velocity gunshot injuries. Airway management was required in 25% of the patients, and 9% sustained major vessel injury. Patients were divided into two groups, depending on site of mandibular fracture: condyle, ramus, and coronoid (n = 10), and angle, body, and symphysis (n = 22). All patients in the condyle, ramus, coronoid group achieved clinical union without infection. Average postinjury maximal mandibular opening was restricted (28 mm), but the average follow-up period was relatively short (2 months). In the angle, body, symphysis group the infection rate was 27%, and in 18% of patients a continuity defect of the mandible developed. The average length of follow-up in this group was 5.4 months with a mean maximal mandibular opening of 36 mm.

3905. Newcombe, F., et al. (1987). "Dissociable visual and spatial impairments following right posterior cerebral lesions: clinical, neuropsychological and anatomical evidence." Neuropsychologia **25**(1B): 149-161.

A double dissociation of visual and spatial performance is reported in two men with chronic focal missile injuries of the right cerebral hemisphere. The clinical, neuropsychological and post-mortem anatomical data are considered in relation to evidence from physiological research of two major cortico-cortical pathways for object-recognition and spatial perception.

3906. Newell, D. W. (1995). "Transcranial Doppler measurements." New horizons (Baltimore, Md.) **3**(3): 423-430.

Transcranial Doppler ultrasonography (TCD) has served a useful purpose in further defining the pathophysiology of disordered cerebrovascular control after head injury. The evaluation of altered cerebrovascular responses in individual patients may be useful in their clinical management. TCD can be a clinically useful tool in the early diagnosis of a variety of complications that can occur in head-injured patients, such as vasospasm, markedly increased intracranial pressure (ICP), low cerebral perfusion pressure, carotid dissection, and disordered cerebral autoregulation. Although the TCD waveforms alone can alert clinicians to the presence of markedly increased intracranial pressure, these waveforms are not specific for predicting moderate ICP increases. Experienced interpreters can identify TCD waveforms that indicate the arrest of the cerebral circulation. Cerebral circulatory arrest can be a useful confirmatory finding in the diagnosis of brain death in questionable cases, and also can be used to shorten the observation period in those patients in whom organ donation is contemplated or discontinuation of ventilatory support and nursing care may be indicated.

3907. Newell, S. W. (1990). "Double penetrating nail injury to the eye: a case report." The Journal of the Oklahoma State Medical Association **83**(3): 119-121.

We report an unusual double penetrating eye injury in which a 26 mm carpenter's nail pierced the eye. The nail penetrated the sclera equatorially and pierced the retina posteriorly just above the superior temporal retinal vascular arcade. Six hours following the injury the nail was removed from the eye, trans-scleral cryotherapy was applied to the entry site, and an episcleral silicone band was used to create an encircling buckle. Visual acuity at 2 months and most recently at 33 months following the injury was 20/30. This case demonstrates that selected double penetrating injuries

of the posterior segment may be successfully managed with conventional scleral buckling techniques and underscores the importance of protective eye wear for hobby work or leisure activities.

3908. Newman, T. L. and P. A. Russo (1998). "Ocular sequelae of BB injuries to the eye and surrounding adnexa." Journal of the American Optometric Association **69**(9): 583-590.

BACKGROUND: BB injuries continue to be one of the most common causes of severe ocular injury among adolescent males. Extraocular and nonperforating anterior globe injuries most commonly result in favorable visual outcomes. The appropriate medical management of both perforating and nonperforating anterior globe injuries resulting from BB trauma and their potential ocular sequelae are reviewed., CASE REPORTS: Three cases illustrating typical as well as atypical anterior globe injuries caused by BBs are presented. Two cases involve nonperforating anterior globe injuries--one with intracranial and one with intraorbital involvement. The third involves a retained intraocular foreign body. The biomicroscopic and ophthalmoscopic features of these injuries are discussed, as are potential complications and management strategies associated with these types of trauma., CONCLUSIONS: Injuries associated with intraocular BBs often result in enucleation if functional vision is not salvageable. Sequelae to such injuries include endophthalmitis, traumatic hyphema, ocular siderosis, and sympathetic ophthalmia. Plain-film radiography and axial computed tomography are critical first steps in determination of the position of any intracranial or intraorbital metallic foreign body. Routine observation for the development of ocular sequelae resulting from retained intraocular, intracranial, and intraorbital BB injuries is recommended.

3909. Ng, J. D., et al. (2004). "Orbital trauma caused by bicycle hand brakes." Ophthalmic plastic and reconstructive surgery **20**(1): 60-63.

PURPOSE: This report aims to increase awareness of an unusual mechanism of orbital injury sustained by bicycle riders., METHODS: In this retrospective small case series, we describe two cases of orbital injury caused by upper eyelid penetration. A 5-year-old boy (patient 1) and a 6-year-old boy (patient 2) presented to our service within a 2-week period. Both had been injured by similarly styled, handlebar-mounted bicycle hand brake levers. Patient 1 had an orbital roof fracture and penetrating brain injury and underwent repair of a left upper eyelid laceration, craniotomy for pseudoencephalocele, and ptosis repair. Patient 2 had orbital hemorrhage and underwent repair of left upper eyelid laceration., RESULTS: In both cases, a handlebar-mounted bicycle hand brake lever perforated the left eyelid when the rider fell onto it. Neither patient was wearing protective headwear or eyewear. Two months after surgery, patient 1 had 20/25 visual acuity OU and excellent cosmetic appearance. Patient 2 had baseline amblyopic vision 2 days after surgery but moved from town and was lost to follow-up., CONCLUSIONS: Orbit injuries from bicycle brake levers are rare, and helmets or protective eyewear probably would not have prevented these injuries. However, a change in the design and/or mounting location of handlebar-mounted brake levers might help prevent further injuries of this type.

3910. Nga, V. D. W., et al. (2015). "Effects of polycaprolactone-based scaffolds on the blood-brain barrier and cerebral inflammation." Tissue engineering. Part A **21**(3-4): 647-653.

Severe pathoanatomical and mechanical injuries compromise patient recovery and survival following penetrating brain injury (PBI). The realization that the blood-brain barrier (BBB) plays a major role in dictating post-PBI events has led to rising interests in possible therapeutic interventions through the BBB. Recently, the choroid plexus has also been suggested as a potential therapeutic target. The use of biocompatible scaffolds for the delivery of therapeutic agents, but little is known about their interaction with cerebral tissue, which has important clinical implications. Therefore, the authors have sought to investigate the effect of polycaprolactone (PCL) and PCL/tricalcium phosphate (PCL/TCP) scaffolds on the maintenance of BBB phenotype posttraumatic brain injury. Cranial defects of 3 mm depth were created in Sprague Dawley rats, and PCL and PCL/TCP scaffolds were subsequently implanted in predetermined locations for a period of 1 week and 1 month. Higher endothelial barrier antigen (EBA) expressions from PCL-based scaffold groups ($p>0.05$) were found, suggesting slight advantages over the sham group (no scaffold implantation). PCL/TCP scaffold group also expressed EBA to a higher degree ($p>0.05$) than PCL scaffolds. Importantly, higher capillary count and area as early as 1 week postimplantation suggested lowered ischemia from the PCL/TCP scaffold group as compared with PCL and sham. Evaluation of interlukin-1beta expression suggested that the PCL and PCL/TCP scaffolds did not cause prolonged inflammation. BBB transport selectivity was evaluated by the expression of aquaporin-4 (AQP-4). Attenuated expression of AQP-4 in the PCL/TCP group ($p<0.05$) suggested that PCL/TCP scaffolds altered BBB

selectivity to a lower degree as compared with sham and PCL groups, pointing to potential clinical implications in reducing cerebral edema. Taken together, the responses of PCL-based scaffolds with brain tissue suggested safety, and encourages further preclinical evaluation in PBI management with these scaffolds.

3911. Nguyen, B. N., et al. (2022). "Clinical and radiographic predictors of the need for facial CT in pediatric blunt trauma: a multi-institutional study." Trauma Surgery and Acute Care Open **7**(1).

Background Facial injuries are common in children with blunt trauma. Most are soft tissue lacerations and dental injuries readily apparent on clinical examination. Fractures requiring operative intervention are rare. Guidelines for utilization of maxillofacial CT in children are lacking. We hypothesized that head CT is a useful screening tool to identify children requiring dedicated facial CT. Methods We conducted a multicenter retrospective review of children aged 18 years and under with blunt facial injury who underwent both CT of the face and head from 2014 through 2018 at five pediatric trauma centers. Penetrating injuries and animal bites were excluded. Imaging and physical examination findings as well as interventions for facial fracture were reviewed. Clinically significant fractures were those requiring an intervention during hospital stay or within 30 days of injury. Results 322 children with facial fractures were identified. Head CT was able to identify a facial fracture in 89% (287 of 322) of children with facial fractures seen on dedicated facial CT. Minimally displaced nasal fractures, mandibular fractures, and dental injuries were the most common facial fractures not identified on head CT. Only 2% of the cohort (7 of 322) had facial injuries missed on head CT and required an intervention. All seven had mandibular or alveolar plate injuries with findings on physical examination suggestive of injury. Discussion In pediatric blunt trauma, head CT is an excellent screening tool for facial fracture. In the absence of clinical evidence of a mandibular or dental injury, a normal head CT will usually exclude a clinically significant facial fracture. Level of evidence III.

3912. Nguyen, F. M., et al. (2019). "Delayed diagnosis of traumatic sciatic neuropathy in setting of severe traumatic brain injury: A case report." PM and R **11**: S122.

Case Description: The patient was admitted to acute rehabilitation 3 weeks after motor vehicle accident and was nonverbal, agitated, and requiring max-total assistance for mobility and ADLs. He subsequently emerged from post-traumatic amnesia and showed gradual improvement in mobility. However, he had a persistently flaccid left ankle, weakness in left hamstrings, and absent sensation over dorsal and plantar foot. Electromyography (EMG) was performed at 6 weeks post-injury and revealed acute denervation without recruitment of motor units in multiple tibial and fibular innervated muscles as well as biceps femoris. As lumbar paraspinals and other left lower extremity muscles not innervated via a sciatic pathway were normal on EMG, a severe axonal sciatic neuropathy was suspected. Further review of outside records revealed patient presented with a small posterior left thigh puncture wound, which was irrigated and closed while attention was given to his life-threatening injuries. MRI of proximal left leg was obtained and demonstrated a transection of the sciatic nerve with 5-cm gap. Patient subsequently underwent surgical sciatic nerve reconstruction with cabled allografts. Setting: Acute Rehabilitation Unit. Patient: A 26-year-old male with severe TBI and major multiple trauma from a motor vehicle accident including liver laceration resulting in hemorrhagic shock and emergent exploratory laparotomy. Assessment/Results: EMG diagnosis of sciatic nerve neurotmesis resulted in patient undergoing surgical reconstruction. Discussion: While difficult to assess in a patient with life threatening injuries, early diagnosis of traumatic nerve injuries may assist in improved outcomes by leading to earlier surgical reconstruction. Physiatrists have a unique ability to assess such patients, including the use of EMG as an extension of physical examination. Conclusion: In cognitively impaired patients such as those with TBI, EMG is a useful tool to evaluate for peripheral nerve lesions and can aid in determining appropriate further diagnostic workup and treatment.

3913. Nguyen, H. S., et al. (2016). "Transnasal Penetration of a Ballpoint Pen: Case Report and Review of Literature." World neurosurgery **96**: 611.e611-611.e610.

BACKGROUND: Transnasal penetration by a nonmissile foreign body is a rare injury. Consequently, appropriate management remains controversial. We report a case of transnasal penetration by a ballpoint pen and review the literature. To our knowledge, this is the first living patient who sustained carotid artery damage from a transnasal penetrating intracranial injury., CASE DESCRIPTION: A 56-year-old female presented with a ballpoint pen lodged through her left nostril. She exhibited right cranial nerve palsies (III, IV, VI, and V1). A computed tomography (CT) scan of the head revealed a foreign body in the left nasal cavity traversing the ethmoid/sphenoid and likely through the right

superior orbital fissure and cavernous sinus, with the distal tip adjacent to the right atrium. CT angiography revealed nonopacification of the right internal carotid artery (ICA) from the mid-petrous segment to the ophthalmic segment. Subsequently, she underwent coil embolization of the proximal right ICA, followed by a right frontotemporal craniotomy with anterior temporal lobectomy to skeletonize the pen and right distal ICA, and finally clipping of the ICA distal to the pen and prompt transnasal endoscopic removal of the pen. There were no hemorrhagic complications. She awoke at her neurologic preoperative baseline., CONCLUSION: Injuries such as the one described here should be managed through a multidisciplinary approach. The trajectory of the foreign body should be delineated through CT imaging, along with vascular imaging if appropriate. If there are signs of vascular injury, then attempts to maintain proximal and distal control are prudent to avoid hemorrhagic complications. This combined endovascular-endoscopic-open craniotomy approach has not been reported previously in the literature.

3914. Nguyen, J., et al. (2008). "Conjunctival squamous cell carcinoma in the anophthalmic socket." Ophthalmic plastic and reconstructive surgery **24**(2): 98-101.

PURPOSE: To describe 2 patients in whom squamous cell carcinoma of the conjunctiva developed in the anophthalmic socket more than 44 years after enucleation and chronic use of an ocular prosthesis., METHODS: Retrospective case reports., RESULTS: These 2 patients did not have known risk factors for squamous cell carcinoma, including solar ultraviolet radiation or exposure (since they wore their prosthesis full-time), HIV infection, chronic orbital inflammatory disease, or immune-compromising systemic disease. Both patients had an orbital exenteration and underwent a full work-up including evaluation of the regional lymph nodes and systemic work-up to rule out distant metastasis., CONCLUSIONS: Squamous cell carcinoma of the anophthalmic socket can develop many years after enucleation. Regular inspection of the anophthalmic socket containing a prosthesis to rule out conjunctival squamous cell carcinoma is prudent.

3916. Nicolaisen, N., et al. (2012). "Field airway management of a construction worker with an impaling rebar injury to the neck and brain." Prehospital emergency care : official journal of the National Association of EMS Physicians and the National Association of State EMS Directors **16**(4): 548-552.

This article discusses a case of airway management by air ambulance emergency medical services (EMS) providers in a 22-year-old man impaled through the neck into the brain with 0.5-inch rebar. Penetrating neck injuries (PNIs) with impalement are extraordinarily rare. It is important for EMS providers and emergency medicine physicians to have an understanding of the initial management of an impaled patient with PNI, including having an organized approach to establishing a definitive airway and recognizing the airway complications that PNI may cause. This article discusses out-of-hospital management of impaled patients.

3918. Nielsen, T. K. and C. H. Hahn (2018). "[Transorbital penetrating injury without sequlae]." Ugeskrift for laeger **180**(26).

A 33-year-old man was admitted to hospital with a butter knife stuck in his head after having attempted to commit suicide by forcing the knife through his skull. Physical examination revealed a stable patient with only minimal associated haemorrhage. A CT scan revealed, that the penetrating knife had passed through the sphenoid bone, the posterior orbit and the ethmoid cells and ended in the contralateral nasal cavity. The knife was removed by its own trajectory. After surgery, the patient was neurologically intact with normal sight and well-functioning eye movements, and he made a full recovery.

3919. Niemcunowicz-Janica, A., et al. (2005). "[Suicide by detonation of an explosive placed in the oral cavity]." Samobojstwo w wyniku zdetonowania ladunku wybuchowego umieszczonego w jamie ustnej. **55**(2): 171-173.

The object of this analysis was a suicide case of a young male (aged 33) who placed and subsequently detonated an explosive in his oral cavity. Medical inspection of the suicide scene at a recreational site, autopsy and results of criminal analysis are discussed. The skull of the corpse was heavily damaged. The characteristic body position featured crossed lower limbs with the right limb overlying and hands positioned regularly on the abdomen.

3920. Niess, C., et al. (2002). "Incidence of axonal injury in human brain tissue." Acta neuropathologica **104**(1): 79-84.

Diffuse axonal injury (DAI) is considered to be the morphological correlate of traumatic brain injury as seen in acceleration/deceleration trauma and is believed to be the main cause for a poor clinical outcome in the absence of detectable intracranial lesions. To estimate the overall incidence of DAI, and since most changes are only seen microscopically to rule out whether there is a high number of undetected cases, 450 non-selected human brains were examined. Samples from two brain areas (pons and cerebrum) were immunostained for beta-amyloid-precursor-protein (betaAPP), and axonal damage was assessed microscopically. Axonal injury was detected in 12% of all cases, but only one third had a history of traumatic brain injury. The majority of the positive cases were associated with drug intoxication, chiefly due to opiates. betaAPP staining was positive in both pons and cerebrum to a much higher extent in intoxication than in trauma cases; the latter showing axonal damage mainly in the pons area. This may reflect a more generalized pathomechanism in the intoxication group as compared to more biomechanical mechanisms in the trauma group. The findings also show that various causes may produce diffuse axonal injury and suggest that traumatic brain injury is not the only and probably not even the main cause of the observed neuropathological changes. A correlation between axonal damage and age-related processes could not be shown.

3921. Nieves, G. G., et al. (2022). "Gunshot wounds and nonsurvivable brain injury: Predictors and barriers of successful organ donation." Critical care medicine **50**(1 SUPPL): 782.

BACKGROUND: Trauma patients are potentially eligible for organ donation. Previous reports demonstrate that the trauma population is underutilized for organ donation. In this pool of trauma patients lies a subset of patients who suffered traumatic brain injuries sustained from gunshot wounds (GSW). Our study aims to identify the barriers to organ donation in this pool of potential donors. METHODS: A dataset from 1/2010 - 6/2021 of potential organ donors (POD) who suffered head GSWs was obtained from our donor program (Gift of Life) in Pennsylvania, Delaware, New Jersey. Patients who died prior to initiation of procurement discussions and patients without family were excluded. 521 patients were included and barriers to donation were analyzed with regards to sex, ethnicity, age, donor designation, family involvement, and hospital demographics (location, trauma center designation, transplant center). RESULTS: Of the 521 patients included, conversion to organ donation was 66%. Nearly all patients were male (89%). Designated donors had a high likelihood of donation, 136 vs 9 ($p< 0.001$). POD with conversion to donation were generally older (31.6 vs 27.5, $p< 0.001$), Hispanic (41 vs 9, $p=0.01$) or White (181 vs 25, $p< 0.001$), and the cause of injury was suicide (178 vs 38, $p< 0.001$). Unsuccessful PODs were younger, African American (138 vs 121, $p< 0.001$) or Asian (3 vs 1, p0.082) and cause of injury was homicide (128 vs 155, $p< 0.001$). On multivariate regression designated donors had highest predictive value of success with OR 8.55 ($p< 0.001$) followed by White patients (OR 6.4, $p< 0.001$) and Hispanic patients (OR 4.5, $p< 0.001$). Hospital demographics (location, trauma center level, transplant designation) had no significant impact on multivariate regression. Similarly, family decision makers, parent, son/daughter, sibling, or spouse had no significant effect on donation decision. CONCLUSION: The most common barriers to donation identified in patients who sustained GSW to the head were non-designated patients, younger patients, African Americans, and homicide as cause of death. Interestingly, hospital demographics and family decision makers had no significant impact on donation success. On multivariate regression, the highest chance of successful donation were patients who were designated donors, White or Hispanic.

3922. Nikolaev, A. G. and A. S. Saribekian (1998). "[Ultrasonic scanning of the brain in the postoperative period in patients with an acute neurosurgical pathology]." Ul'trazvukovoe skanirovanie golovnogo mozga v posleoperatsionnom periode u bol'nykh s ostroi neirokhirurgicheskoi patologiei.(2): 19-23.

Authors present the results of ultrasound scanning in 130 adult patients with CNS trauma, brain tumors and hemorrhagic stroke. Forty three variants of ultrasound pictures were described. There was a discrepancy between

ultrasound and CT-based diagnoses in 44% of cases. The method is recommended for routine use in neurosurgical clinics, especially in those unequipped with CT scans.

3927. Nikolic, S., et al. (2012). "Suicidal single gunshot injury to the head: differences in site of entrance wound and direction of the bullet path between right- and left-handed--an autopsy study." The American journal of forensic medicine and pathology **33**(1): 43-46.

The aim of this study was to determine the differences in the anatomical site of a gunshot entrance wound and the direction of the bullet path between right- and left-handed subjects who committed a suicide by a single gunshot injury to the head. The retrospective autopsy study was performed for a 10-year period, and it included selected cases of single suicidal gunshot head injury, committed by handguns. We considered only contact or near-contact wounds. The sample included 479 deceased, with average age 47.1 +/- 19.1 years (range, 12-89 years): 432 males and 47 females, with 317 right-handed, 25 left-handed, and 137 subjects with unknown dominant hand. In our observed sample, most cases involved the right temple as the site of entrance gunshot wound (about 67%), followed by the mouth (16%), forehead (7%), left temple (6%), submental (2%), and parietal region (1%). The left temple, right temple, and forehead were the sites of the gunshot entrance wounds, which were the best predictors of the handedness of the deceased (Spearman rho = 0.149, P = 0.006). Our study showed that the direction of the bullet intracranial path in cases of suicide was even a more potent predictor of the handedness of the deceased (Spearman rho = 0.263, P = 0.000; Wald = 149.503, P = 0.000).

3928. Nikolic, S., et al. (2011). "Planned complex occupation-related suicide by captive-bolt gunshot and hanging." Journal of forensic sciences **56**(1): 248-251.

Planned complex suicides are committed by using two or more previously planned methods simultaneously to make sure that death will occur even if one method fails. Herein, we presented a case of occupation-related planned complex suicide, committed by captive-bolt gunshot and hanging. A 29-year-old man, who worked as a butcher, was found dead in the stable, hanging by the neck with a captive-bolt gun embedded in the forehead region of his head. The hanging was complete. Along the bolt canal were bone fragments, and at the end of the path was the punched-out fragment of the skin and soft tissue. There were no fractures of the hyoid bone and laryngeal cartilages, and a superficial hemorrhage was present in the right sternocleidomastoid muscle. Our case underlines the utility of forensic autopsy and death scene investigation in reconstructing the mechanism of death, as well as the dynamics of the event.

3929. Nikova, A. S., et al. (2019). "Does nationality matter for the gunshot brain injury? Ten-year retrospective observational cadaveric comparative study for gunshot tbi between Greece and Bulgaria." Korean journal of neurotrauma **15**(2): 95-102.

Objective: Penetrating brain trauma (PBT) caused by gunshot is one of the most lethal traumatic brain injuries (TBIs) and its management and confrontation is of great importance. Methods: The authors searched retrospectively the archives from 2 similar autonomous laboratories of forensic science and toxicology in the Balkan peninsula for a 10-year period of time and included only fatal penetrating brain injuries. Results: The study is conducted in 61 cadavers with gunshot PBT. All of the cadavers were victims of suicide attempt. The most common anatomical localization on the skull were the facial bones, followed by skull base, temporal and parietal bone, conducting a trajectory of the gunshot. Additional findings were atherosclerosis of the blood vessels and chronic diseases such as chronic obstructive pulmonary disease, cancer and fatty liver. Conclusion: PBI has a high mortality rate. There are factors and findings from the collected data differing between the 2 aforementioned nations. Either way, better preventative measures, gun control and healthcare system are highly necessary.

3930. Nilles, E. J. and D. M. Spiro (2007). "Delayed intracerebral hemorrhage from an extracranial ball bullet pellet." Pediatric emergency care **23**(6): 409-411.

The evaluation of superficial penetrating injuries to the face and scalp is common in the emergency department. We present a patient who presented with a ball bullet pellet to the forehead with an initially negative computerized tomographic (CT) scan of the head, who represented 18 hours later with nausea, vomiting, and mental status changes. A repeat CT scan of the head revealed intraparenchymal hemorrhage immediately posterior to the site of pellet entry. Upon review, the initial CT scan was limited by scatter artifact. In this case report, we discuss the potential for significant injury with compressed air-driven arms, the limitation of CT in the presence of metallic foreign bodies, and the significant risks associated with pediatric radiation exposure.

3931. Nilsson, L. N., et al. (2001). "Alpha-1-antichymotrypsin promotes beta-sheet amyloid plaque deposition in a transgenic mouse model of Alzheimer's disease." The Journal of neuroscience : the official journal of the Society for Neuroscience **21**(5): 1444-1451.

Alpha(1)-antichymotrypsin (ACT), an acute-phase inflammatory protein, is an integral component of the amyloid deposits in Alzheimer's disease (AD) and has been shown to catalyze amyloid beta-peptide polymerization in vitro. We have investigated the impact of ACT on amyloid deposition in vivo by generating transgenic GFAP-ACT-expressing mice and crossing them with the PDGF-hAPP/V717F mice, which deposit amyloid in an age-dependent manner. The number of amyloid deposits measured by Congo Red birefringence was increased in the double ACT/amyloid precursor protein (APP) transgenic mice compared with transgenic mice that only expressed APP, particularly in the hippocampus where ACT expression was highest, and the increase was preceded by elevated total amyloid beta-peptide levels at an early age. Our data demonstrate that ACT promotes amyloid deposition and provide a specific mechanism by which inflammation and the subsequent upregulation of astrocytic ACT expression in AD brain contributes to AD pathogenesis.

3932. Niño-Taravilla, C., et al. (2021). "Intracranial Injury after a Dog Attack in a Neonate." Journal of Pediatric Neurology **19**(3): 173-176.

Dog bites are a common event, especially in the pediatric population. Common anatomic site of dog bites is the head. Despite this, intracranial injuries due to dog bites are reported anecdotally, especially in neonates. In this article, we reported a 7-day-old female neonate attacked in the head by the family dog. She presented penetrating bilateral intracranial injuries that required urgent surgery and pediatric intensive care unit (PICU) admission. She received rabies and tetanus prophylaxis, wide-spectrum antibiotic, and anticonvulsive prophylaxis. She was hospitalized in PICU for 9 days, developing intracranial hypertension. One year after the dog bite, she showed moderate psychomotor retardation and focal epilepsy.

3933. Niryana, W., et al. (2018). "An intracerebral penetration of air shotgun pellet in toddler: A case without neurological sequelae." Open access Macedonian journal of medical sciences **6**(8): 1446-1449.

BACKGROUND: A non-powder firearm including air shotgun remains a significant source of injury to children. It causes severe damage and can involve the brain, eyes, heart, abdomen, and other body parts. CASE REPORT: A toddler boy was accidentally shot by an air shotgun at the forehead, and there was no sign of neurological deficit, both before and after surgical removal of the pellet. Herein, we report a case of air shotgun pellet which penetrated a toddler's head

from the forehead, all the way up to the occiput. Removal of the pellet was successfully performed without eliciting any neurological sequelae. CONCLUSION: Air shotgun pellet may potentially cause severe injury to the central nervous system when the head is affected, which can be safely prevented by a prompt but deliberate surgical removal. The study would also like to emphasise the importance of education to reduce gunshot incidence in the pediatric population.

3934. Nisanci, M., et al. (2003). "Reconstruction of the middle and lower face with three simultaneous free flaps: combined use of bilateral fibular flaps for maxillomandibular reconstruction." Annals of plastic surgery **51**(3): 301-307.

A 23-year-old man sustained massive maxillofacial destruction from a close-range, high-velocity gunshot injury. The devastating nature of the injury led to extensive soft-tissue and bone loss involving nearly the total middle and lower portions of his face, including the deeper anatomic structures. Reconstruction of this extraordinarily extensive and three-dimensional defect was accomplished by simultaneous transfer of three free flaps during one session. A specially designed radial forearm flap replaced the internal lining and external cover of the nose, a large fibular osteocutaneous flap restored the lower face, and a second fibular osteocutaneous flap harvested from the other leg restored the midface. The second fibular flap was revascularized by combining it with the first one in a flow-through manner, and its pedicle vessels were anastomosed to the distal ends of the vessels of the first flap. Dorsal nasal reconstruction with an expanded paramedian forehead flap, commissurotomy, and intraoral flap debulking were additional procedures performed to improve cosmetic and functional outcome during the following 1-year period. Along with a radial forearm flap, combined use of bilateral osteocutaneous fibular flaps provided simultaneous, single-stage reconstruction of a huge facial defect involving both the lower and middle face with an acceptable result.

3935. Nishihara, T., et al. (1995). "A case of transsphenoidal penetrating skull base injury by gerdening prop." Japanese Journal of Neurosurgery **4**(3): 311-313.

The authors report a rare case of transnasal penetration of the skull base from injury by a gardening prop. When a 57-year old female stambled and fell over, the prop was impaled a length of about 5 cm into her left nostril. She had a nose bleed with a severe headache just after it was pulled out. On her admission, she was clearly conscious, and there was cerebrospinal fluid (CSF) leaking from her left nostril. Plane skull X-rays showed a fracture of the sellae turcica, and a computed tomography (CT) scan showed a lot of air in the subarachnoid space and ventricles. We diagnosed CSF rinorrhea and pneumocephalus due to the perforation of the tuberculum sellae. At that time an emergency operation was performed. The operative findings showed that small bone fragments could be seen in the scarred pituitary fossa. The floor of the sellae turcica was repaired with temporal muscle and fascia. She had a good postoperative course. While the clinical signs and symptoms of a patient with a transnasal penetrating injury of the nasal cavity are occasionally not so serious, we should keep in mind the possibility of intracranial complications and perform radiologic evaluations, particularly using CT scan and/or magnetic resonance imaging (MRI).

3936. Nishihiro, S., et al. (2014). "[A case of penetrating brain injury by a javelin]." No shinkei geka. Neurological surgery **42**(3): 243-248.

3937. Nishiike, S., et al. (2005). "Brain herniation into the middle ear following temporal bone fracture." Acta oto-laryngologica **125**(8): 902-905.

Otorrhea of leaked cerebrospinal fluid and meningitis in a 33-year-old male originated from an encephalic herniation into the middle ear following traumatic temporal bone fracture. CT demonstrated a mixed-type fracture consisting of a longitudinal fracture and a posterior oblique fracture of the left temporal bone. The left tegmen tympani was broken into a bellows-like shape and a bone splinter from it had stuck in the epitympanum at the level of the incus body. Surgery via a middle cranial fossa approach confirmed penetration of the brain tissue between the incus and lateral semicircular canal. The diagnosis and management of this condition are discussed in the context of a literature review.

3938. Nishijima, D. K., et al. (2017). "Do EMS Providers Accurately Ascertain Anticoagulant and Antiplatelet Use in Older Adults with Head Trauma?" Prehospital emergency care : official journal of the National Association of EMS Physicians and the National Association of State EMS Directors **21**(2): 209-215.

OBJECTIVE: Prehospital provider assessment of the use of anticoagulant or antiplatelet medications in older adults with head trauma is important. These patients are at increased risk for traumatic intracranial hemorrhage and therefore field triage guidelines recommend transporting these patients to centers capable of rapid evaluation and treatment. Our objective was to evaluate EMS ascertainment of anticoagulant and antiplatelet medication use in older adults with head trauma., METHODS: A retrospective study of older adults with head trauma was conducted throughout Sacramento County. All 5 transporting EMS agencies and all 11 hospitals in the county were included in the study, which ran from January 2012 to December 2012. Patients >=55 years who were transported to a hospital by EMS after head trauma were included. We excluded patients transferred between two facilities, patients with penetrating head trauma, prisoners, and patients with unmatched hospital data. Anticoagulant and antiplatelet use were categorized as: warfarin, direct oral anticoagulants (DOAC; dabigatran, rivaroxaban, and apixaban), aspirin, and other antiplatelet agents (e.g., clopidogrel and ticagrelor). We calculated the percent agreement and kappa statistic for binary variables between EMS and emergency department (ED)/hospital providers. A kappa statistic >=0.60 was considered acceptable agreement., RESULTS: After excluding 174 (7.6%) patients, 2,110 patients were included for analysis; median age was 73 years (interquartile range 62-85 years) and 1,259 (60%) were male. Per ED/hospital providers, the use of any anticoagulant or antiplatelet agent was identified in 595 (28.2%) patients. Kappa statistics between EMS and ED/hospital providers for the specific agents were: 0.76 (95% CI 0.71-0.82) for warfarin, 0.45 (95% CI 0.19-0.71) for DOAC agents, 0.33 (95% CI 0.28-0.39) for aspirin, and 0.51 (95% CI 0.42-0.60) for other antiplatelet agents., CONCLUSIONS: The use of antiplatelet or anticoagulant medications in older adults who are transported by EMS for head trauma is common. EMS and ED/hospital providers have acceptable agreement with preinjury warfarin use but not with DOAC, aspirin, and other antiplatelet use.

3939. Nishimon, S., et al. (2010). "An autopsy case of missile head injury who survived 68 years." Neuropathology **30**(3): 336.

Case: 90-year-old male,an invalid soldier. At the age of 22,during the Second World War, he sustained a penetrating gunshot injury from the upper part of the right orbit laterally. He became blind in the right eye and was in a comatose state for 2 days. He worked as a barber with tenacious personality. In 1993,paresis of right leg, hypoacousia and intellectual deterioration incapacitated him. He was admitted to our hospital. In 1999,CT scan revealed a large low density area in the right frontal white matter and a cystic lesion in the right temporal pole. He became bedridden without any response to phonetic stimuli. He died of pneumonia in 2007. Neuropathology:Brain weighed 1,320 g.Marked tissue defect was noted in the right base of the fronto-temporal lobes with diffuse ventricular dilatation. There were a moderate number of senile plaques (SPs) which were scattered all over the cerebral cortices. By contrast, only small number of neuro-fibrillary tangles (NFTs) were found in the parahippocampal gyrus. Protoplasmic astrocytes were noted in the 2nd and 3rd layers of the cerebral cortex and in the deep white matter. Discussion: The predominance of SP over NFTs might be related to the penetrating head injury.

3940. Nishioka, T., et al. (2002). "Unexpected delayed rupture of the vertebral-posterior inferior cerebellar artery aneurysms following closed head injury." Acta neurochirurgica **144**(8): 839-845.

Subarachnoid haemorrhage secondary to closed head injury is rarely associated with traumatic aneurysms of the posterior circulation. We report two cases of ruptured vertebral-posterior inferior cerebellar artery (VA-PICA) pseudoaneurysms following closed head injuries. In each case, there was no associated penetrating injury or skull fracture. The first patient was kicked followed by disturbed consciousness. The computerized tomography (CT) scan on admission and cerebral angiography on the 11th day after the trauma revealed a massive subarachnoid haemorrhage (SAH) with pan-ventricular haemorrhage and an aneurysm of the right PICA near its origin. Further ruptures occurred on the 12th, 15th, and 66th day, and he died on the 69th day. The second patient complained of persistent headache and nausea following a fight on the previous day. A CT scan and angiography on the 1st day after the trauma showed posterior fossa SAH with fourth ventricular blood and a tiny protrusion of the left VA-PICA. On the 14th day, repeated angiography revealed a remarkable growth of the aneurysm, followed by the second rupture. The repair of the VA-PICA junction was urgently performed with successful exclusion of the aneurysm. To our knowledge, only eight cases of traumatic aneurysms located at the VA or the PICA near its origin have been reported. When intraventricular blood is

found with massive subarachnoid blood or with posterior fossa SAH, this ominous complication should be considered. Traumatic VA-PICA pseudoaneurysms are curable by refined microsurgical techniques, if diagnosed in time.

3941. Niu, X. G., et al. (2020). "Clinical use of internal distraction osteogenesis in the rehabilitation of gunshot injuries of the mandible." The British journal of oral & maxillofacial surgery **58**(3): 324-328.

Rehabilitation of gunshot injuries that require combined reconstruction of bone and soft tissue poses a considerable challenge. We describe three cases of rehabilitation for mandibular defects and deformities caused by gunshot injuries. After debridement, three kinds of internal distractors were used. The bony transport discs were distracted about 10-22mm, and the new bone formed well in the distracted gaps. There was no evidence of infection during the consolidation period or follow up. Aesthetic appearance was also pleasing after treatment. Internal distraction osteogenesis after debridement might be a practical way of synchronously reconstructing bony and soft tissue after mandibular gunshot injuries.

3944. Nobe, J. R., et al. (1990). "Results of penetrating keratoplasty for the treatment of corneal perforations." Archives of ophthalmology (Chicago, Ill. : 1960) **108**(7): 939-941.

We retrospectively analyzed 46 consecutive cases of penetrating keratoplasty performed as part of the treatment of corneal perforations; the minimum follow-up time after keratoplasty was 7 months. Predisposing conditions leading to perforation were an infectious keratitis in 26 eyes (57%), trauma in 14 eyes (30%), and corneal melt associated with ocular surface disorder in 6 eyes (13%). The success of penetrating keratoplasty in the treatment of corneal perforation depended on the timing of surgery and the cause of the perforation. If the perforation was traumatic in origin, delaying surgery for at least 3 months significantly improved the chances for graft success. Eighty percent of the penetrating keratoplasties delayed 3 months following primary repair of corneal laceration remained clear, and 50% of these patients had a visual acuity of 20/60 or better. If penetrating keratoplasties were performed for an infectious corneal perforation, grafts had a better chance to remain clear if surgery could be delayed. All grafts performed for corneal perforation associated with melting and ocular surface abnormalities failed.

3945. Nobe, M. Y., et al. (2010). "Deep penetrating orbitocerebral steel spring injury with minimal sequelae: a case report." Ophthalmic plastic and reconstructive surgery **26**(6): 475-479.

The authors report a penetrating orbitocerebral steel mattress spring injury without permanent ophthalmic or neurologic sequelae. A 44-year-old female mattress factory worker sustained an injury to her right orbit by a high-velocity projectile foreign body. Imaging revealed a metallic spring in the right orbit traversing the optic nerve and superior orbital fissure and lodging in the temporal lobe of the brain. Cerebral angiography demonstrated the steel coil around, but not damaging, the middle cerebral artery and other vessels. With a combined craniotomy and frontal orbitotomy, the spring was removed by meticulous counterclockwise rotation. Postoperatively, the patient had mild left-sided weakness that resolved after several weeks. Ocular examination was normal, including full extraocular movements and a visual acuity of 20/20 in each eye. The authors theorize that the spiral shape and on-axis rotational movement allowed the projectile to follow a path of least resistance penetrating deeply and coiling around, but not injuring, vital structures. Careful counterclockwise rotation under direct intracranial and intraorbital visualization was effective in removing the spring.

3946. Nocini, P. F., et al. (2000). "Vertical distraction of a free vascularized fibula flap in a reconstructed hemimandible: case report." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **28**(1): 20-24.

The authors report a case of vertical distraction osteogenesis of a free revascularized fibula flap used to reconstruct an hemimandible lost as a result of a gunshot injury. The reconstruction procedure and the distraction protocol are described; clinical and radiological results are presented. The vertical discrepancy between the fibula and the native right hemimandible was corrected.

3947. Nohra, G., et al. (2002). "[Infections after missile head injury. Experience during the Lebanese civilian war]." Infections et plaies crAnio-cerebrales par arme a feu. **48**(4): 339-344.

OBJECTIVE: Establish the risk factors for infection following missile head injuries (MHI)., METHODS: Between 1975 and 1990, 500 cases of MHI were admitted, with only 272 responding to inclusion criteria. After initial evaluation including CT scan for 177 patients, all underwent craniectomy with debridement and duroplasty. A retrospective study was undertaken in order to identify the risk factors that increase the infection rate., RESULTS: The global infection rate was 11.39%. Among the studied factors, those increasing the infection rate were: coma on admission (17.6% vs 7.6%), penetrating wounds (12.93% vs 7% for tangential wounds), intracerebral trajectory length over 6 cm (18.42% vs 6.32%), air sinuses effraction (25.8% vs 9.54%), a surgical delay over 72 hours (41.6% vs 10.6%), inadequate duroplasty (28% vs 7.33%), cerebrospinal fluid (CSF) fistulae (58.62% vs 5.76%). The presence of postoperative bone fragments did not increase the infection rate (11.4% vs 11.2%)., DISCUSSION AND CONCLUSION: Adequate duroplasty and aggressive treatment of CSF fistulae decrease the infection rate. There is no need to reoperate on residual bone fragments after adequate debridment. A delay of 24 to 48 hours should be considered, to facilitate the procedure without increasing the infection risk.

3948. Noje, C., et al. (2016). "Disposition of children with mild to moderate traumatic brain injury and positive head imaging." Critical care medicine **44**(12): 276.

Learning Objectives: The optimal disposition of infants and young children with isolated, mild-moderate traumatic brain injury (TBI) with neuroimaging findings is unknown, due to paucity of data and lack of expert consensus. As such, we present our 3 year experience with mild-moderate TBI and positive neuroimaging at a level one pediatric trauma center. Methods: We reviewed the charts of all children ≤ 4 years of age with isolated mild-moderate TBI (GCS 9-15) and positive neuroimaging evaluated at Johns Hopkins pediatric trauma center between 01/01/2013 and 12/31/2015. Patients requiring intubation, vasoactive infusions, and polytrauma victims were excluded. Results: A total of 221 children (mean age/weight/GCS: 14 months/8.8 kg/14.5) met inclusion criteria. The most common mechanism of injury was fall (77%). Only 10% had loss of consciousness or seizures. Most neuroimaging showed skull fractures with extra-axial hemorrhage/no midline shift (MLS) (29%), non-displaced skull fractures (22%), and intracranial hemorrhage (ICH) without fractures/MLS (21%). Trauma bay disposition varied: ICU (48%), ward (37%), intermediate care unit (IMC) and home (7% each). All patients with MLS and most patients (60%) with displaced/comminuted skull fractures and ICH with/without fractures were admitted to the ICU, whereas most patients (60%) with non-displaced/ minimally displaced/multiple skull fractures were admitted to the ward. Less than 2% required intubation, 4% seizure management and 5.8% neurosurgical procedures. Ultimately, 17% were diagnosed with non-accidental trauma. None of the ward/IMC patients required transfer to ICU. Only 18% of ICU patients required neurocritical care/neurosurgical interventions. Median ICU/hospital length of stay was 2 days. Most patients (97%) were discharged home without neurologic deficits, with 3.5% readmitted within 7 days. Conclusions: In our cohort, nearly half of the patients were briefly monitored in the ICU, yet only 10% required ICU-specific interventions, suggesting that a less conservative approach to patient disposition may preserve safety while optimizing healthcare resource utilization.

3949. Nonaka, S., et al. (2021). "Traumatic cervical vertebral artery aneurysm associated with suicidal stabs." Surgical neurology international **12**.

Background: Cervical vertebral artery (VA) aneurysm occasionally develops in association with penetrating injury. However, its treatment strategy is not yet determined. Case Description: A 50-year-old woman with bipolar disorder attempted suicide by stabbing herself in the lateral neck. At presentation, focal neurological deficits were not observed. Spinal computed tomography (CT) showed unclear delineation of the VA in the right C4/5 intervertebral

foramen. CT performed 7 days later identified an aneurysm of the right VA at C4/5, with abnormal arteriovenous shunts between the aneurysm and paravertebral venous plexus. The patient underwent coil embolization of the VA segment involving the aneurysm on the same day that was complicated by cerebellar ataxia due to procedure-associated infarction. Conclusion: Traumatic VA aneurysms associated with penetrating injuries should be carefully managed with a detailed presurgical evaluation of the relevant cranial and spinal structures.

3950. Nongnuch, A., et al. (2014). "Brain-kidney crosstalk." Critical care (London, England) **18**(3): 225.

Encephalopathy and altered higher mental functions are common clinical complications of acute kidney injury. Although sepsis is a major triggering factor, acute kidney injury predisposes to confusion by causing generalised inflammation, leading to increased permeability of the blood-brain barrier, exacerbated by hyperosmolarity and metabolic acidosis due to the retention of products of nitrogen metabolism potentially resulting in increased brain water content. Downregulation of cell membrane transporters predisposes to alterations in neurotransmitter secretion and uptake, coupled with drug accumulation increasing the risk of encephalopathy. On the other hand, acute brain injury can induce a variety of changes in renal function ranging from altered function and electrolyte imbalances to inflammatory changes in brain death kidney donors.

3952. Noorian, A., et al. (2012). "Impact of point-of-care platelet function testing by verifynow on periprocedural antiplatelet therapy in neuroendovascular stenting." Journal of neurointerventional surgery **4**: A36.

Background Proper platelet inhibition is essential for prevention of thromboembolic complications in patients undergoing stent placement. Objective The aim of this study was to analyze the impact of VerifyNow® assay (VNA) on the management of periprocedural antiplatelet therapy in cerebrovascular stenting. Design/Methods Consecutive patients were retrospectively categorized in three groups: elective (Clopidogrel+aspirin (C+A)≥7 days), urgent (C+A for 12-72 h including clopidogrel bolus), and emergent (no previous C+A, intra-procedural abciximab and postprocedural C +A) stenting groups. Clopidogrel resistance (CR) and hypersensitivity (CH) were defined as <20% and >80% platelet inhibition measured by VNA, respectively. Results A total of 72 consecutive patients undergoing cerebrovascular stenting were included in the analysis. Twenty-three patients (age 64614; 65% male) underwent elective stenting to treat symptomatic atherosclerotic lesions. The rates of CR and CH were 26% and 13%, respectively. Three of the six CR patients were treated with abciximab to achieve platelet inhibition. In one of the patients with CH (96% inhibition), stenting procedure was aborted. There were no hemorrhagic or ischemic complications. Twenty patients (age 60612; male, 75%) underwent urgent stenting to treat symptomatic atherosclerotic lesions (n=18), medically refractory carotid dissection (n=1), and carotid pseudoaneurysm due to a gunshot wound (n=1). The rates of CR and CH were 60% (12/20) and 5% (1/20), respectively. Nine of the twelve CR patients were treated with abciximab to achieve an average 42%614% platelet inhibition (range, 22%e52%). There were two hemorrhagic (gastrointestinal bleeding and spontaneous intracranial hemorrhage) with no ischemic events in the CR group. The patient with CH had a spontaneous fatal ICH in the unaffected cerebral hemisphere. Twenty-nine patients (age, 65615; male, 50%) underwent emergent stenting all presenting with acute ischemic stroke. None of these patients were on chronic outpatient C+A therapy. Two received boluses of Clopidogrel before the procedure. The remaining patients received intra-procedural intravenous abciximab (3-13 mg) to achieve 29%e94% platelet inhibition. There was one intracranial and one systemic hemorrhage with no ischemic events. Conclusions Our results suggest the applicability of VNA in assuring adequate platelet inhibition. Future studies are needed to manage CR and CH optimally to prevent thrombosis or hemorrhage.

3953. Norazit, A., et al. (2011). "Vascular endothelial growth factor and platelet derived growth factor modulates the glial response to a cortical stab injury." Neuroscience **192**: 652-660.

Traumatic injury to the brain initiates an increase in astrocyte and microglial infiltration as part of an inflammatory response to injury. Increased astrogliosis around the injury impedes regeneration of axons through the injury, while activated microglia release inflammatory mediators. The persistent inflammatory response can lead to local progressive cell death. Modulating the astrocyte and microglial response to traumatic injury therefore has potential therapeutic benefit in brain repair. We examine the modulatory effect of a single bolus of vascular endothelial growth factor (VEGF) and platelet derived growth factor (PDGF) in combination on astrocytes and microglia to acute cerebral injury. A combination of VEGF and PDGF (20 pg) was injected into the striatum of adult male Sprague-Dawley rats. The effects of treatment were assessed by quantitative immunofluorescence microscopy analyzing astrocytes and microglia across the stab injury over time. Treatment delayed the onset of astrogliosis in the centre and edge of the stab injury up to day 5; however, increased astrogliosis at areas remote to the stab injury up to day 5 was observed. A persistent astrocytic response was observed in the centre and edge of the stab injury up to day 60. Treatment altered microglia cell morphology and numbers across the stab injury, with a decrease in ramified microglia, but an increase in activated and phagocytic microglia up to day 5 after stab injury. The increased microglial response from 10 until day 60 was comprised of the ramified morphology. Thus, VEGF and PDGF applied at the same time as a stab injury to the brain initially delayed the inflammatory response up to day 5 but evoked a persistent astrogliosis and microglial response up to 60 days.

3954. Norris, O., et al. (2013). "Maxillofacial gunshot injuries at an urban level I trauma center-10-year analysis." Journal of oral and maxillofacial surgery **71**(9): e96-e97.

Purpose: Optimal management of facial gunshot trauma remains controversial in terms of timing and reconstruction techniques. To analyze current trends in surgical management, a 10-year retrospective study of patients admitted with facial gunshot wounds was undertaken. Materials: Retrospective analysis of facial gunshot injuries in patients treated at Boston Medical Center, by the Department of Oral and Maxillofacial Surgery, from 2001 to 2011. Data was obtained from the institutional trauma registry and hospital records; and analyzed with respect to length of hospitalization, patient demographics, treatment cost and payments to hospital, using bivariate and multivariate logistic regression, Fisher's exact test, Wilcoxon rank sum test, and Kruskal- Wallis test. Results: During the study period, there were total of 1,957 patients admitted with gunshot wounds to Boston Medical Center, with 136 (6.9%) involving the facial region. 55 patients met inclusion criteria and were selected for the study. Age ranged from 16 to 61 years, with mean age being 25 years for men and 34 for women. 48/55 (87%) were males and 7/55 (13%) were females. The most common injury was to neck zone III; mandible fractures were encountered in 26 (47%) patients. Fractures were treated within 72 hours from admission for the majority of patients. 12 (22%) patients returned for secondary treatment. 20% patients had associated neurological injuries 9% had cervical spine fractures. Angiography was performed in 33 (60%) patients with 7 (13%) requiring embolization. 38 (70%) patients required airway management. Overall mortality was 9%, and most cases were associated with brain injury or severe bleeding from chest or abdominal injuries; no death occurred from isolated facial gunshot injuries. 18% of patients had private third party medical insurance, 45% had public insurance, and 23% had no insurance. Estimated hospital profit (not including the physician charges) was 11% from treating patients with private insurances. In contrast, there was a loss of 50% while treating patients with public insurance; and a 100% loss when treating uninsured patients. Conclusions: Airway compromise was the most lifethreatening early problems; requiring establishment of definitive airway upon assessment. Brain, vascular and cervical spine injuries were common and warranted further investigation. Patients admittedwith higher stages of shock and lower mental status, due to brain, vascular and/or spinal cord injuries: correlated with prolonged hospitalization, increased treatment costs and extended rehabilitation. We advocated early intervention (less than 72 hours), conservative approach, one-stage reconstruction of all involved bony and soft tissue injuries. In our study, African Americans were more frequently injured as compared to other ethnic groups; this was due to the geographic location of our hospital and mission to serve the underprivileged/ low income patients. The majority of the facial gunshot injuries were not presented as life threatening; but typically resulted in significant morbidity. With respect to the cost of healthcare, the vast majority of patients relied on public aid and had no insurance; in all cases the cost of care was more than the reimbursement provided.

3955. North, S. H., et al. (2012). "Rapid analytical methods for on-site triage for traumatic brain injury." Annual review of analytical chemistry (Palo Alto, Calif.) **5**: 35-56.

Traumatic brain injury (TBI) results from an event that causes rapid acceleration and deceleration of the brain or penetration of the skull with an object. Responses to stimuli and questions, loss of consciousness, and altered behavior are symptoms currently used to justify brain imaging for diagnosis and therapeutic guidance. Tests based on such symptoms are susceptible to false-positive and false-negative results due to stress, fatigue, and medications. Biochemical markers of neuronal damage and the physiological response to that damage are being identified. Biosensors capable of rapid measurement of such markers in the circulation offer a solution for on-site triage, as long as three criteria are met: (a) Recognition reagents can be identified that are sufficiently sensitive and specific, (b) the biosensor can provide quantitative assessment of multiple markers rapidly and simultaneously, and (c) both the sensor and reagents are designed for use outside the laboratory.

3956. Nortje, C. J. (2008). "General practitioner's radiology case 67. Jael's syndrome." SADJ : journal of the South African Dental Association = tydskrif van die Suid-Afrikaanse Tandheelkundige Vereniging **63**(8): 454.

3957. Notarianni, C., et al. (2014). "Penetrating foreign body to the cranial vault in a young child." Pediatric emergency care **30**(12): 902-903.

We present a case of penetrating trauma with a blunt object to the calvarium of a young child. Presentation, emergency room management, radiology, and surgical treatment are illustrated and discussed. It is of utmost importance in these cases to proceed in a way so as to minimize secondary injury that may be caused in removal of the foreign body.

3958. Noterman, J., et al. (1974). "Cerebral bullet wounds. Report on a case with a bullet localized in the lateral ventricle." Acta chirurgica Belgica **73**(4): 458-464.

The authors present a case of missile located in the lateral ventricle. Surgical indications and problems related to antibiotics in cerebral wounds are analyzed.

3959. Nouma, Y., et al. (2016). "Forensic examination after exhumation: Contribution and difficulties after more than thirty years of burial." Journal of forensic and legal medicine **44**: 120-127.

We report a case of a Tunisian footballer who was found dead abroad under suspicious circumstances. The cause of death was, originally, attributed to a lightning strike. The corpse was buried without/autopsy. Over thirty years later, the family requested the exhumation to verify the identity and the cause of death. The exhumation was performed in 2011. DNA profiling from teeth and femur bone samples confirmed the identity of the deceased. The dry bone study revealed defects in the skull and the pelvis evoking firearm injuries. Post-mortem CT with three-dimensional (3-D) reconstruction allowed to confirm the characteristics of firearms injuries and to speculate about the number and the trajectories of potential shots. Nevertheless, the vitality of these injuries as well as the eventual fatal shot and the shooting distance could not be determined. Likewise, the type of the eventual weapon could not be clarified as there were no bullets or any metallic projectile fragments. Despite all doubts, the forensic explorations have allowed to verify the identity of the deceased, to evoke firearms injuries and, mainly, to deny the proposed cause of death after more than thirty years of burial. Moreover, the loss of soft tissues and bone fragility were the major obstacles.

3960. Novák, I., et al. (2003). "Cardiopulmonary resuscitation of children in the Czech Republic." Cesko-Slovenska Pediatrie **58**(6): 356-358.

In 2000 and 2001 physicians of the Medical Emergency Service (MES) resuscitated in the CR 12 861 adults, i.e. 125/100 000 population (on average 62.5/100 000 per year). Of these 5381, i.e. 41.80 % were resuscitated successfully. During the same period 372 children (228 boys - 61.3%) aged under 14 years were resuscitated (on average 10.8/100 000 per year). Resuscitation of children under 14 years was successful in 231 cases, i.e. 62.1%. These data pertain to primary visits of MES (incl. flights of the airborn emergency service). While in adults the reason to start cardiopulmonary resuscitation is circulatory failure in ischaemic heart disease (1), the reasons for resuscitation in children were unknown. The authors addressed several MES and obtained 40 valid replies from all regions of the CR (i.e. 45% of the network of

MES), among others they obtained information from territorial MES in Prague, Brno, Ostrava, Olomouc, Zlín, Jihlava, Plzeň and Ústí nad Labem. Almost no information was obtained from the south and west Bohemian regions, while there was almost complete information from MES from the whole of Moravia. In 2000 and 2001 the respondents resuscitated a total of 148 children (39.87.% of all resuscitated subjects in the given period) incl. 90 boys (39.87%). Resuscitation was successful in 86 children (i.e. 58.1%). As reasons for resuscitation the respondents report (listed by frequency): drowning (23.5%), polytrauma (18.5%), inflammatory obstruction of the respiratory pathways (14.2%), arrhythmia and asphyxia in children with congenital heart disease (10.1%), choking - strangulation, aspiration (8.4%), craniocerebral injuries (8.1%), sudden death syndrome in infants (7%), unconsciousness (4.5%), intoxication (4.5%). Other causes were rare (sepsis, metabolic breakdown, gun shot injury) or the reason for resuscitation was not given. Serious injuries and drowning combined account for more than 50% of urgent resuscitation. Primary, "cardiogenic" reasons account for more than 10%.

3961. Novitskii, I. I. (2003). "[Place of the transplantation of the amniotic membrane in the treatment of corneal diseases concomitant with corneal neovascularization]." Mesto transplantatsii amnioticheskoi obolochki v lechenii zabolevanii rogovitsy, soprovozhdaiushchikhsia ee neovaskuliarizatsiei. **119**(6): 9-12.

Published data and authors' independent observations related with the influence produced by the transplantation of the amniotic sac on corneal neovascularization are described. The epithelial-and-stromal corneal defect as well as the limbic epithelium deficit with a subsequent conjunctivization of the corneal epithelium and corneal neovascularization are one of the key mechanisms of corneal neovascularization. The amniotic sac transplantation, made for the purpose of reconstructing the eye surface, ensures the conditions for a fast recovery of the corneal epithelium and, thus, prevent the corneal neovascularization. The surgery can be recommended as an effective treatment technique applicable to corneal pathologies concomitant with the limbic epithelium deficit, persistent epithelial-and-stromal corneal defect and with the corneal neovascularization.

3962. Novozhilova, A. P., et al. (1996). "[The cerebral cortex in severe penetrating gunshot craniocerebral trauma (an experimental study)]." Sostoianie kory bol'shogo mozga pri tiazheloi pronikaiushchei ognestrel'noi cherepno-mozgovoi travme (eksperimental'noe issledovanie). **109**(2): 17-22.

Gunshot disturbances of different severeness were induced in rabbit brain by means of specifically worked out experimental model. Cerebral cortex was studied using light and electron microscopy in severe gunshot craniocerebral trauma (SGCT), accompanied with cranial bones and cerebral disorders, plentiful external and internal hemorrhages and death of the animals 1-5 minutes after the shot. Peculiarities of responsiveness to trauma were demonstrated in microcirculatory bed elements, neurons and glial cells. SGCT causes rapid appearance of destructive changes in cerebral cortex with degenerative processes not following hemomicrocirculatory bed disturbances, but developing simultaneously with them.

3963. Novozhilova, A. P., et al. (1996). "[Changes in the cerebral cortex in closed craniocerebral trauma of gunshot origin (experimental research)]." Izmeneniia kory golovnogo mozga pri zakrytoi cherepno-mozgovoi travme ognestrel'nogo proiskhozhdeniia (eksperimental'noe issledovanie). **110**(6): 25-31.

Cerebral cortex was studied morphologically in rabbits with concussion of brain induced by gunshot injury. The extent of severity was modelled by the bullet rate. No significant bleeding followed the injury allowing to observe the animals during the necessary terms (7-14 d.) Morphological study included light optical and electron microscopy. In neurons, glial cells and synapses a series of essential destructive changes in shown detectable predominantly on ultrastructural level that might be the base of psychoneurological complications of a distant period. Ballistic properties of a bullet were obviously fundamental to pathogenesis of brain concussion in these experiments as kinetic energy of the bullet was only sufficient for non significant damage of the skull soft tissue. But in contrast to the dull trauma, the blow was of a high speed and despite mild clinical characteristics caused essential diffuse structural disturbances in brain tissues.

3964. Nozawa, H., et al. (2005). "2. An unusual death due to the impalement of a gear stick into the brain stem through the nasal cavity: a case report." Medicine, science, and the law **45**(2): 176-178.

A 59-year-old male was driving a car on the road and was involved in a traffic accident, colliding with a tanker and a big lorry. When an ambulance arrived at the scene, he was in a state of cardiopulmonary arrest and was bleeding profusely from his right nostril. He was confirmed dead at hospital. The autopsy showed a laceration of the right upper lip extending to the right nostril. In the basal skull there was a notable perforation at the ethmoid bone together with the central part of the sphenoid bone including the sella turcica. In accordance with the basal skull bone fractures, there were pronounced contusion injuries at the brain stem and a contusion injury was also observed in the right part of the cerebellum. After careful investigation of a causative stick-like item that was present inside the car, it was concluded that a severe movement of the man's body, as a result of the traffic collision, caused the gear stick which was fixed to the steering wheel to become impaled in the man's right nostril. The gear stick passed through the nasal cavity and into the basal skull bones, resulting in fatal brain stem injuries.

3965. Nussbaum, E. S., et al. (2018). "Air gun orbitocranial penetrating injury: emergency endovascular treatment and surgical bypass following pellet migration to middle cerebral artery: case report." Journal of neurosurgery. Pediatrics **21**(3): 270-277.

The authors describe a 14-year-old boy presenting with an orbitocranial penetrating injury (OPI) from a metallic air gun pellet to the left eye who developed hemiparesis and speech difficulty due to migration of the pellet to the left middle cerebral artery. They highlight the potential complications associated with both OPIs and intravascular foreign body migration and occlusion by describing the patient's presentation, results of imaging evaluation, and the combined endovascular treatment and extracranial-intracranial bypass, which resulted in rapid restoration of blood flow and full neurological recovery with intact vision. Based on this case and a review of the literature on intracranial foreign body migration with resultant vascular occlusion, the authors recommend that complex OPIs be treated at centers that offer both neuroendovascular and neurovascular surgical capabilities on an urgent basis to manage both the primary injury and potential secondary vascular compromise.

3966. Nwafor, D. C., et al. (2022). "Pediatric Traumatic Brain Injury: An Update on Preclinical Models, Clinical Biomarkers, and the Implications of Cerebrovascular Dysfunction." Journal of central nervous system disease **14**: 11795735221098125.

Traumatic brain injury (TBI) is a leading cause of pediatric morbidity and mortality. Recent studies suggest that children and adolescents have worse post-TBI outcomes and take longer to recover than adults. However, the pathophysiology and progression of TBI in the pediatric population are studied to a far lesser extent compared to the adult population. Common causes of TBI in children are falls, sports/recreation-related injuries, non-accidental trauma, and motor vehicle-related injuries. A fundamental understanding of TBI pathophysiology is crucial in preventing long-term brain injury sequelae. Animal models of TBI have played an essential role in addressing the knowledge gaps relating to pTBI pathophysiology. Moreover, a better understanding of clinical biomarkers is crucial to diagnose pTBI and accurately predict long-term outcomes. This review examines the current preclinical models of pTBI, the implications of pTBI on the brain's vasculature, and clinical pTBI biomarkers. Finally, we conclude the review by speculating on the emerging role of the gut-brain axis in pTBI pathophysiology. Copyright © The Author(s) 2022.

3967. Nzeh, D. A., et al. (2006). "Sonographic evaluation of ocular trauma in Ilorin, Nigeria." European journal of ophthalmology **16**(3): 453-457.

UNLABELLED: PURPOSE .: Ultrasound (US) evaluation of the eye and orbit has become an essential component of clinical ophthalmology. Requests for its use are frequent in the authors' hospital in spite of the absence of a dedicated eye scanner. The extent to which this has influenced the authors' patient management, especially for those with orbito-ocular trauma, informed the decision to carry out this study., METHODS: A retrospective review of cases of orbito-ocular trauma with media opacities and/or intraocular hemorrhage sent for ultrasonography over a 5-year period (January 1997-December 2001) at the University of Ilorin Teaching Hospital (UITH), Ilorin, Nigeria, was carried out. The sonographic diagnosis was reviewed with the management outcomes as found in the patients' records., RESULTS: A total of 71 patients (45 male, 26 female) were included in the study (M:F=1:1.7). The minimum age was 1 1 /2 years and maximum was 70 years. The 11- to 20-year age group was mostly affected by trauma (31%). Retinal detachment (22.5%) was the most common posterior segment lesion diagnosed, followed by vitreous hemorrhage (18.3%) and hyphema (11.3%). Visual acuity improved to between 6/9 and 6/18 in 23 (41.4%) of the 56 injured eyes., CONCLUSIONS: The

usefulness of orbito-ocular ultrasonography in ophthalmic trauma management has been demonstrated in this study, especially using nondedicated eye scanners when a dedicated one is unavailable.

3969. Obajimi, M. O., et al. (2004). "Computed tomography (CT) in civilian gunshot head injuries in Ibadan." West African journal of medicine **23**(1): 58-61.

BACKGROUND: There is data on civilian gunshot injuries in Nigerians. The purpose of the study is to describe the Computed Tomography findings of civilian gunshot injuries (GSI) to the head in Ibadan, Nigeria., METHOD: This is a retrospective study of Computed Tomography (CT) films and clinical records of 28 consecutive civilian gunshot injuries to the head from 1996 to 1999., RESULTS: The gunshot injuries to the head were mostly armed robbery related. Though there was a steady annual increase of civilian gunshot injuries during the study period, a low CT Scan frequency (0.61%) was recorded. The following CT findings were present in all the patients; bullet fragments, intraparenchymal haemorrhage, vault fractures and soft tissue swelling. The resting position of the bullets showed a predilection for the parietal lobe (32.1%) and the most common fracture site was also the parietal bone (42.8%)., CONCLUSION: CT findings simplified the management of civilian gunshot injuries to the head in the patients studied by demonstrating the exact pathology sequel to the injury. Despite important constraints, CT remains a cost effective means of managing GSI to the head.

3970. Obradovic, A., et al. (2007). "[Invasive mycoses and trauma]." Invasive Mykosen und Trauma. **157**(19-20): 482-489.

Perforating injury allows the dispersion of environmental fungi and fungal spores together with miniscule foreign bodies into traumatized tissue where they can multiply and cause invasive infection. Acute invasive fungal infection after open fractures is uncommon. The severity of the fungal infections depends on the type of injury (perforating, presence of foreign material), the body area and the general condition of the patient. Fungal infections of the immuncompetent host are generally localized within the dermis, invasion of the fascia, muscles and the bone is rare. Injury-related fungal infections of the immuncompromised host may lead to rapid invasion and generalization of the fungal infection. The following review will focus on the fungal infections after perforating injuries and open fractures including the invasive mycoses as a direct consequence of the trauma, post-traumatic fungal infections, tropical fungal infections (mycetoma), invasive fungal infections after near-drowning and nosocomial invasive fungal infections of the critically ill post-traumatic patient admitted to the intensive care unit.

3971. O'Brien, D., Jr., et al. (1997). "Delayed traumatic cerebral aneurysm after brain injury." Archives of physical medicine and rehabilitation **78**(8): 883-885.

Traumatic aneurysms (TAs) are an unusual etiology for late neurological deterioration after traumatic brain injury (TBI) and represent less than 1% of all cerebral aneurysms. TAs most often are diagnosed acutely but may be delayed in presentation. To increase awareness of this serious but treatable condition when diagnosed early, we report a delayed TA after a motor vehicle accident. The patient experienced a seizure on day 46 postinjury while in rehabilitation and demonstrated persistent lethargy and hemiparesis. Neuroimaging revealed a large, ruptured left pericallosal artery TA, which was surgically clipped. The patient completed his rehabilitation course and was eventually discharged home with family. Among TBIs, TAs are associated with penetrating injuries and skull base or anterior cranial fossa fractures. Associated mortality is high, especially if rupture has occurred. Although TAs are rare, the clinician should be vigilant in the at-risk patient.

Charakterystyka kliniczna urazow penetrujacych narzadu wzroku z obecnoscia ciala obcego wewnatrz galki ocznej. Czesc I. Patogeneza i obraz kliniczny. **112**(1-3): 70-76.

Intraocular foreign bodies (IOFBs), are the major cause of penetrating ocular trauma and the most serious problem is the resulting impairment of visual function. In this paper, based on published reports and their clinical experience, authors discuss questions of pathogenesis, epidemiology and clinical features of IOFB injuries. Special

attention was paid on primary and secondary complications, which include mechanical lesions of the ocular tissues, metallosis and endophthalmitis.

3973. Obuchowska, I., et al. (2010). "[Clinical characteristics of penetrating ocular injuries with intraocular foreign body. Part II. Diagnostics and treatment]." Charakterystyka kliniczna urazow penetrujacych narzadu wzroku z obecnoscia ciala obcego wewnatrz galki ocznej. Czesc II. Diagnostyka i leczenie. **112**(1-3): 77-81.

Ocular trauma remains a major cause of blindness, particularly in the working-age population. Intraocular foreign bodies (IOFBs), frequently accompany penetrating ocular injuries and can lead to increased ocular morbidity. In this paper, based on published reports and their authors clinical experience, we discuss questions of advantages and disadvantages of three imaging methods (radiology, ultrasound and tomography), and evaluate the value of these methods in the diagnosis of IOFBs. Authors discuss also management options in patients with IOFB injuries and describe techniques of primary surgical repair and foreign body removal, especially pars plana vitrectomy.

3975. Odebode, O., et al. (2015). "Ocular and visual complications of head injury." Journal of Head Trauma Rehabilitation **30**(3): E95.

Introduction/Rationale The purpose of the study was to evaluate the pattern of ocular and visual complications of head injury. Method/Approach A prospective 225 head-injured patients were part of the study. For the purpose of extracting visual complications, a neurosurgeon and an ophthalmologist examined each patient and conducted appropriate investigations. Patients with ocular morbidity were analysed for age, sex, cause of injury, Glasgow Coma Score (GCS) at admission, and associated injuries, in addition to findings from the neurosurgical and ophthalmic evaluations. Results/Effects Two major types of ocular and visual complications were observed in 57 (25.3%) of 225 head-injured patients studied. Soft-tissue injury to the globe and adnexae included periorbital ecchymosis, subconjuctival haemorrhage, lid laceration, or globe rupture in 29 patients. Neuro-ophthalmic ocular cranial nerve palsies occurred in 28 patients, while orbital fracture was encountered in two patients. Ocular injuries were present multiple in 60% of the cases. The patients (aged 9 months to 57 years), and were comprised of 37 male and 20 female subjects. The leading cause of head injuries (84.2%) was traffic accidents. Other causes included falls from heights, assaults and gunshots. Conclusions/Limitations Injury to the globe and adnexae and ocular cranial nerve palsies constitute the most common oculovisual complications following head injury in our center.

3976. O'Dell, M. W., et al. (2015). "Abobotulinumtoxina (Dysport) in the treatment of adult patients with upper limb spasticity due to traumatic brain injury." PM and R. (var.pagings) **7**(9 SUPPL. 1): S103.

Objective: To determine the efficacy and safety of abobotulinumtoxinA 4 weeks after injection in patients with upper limb spasticity (ULS) caused by traumatic brain injury (TBI). Design: Sub-analysis in a randomized, placebo-controlled, doubleblind clinical trial. Setting: International, multicenter study. Participants: Twenty three of 243 (9.5%) hemiparetic patients with ULS caused by TBI. Interventions: In the initial treatment cycle, 14 subjects received abobotulinumtoxinA (500 U or 1000 U) and 9 received placebo, intramuscularly. Main Outcome Measures: Modified Ashworth Scale (MAS); Disability Assessment Scale (DAS); Tardieu scale (TS); Active range of motion (AROM); Physician Global Assessment (PGA), adverse events (AE). Results or Clinical Course: Mean age (SD) of the 23 patients was 35 (13) years and males represented 65%. They had suffered closed (74%) or penetrating brain injury (26%) 10 years (mean) earlier. The majority (74%) had previously been treated with botulinum toxin. Four weeks after injection, a higher proportion of patients treated with abobotulinumtoxinA compared to placebo were responders in terms of tone reduction (>1 point improvement in MAS): 64% versus 22%. This improvement was accompanied by improvement in subjective function (>1 grade decrease from baseline for the principal target of treatment on the DAS scale): 71% versus 22% for placebo. With abobotulinumtoxinA, the angle of catch (XV3 of the TS) improved in finger (+35degree), elbow (+22degree) and wrist (+12degree) flexors, resulting in a gain in active muscle extension of at least 5degree (AROM). The overall clinical improvement (mean PGA score reaching at least grade 1) was higher with abobotulinumtoxinA versus placebo (93% versus 33%). 7 of 23 patients experienced a treatment emergent AE, none were unexpected. Conclusion: In this small sub-population of hemiparetic adults with ULS due to TBI, abobotulinumtoxinA improved muscle tone,

spasticity, passive function and active movements). Efficacy and safety of abobotulinumtoxinA in patients with ULS after a TBI were consistent with the results observed for the total population (TBI and post-stroke patients) in this international placebo controlled study.

3978. Odhiambo, W. A., et al. (2011). "Intra-myocardial bullet causing heart block in a patient with multiple gunshot wounds: Case report." Annals of African Surgery **7**: 54-57.

Elective removal of intra-myocardial bullet remains a controversial subject. A non-operative approach has been recommended as appropriate for a stable asymptomatic patient. In the presence of complications such as bleeding, perforation leading to cardiac tamponade, thrombus formation, embolization, rhythm disturbances and infections, surgical removal may be advised. We present a patient who survived multiple gunshot wounds with a bullet lodged in the wall of the left ventricle of the heart. Details of the injuries sustained, operative removal of the bullet and the challenges that ensued are illustrated.

3980. O'Donoghue, G. T., et al. (2005). "Unsuspected orbitocranial penetrating injury by a plastic pen cartridge: case report." The Journal of trauma **58**(3): 634-637.

3981. Oearsakul, T., et al. (2021). "Multidisciplinary management of a penetrating cerebellar injury by a fishing speargun: A case study and literature review." Surgical neurology international **12**.

Background: Fishing spearguns are a rare cause of nonmissile penetrating brain injuries (PBIs). Discussion of their injury patterns and treatments has been published only sporadically. Here, we report a case of a self-inflicted PBI caused by this type of weapon and present an extensive review of previous case reports to help ascertain the appropriate surgical approach. Case Description: A 26-year-old man with a preexisting psychiatric illness was transferred to our hospital after a self-inflicted shot with a fishing speargun through his mouth. The ensuing injuries included the

impalement of a spear intracranially through the soft palate and posterior oropharyngeal wall. The spear was surgically accessed by the otolaryngology team by splitting the soft palate and was removed by the neurosurgery team in the retrograde direction. Cerebral angiographies were done pre- and postoperatively, and these did not detect any vertebrobasilar arterial system injuries. The patient's postoperative care was uneventful, and he was followed up by a psychiatrist for his long-term care. Conclusion: This example of a complicated case of nonmissile PBI caused by an uncommon type of weapon shows how this type of medical emergency can be managed successfully with effective teamwork using a multidisciplinary approach.

3982. Oehmichen, M. (1982). "Are resting and/or reactive microglia macrophages?" Immunobiology **161**(3-4): 246-254.

According to recent submicroscopic, cytokinetics, and functional (particularly cytoimmunologic) investigations, no relationship exists between "resting" microglia (the small argyrophilic cells appearing in undamaged brain tissue, first described by Rio Hortega) and "reactive" microglia (the argyrophilic cells appearing under pathologic conditions). While "resting" microglia are apparently cells of neuro-ectodermal origin, all observations tend to indicate that "reactive" microglia are derived from extravasated blood monocytes and should be called brain macrophages. In the intact brain parenchyma, no macrophages are demonstrable. Free subarachnoidal cells in the cerebrospinal fluid (CSF), perivascular cells, and epiplexus and/or supraependymal cells in the CSF-containing spaces of the normal central nervous system are cells of the mononuclear phagocyte system and must be considered as CSF macrophages. According to rough estimates, the normal adult central nervous system contains a maximum of 280,000 CSF macrophages.

3983. Oehmichen, M., et al. (2003). "Forensic pathological aspects of postmortem imaging of gunshot injury to the head: documentation and biometric data." Acta neuropathologica **105**(6): 570-580.

To determine the value of imaging procedures such as computer tomography (CT) and magnetic resonance imaging (MRI) of the head in providing additional information of forensic relevance, we examined 17 cadavers of human victims of gunshot wounds to the head. Three of the victims briefly survived the gunshot wound. The weapons involved were all guns with low muzzle energy (<550 J), i.e., handguns and low-velocity rifles. In the majority of cases (n=15) a penetrating wound to the head was found, only two cases showed the bullet lodged in the brain. In some cases, imaging of the skull and brain was performed prior to autopsy; in others imaging took place after autopsy on the isolated, formalin-fixed brain. The imaging findings were correlated with the criminological data and the results of macroscopic and microscopic examination of the brain. The findings on the bony structures of the head provided imaging criteria for differentiation between entrance and exit of the gunshot wounds, which corresponded to the forensic pathological findings at autopsy. CT scans and MRI of the cerebral parenchyma revealed lanes of opaque bone and missile fragments along the course of the missile, which allowed recognition of the missile track in 3D reconstruction. Biometric reconstruction allowed easy determination of the angle of the missile track in all three planes. Examination of the parenchymal structures and imaging of the isolated, formalin-fixed brain enabled tracking of the missile path directly along the zone of destruction as well as demonstration of secondary changes such as air bubbles along the bullet course, hemorrhage and edema. The significance of a translucent zone surrounding the missile track in several cases remains unclear; it probably represents tissue destruction secondary to temporary cavitation. The imaging procedures described here allowed excellent documentation of in situ conditions, while the storing of data enabled biometric reconstruction for determination of the angle of trajectory, of entrance and exit wounds, and the extent of tissue damage along the missile track and, possibly, in the zone of temporary cavitation.

3984. Oehmichen, M. and C. Meissner (2009). "Routine techniques in forensic neuropathology as demonstrated by gunshot injury to the head." Legal medicine (Tokyo, Japan) **11 Suppl 1**: S50-53.

It will be vital to the practical activity of every forensic and/or clinical pathologist to be able to answer three questions regarding the reconstruction of a lethal event: the type and cause of death, as well as the survival time. The authors offer an overview of the application of selected morphological techniques in general forensic neuropathology, techniques that provide answers to some of the main questions in forensic neurotraumatology. The methods are illustrated by individual cases of lethal gunshot injury to the head from low velocity handguns. Besides the general forensic tasks of interpretation of the crime scene and postmortem external examination of the victim's body a computed tomography is recommended for documentation and reconstruction of the missile track. The microscopic techniques involve Nissl-stain for neurons, hematoxylin and eosin for delayed ischemic neuronal alterations,

microtubule-associated protein (MAP) expression for acute neuronal ischemia, luxol-fast-blue-stain for myelin destruction (and demyelination), silver-stain for axons, beta-amyloid precursor protein (beta-APP) for axonal injury, glial fibrillary acidic protein (GFAP) for astrocytic characterization, naphthol AS-D-chloroacetate esterase for neutrophilic infiltration and CD68-expression for microglial reaction. The pattern of methods lead--in the case of gunshot injury as well as in any traumatic impact to the head--to answers according the extent of tissue destruction (and the cause of death), the biometric reconstruction of the criminal event, and the timing of (gunshot) wounds of the brain. These methods will be indispensable for the preparation of future neuropathological expert reports addressing questions of type of injury, the consequent pathological symptoms, timing of the injury, and the cause of death.

3985. Oehmichen, M., et al. (2001). "Brain injury after survived gunshot to the head: reactive alterations at sites remote from the missile track." Forensic science international **115**(3): 189-197.

Gunshot wounds to the brain usually lead to acute respiratory arrest or death after a brief survival period, even in cases involving only slight direct tissue damage. It can be assumed therefore that the damage extends beyond the zone of recognizable destruction and hemorrhages. To determine the true extent of the tissue injury resulting from gunshot wounds to the brain, we carried out microscopic investigations for reactive changes (emigration of leukocytes and macrophages, axonal expression of beta-amyloid precursor protein (beta-APP) in 10 cases of gunshot wound to the narrow channel of the brain with survival times >2h. Demonstration of leukocytes expressing naphthol AS-D chloroacetate esterase activity in the brain tissue at the border of the missile track established the vitality of the gunshot effect. The presence of macrophages (CD68-epitope) allowed demarcation of a 1-2mm wide necrotic zone around the permanent cavity. Within this zone and beyond, beta-APP showed an initial increase followed by a decline in the number of injured axons. Three types of beta-APP positive staining could be differentiated. In the immediate vicinity of the missile track beta-APP positive neurons were present at a distance of 2-4mm from the margin of the permanent cavity (type 1) as a result of primary injured neuronal tissue by the gunshot itself. At longer distances from the narrow channel and the permanent cavity single beta-APP positive axons or axon fragments and two additional types were found; type 2 shows a parallel, wave-like arrangement of the damaged fibers, which suggests that the injury was produced by mechanical acceleration of the brain tissue created by the energy the projectile expended within the brain; irregular aggregation of beta-APP positive axons or axon fragments within a local edema represents type 3, which may be attributed to secondary ischemia or edema.

3986. Oehmichen, M., et al. (2004). "Gunshot injuries to the head and brain caused by low-velocity handguns and rifles. A review." Forensic science international **146**(2-3): 111-120.

OBJECTIVES: Reconstruction of brain injuries is a basic task of forensic neuropathology. For better understanding of the wound ballistics of gunshot injuries to the brain caused by low-velocity firearms (E(o) < 550 J), we reviewed the respective contributions of: (1) biomechanical reconstruction by postmortem imaging techniques, (2) biometry of the extent of very early microscopic tissue destruction, and (3) microscopic studies on the type and extent of early microscopic reactions around the permanent missile track., MATERIAL AND METHODS: A selected case material of 47 victims of lethal gunshot wounding to the brain was studied. (1) Computed tomography (CT) and magnetic resonance imaging (MRI) techniques were compared with macroscopic findings in 17 cases. (2) Morphometric evaluation of the zones of cellular and axonal destruction around the permanent track was performed in 20 cases (survival time: <90 min). (3) Microscopic studies of the emigration of leukocytes and macrophages plus axonal expression of beta-amyloid precursor protein (beta-APP) were conducted in 10 cases (survival time: >90 min)., RESULTS AND CONCLUSIONS: (1) Imaging procedures provided valuable information on entrance and exit wounds, the missile track and secondary changes. (2) Biometry revealed a destruction zone of ca. 3.6 cm around the permanent track corresponding to the "temporary cavity". (3) Microscopic studies of reactive changes demonstrated axonal injury at sites remote from the permanent cavity that could explain the very early respiratory arrest following low-velocity gunshot injury.

3987. Oesterhelweg, L., et al. (2007). "Virtopsy: fatal stab wounds to the skull--the relevance of ante-mortem and post-mortem radiological data in case reconstructions." Legal medicine (Tokyo, Japan) **9**(6): 314-317.

Homicides with a survival of several days are not uncommon in forensic routine work. Reconstructions of these cases by autopsy alone are very difficult and may occasionally lead to unsatisfying results. For the medico-legal reconstruction of these cases, ante-mortem and post-mortem radiological imaging should always be included in the

expertise. We report on a case of fatal penetrating stab wounds to the skull in which a case reconstruction was only possible by combining the radiological ante- and post-mortem data with the autopsy findings.

3988. Offiah, C. and S. Twigg (2009). "Imaging assessment of penetrating craniocerebral and spinal trauma." Clinical radiology **64**(12): 1146-1157.

Craniocerebral and spinal penetrating trauma, which may be either missile (most typically gun-related) or non-missile (most typically knife-related), is becoming an increasingly common presentation to the urban general and specialized radiology service in the UK. These injuries carry significant morbidity and mortality with a number of criteria for prognosis identifiable on cross-sectional imaging. Potential complications can also be pre-empted by awareness of certain neuroradiological features. Not all of these injuries are criminal in origin, however, a significant proportion will be, requiring, on occasion, provision of both ante-mortem and post-mortem radiological opinion to the criminal investigative procedure. This review aims to highlight certain imaging features of penetrating craniocerebral and spinal trauma including important prognostic, therapeutic, and forensic considerations.

3989. Ogawa, Y., et al. (1994). "Penetration injury of the pyramis caused by a kick from a racehorse." Neurosurgical review **17**(3): 217-219.

A 56-year-old man presented with an unusual cranial penetration injury due to a horse's hoof. The CT number of the hoof was 269, and thus clearly not that of a wooden fragment or bone. An emergency operation was performed to remove the foreign body. The operation went well, and no infection developed. Eight months later he could walk unaided and had only mild disorientation.

3990. Ogilvy, C. S., et al. (1988). "Embolism of cerebral tissue to lungs: report of two cases and review of the literature." Neurosurgery **23**(4): 511-516.

Two patients with head injury and pulmonary emboli of brain tissue are described. Both patients developed persistent bleeding with elevations of prothrombin time, partial thromboplastin time, and decreased platelet counts. Postmortem examination identified multiple skull fractures, subdural and subarachnoid blood, cortical tears, and intraparenchymal hemorrhages. Lacerations of dural venous sinuses were documented in each case. Multiple pulmonary arteries contained plugs of cerebral tissue, including fragments of cerebral and cerebellar cortex, and white matter. The literature concerning brain tissue emboli is reviewed. In neonates, three patients who survived longer than 1 hour were found to have evidence of persistent hemorrhage. Among both children and adults, our two cases are the only ones reported with associated clotting abnormalities. Brain tissue embolism in neonates occurs after difficult vaginal deliveries, often in conjunction with the use of forceps. Tears of the tentorium cerebelli or falx cerebri have been documented at postmortem examination in the majority of these cases. By contrast, brain tissue embolism in children and adults occurs in association with severe closed or penetrating head injury. In several cases, as in the two reported here, postmortem examination has demonstrated a large cerebral venous defect as the probable site of entry of brain tissue into the systemic circulation.

3991. Ogun, O. A., et al. (2008). "Unnoticed eyelid foreign body presenting as ptosis." Neuro-Ophthalmology **32**(5): 273-276.

A patient sustained right orbital trauma with unnoticed penetrating injury and a retained eyelid foreign body. She presented six weeks later with a complaint of persistent ptosis. The circumstances surrounding her injury are described, the issues arising and successful management of the case are discussed.

3992. Ogunleye, A. O. A., et al. (2004). "Arrow injury to the skull base." West African journal of medicine **23**(1): 94-96.

An unsual case of penetrating nasal injury with middle skull base involvement, from fired arrow is reported. The arrow was surgically removed and the patient remains well with no sequelae. We therefore present this case because of its rarity. The anatomical principles underlying the surgical management of the lesions are discussed.

3993. Ogura, K., et al. (2006). "New microsurgical technique for intraparenchymal lesions of the brain: transcylinder approach." Acta neurochirurgica **148**(7): 779-785.

BACKGROUND: Although various minimally invasive approaches, including endoscopic, stereotaxic, and ultrasound-guided surgery, have been introduced to minimize damage to healthy brain tissue, the microsurgical technique has retained a significant role in contemporary neurosurgery. A new microsurgical approach to intraparenchymal brain lesions, namely, the transcylinder approach, was developed to realize both minimal surgical access and sufficient microsurgical technique., METHOD: A 0.1-mm transparent polyester film was used to create a cylindrical surgical route. The film was rolled into a thin stick and used to penetrate the brain, and a computer-aided navigation system was used from inside the stick to access the lesion accurately. After the stick gained access to the lesion, it was dilated to 2 cm, and this diameter was maintained during surgery., FINDINGS: The transcylinder approach was used in 11 cases, including intraparenchymal tumours and haematomas, and the usual microsurgical procedure was performed without difficulty. The film avoided unnecessary enlargement of the surgical field and minimized injury to the brain. Intra-operative ultrasonography also can be used to identify the lesion through the cylinder because the polyester film does not reflect the ultrasound beam. The surgical route was observed to recover to almost the same size as the initial cortical incision after removal of the cylinder., CONCLUSIONS: The transcylinder approach could be advantageous for removing tumours or haematomas in the intraventricular or intraparenchymal regions. By avoiding unnecessary retraction, it significantly reduces the risk of injury to surrounding brain tissue while facilitating precise microsurgical technique. The accuracy of this minimally invasive technique can be enhanced when used in conjunction with frameless stereotaxy and intra-operative ultrasound guidance.

3995. Oh, C., et al. (2020). "Traumatic Cranio-Orbital Injury: Reconstruction Using Extraocular Muscles." The Journal of craniofacial surgery **31**(3): e258-e259.

Cranio-orbital trauma is an uncommon yet devastating injury, especially one in the setting of a high-energy gunshot wound. Such injuries were historically reported in the setting of military conflict, and are associated with vision-threatening complications, often resulting in anophthalmos. The authors report a case of a self-inflicted gunshot wound to the eye, which requires orbital enucleation with exposed frontal lobe dura. To address the exposed dura, the extraocular muscles were utilized from the enucleation procedure to cover the defect in the acute setting prior to final staged reconstruction.

3996. O'Halloran, H. S., et al. (1997). "Accidental ocular perforation from self-inflicted facial palsy." Retina (Philadelphia, Pa.) **17**(2): 164-166.

3997. Oikonomou, A., et al. (2011). "Head trauma by captive bolt gun." BMJ case reports **2011**.

An 80 year-old former cattle-breeder committed suicide with a captive bolt gun. He was transmitted unconscious to emergency department. He had a large penetrating wound in right temporal area. Lateral radiograph of skull revealed a large rounded bony defect. CT verified a large rounded entry site and bony defect at the right pterion. It disclosed a wide, zonal-like haemorrhagic wound canal bearing intraparenchymal bony fragments at its end with no associated metallic fragments. Subarachnoid haemorrhage with bilateral subepidural hematomas and significant brain oedema was demonstrated.

3998. Okada, T., et al. (1993). "Penetrating injury of the transverse sinus by a nail-gun--case report." Neurologia medico-chirurgica **33**(10): 703-705.

A 46-year-old male presented with a penetrating injury of the transverse sinus caused by a nail-gun. Open craniotomy reflected a doughnut-shaped bone flap and the 45 mm long nail, which was fortunately only touching the edge of the sinus, successfully removed. A wide surgical exposure and careful manipulation of the embedded nail are

important to avoid inadvertent injury to the venous sinus and the surrounding brain tissues during the surgical procedure.

3999. Okada-Rising, S., et al. (2022). "INTRANASAL ADMINISTRATION OF ST266 IN A RODENT MODEL OF TRAUMATIC BRAIN INJURY." Journal of neurotrauma **39**(11-12): A56-A57.

ST266 is human amnion-derived multipotent progenitor cell secretome that is currently being evaluated clinically for ophthalmological/antiinflammatory indications and received FDA approval for Phase 1 intranasal nose-to-brain study in humans. Intracerebroventricular infusion of ST266 after traumatic brain injury (TBI) has significantly improved motor function and moderated neuroinflammation in rats. However, intracranial administration is not clinically feasible, whereas intranasal drug delivery bypasses the blood brain barrier and limits adverse systemic effects. The current study was designed to test the potential efficacy of intranasal administration of ST266 following severe penetrating TBI (pTBI) in rodents. Adult Sprague-Dawley rats were subjected to pTBI and received 48µl ST266 or saline delivered in 8µl drops to each nostril. Experimental groups included: (1) sham, (2) pTBI with saline (pTBI+Veh), (3) pTBI with ST266 (pTBI+ST266), and (4) pTBI with a topical bolus of ST266 followed by intranasal delivery (pTBI+Topical). ST266 was administered immediately after brain injury and at 2hr, 6hr, and 24hr post-injury. Brain tissue from regions of interest were collected for assessment of TNF, IL-1β, IL-6, and IFN-γ. Plasma was collected prior to injury, and at 4h, 24h, and 28h post-injury for quantification of GFAP, UCH-L1, NF-L, and Tau using Quanterix Simoa digital ELISA assay. Intranasal administration of ST266 showed a trend towards reducing inflammatory cytokines in brain tissue. However, ST266 did not ameliorate injury-induced increases of GFAP, UCH-L1, NF-L, and Tau in plasma, which may due to the severity of the injury. Additional work evaluating intranasal administration of ST266 in models of concussion may be warranted.

4000. Okada-Rising, S., et al. (2019). "Tacrolimus-based immune suppression following traumatic brain injury negatively affects cognition." Journal of neurotrauma **36**(13): A134.

Tacrolimus is a calcineurin inhibitor with immunosuppressive properties that is frequently employed in post-transplant immunosuppressant cocktails with mycophenolate and steroids. Tacrolimus has demonstrated neuroprotective effects in models of ischemia, spinal cord injury (SCI), and traumatic brain injury (TBI). Thus, utilization of tacrolimus in cell-based therapy for central nervous system (CNS) injury or disease may confound results. This study aimed to identify any potential neuroprotective effects of tacrolimus-based immunosuppression in a preclinical model of penetrating ballistic-like TBI (pTBI). Adult rats were randomized into TBI or Sham groups with or without immune suppression. PTBI was performed unilaterally in the right hemisphere of anesthetized rats. Five days post-pTBI, daily intraperitoneal (IP) administration of 1mg/kg tacrolimus (Prograf) was initiated. 30mg/kg mycophenolate mofetil (CellCept) was administered IP daily 7-16 days post-PBBI. 10mg/kg methylprednisolone acetate (Depo-Medrol) was delivered 7 days post-injury IP and then weekly at 1mg/kg. Control treatment groups received saline (vehicle). Rotarod (7 days and 6 weeks) and Morris water maze (MWM; 5 weeks) assessments were conducted post-treatment. Peripheral blood was sampled on 2, 7, 30, and 90 days post-treatment at 1hour postdrug administration for complete blood count (CBC) analysis. Histopathological analysis for lesion volume and astrocyte activation were conducted at 1, 6, and 12 weeks post-treatment. By treatment day 7, the Tacrolimus-based cocktail significantly decreased the white blood cell (WBC) count, primarily affecting the lymphocyte population, indicating that 7 days of Tacrolimus-based immune-suppression is optimal for neural stem cell transplantation studies. No neuroprotective effects from Tacrolimus were detected on lesion volume and cortical volume loss assessments. Nor were any beneficial effects observed on motor or cognitive outcomes. In fact, pTBI and sham animals treated with Tacrolimus actually performed worse in the MWM task versus vehicle-treated controls which suggests the longlasting lymphocyte population reduction may be associated with the worsened cognitive outcome.

4001. Okada-Rising, S., et al. (2022). "FDA-APPROVED HUMAN FETAL-DERIVED NEURAL STEM CELLS FAIL TO IMPROVE COGNITIVE OR MOTOR OUTCOMEINARODENTMODELOFTRAUMATIC BRAININJURY." Journal of neurotrauma **39**(11-12): A57.

Penetrating traumatic brain injury (pTBI) inflicts a defined focal injury with neurological impairment. Cellular replacement therapy is a potential restorative strategy. NSI-566 are a FDA-approved human neural stem cell (NSC) line with neuronal differentiation capacity used in stroke and spinal cord injury Phase I and II clinical trials. Preclinical studies

demonstrated NSI-566 transplantation mitigates motor dysfunction. This study evaluated the neuroprotective potential of NSI-566 transplantation into the striatum (STR) or hippocampus (HC) following pTBI. Unilateral pTBI was performed on anesthetized rats. At 7 days post-injury, NSCs or vehicle (VEH) were injected into STR or HC regions in injured hemisphere as experimental groups: sham, STR-NSC, STR-VEH, HC-NSC, and HC-VEH. Rotarod testing assessed prior to transplantation (6 days post-pTBI), 8 and 21 days posttransplant. Morris water maze tasks performed at 5 and 6 weeks posttransplant. Significant motor deficits were found in injured groups prior to transplantation ($p < 0.05$ vs sham); however, this was not true following transplantation, regardless of transplant locations (STR, $p = 0.35$. HC, $p = 0.2$). Significant cognitive deficits were found in injured groups vs shams. Transplantation into injured striatal (i.e. perilesional) region nor hippocampus did not yield cognitive benefits. Our results revealed intracerebral targeted treatment with NSI-566 failed to provide significant therapeutic outcomes regardless of the transplant location. The lack of therapeutic effects for NSC transplantation was unexpected and may preclude continued pre-clinical research on this cell line for TBI.

4002. Okay, O., et al. (2009). "Orbitocerebral injury by a knife: case report." Neurocirugia (Asturias, Spain) **20**(5): 467-469.

Orbital penetrating injuries may cause significant harm to the optic nerves and eyeball as well as to the brain and cerebral vessels. Management of orbital foreign bodies should include prompt recognition of the extent of the injury, broad-spectrum parenteral antibiotics, tetanus prophylaxis, anticonvulsant medication and early surgical intervention under direct vision to remove the foreign body and to avoid immediate and long-term complications. We report a penetrating orbital injury caused by a bread knife that extended from the orbit to the tegmental dura mater of the temporal bone. The knife's main trajectory coursed through the temporal lobe. Adjacent cerebral structures were explored before removal of the knife.

4003. O'Kelly, F., et al. (2010). "Gun shot-101: an 8-year review of gunshot injuries in an Irish teaching hospital from a general surgical perspective." Irish journal of medical science **179**(2): 239-243.

BACKGROUND: Gun-related crime offences have increased in the Republic of Ireland steadily over the past number of years. Regional trauma units are witnessing unprecedented numbers of injuries in the Republic of Ireland with limited prior experience., AIMS: Eight-year retrospective study analysing demographic data, management and outcome of firearm-related injuries., RESULTS: Patients who experience gunshot injuries in this region are statistically likely to be young, male and unemployed with a single shotgun injury to an extremity. Post-operative survival rates of 100% for those who undergo an exploratory laparotomy., CONCLUSION: Ireland has comparable survival outcomes to other international centres with similar patient demographics due to timely and appropriate operative intervention. These results serve to provide a template for further patient management.

4004. Oki, T., et al. (2010). "Unusual intracranial stab wounds inflicted with metal tent stakes for a case involving a family murder suicide." Forensic science international **202**(1-3): e19-21.

This article presents a highly unusual homicide involving intracranial stab wounds. Of three members of a family killed by intracranial stab wounds apparently inflicted with metal tent stakes, two also showed signs of wounds inflicted during an apparent struggle with the assailant. A wooden mallet appears to be the implement use to drive the metal stakes into the cranial cavity. In all victims, toxicological analysis indicated the presence of brotizolam at concentrations ranging from 30 to 50ngml(-1). The one victim who showed no signs of wounds incurred during a defensive struggle was found to have blood alcohol levels of 2.87mgml(-1). The assailant, another family member with a history of major psychiatric disorders, apparently committed suicide by drowning following the attacks.

4005. Oksa, H. and A. Pasternack (1981). "Availability of cadaver kidneys for transplantation from brain-dead donors." Scandinavian journal of urology and nephrology **15**(3): 291-294.

The number of potential donors of cadaver kidneys in Finland was estimated on the basis of the death certificates in 1975. Only patients who had died via one of the two main causes of brain death--subarachnoid haemorrhage and head injury--were included. Exclusions were made on grounds of age at death, quality of hospital,

concomitant disease and survival time in hospital. After these exclusions, 209 patients could be regarded as potential donors of cadaver kidneys, a figure which in relation to the total mean population is 45 million and year. The cadaveric kidney potential, 90 kidneys per million population and year, is considered to be more than twice the demand.

4006. Okunaga, T., et al. (2010). "[A case of transorbital penetrating brain injury by a blunt metal rod]." No shinkei geka. Neurological surgery **38**(3): 293-298.

This report presents a case of a transorbital penetrating brain injury caused by a metal rod. A 47-year-old male injured his left lower eyelid with no witness during working hours. The two days later, he presented with a right hand tremor and abnormal behavior, and was admitted to the hospital. A CT showed a bone fracture of the left orbital roof and a low-density lesion of the left frontal lobe. The initial diagnosis was a cerebral contusion due to a blow-out fracture. However, sagittal MR images on the tenth day in the hospital demonstrated a penetrating tract that was running linearly from the left orbital roof to the left caudate head. Therefore, the final diagnosis was a transorbital penetrating brain injury. This case had no severe complications in spite of the delayed diagnosis. Careful examinations are thus required in order to make a correct diagnosis at the first examination, because a transorbital penetrating brain injury might initially present as a slight wound with no neurological signs.

4007. Okunlola, A. I., et al. (2020). "Awake craniotomy in neurosurgery: Shall we do it more often?" Interdisciplinary Neurosurgery: Advanced Techniques and Case Management **21**.

Background: Awake craniotomy allows intraoperative cortical mapping to prevent injury to the eloquent brain region and minimizes the complications of general anaesthesia. The initial indications include epilepsy surgery and excision of diffuse glioma in eloquent brain region. There have been a remarkable development in the fields of neurosurgery and anaesthesia. Aim: To emphasis the role of awake craniotomy in lesions other than diffuse glioma. Method: Prospective review of awake craniotomies by the corresponding author over eighteen month's period. We obtained consent for surgery as routine surgical procedure with emphasis on awake procedure to avoid the possible complications of general anaesthesia. Awake and cooperative patients with suitable lesion location in the brain convexity whose surgery were expected to last not more than four hours had awake craniotomies under scalp nerve block with local anaesthetic solution containing 0.5% xylocaine with adrenaline and 0.125% Bupivacaine. Results: Eight awake craniotomies were done within the period. The age range was 25–92 years. Male: female ratio was 1:1. There were three tumours, one intracerebral abscess, two acute subdural haematoma, a case of intracerebral haematoma secondary to ruptured AVM and craniotomy for removal of posterior left frontal intacerebral metallic object. There was no intraoperative seizures and there was no need to convert to general anaesthesia in any of the cases. A patient with intracerebral haematoma secondary to ruptured arteriovenous malformation (AVM) had excessive primary haemorrhage which was controlled. There was no neurological deficit or seizures and no incidence of wound infection. Conclusion: Awake craniotomy is beneficial in a variety of supratentorial brain lesions provided the patient comfort is not compromised. Awake craniotomy in suitable patients, will reduce the possible anaesthetic complications associated with general anaesthesia with endotracheal intubation and need for post-operative intensive care unit admission.

4008. Okura, H., et al. (2021). "An unprecedented case of penetrating head trauma caused by shoji (a Japanese-style paper sliding door)." Trauma case reports **36**: 100533.

Penetrating head trauma (PHT) includes any traumatic injury where an object pierces the skull and breaches the dural membrane surrounding the brain. PHTs are less prevalent than blunt head injuries. However, they often have more complex damage, worse prognosis, and higher rates of morbidity and mortality. An 83-year-old man fell at his home and hit his head on the right side toward a shoji (a Japanese-style paper sliding door). He reported to the emergency room the following day with his family. He had a small wound before the right ear, which was sutured in the emergency room. A CT scan demonstrated tiny pieces of bone fragments inside the brain, as well as right temporal subcortical hemorrhage and pneumocephalus. He was admitted to the hospital and received intensive prophylaxis with antibiotics. He developed life-threatening skin disease and subsequent acute kidney disease requiring hemodialysis. He fully recovered from his life-threatening condition. Here, we report an unprecedented case of a penetrating head injury of an older adult caused by a shoji.

4009. Olabe, J., et al. (1993). "[Frontal sinus osteoma associated with intracranial porencephalic cavity]." Osteoma de seno frontal asociado a cavidad porencefalica intracraneal. **44**(6): 461-464.

A case of an eighteen-year-old student, complaining of frontal and periorbital headache is presented. Using conventional radiographies and CT Scan a frontal sinus osteoma is diagnosed, finding a hypodense image located in the left frontal cerebral lobe, without perilesional oedema or contrast uptake. During the surgical act, a destruction of the posterior wall of the left frontal sinus is found, penetrating the anterior cerebral fossa and connecting with the cerebral cavity in the left frontal cerebral lobe through a fistula of mucosal tissue that passes through the dura mater. Complete tumoral exeresis was undertaken as well as plastic reconstruction with excellent clinical and cosmetic results. We conclude that the early diagnosis and treatment of these benign lesions should be undertaken in order to avoid the potential complications they can provoke.

4010. Olack, B., et al. (2021). "Causes of preterm and low birth weight neonatal mortality in a rural community in Kenya: evidence from verbal and social autopsy." BMC pregnancy and childbirth **21**(1): 536.

BACKGROUND: Under-five mortality in Kenya has declined over the past two decades. However, the reduction in the neonatal mortality rate has remained stagnant. In a country with weak civil registration and vital statistics systems, there is an evident gap in documentation of mortality and its causes among low birth weight (LBW) and preterm neonates. We aimed to establish causes of neonatal LBW and preterm mortality in Migori County, among participants of the PTBI-K (Preterm Birth Initiative-Kenya) study., METHODS: Verbal and social autopsy (VASA) interviews were conducted with caregivers of deceased LBW and preterm neonates delivered within selected 17 health facilities in Migori County, Kenya. The probable cause of death was assigned using the WHO International Classification of Diseases (ICD-10)., RESULTS: Between January 2017 to December 2018, 3175 babies were born preterm or LBW, and 164 (5.1%) died in the first 28 days of life. VASA was conducted among 88 (53.7%) of the neonatal deaths. Almost half (38, 43.2%) of the deaths occurred within the first 24 h of life. Birth asphyxia (45.5%), neonatal sepsis (26.1%), respiratory distress syndrome (12.5%) and hypothermia (11.0%) were the leading causes of death. In the early neonatal period, majority (54.3%) of the neonates succumbed to asphyxia while in the late neonatal period majority (66.7%) succumbed to sepsis. Delay in seeking medical care was reported for 4 (5.8%) of the neonatal deaths., CONCLUSION: Deaths among LBW and preterm neonates occur early in life due to preventable causes. This calls for enhanced implementation of existing facility-based intrapartum and immediate postpartum care interventions, targeting asphyxia, sepsis, respiratory distress syndrome and hypothermia.

4011. Olasoji, H. O., et al. (2005). "Penetrating arrow injuries of the maxillofacial region." The British journal of oral & maxillofacial surgery **43**(4): 329-332.

We operated on four civilian patients who had unusual penetrating maxillofacial injuries that resulted from assault with arrows. The patients were fully conscious at the time of presentation. Recovery was uneventful in three, but one died.

4012. Olayemi, A. B., et al. (2013). "Pattern, severity, and management of cranio-maxillofacial soft-tissue injuries in Port Harcourt, Nigeria." Journal of Emergencies, Trauma and Shock **6**(4): 235-240.

Background: The pattern of craniofacial soft-tissue injuries occurring either in isolation or in association with fractures vary in different societies and is multiply influenced. The effects are enormous because of the prominence of the face; therefore, the purpose of this study was to document any changing pattern, severity and management of these craniofacial injuries in our center. Patients and Method: Cranio-maxillofacial region was classified into upper, middle and lower face. The cause, type, and site of the injuries were documented. Gunshot injuries were further categorized as penetrating, perforating or avulsions. Further, classification of injuries into mild, moderate, and severe was carried out based on multiple factors. Result: A total of 126 patients with soft-tissue injuries presented to our hospital out of which 85 (67.5%) were males and 41 (32.5) were females. The age range of the patients was between 10 months and 90 years with a mean ± SD of 26.4 ± 15.5 years. Road traffic accident was the most common etiology of which vehicular accidents constituted 50 (54.9%) and the motorcycle was 2 (2.2%). Assault contributed 16 (17.6%) while cases due to gun shots were 13 (14.3%). A total of 19 (15.1%) patients had associated head injuries, 11 (8.7%) patients had craniofacial fractures involving any of the bones while 3 (2.4%) patients had limb fractures and 2 (1.6%) patients had rib fractures. There were 51 (41.8%) cases classified as mild injuries, 37 (30.3%) cases as moderate injuries and 24 (19.7%) cases as severe injuries.

Total of 126 cases managed, 121 (96.0%) received primary closure of the wounds while 5 (4.0%) received delayed closure under general anesthesia.

4013. Olding, J., et al. (2019). "Penetrating head & neck trauma - Epidemiology and injury characteristics in terror-related violence, interpersonal violence and deliberate self-harm at a level 1 trauma centre." The surgeon : journal of the Royal Colleges of Surgeons of Edinburgh and Ireland **17**(3): 133-138.

INTRODUCTION: Penetrating trauma to the head and neck presents specific clinical challenges. Aetiologies include interpersonal violence, deliberate self-harm and terror-related violence. King's College Hospital is a Major Trauma Centre serving inner-city London boroughs with a high incidence of knife and gun crime. It also received victims of the terrorist attack at London Bridge in June 2017., METHODS: Data was collected prospectively on all patients presenting with penetrating trauma to the head and neck over a one-year period (August 2016-July 2017)., RESULTS: Overall figures for penetrating trauma are the highest since comparable records began with 478 cases (2016/17) compared with 172 (2010/11). Most patients had injuries resulting from interpersonal violence (83%); a group consisting mostly in males (88%) under the age of 30 (69%). The sole fatality among all patients was a result of repeat deliberate self-harm. Terror-related violence victims were equally gender split and older; all patients in this group required surgical intervention and had longer lengths of stay (16.3 days) compared with interpersonal violence (6.3 days) and deliberate self-harm (3 days)., CONCLUSION: Violent crime is increasing. Overall penetrating injury has more than doubled in 6 years. The injury characteristics observed are distinct depending on the assailants and motives. Head and neck trauma requires a multidisciplinary approach, with an understanding of the care needs of patients. Interpersonal violence is the most common aetiology and as such efforts to tackle rising violent crime must involve police and the community. In addition, terror-related violence is evolving in the United Kingdom and globally, and as such healthcare professionals must understand differences in aetiologies to promote optimal patient care.

4014. Olding, M., et al. (1993). "Emergency free flap reconstruction of a facial gunshot wound." Annals of plastic surgery **31**(1): 82-86.

An emergency free rectus abdominis myocutaneous flap was used to reconstruct a massive facial gunshot wound with associated cranial communication immediately after the primary debridement. The bony defect was reconstructed with split calvarial and rib grafts, plates, and screws. The free flap provided adequate coverage of the bony reconstruction and separation of the cranial and sinus cavities.

4015. Oley, M. C., et al. (2021). "Penetrating facial injuries may cause intracranial damage." Journal of Pediatric Surgery Case Reports **75**.

Background: Due to the various injuries that can occur during the removal of odd objects, a penetrating facial trauma injury can cause a wide range of injuries. To avoid ophthalmic and/or neurological abnormalities in addition to the risk of infection and or bleeding, accurate diagnosis and prompt treatment are critical. An optimal treatment outcome is achieved through a thorough examination, radiological evaluation, and prompt decision-making. Case presentation: We report two cases of penetrating facial trauma injury caused by metal objects. Immediate medical examination and multidisciplinary intervention are critical for enhancing prognosis, ensuring a successful neurological recovery, and avoiding delayed consequences. At admission and before and after surgery, our client revealed no neurological deficits. Conclusions: Because of the potential for ocular and cerebral damage, penetrating fascial trauma injuries from metal items must not be overlooked. As a result, the purpose of this paper is to raise awareness of the complexity and severity of intracranial damage in addition to infection-related consequences caused by these types of injuries.

4017. Olivecrona, M., et al. (2012). "Prostacyclin treatment and clinical outcome in severe traumatic brain injury patients managed with an ICP-targeted therapy: a prospective study." Brain injury **26**(1): 67.

OBJECTIVE: To prospectively assess clinical outcome in patients with severe traumatic brain injury (sTBI) managed according to an ICP-targeted programme as well as additional treatment with prostacyclin., MATERIALS AND METHODS: Inclusion criteria were GCS ⩽8, age 15-70 years, first recorded cerebral perfusion pressure (CPP) > 10 mm Hg. Exclusion criteria were pregnancy, breastfeeding or penetrating brain injury. The patients were treated using the same ICP-guided protocol, with one group randomized to receive prostacyclin in a low dose (0.5 ng kg(-1)min(-1)). The clinical outcome was prospectively assessed at 3, 6, 12, 18 and 24 months using structured interviews., RESULTS: Forty-eight patients were included, mean age 35.5 years, median GCS 6 (3-8), 69% were multi-traumatized. Mortality at 3 months was 12.5%. Median Glasgow Outcome Scale (GOS) at all follow-up points was 4. Favourable outcome (GOS 4-5) at 3 months was 52%, at 24 months 64%. Favourable outcome increased over time. There was a statistically significant association between GOS, GCS at admission and age. Higher ICP(max) was associated with worse outcome., CONCLUSION: With this treatment protocol, a low number of deaths and a high number of favourable outcomes in sTBI were observed. Prostacyclin in this low dose does not seem to improve the outcome. ICP(max) is a positive predictor of worse outcome. Higher GCS at admission and lower age are correlated to better outcome.

4019. Oliveira, E. S., et al. (2019). "Facial trauma caused by sharp weapon: case report." International journal of oral and maxillofacial surgery **48**: 201.

Background: Violence is one of the main causes of facial trauma (FT)it represents a significant part of emergency care and differs to others due to the related physical, psychosocial and economic impacts. Sharp weapon traumas occur less frequently in the face, being men more affected. Objectives: Describe a case of aggression and it's followed up. Methods: A 40 years old man, presented at the Metropolitan Hospital of Urgency and Emergency of the state of Pará, Brazil, were victim of physical aggression by a sharpened weapon (machete). After evaluation and stabilization according to the Advanced Trauma Life Suport, the maxillofacial surgery team attended and diagnosed the patient with right zygomatic complex, naso-orbitoethmoid complex and left Le Fort II fractures. Findings: Physical examination revealed a laceration wound involving the right zygomatic, nasal root and left infraorbital region, with considerable mobility of the middle third of the face with lesion of the right eyeball. Under general anaesthesia, fractures were approached through the wound and debridement was performed followed by medial canthopexy. Right zygomaticofrontal and frontonasal suture, right zygomatic arch and left infraorbital rhyme, lateral nasal and frontal process of maxilla were reduced and fixated. Postoperative course was uneventful and the ophthalmology team eviscerated the right eye after 4 days, being discharged on the 5th day. Conclusion: Sharpened FTs present great potential for aesthetic and functional losses, as well as greater risk of infection, however, with correct diagnosis, adequate planning and immediate surgical treatment, the maxillofacial surgeon is able to minimize sequelae and ensure patient rehab. Three-dimensional visualization is an important tool in the evaluation and demonstration of injury. Creating convincing graphics, however, requires strict distinction between illustrative and reconstructive visualizations and a method of validation. We present a case in which we used a radiation-planning tool to provide a 3-dimensional illustrative visualization of a contact gunshot wound to the head, and validated the result by comparing computed radiographs with radiographs taken at autopsy. We discuss the use of visualization tools for data exploration in forensic pathology.

4025. Omari, A., et al. (2022). "Globe dislocation and optic nerve avulsion following all-terrain vehicle accidents." American Journal of Ophthalmology Case Reports **27**.

Purpose: Open-air motor vehicles present unique trauma risks to the eyes and face. We describe two patients who suffered a crash while riding an all-terrain vehicle (ATV), leading to globe dislocation with optic nerve avulsion in order to raise awareness about the risks associated with ATV accidents. Observations: In both cases, the injury was caused by high-speed trauma to the orbit involving a tree branch. One patient sustained a life threatening arrythmia requiring a short stay in the intensive care unit, and both patients required emergent surgical management and eventual socket reconstruction. Conclusions and Importance: These cases highlight the need for greater advocacy on behalf of rider safety. The authors encourage ophthalmologists to counsel patients who use ATVs to wear helmets, seatbelts, and protective eyewear to prevent these types of injuries in the future.

The content of prostaglandin F2 alpha was evaluated in the venous blood of 114 young male patients with acute craniocerebral injury of light to moderate severity. Prostaglandin content was determined by a gas/liquid chromatography technique. In the investigations carried out, the blood level of prostaglandin F2 alpha was found to show a strong tendency to increase from the moment of injury and up to day 3 to 5 following which day it began to slowly decline. There seems to be an association between the above process and severity of injury. Mathematic analysis has shown the blood level of prostaglandin to correlate primarily with disorders in the vegetative subdivision of the nervous system.

4029. Ondracek, R., et al. (2022). "An Unexpected Turn After MVA: Multiple Brain Abscesses and CSF Leak Complicating a Severe Blunt Traumatic Brain Injury." American Journal of Respiratory and Critical Care Medicine **205**(1).

Traumatic brain injuries are a common entity in the United States with roughly 5 million TBIs occurring annually. Complications of TBIs vary from cognitive impairment, diffuse axonal injury, seizures, and permanent coma. Brain abscess formation is a rare complication of TBI that presents a complex treatment challenge in which mortality has decreased over time due to the advancement in surgical techniques. A 25 year old male with no past medical history that presented as a level 1 trauma with a blunt force head injury from a motorcycle accident. Patient presented with a GCS-6 and closed head injuries which included multiple facial fractures, diffuse subarachnoid hemorrhage, intraparenchymal hemorrhage, and subdural hematoma. Patient underwent an extensive ICU course including prolonged stay on mechanical ventilation, ICP monitor, treatment of Acinetobacter ventilator associated pneumonia, tracheostomy, PEG tube placement. Patient was slowly weaned off mechanical ventilation and eventually underwent decannulation of tracheostomy. While on the medical floor awaiting placement the patient became more lethargic prompting further imaging which demonstrated pneumocephalus and several air fluid levels concerning abscess formation. The patient underwent a bicoronal craniotomy, abscess drainage with frank pus evacuated, cranialization of frontal sinus and CSF leak repair, and frontal sinus obliteration. The patient's OR cultures did not grow any bacteria however the patient was treated with broad spectrum antibiotics for 6 weeks postoperatively and discharged to rehab. Post traumatic brain abscess formation is a rare complication most often seen in open skull fractures or penetrating trauma with reported incidence ranging from 3 to 16%. Very few incidences of brain abscess formation have been described after closed head injuries, but can occasionally be seen with the presence of residual bone fragments or debris. Here we describe a unique development of brain abscess after blunt force injury. No organism was isolated in our perioperative culture, which has been reported in around 1 out of every 3 brain abscess cases. Similar to our patient, the average time between injury and abscess formation has been documented as 113 days which is an important, delayed complication for clinicians to be aware of.

4030. Ondruschka, B., et al. (2016). "Unusual planned complex suicide committed with a muzzle-loading pistol in combination with subsequent hanging." Archiv fur Kriminologie **238**(5-6): 207-217.

In Germany, suicides by firearms are not very common in contrast to deaths by hanging and intoxications. The use of historical muzzle-loading firearms in the context of suicides is a rarity. Contact shots from muzzle loaders cause an unusual wound morphology with extensive soot soiling. We report the case of a 59-year-old man, who committed a planned complex suicide by shooting into his mouth with a replica percussion gun in combination with hanging. The gunshot injury showed strong explosive effects in the oral cavity with fractures of the facial bones and the skull associated with cerebral evisceration (so-called Kronlein shot). Due to the special constellation of the case with hanging immediately after the shot, external bleeding from the head injuries was only moderate. Therefore, the head injuries could be assessed and partially reconstructed already at the scene.

4031. O'Neill, O. R., et al. (1994). "Transorbital penetrating head injury with a hunting arrow: case report." Surgical neurology **42**(6): 494-497.

The development of more complex and diverse hunting weapons may result in an increase of uncommon forms of penetrating injury to the brain. We present a case of nonfatal transorbital arrow injury to the brain. High velocity projectile injuries merit certain management adaptations from gunshot or low velocity stab wounds. This case highlights the necessity for anterograde removal of the arrow in the direction of its line of trajectory. Early assessment of the patient with cerebral angiography to identify surgically correctable vascular injury is recommended.

4032. O'Neill, P. J., et al. (2009). "Significant pediatric morbidity and mortality from intracranial ballistic injuries caused by nonpowder gunshot wounds. A case series." Pediatric neurosurgery **45**(3): 205-209.

Nonpowder (ball-bearing and pellet) weapons derive their source of energy from compressed air or carbon dioxide. Such weapons are dangerous toys that cause serious injuries and even death to children and adolescents. A retrospective chart review study was undertaken to describe nonpowder gun injuries at a southwestern US urban level I adult and pediatric trauma center. Specific emphasis was placed on intracranial injuries. Over the past 6 years, a total of 29 pediatric and 7 adult patients were identified as having nonpowder firearm injuries. The patient population was overwhelmingly male (89.7%; mean age, 11 years). Overall, 17 out of 29 pediatric patients (56.8%) sustained serious injury. Nine patients (30.0%) required operation, 6 (20.7%) sustained significant morbidity, and there were 2 deaths (6.9%). Injuries to the brain, eye, head, and neck were the most common sites of injury (65.6%). Specific intracranial injuries in 3 pediatric patients are described that resulted in the death of 2 children. We suggest that age warning should be adjusted to 18 years or older for unsupervised use to be considered safe of these potentially lethal weapons.

4033. Ongom, P. A., et al. (2014). "Atypical gunshot injury to the right side of the face with the bullet lodged in the carotid sheath: A case report." Journal of medical case reports **8**(1).

Introduction. Gunshot injuries of the head and neck from the AK-47 rifle (a common assault rifle, submachine gun type) are a significant contributor to morbidity and mortality among civilians in Sub-Saharan Africa. They may cause significant damage to the closely arranged structures in this region, and the bullet's trajectory can be very difficult to determine. We present an unusual case of gunshot injury with an atypical bullet entry wound, profound injury to the face, lodgment in the right carotid sheath, and 'wandering'; a first of its kind in East Africa. Case presentation. A 27-year-old African-Ugandan woman of Nilotic ethnicity was referred to the Accident and Emergency Department of a tertiary hospital in Uganda, having sustained complex injuries due to an inadvertent AK-47 rifle gunshot injury. The gunshot injury was to the right side of her face with a large ragged entry wound and no exit wound. Prior basic wound care and radiological imaging showed a comminuted fracture of her mandible with lodgment of the bullet in her neck, anterior to her sixth and seventh cervical vertebrae. Standard debridement of her wound was done. A computed tomography scan showed an apparent cephalad shift ('wandering') of the bullet, leaving it lying partially anterior to her fifth cervical vertebra as well as within her carotid sheath. Other injuries were to her facial and trigeminal nerves, and her middle ear. The 'wandering' bullet was successfully removed surgically. It had caused no damage to any part of her neck structure. Conclusion: AK-47 rifle bullet injuries may present with uncharacteristically large entry wounds and cause complex structural injuries at the area of impact. The consequent trajectory is difficult to predict making regional examination and radiological investigations essential in management. Bullets may be retained, leaving no exit wound. Securing the airway, controlling hemorrhage and identifying other injuries are the first vital steps. This case illustrates all these interventions and the important decision to extract the entrapped bullet from the patient's neck because it had started to 'wander' and could have caused grave injury over time with further migration. Maxillofacial, plastic, trauma, general and military surgeons, otorhinolaryngologists and emergency physicians can gain from this experience because it calls for a multidisciplinary team approach.

4034. Onifer, D. J., et al. (2019). "Management of Hemorrhage From Craniomaxillofacial Injuries and Penetrating Neck Injury in Tactical Combat Casualty Care: iTClamp Mechanical Wound Closure Device TCCC Guidelines Proposed Change 19-04 06 June 2019." Journal of special operations medicine : a peer reviewed journal for SOF medical professionals **19**(3): 31-44.

The 2012 study Death on the battlefield (2001-2011) by Eastridge et al.1 demonstrated that 7.5% of the prehospital deaths caused by potentially survivable injuries were due to external hemorrhage from the cervical region. The increasing use of Tactical Combat-Casualty Care (TCCC) and other medical interventions have dramatically reduced the overall rate of combat-related mortality in US forces; however, uncontrolled hemorrhage remains the number one cause of potentially survivable combat trauma. Additionally, the use of personal protective equipment and adaptations in the weapons used against US forces has caused changes in the wound distribution patterns seen in combat trauma. There has been a significant proportional increase in head and neck wounds, which may result in difficult to control hemorrhage. More than 50% of combat wounded personnel will receive a head or neck wound. The iTClamp (Innovative Trauma Care Inc., Edmonton, Alberta, Canada) is the first and only hemorrhage control device that uses the hydrostatic pressure of a hematoma to tamponade bleeding from an injured vessel within a wound. The iTClamp is US Food and Drug Administration (FDA) approved for use on multiple sites and works in all compressible areas, including on large and irregular lacerations. The iTClamp's unique design makes it ideal for controlling external hemorrhage in the head and

neck region. The iTClamp has been demonstrated effective in over 245 field applications. The device is small and lightweight, easy to apply, can be used by any level of first responder with minimal training, and facilitates excellent skills retention. The iTClamp reapproximates wound edges with four pairs of opposing needles. This mechanism of action has demonstrated safe application for both the patient and the provider, causes minimal pain, and does not result in tissue necrosis, even if the device is left in place for extended periods. The Committee on TCCC recommends the use of the iTClamp as a primary treatment modality, along with a CoTCCC-recommended hemostatic dressing and direct manual pressure (DMP), for hemorrhage control in craniomaxillofacial injuries and penetrating neck injuries with external hemorrhage. Copyright 2019.

4035. Onizuka, M., et al. (2001). "[Penetrating head injury caused by an icepick]." No shinkei geka. Neurological surgery **29**(11): 1101-1105.

The patient was a 39-year-old man, with a three year history of schizophrenia, who attempted suicide by piercing his head with an icepick. Spinal cord injuries and shock caused by falling from the fifth floor of the building following this penetrating injury were also noted on admission. The CT scan revealed that the icepick had deeply penetrated the posterior fossa from the forehead. No new neurological deficits or cerebrospinal fluid leakage appeared after admission. The icepick was removed completely without difficulty. In penetrating head injuries, early assessment with cerebral angiography to determine the extent of vascular injury is useful for deciding if surgery should be performed.

4036. Onose, G., et al. (2009). "Neuroprotective and consequent neurorehabilitative clinical outcomes, in patients treated with the pleiotropic drug cerebrolysin." Journal of medicine and life **2**(4): 350-360.

BACKGROUND: Discovery of neurotrophic factors--emblematic: the nerve growth factor (NGF)--resulted in better approaching central nervous system (CNS) lesions. Recently, another crucial property has been unveiled: their rather unique pleiotropic effect. Cerebrolysin is a peptide mixture that penetrates the blood-brain barrier in significant amounts and mimics the effects of NGF., METHODS: Comparative analysis: Cerebrolysin treated (10 ml x 2/day, i.v. x 3 weeks) vs. non-treated, in patients (all received aside, a rather equivalent complementary, pharmacological and physical, therapy). Two lots of patients, admitted in our Physical & Rehabilitation (neural-muscular) Medical-PR(n-m)M-Clinic Division, during 2007-2009: 69 treated with Cerebrolysin (22 F, 47 M; Average: 59.333; Mean of age: 61.0 Years old; Standard deviation 16.583) and 70 controls (41 F, 29 M; A: 70.014; M.o.a.: 70.5 Y.o.; S.d.: 6.270) were studied. The total number of assessed items was 13: most contributive in relation with the score of Functional Independence Measure at discharge (d FIM), were: admission (a FIM), number of physical therapy days (PT), number of hospitalization days (H), age (A) and--relatively--days until the first knee functional extension (KE). Concomitantly, the main/key, focused on neuro-motor rehabilitative outcomes, functional/analytical parameters, have been assessed regarding the speed in achieving their functional recovery., RESULTS: Concerning d FIM, there have not been objectified significant differences between the two lots (p=0.2453) but regarding key, focused on neuro-motor rehabilitative outcomes, functional/analytical parameters: KE (p=0.0007) and days until the first time recovery of the ability to walk between parallel bars (WPB--p=0.0000)--highly significant differences in favor of Cerebrolysin lot resulted., CONCLUSION: Cerebrolysin administration, as neurorehabilitative outcomes, proved to hasten, statistically significant, especially the recovery of some critical, for standing and walking, parameters. Thus encouraged, we have now initiated a comprehensive national, 5 year retrospective, multi-centre--based on unitary data acquisition frame and mathematical apparatus--study, to evaluate the results of the treatment with Cerebrolysin in traumatic brain injuries (TBI).

4037. Opeskin, K. and S. Cordner (1990). "Nail-gun suicide." The American journal of forensic medicine and pathology **11**(4): 282-284.

Two cases are reported of young men who committed suicide using a nail gun. One shot himself through the heart and left lung. The other shot himself in the head. No cases of completed suicide by nail gun have previously been reported in the English literature. These cases are reported because of their uncommon nature and because they represent a potentially fatal use of a relatively common industrial implement.

4038. O'Phelan, K. H., et al. (2015). "Therapeutic temperature modulation is associated with pulmonary complications in patients with severe traumatic brain injury." World journal of critical care medicine **4**(4): 296-301.

AIM: To examine complications associated with the use of therapeutic temperature modulation (mild hypothermia and normothermia) in patients with severe traumatic brain injury (TBI)., METHODS: One hundred and fourteen charts were reviewed. Inclusion criteria were: severe TBI with Glasgow Coma Scale (GCS) < 9, intensive care unit (ICU) stay > 24 h and non-penetrating TBI. Patients were divided into two cohorts: the treatment group received therapeutic temperature modulation (TTM) with continuous surface cooling and indwelling bladder temperature probes. The control group received standard treatment with intermittent acetaminophen for fever. Information regarding complications during the time in the ICU was collected as follows: Pneumonia was identified using a combination of clinical and laboratory data. Pulmonary embolism, pneumothorax and deep venous thrombosis were identified based on imaging results. Cardiac arrhythmias and renal failure were extracted from the clinical documentation. acute respiratory distress syndrome and acute lung injury were determined based on chest imaging and arterial blood gas results. A logistic regression was conducted to predict hospital mortality and a multiple regression was used to assess number and type of clinical complications., RESULTS: One hundred and fourteen patients were included in the analysis (mean age = 41.4, SD = 19.1, 93 males), admitted to the Jackson Memorial Hospital Neuroscience ICU and Ryder Trauma Center (mean GCS = 4.67, range 3-9), were identified and included in the analysis. Method of injury included motor vehicle accident (n = 29), motor cycle crash (n = 220), blunt head trauma (n = 212), fall (n = 229), pedestrian hit by car (n = 216), and gunshot wound to the head (n = 27). Ethnicity was primarily Caucasian (n = 260), as well as Hispanic (n = 227) and African American (n = 223); four patients had unknown ethnicity. Patients received either TTM (43) or standard therapy (71). Within the TTM group eight patients were treated with normothermia after TBI and 35 patients were treated with hypothermia. A logistic regression predicting in hospital mortality with age, GCS, and TM demonstrated that GCS (Beta = 0.572, P < 0.01) and age (Beta = -0.029) but not temperature modulation (Beta = 0.797, ns) were significant predictors of in-hospital mortality [chi(2) (3) = 22.27, P < 0.01] A multiple regression predicting number of complications demonstrated that receiving TTM was the main contributor and was associated with a higher number of pulmonary complications (t = -3.425, P = 0.001)., CONCLUSION: Exposure to TTM is associated with an increase in pulmonary complications. These findings support more attention to these complications in studies of TTM in TBI patients.

4039. Oppenheimer, D., et al. (1987). "Left-hemisphere missile injury. A clinical and anatomical case study, with 25-year follow up." Archives of neurology **44**(8): 857-861.

A case is reported of left-hemisphere missile injury sustained in 1944. A stable pattern of selective loss (dysphasia, dyslexia, dysgraphia, and verbal memory impairment) and intact abilities (perceptual and spatial skills and nonverbal memory) was followed up for 25 years. No progressive or generalized intellectual deterioration to suggest interaction between this brain injury and normal aging was observed. The clinical and neuropsychological sequelae are related to the detailed postmortem findings.

4040. Orbay, A. S., et al. (1997). "Unusual penetrating faciocranial injury caused by a knife: a case report." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **25**(5): 279-281.

Penetrating head and neck trauma in children is uncommon and are potentially life-threatening injuries. Penetrating trauma to the head in children is a challenging problem for both the initial evaluating physicians and surgeons. We report upon a patient who had fallen from a tree while cutting vegetables and sustained a penetrating faciocranial injury caused by his knife. Clinical examination showed a knife which had entered his face in the right preauricular, pre-temporomandibular joint area below the zygomatic arch. His left bulbus oculi was exophthalmic and a complete ptosis was present. He was fully conscious. The only abnormal finding was complete left visual loss. The other neurological ophthalmological and systemic physical evaluations were normal. The Glasgow Coma scale score was 14. The modalities of treatment and the outcome of the operation are described and the management of similar injuries is discussed.

4041. Ordia, J. I. (1989). "Neurologic function seven years after crowbar impalement of the brain." Surgical neurology **32**(2): 152-155.

The management of impalement injuries to the brain presents formidable problems. A 39-year-old man was impaled by a crowbar which penetrated the brain. The prompt rescue and resuscitation, thorough surgical debridement, control of intracranial pressure and rehabilitation are described.

4042. Ordia, J. I. (2009). "Brain impalement by an angle metal bar." Clinical neurology and neurosurgery **111**(4): 368-372.

The author reports the case of a 37-year-old right-handed man who was impaled in the head by an angle metal bar at a construction work site. Impalement injuries of the brain are rare, and their management is complex. The surgical treatment of the injury and the medical management of complications are described in detail. The patient made a good recovery although he has functional deficits related to the injury to his frontal lobes.

4043. Origitano, T. C. (2011). "Use of abdominal free fat for cosmetic augmentation and primary CSF closure in supratentorial skull base surgery: Managing the stigmata of the temporal defect." Skull Base **21**.

The most prominent stigmata of supratentorial skull base surgery is the defect from the wasting of the temporalis muscle. The cause of tissue volume loss can be denervation/devascularization, loss of muscle anatomical insertion, direct trauma, and/or rotation as an in situ vascularized graft. These events lead to temporal defect know to the patient as “the divot in my head” or the perceived swollen cheek. Abdominal free fat is used freely to close posterior fossa defects with excellent results. Over the past 36 months abdominal free fat grafts have been used to bolster the closure of supratentorial skull base surgery 18 times: (1) 2 for primary closure for resected dura, (2) 6 to fill the deficit caused from the rotation of the temporalis muscle as an in situ graft, (3) 2 for primary volume loss from penetrating trauma, (4) 3 for volume loss from previous operations, and (5) 4 for primary closures after extensive removal of orbital and sphenoid bone. Fat was applied in a volume that allowed for 30% loss in the following locations: (1) over the periorbitum under the muscle, (2) over the muscle under a temporalis fascia/pericranium graft, and (3) between the bone flap and muscle. The final contour of the head occurred between 3 and 6 months. One patient required liposuction for cosmesis. The use of fat for supplemental cranioplasty is fiscally prudent - there is little risk of rejection or infection, it serves well to contain CSF leak, and it is readily available. In addition it serves well as an interface for future imaging of recurrence or progression. The cosmetic results were gratifying, especially in the reoperations, which resulted in resolution of previous defects. The basic technique will be presented.

4044. Origitano, T. C., et al. (1992). "Complex cranial base trauma resulting from recreational fireworks injury: case reports and review of the literature." Neurosurgery **30**(4): 570-576.

Two patients who sustained complex skull base trauma secondary to recreational fireworks injuries are reported. Initial assessment and management included axial and coronal computerized tomography, control of hemorrhage, debridement of wound and brain, isolation of brain from external environment, and reconstruction of the cranial base floor. Secondary orbital and facial reconstruction used available bone fragments and iliac bone graft in one patient and vascularized free tissue transfer in the other. In both patients, reconstruction of both the intracranial and extracranial compartments was successful with acceptable cosmetic result. Modification of multiple conventional approaches, along with a multispecialty surgical team, was used to deal effectively with these unique cases.

4045. Orlov, V. P. (2016). "[Comparative evaluation of drainage methods used for penetrating gunshot cerebral injuries]." Voenno-meditsinskii zhurnal **337**(4): 15-20.

The paper presents a comparative evaluation of the methods of gunshot craniocerebral wounds draining, applied when the primary surgical treatment at the stages of medical evacuation of the limited contingent of Soviet troops in Afghanistan. An analysis of occurring infectious complications and outcomes of surgical treatment of the wounded is given. Based on clinical observations revealed most effective method of the active drainage gunshot traumatic brain injuries. The advantages of tidal drainage, appropriate for mechanical cleaning of wounds, allows controlling hemostasis, using antibacterial solutions are given.

4046. Orman, J. A., et al. (2012). "Epidemiology of moderate-to-severe penetrating versus closed traumatic brain injury in the Iraq and Afghanistan wars." The journal of trauma and acute care surgery **73**(6 Suppl 5): S496-502.

BACKGROUND: US combat operations in Iraq and Afghanistan have resulted in a greater proportion of service members with head and neck wounds caused by explosions compared with that of previous wars. Although penetrating traumatic brain injury (TBI) is frequently associated with these wounds, the epidemiology of penetrating TBI from these conflicts has not been well described., METHODS: The Joint Theater Trauma Registry was queried for January 2003 through December 2010 to identify all patients with moderate-to-severe brain injury with a maximum Abbreviated Injury Scale (AIS) score of the head of 3 or greater and a diagnosis of penetrating or closed TBI in accordance with the Department of Defense Traumatic Brain Injury Surveillance definition. The epidemiology of these injuries was examined, including demographics, TBI severity, overall injury severity, and surgical interventions provided., RESULTS: A total of 1,255 TBI patients (774 penetrating, 481 closed) meeting criteria were identified. Penetrating brain injuries were more severe, more likely to be battle related, and less likely to be isolated injuries than a group of moderate-to-severe closed TBIs within the same range of anatomic injury severity. During the 5-year period of the Iraq war with the largest numbers of TBIs (2004-2008), the numbers of penetrating TBIs exceeded closed TBIs by a ratio of 2:1. During the 3-year period of the Afghanistan war with the greatest numbers of TBIs (2008-2010), the ratio of penetrating to closed TBIs was substantially lower, approximately 1.3:1., CONCLUSION: This study represents the first comprehensive report on the epidemiology of moderate-to-severe penetrating and closed TBIs resulting from the wars in Iraq and Afghanistan using Joint Theater Trauma Registry data. With the maturing theater of conflicts, penetrating TBIs were substantially less predominant compared with closed TBIs. While this finding may reflect changes in the use of protective measures and tactics or improvements in diagnosis of closed TBIs, additional research is needed to identify the reason for this shift and the subsequent effect on outcome after combat-related TBIs., LEVEL OF EVIDENCE: Epidemiologic study, level III.

4047. Orrison, W. W., Jr., et al. (1994). "MR 'hot nose sign' and 'intravascular enhancement sign' in brain death." AJNR. American journal of neuroradiology **15**(5): 913-916.

Three cases of MR with gadopentetate dimeglumine in patients diagnosed with cerebral death are presented. Observation of an MR "hot nose sign" and an "intravascular enhancement sign" provided additional imaging support in the clinical diagnosis of brain death. The MR findings in brain death include: 1) transtentorial and foramen magnum herniation, 2) absent intracranial vascular flow void, 3) poor gray matter/white matter differentiation, 4) no intracranial contrast enhancement, 5) carotid artery enhancement (intravascular enhancement sign), and 6) prominent nasal and scalp enhancement (MR hot nose sign). Additional modalities for confirming brain death are discussed.

4048. Orszagh, M., et al. (2009). "Transorbital intracranial impalement injuries by wooden foreign bodies: clinical, radiological and forensic aspects." Forensic science international **193**(1-3): 47-55.

Facial impalement injuries involve the danger of diagnostic pitfalls. Even if the penetrating object extends into the cranial cavity, the clinical symptoms and the radiological signs may be uncharacteristic. In order to illustrate the diagnostic problems, two cases of accidental impalement are reported. In both of them, a wooden foreign body penetrated via the orbita into the cranium and remained undetected at first. Imaging by CT and MRI is presented and compared with regard to the respective diagnostic validity of these methods. Due to its specific anatomic configuration, the orbita constitutes a predilective pathway for low-velocity foreign bodies entering the skull. Based on the clinical data and the radiological findings, transorbital impalement wounds inflicted by wooden objects are discussed under neurosurgical and medicolegal aspects.

4049. Ortakoglu, K., et al. (2006). "Vertical distraction osteogenesis of fibula transplant for mandibular reconstruction: a case report." Oral surgery, oral medicine, oral pathology, oral radiology, and endodontics **102**(4): e8-11.

Bone continuity defects in the mandible are caused by tumor surgery, trauma, infection, or osteoradionecrosis. Today, reconstruction of long-span mandibular defects with a free fibular flap is a routine procedure. However the bone height of the mandible after reconstruction is about half that of the dentulous mandible. Therefore, the deficiency in bone height makes implant placement impractical. In our case, because it was necessary to restore the mandibular height, a vertical distraction osteogenesis was performed on the grafted mandible of the patient who was referred to our clinic with a reconstructed mandible owing to a gunshot injury. As a result, the vertical discrepancy between the fibula and the native hemimandible of the patient was corrected. And the placement of dental implants was performed without any complications. In conclusion, we believe that the vertical distraction osteogenesis of free vascularized fibula flaps is a reliable technique that optimizes implant positioning for ideal prosthetic rehabilitation.

4050. Ortmann, J., et al. (2016). "Lethal hypothermia after firing a suicidal shot to the head in a car." Archiv fur Kriminologie **238**(5-6): 188-197.

In suicide cases involving an automobile, the car is mostly used as a tool/instrument for the suicide (intoxication by exhaust fumes, crash against solid objects such as a pylon). However, a car is uncommonly also used only as the location for a suicide. In the present case, a 70-year-old man had been found dead on the passenger seat of his car. According to witnesses, the car had not been parked there at the same time of the previous day. During that period, the weather had been dry, with temperatures ranging from -10 C at night to +50 C during the day. The man had shot himself with a small-caliber revolver (so-called bulldog-revolver) almost horizontally in the left temple (transtemporal shot through the frontal lobes). Obviously, the suicide had retained the capability to act at least for a short time, as the revolver was found under his left bottom. As morphological signs of prolonged agony some findings of hypothermia were observed (e. g. Wischnewski spots of the stomach).

4053. Oseni, A., et al. (2019). "Outcome of traumatic brain injury at a neurocritical care unit: A review of 189 patients." Southern African Journal of Critical Care **35**(1): 31-32.

Background. Traumatic brain injury (TBI) is a major public health concern, particularly in resource-constrained environments. Management focuses on neuroprotection and the prevention of both secondary brain injury and non-neurological complications. Objective. To retrospectively analyse patients with TBI admitted into neurosurgical ICU in a tertiary hospital between January 2018 and December 2018. Methods. Patients' basic demographics, mechanism of injury, admitting Glascow Coma Score (GCS), radiological findings and clinical diagnosis on ICU admission were reviewed. ICU length of stay, surgeries undergone, complications and adverse events during ICU course were also evaluated. The primary outcome was either survival or death. Results. One hundred and eighty-nine patients (n=166; 87.8% male) with TBI were admitted into the ICU over the study period. The most common mechanism of injury was interpersonal assault, accounting for 40.4% (n=86) of cases, followed by road traffic accidents (22.1%) and head gunshot wound (11.1%). Overall, 13.1% of patients developed complications during the ICU stay, most commonly respiratory (5.2%; including ventilator-associated pneumonia, lung collapse and pneumothoraxes), followed by sepsis (3.8%). The crude ICU death rate among TBI patients was 6.4%. Of the survivors, 59.7% were discharged to the step-down ward with Glascow Outcome Score (GOS) >3. There was significant correlation between admitting GCS and in-ICU mortality. Conclusion. TBI continues to have significant morbidity and mortality; however, with dedicated neurosurgical intensive care focused on preventing secondary brain injury, the immediate short-term outcome appears to have improved.

4054. O'Shaughnessy, B. A., et al. (2005). "Transarterial coil embolization of a high-flow vertebrojugular fistula due to penetrating craniocervical trauma: case report." Surgical neurology **64**(4): 335-340.

BACKGROUND: Vertebrojugular fistulas after penetrating cervical trauma (gunshot or stab wounds) are rarely reported. Successful endovascular coil embolization of an acute fistulizing vertebral artery pseudoaneurysm involving an obstructed internal jugular vein is presented and the various treatment strategies for such a lesion are described., CASE DESCRIPTION: A 23-year-old man presented from an outside institution after sustaining 2 gunshot wounds in a civilian conflict. Neuroimaging revealed a right vertebral artery pseudoaneurysm, which formed a fistulous connection with the internal jugular vein. Because venous outflow obstruction was present just below the fistula, a high-flow shunt was directed intracranially. Both the pseudoaneurysm and arteriovenous fistula were accessed percutaneously via a transfemoral route and coil embolization was performed. Perfusion of the basilar artery circulation was assumed by the contralateral vertebral artery. The ipsilateral posteroinferior cerebellar artery filled through retrograde flow down the vertebral confluence., CONCLUSIONS: Coil embolization is a safe and reliable strategy by which to obliterate an acute

traumatic vertebrojugular fistula as well as pseudoaneurysm. Serial angiographic follow-up is mandatory to document a persistent cure.

4055. O'Shaughnessy, B. A., et al. (2005). "Ruptured traumatic vertebral artery pseudoaneurysm in a child treated with trapping and posterior inferior cerebellar artery reimplantation. Case report and review of the literature." Journal of neurosurgery **102**(2 Suppl): 231-237.

The authors present the case report of a pediatric patient with a ruptured traumatic pseudoaneurysm of the intracranial vertebral artery (VA) from which the posterior inferior cerebellar artery (PICA) emerged. After considering multiple therapeutic options, the patient was treated surgically by trapping of the aneurysm segment and direct reimplantation of the PICA distal to the rupture site. In addition to presenting this unique case, the authors discuss the treatment of VA pseudoaneurysms and the various techniques for PICA revascularization. A review of the literature on PICA reimplantation is provided as an adjunct in the treatment of complex VA aneurysms.

4056. Oshry, T. and T. Lifihitz (2001). "Traumatic wound dehiscence after corneal graft." Ophthalmic surgery and lasers **32**(6): 470-473.

BACKGROUND AND OBJECTIVE: Any trauma to a corneal transplanted eye is likely to lacerate the corneal wound because of persistent wound weakness, even years after keratoplasty. We evaluate the risks and consequences of trauma after penetrating keratoplasty (PKP)., METHODS: Records of 11 patients who had been treated in our department from 1992 to 1998 for traumatic wound dehiscence after PKP were reviewed for the type of insult, visual acuity, operative methods, and outcome., RESULTS: The period between corneal grafting and wound rupture ranged from two months to three years. In 9 patients, the sutures were still in place. All the ruptures occurred at the donor-recipient interface. In 5 patients, the rupture was in the inferior half of the wound, in another 5 patients in the superior half, and in 1 patient it was nasal. In all the patients, the extent of the rupture was over 120 degrees and the lens was effected. All the patients had posterior segment involvement, the extent of which was related to the visual outcome. One eye was enucleated, another eye regrafted, and 8 of the remaining 9 grafts were restored and remained transparent., CONCLUSIONS: Despite severe trauma, most of the grafts' clarity can be restored, and good visual results can be achieved.

4057. Osiac, E., et al. (2021). "Optical coherence tomography microscopy in experimental traumatic brain injury." Microscopy research and technique **84**(3): 422-431.

Worldwide elderly traumatic brain injury (TBI) patients tend to become an increasing burden to the society. Thus, a faster and less expensive way of evaluating TBI victims is needed. In the present study we investigated if optical coherence tomography (OCT) could be used as such a method. By using an animal model, we established if OCT can detect cortical changes in the acute phase of a penetrating TBI, in young (5-7 months) and old (20-22 months) rats. Due to the long-term evolution of TBI's, we wanted to investigate to what extent OCT could detect changes within the cortex in the chronic phase. Adult (7-12 months) male rats were used. Surprisingly, OCT imaging of the normal hemisphere was able to discriminate age-related differences in the mean gray values (MGV) of recorded pixels ($p = .032$). Furthermore, in the acute phase of TBI, OCT images recorded at 24 hr after the injury showed differences between the apparent damaged area of young and aged animals. Changes of MGV and skewness were only recorded 48 hr after injury. Monitoring the chronical evolution of the TBI with OCT revealed changes over time exceeding the normal range recorded for MGV, skewness and kurtosis, 14 and 21 days after TBI. Although in the present study we still used an extremely invasive approach, as technology improves, less invasive and non-harmful ways of recording OCT may allow for an objective way to detect changes within the brain structure after brain injuries.

4058. Osian, G., et al. (2011). "[Non-ulcerous duodenal perforations: a clinical analysis of 23 cases]." Perforatiile neulceroase ale duodenului: analiza a 23 de cazuri. **106**(3): 321-325.

Non-ulcerous duodenal perforations are a rare and seldom studied pathology. The present retrospective study analyses a group of 23 patients, over a 10 year period (Jan 1st 2000 - Dec 31st 2009) with this pathology. The most frequent etiology was iatrogenic (52.17 % after ERCP and 17.39% after upper gastrointestinal endoscopy). Other rare

etiologies included were tumoral perforations, penetrating wounds, and ingestion of foreign bodies. The lesions vary from millimetric perforations to total necrosis of the wall of a duodenal segment and are often associated with other complex lesions. The overall mortality was 52.17%, a little lower for the post ERCP injuries (40%). Usually the iatrogenic lesions are diagnosed earlier (ex. 54.54% of the post ERCP lesions undergo surgery during the first 24 h), probably increasing the chance of surviving. 43.47% of cases undergo surgery in the condition of severe sepsis, with multiple organ failure, thus aggravating the prognosis. Sometimes the patient required multiple interventions (with a maximum of 8 in our group). In 26% of the cases the primary intervention was just paraduodenal and/or retroperitoneal drainage, suture of the duodenum (6 cases - 26%), usually under the protection of a gastro-enteroanastomosis (4 cases - 17.39%), suture of the duodenum around a decompression tube (26%), sometimes suture of the duodenum with a jejunal serous patch or duodeno-jejunal anastomosis. The bile drainage and the jejunostomy were associated sometimes. The procedures in this pathology have a significant morbidity, with a high rate of reinterventions (30.4%).

4059. Osifo, O. D., et al. (2012). "Epidemiology and pattern of paediatric and adolescent trauma deaths in a level 1 trauma centre in Benin city, Nigeria." Injury **43**(11): 1861-1864.

BACKGROUND: Trauma is a common cause of death amongst children/adolescents, and data on its epidemiology and pattern are crucial for policy formulation. The aim of this study was to determine the epidemiology and pattern of paediatric/adolescent trauma death in a Nigerian referral trauma centre., METHODS: The clinical and autopsy data of all paediatric/adolescent trauma death at the University of Benin Teaching Hospital between 1999 and 2010 were analysed in a retrospective study., RESULTS: Of 905 trauma-related deaths, 78 (9%) involved children/adolescents who comprised 49 males and 29 females, with a male/female ratio 1.7:1 and a mean age of 9.2 +/- 5 years (range <1-18 years). The Injury-Arrival time varied from 1h to 4 days (mean 18 h). Thirteen (17%) cases were dead on arrival (DOA), and majority of the deaths occurred within the first week on admission. Road traffic accident (RTA), accounting for 61 (78%) cases, was the leading cause of trauma death. Other causes included burns, eight (10%); gunshot injury, five (6%); and stab and sport injuries, two (3%) cases each. Head injury which occurred in 44 (56%) cases was the commonest cause of death, followed by haemorrhagic shock in 25 (32%), hypovolaemic shock in five (6%), septic shock in three (4%) and spinal cord injury in one (1%)., CONCLUSION: Head injury following RTA was the major cause of paediatric/adolescent trauma deaths. Increased road safety campaign, appropriate injury control policies, legislations, enforcement, development of high-quality trauma system, and emergency medical services are advocated.

4060. Osman, F. A. O., et al. (2022). "Isolated temporal infarct due traumatic vertebral artery dissecting pseudo-aneurysm: a rare case report." Radiology Case Reports **17**(10): 3574-3577.

The authors describe a rare case of traumatic vertebral artery dissecting pseudo-aneurysm with temporal lobe infarct in the pre-foramina segment of the left vertebral artery following knife injury of the left anterolateral neck area. A 40 years old man was admitted to the emergency department after a penetrating injury in the left anterolateral neck. On contrast-enhanced CT and Doppler ultrasonography in the neck, a dissecting pseudo-aneurysm of the vertebral artery was revealed. On day 2, MRI scanning revealed an ischemic infarct in the temporal lobe, which can be attributed to vertebral artery injury. The case was treated conservatively and the patient was discharged on the fourth hospital day. Owing to the position of the artery, traumatic vertebral artery dissections are uncommon, and they are linked with a high mortality rate due to aneurismal rupture and embolic impact of the dissections, culminating in stroke in young people. Our findings demonstrate the necessity of imaging in head and neck traumatic injuries to detect vertebral artery injuries far sooner in order to prevent complications.

4061. Osorio, J. P., et al. (2011). "Carotid-cavernous fistulae: Clinical and angiographic results in patients treated by the Neuro-radiology Group at a third-level University Hospital in Medellín, Colombia, 1995-2007." Iatreia **24**(2): 146-156.

Introduction: Carotid-cavernous fistulae are frequently found in Medellín, Colombia and their surgical treatment associates with a high rate of complications due to the peculiarities of this anatomic zone. Endovascular therapy has become the first option in patients with these lesions. Objective: to describe the main demographic, clinical and angiographic features of a group of patients with carotid-cavernous fistulae, the therapeutic approach used in them, and the results obtained from the clinical and angiographic standpoints. Patients and methods: We reviewed the clinical charts of 51 patients treated by the Neuro-radiology Group at Hospital Universitario San Vicente de Paúl, in Medellín,

Colombia, between 1995 and 2007. The following information was taken into account: demographic variables, etiology, initial and final clinical situation, therapeutic procedures, and angiographic results. Results: A total of 51 patients were found, three of which had bilateral lesions. Two patients had spontaneous resolution of their fistulae and in one more it resolved with carotid massage. Endovascular treatment was therefore carried out in only 48 patients. Average age was 35 years, and 74.5% of the patients were males. Fistulae were traumatic in 47 patients (92.2%) and spontaneous in four (7.8%). Out of the 47 traumatic fistulae, 33 (70.2%) were due to closed cranio-encephalic trauma. In 12 they were produced by firearm wounds and in two they were due to wounds with sharp instruments. In decreasing order of frequency clinical manifestations were: chemosis, proptosis, murmur, pain, decreased visual acuity and intracranial bleeding. Concerning the type of fistula (Barrow classification), they were type A in 86.0%, type B in 9.8%, type C in 1.9% and type D in 1.9%. In 32 patients (62.7%) carotid artery permeability was restored while in 19 (37.3%) occlusion was necessary. The most frequently used endovascular procedure was the balloon (34 cases) both for occlusion of the fistulous site and to carry out the trapping. Coils were used in 14 patients, stents in three and NCBA (N-butylcyanoacrylate) in four. More than one procedure was carried out in several patients. Arterial access was used in 44 cases (91.7%) and venous access in the remaining four (8.3%). Direct access by ophthalmic artery catheterization was used in two cases. Occlusion was achieved in 48 fistulae (94.1%) and a decrease in the flow in three (5.9%). Clinical follow-up, with a median of two months, revealed that 46 patients (90.2%) had complete resolution of their symptoms, four had partial resolution and one had worsening. Conclusion: This series, the largest so far published in Colombia on this subject, demonstrates the clinical and angiographic effectiveness of endovascular treatment of patients with carotid-cavernous fistulae.

4062. Ospina-Delgado, D., et al. (2018). "Characterization of 95 patients with traumatic brain injury due to gunshot wounds at a referral center in Cali, Colombia." Caracterizacion de 95 pacientes adultos con trauma craneoencefalico debido a herida por proyectil de arma de fuego en un centro de referencia en Cali, Colombia. **29**(5): 217-224.

OBJECTIVE: This study aims to describe cases of traumatic brain injury due to gunshot wounds in civilian population over 18 years of age, treated at a referral hospital in Cali, Colombia and compare the clinical outcomes at discharge., METHODS: An observational, descriptive cross-sectional study was conducted by retrospectively collecting clinical data related to adult patients that presented traumatic brain injury due to civil gunshot-wounds and that consulted to the emergency room at Fundacion Valle del Lili Hospital in Cali, Colombia between January 2010 and February of 2016. A univariate analysis was performed to determine factors associated with death and adverse clinical outcomes., RESULTS: A total of 95 patients older than 18 years, with traumatic brain injury by gunshot were included in the civil context. The 91.6% were male. The main context was interpersonal violence with 54.7%. The most common method of transportation was by ambulance (79%). The Glasgow score at admission was 3-8 in 64.2% of cases; 9-12 in 6.32% and 13-15 in 28.4%. On admission, head CT scan was performed in 82 (86.3%) patients within the first hour, finding a Marshall-Score between I-III in 60.9%, of IV in 17.8% of cases and a score between V-VI and in 4.1%. The trajectory was non-transfixing penetrating in 43.2%, transfixing in 27.3% and tangential in 9.5%. Mortality was 45.3% in total, 39% died within the first 24hours., CONCLUSIONS: A major compromise on admission determines an overall poorer prognosis and a high likelihood of death in the first 24-hours.

4063. Ossoinig, K. C., et al. (1975). "Echographic detection and localization of BB shots in the eye and orbit." Bibliotheca ophthalmologica : supplementa ad ophthalmologica(83): 109-118.

BB shots and other spherical foreign bodies produce long chains of rapidly successive echo spikes which gradually decrease in height. These patterns are specific for this type of foreign bodies and allow their reliable detection and accurate localization. A-scan echography has become a very useful addition to X-ray examination in order to determine whether such foreign bodies are intra- or extraocular. Echography also helps to localize such foreign bodies during surgery and to evaluate the posterior segment of the eye in the presence of opaque ocular media (hemorrhages, cataract). Although it is sometimes possible to demonstrate specific B-scan patterns of spherical foreign bodies, A-scan echography is the method of choice since it is faster, more reliable and more accurate.

4064. O'Sullivan, R. M., et al. (1991). "Carotid and vertebral artery trauma: clinical and angiographic features." Australasian radiology **35**(1): 47-55.

Injury to the carotid or vertebral artery is an important clinical entity that requires angiography for definitive diagnosis and evaluation. The common carotid artery may be injured by penetrating trauma while the internal carotid artery is usually damaged by either trivial or blunt trauma. With trivial trauma extracranial internal carotid artery dissection should be considered if there is unilateral headache, Horner's syndrome or delayed transient ischaemic attack, and intracranial dissection if a profound neurological defect occurs immediately following trauma. Injury to the internal carotid artery following blunt trauma includes dissection of the extracranial internal carotid artery, carotid-cavernous fistula and pseudoaneurysm formation. These should be considered in a patient with delayed neurological deficit, mandibular or skull fracture, a constellation of orbital signs or diffuse subarachnoid haemorrhage, respectively. Vertebral artery injury is less frequent. Dissection typically follows abrupt cervical rotation and occurs at C1-2, whereas penetrating trauma may involve either the proximal or distal vertebral artery and occlusion, arteriovenous fistula or pseudoaneurysm may be found. Endovascular techniques may be used in either the carotid or vertebral artery to close fistulae or occlude an extensively damaged vessel.

4065. Ott, K., et al. (1976). "Retained intracranial metallic foreign bodies. Report of two cases." Journal of neurosurgery **44**(1): 80-83.

The authors discuss two examples of extensive migration of retained metallic foreign bodies. The potential for further neurological injury from migration, formation of neurotoxic breakdown products, and the danger of infection are factors to be assessed when considering the removal of retained intracranial metallic foreign bodies.

4066. Oudega, M., et al. (1999). "Long-term effects of methylprednisolone following transection of adult rat spinal cord." The European journal of neuroscience **11**(7): 2453-2464.

Clinically, high-dose treatment with the glucocorticosteroid, methylprednisolone (MP), within 8 h after spinal cord injury, has been shown to improve neurological recovery. The current standard of care is to administer MP as a bolus of 30 mg/kg followed by a 23-h infusion of 5.4 mg/kg/h to spinal cord injured patients. To better understand the role of MP in neuroprotection, we have studied how MP administration affects macrophage accumulation, tissue loss, and axonal dieback at 1, 2, 4 and 8 weeks after a complete transection of the eighth thoracic spinal cord in the adult rat. A 30 mg/kg dose of MP was administered intravenously at 5 min, and 2 and 4 h after injury. The number of ED1 (antibody against microglia/macrophages) -positive cells was quantified in a 500-micrometer-wide strip of tissue directly adjacent and parallel to the transection. At all time points, MP treatment led to a significant decrease in the number of ED1-positive cells in both rostral and caudal stumps. Over the 2-month post-transection period, the average MP-induced reduction in the number of ED1-positive cells was 82% in the rostral cord stump and 66% in the caudal stump. Using a computerized image analysis system, it was observed that MP treatment resulted in a significant reduction in tissue loss in both cord stumps at 2, 4 and 8 week post-injury. Over the 2-month post-lesion period, the average MP-induced reduction in tissue loss in the caudal cord stump was higher than that in the rostral stump; 48 versus 37%, respectively. Immunostaining for neurofilaments and growth-associated protein-43 (GAP-43) revealed the presence of numerous axons near and in the lesion site. Anterograde neuronal tracing with biotinylated dextran amine showed that, in MP-treated animals, dieback of vestibulospinal fibres, but not of corticospinal fibres, was significantly diminished at all time points studied. In addition, with MP administration, 1 and 2 weeks after injury, an increase in the number of vestibulospinal fibres was found at 1 and 2 mm from the transection, suggesting transient regenerative sprouting of these fibres. The results demonstrate that treatment with MP shortly after spinal cord transection in the adult rat led to a long-term reduction of ED1-positive cells and spinal tissue loss, reduced dieback of vestibulospinal fibres, and a transient sprouting of vestibulospinal fibres near the lesion at 1 and 2 weeks post-lesion. The possible relationships between the inflammatory changes, spinal tissue sparing, and axonal survival and sprouting are complex and need to be further explored.

4067. Oudrhiri, M. Y., et al. (2017). "The Transcranial Stab Wound and the Life-Saving Zygomatic Arch Clinical Report." The Journal of craniofacial surgery **28**(1): 218-219.

A 58-year-old man presented to the neurosurgical emergencies for a transzygomatic transcranial stab wound with a retained broken knife. The patient was neurologically intact. After radiographic evaluation the knife was found to be penetrating the temporal lobe, neighboring the intracavernous portion of the carotid artery. The patient was successfully managed in a conservative way. No abnormalities were seen at 12 months of follow-up. Dealing with

penetrating head injuries is a usual condition in neurosurgical practice. Some situations are though really challenging, especially when the offending object is still in place, with a close connection to vital structures. This clinical reports an unusual penetrating head injury, highlighting the importance of careful radiographic evaluation and trying to discuss clear management options.

4070. Owusu-Brackett, N., et al. (2012). "Incidence and outcome of intracranial hematoma expansion in children after moderate and severe TBI." Journal of neurotrauma **29**(10): A87.

Introduction Computed tomography (CT) is integral in the early diagnosis and management of TBI. Follow-up head CT imaging is common in the management of acute intracranial hematomas after closed head injury. This study aims to quantify the temporal profile and outcome of intracranial hematoma expansion in children after TBI. Methods Patients were screened from a prospective cohort database of longterm TBI at a large level 1 pediatric trauma center. All patients were ages 0 to 13 years with a moderate or severe TBI resulting in either an epidural (EDH), subdural (SDH), intraparenchymal hematoma (IPH) and/or cortical contusion (CC). Patients with spontaneous hemorrhages, penetrating injury, non-accidental trauma or craniotomy prior to a second CT were excluded. All patients had an initial head CT scan within 12 hours of injury and at least one repeat CT scan within 72 hours from injury. An attending pediatric neuroradiologist reviewed each CT scan for lesion type, the volume of each hematoma was then determined using the ABC/2 method and compared to the baseline measurement. Hematoma progression was considered significant if the volume percent change from baseline was greater than 33%. Results 58 children met inclusion criteria, from which 181 hematomas were identified, Overall, 55/118 (46%) of hematomas increased to the threshold significance value of > 33% from baseline. There was a minor difference in the percentage of hematoma types which increased > 33% with cortical contusions increasing the most frequently and epidural hematomas the least, CC 24/42 (57%), IPH 11/23 (47%), SDH 13/37 (44%), EDH 7/16 (35%). We next examined whether the presence of hypotension or hypoxia (within 8 hours of injury) or skull fracture increased the risk for hematoma expansion. Combining all hematoma types, there was no association between hypotension, hypoxia or skull fracture with increase in hematoma size. However, Fisher's Exact Test showed a significant association between skull fracture and increase in the size of cortical contusion hematomas ($p = 0.004$). There are 31cortical contusion patients with a skull fracture, 71% of those patients had a > 33% increase in size within 72 hours. To examine the effect of hematoma expansion on functional outcome, we examined candidate predictors and 12-18 month neurologic outcome using the Glasgow Outcome Scale Extended-Pediatrics (GOSEP). Candidate predictors were field GCS, hypotension, hypoxia and > 33% increase in hematoma size. Both forwards and backwards Stepwise methods showed that hypotension ($p = 0.004$) and > 33% increase in hematoma size ($p = 0.03$) were significant predictors for outcome. Conclusions In this study of children with moderate and severe TBI we found a surprisingly high incidence of hematoma expansion after TBI. Our findings are summarized by the following: 1) cranial hematomas increased in size > 33% in 35-57% of lesions examined, 2) hypoxia and hypotension within 8 hours of injury did not appear to increase the risk for hematoma expansion 3) cortical contusions associated with skull fracture had the highest risk for expansion and 4) hypotension and > 33% increase in hematoma size are significant predictors for neurologic outcome. These findings need to be supported in larger samples, however this study adds to the evidence based practice to support safe and judicious use of head CT scans in children after TBI.

4071. Oxley, D. W. (1977). "An unusual tear-gas gun fatality." Journal of forensic sciences **22**(3): 606-609.

A case of death involving a tear-gas pen gun, firing .45 ACP metallic ammunition, is presented, in which the recoil generated by the cartridge converted the weapon into a missile, penetrating the brain of the shooter. The injury potential to shooter and shooting victim is briefly discussed, and the added hazard to the shooter illustrated by this case is noted.

4072. Oya, S. (2019). "[The Skin Findings Associated with Neurotrauma]." Brain and nerve = Shinkei kenkyu no shinpo **71**(4): 309-315.

Head trauma is a common condition, but often, serious pathological conditions associated with it are hidden. Skin findings in child abuse cases, such as skull base fracture, battle signs, raccoon eye, open head injury, penetrating wounds, traumatic aneurysm of the superficial temporal artery, traumatic carotid cavernous sinus fistula, and fat embolism have been presented in this paper. It is necessary to observe and record skin findings at the time of consultation and to listen to the detailed medical history that resulted in such an injury. It is important to comprehensively diagnose skin findings through medical history, and image inspection.

4073. Ozay, R., et al. (2017). "Trans-nasal-trans-sphenoidal brain injury by a fencing foil: an unusual case report and brief literature review." The Journal of sports medicine and physical fitness **57**(11): 1494-1498.

In this report, the authors present an unusual case of a 10-year-old child who suffered a severe headache and rhinorrhea that occurred as a result of fencing foil sports injury via trans-nasal-trans-sphenoidal (TNTS) pathway. Following trauma, the child had shown neurological symptoms such a pupil dilatation, change in consciousness and mild hemiparesia. Imaging demonstrated destruction of bone structures including posterior wall of sphenoid sinus and antero-superior part of sella turcica, and also a contusion at right thalamic region. For treatment of rhinorrhea lumbar drainage system (LDS) had planted in order to relieve cerebrospinal fluid (CSF) leakage. After the treatment, the patient had fully recovered without any need of further surgical intervention. CSF leakage had prevented and neurological symptoms were completely treated. This case represents the first report of brain injury via TNTS pathway in a sports practice. Diagnosis, clinic follow-up and treatment options of this rare accidental sports injury are discussed.

4074. Özdemir, A. and E. Orhan (2018). "An unusual transoral penetrating injury by scissors in a child and principles of management." Journal of Clinical and Analytical Medicine **9**(2): 155-157.

Injuries caused by the penetration of foreign bodies into the hard and soft tissue are called penetrating injuries. Penetrating injuries on the head and neck region are often the result of deliberate injuries performed by another person. A 4-year-old girl was admitted to the emergency room with penetrating injury due to the insertion of scissors to the right cheek. In her physical examination, it was observed that a sharp object of approximately 7cm (tip of scissors) had penetrated towards the base of the skull from the right cheek of the patient. No neurological deficits were detected. After antibiotic therapy and tetanus prophylaxis, the patient was operated on, and the penetrant object was removed. No neurological damage was detected in the postoperative 1-year follow-up.

4075. Ozdemir, M. and A. Unlu (2009). "Gunshot injuries due to celebratory gun shootings." Turkish neurosurgery **19**(1): 73-76.

UNLABELLED: Traditional shooting with guns often occurs and leads to unwanted gunshot injuries in areas where celebrations are held. Such injuries have been classified as celebratory gun shooting injury in the international disease classification system., CASE: An 8-year-old female patient presented with respiratory arrest. The heartbeats normalized upon cardiopulmonary resuscitation. On physical examination, the only pathological finding was a skin defect measuring 1 x 1 cm on the midline and located 2 cm in front of the coronal suture. Cranial CT revealed a bone defect of 0.5 cm in the area 2 cm in front of the coronal suture on the midline, tetraventricular and extensive subarachnoid hemorrhage and parenchymal hematoma in the frontal area. It was initially thought to be a gunshot injury; however, on cranial CT, no bullet fragments or bullet exit hole was observed. A cervicothoracal direct graph was obtained and an image that might have been compatible with a bullet core was detected at Th 2-3 vertebra level., CONCLUSION: Although gunshot injuries are generally well- known, this may not be a very familiar topic for neurosurgeons. The primary aim of this report is to emphasize that a bullet round randomly fired into the air ascends in reverse direction to gravity and after reaching a zero point, it returns to the ground at a high velocity that facilitates its penetration into the skull according to a principal physics law.

4076. Ozen, S., et al. (2013). "Psychiatry cases alleged as malpractice that were evaluated by the 3rd speciality board of council of turkish forensic medicine; An archival research between the years 2005-2010." Klinik Psikofarmakoloji Bulteni **23**: S200-S201.

Objective: Malpractice lawsuits are increasing in our country as well as around the world recently. Malpractice lawsuits in our country in the field of psychiatry are less than other medical branches. In a study (Pakis et al. 2008) evaluating 525 malpractice cases, which resulted in death; there were only two psychiatry cases (0.4%). Insufficient patient safety, early discharge of patients, misdiagnosis, lack of consultation, the side effects and also drug abuse due to high-dose drug usage are the common causes of malpractice complaints in abroad. There are few studies in the field of psychiatric malpractice in Turkey. Therefore in this study our aim is to evaluate the results of medico-legal malpractice cases in the field of psychiatry. Methods: This study was conducted in Istanbul, the archive records of evaluated malpractice cases by the 3rdSpeciality Board of Council of Turkish Forensic Medicine between the years 2005-2010 were reviewed and 27 cases related Psychiatry were included. Results: Eight of the grievances occurred in dispensaries and military hospitals, 7 in psychiatric hospitals, 6 in emergency services and the others were in different places. 23 of the defendants were psychiatrists and 4 of them were medical doctors from other clinics. 9 of the defendants were complained together with medical doctors from other clinics or health care workers. 16 of the defendants were male, 11 of them were female. 3th Speciality Board of Institute of Forensic Medicine's decisions about the cases were as below; in 14 of the cases there were no malpractice, in 9 of the cases there was malpractice, 3 of them couldn't be evaluated and in one of the cases must be evaluated by the court because of missing file. 16 of the victims were male and 11 of them were female. The average age of the cases was 35.1, (between 19 and 66 years old) 22 of the victims were dead, 5 of them were alive and well and one of them was disabled because of sequel of encephalitis. The autopsy was performed for 16 of dead victims and not performed for the rest of them. The boards decisions about the cause of death were as below: 7 of them couldn't be determined, 3 of them were because of pneumonia, 2 of them were due to hanging, and the others were different causes like sepsis, brain damage due to gun shot injury, gastric perforation and hemorrhage due to taking a corrosive substance, myocardial infarction, cardiac arrest due to taking haloperidol, cardiovascular disease resulting pulmonary edema, cerebral hemorrhage, blunt head-abdominal and thoracic trauma, penetrating thoracic injury, general body trauma due to jump from a height. Conclusion: Most of the victims were young adults. Most of the complaints about Psychiatric malpractice were cases with death. Therefore psychiatrists have to do a detailed evaluation, be careful and intentive about requested consultations from emergency services or other clinics, exclude the organic etiology and also be aware of the risk of suicide.

4077. Ozen, S., et al. (2013). "Psychiatry cases alleged as malpractice that were evaluated by the 3rd Speciality Board of Council of Turkish Forensic Medicine; an archival research between the years 2005-2010." Bulletin of Clinical Psychopharmacology **23**: S201.

Objective: Malpractice lawsuits are increasing in our country as well as around the world recently. Malpractice lawsuits in our country in the field of psychiatry are less than other medical branches. In a study (Pakis et al. 2008) evaluating 525 malpractice cases, which resulted in death; there were only two psychiatry cases (0.4%). Insufficient patient safety, early discharge of patients, misdiagnosis, lack of consultation, the side effects and also drug abuse due to high-dose drug usage are the common causes of malpractice complaints in abroad. 4078. Ozer, S., et al. (2010). "Craniocerebral injury resulting from pencil penetration." European archives of oto-rhino-laryngology : official journal of the European Federation of Oto-Rhino-Laryngological Societies (EUFOS) : affiliated with the German Society for Oto-Rhino-Laryngology - Head and Neck Surgery **267**(1): 155-157.

Penetrating craniofacial trauma in pediatric age group is quite rare. A case is reported that presented with a pencil penetration injury entering from the anterior maxillary sinus through the orbital medial wall, and ethmoidal cells and septum, reaching the contralateral gyrus rectus of the frontal lobe. All the vital structures were preserved. The patient was first treated with manual extraction of the pencil, without any immediate complications; however, rhinorrhea followed the procedure 4 h later. Early endoscopic surgical intervention was performed and the rhinorrhea was successfully treated in this case. This report discusses radiological and surgical characteristics of this unusual penetrating craniofacial trauma.

4079. Őzgenel, G. Y. and M. Özcan (2004). "Two-stage reconstruction of a massive gun-shot wound of the midface with a free radial forearm flap and a parietal osteofasciocutaneous flap." European Journal of Plastic Surgery **27**(4): 200-203.

Treatment of midface gunshot injuries and their reconstruction remains one of the difficult problems of reconstructive surgery. Several flaps have been described for the reconstruction of total lip and nasal defects. We present a case of a gunshot wound to the midface in which a two-stage procedure was performed. In the first stage, a free radial forearm flap was successfully transferred for the reconstruction of the total nose. In the second stage, total upper lip reconstruction was achieved using a parietal osteofasciocutaneous flap pedicled to the parietotemporal fascia based on the superficialis temporal artery. At a mean follow-up period of 18 months, near-normal functional and cosmetic results were obtained. © Springer-Verlag 2004.

4080. Ozkan Arat, Y., et al. (2015). "Cerebrovascular complications of transorbital penetrating intracranial injuries." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES **21**(4): 271-278.

BACKGROUND: Cerebrovascular trauma secondary to transorbital intracranial penetrating injury (TIPVI) is rare. Relatively benign initial presentation may mask the underlying life-threatening vascular injury in transorbital intracranial penetrations. The aim of this study was to evaluate clinical features and endovascular treatment of TIPVI., METHODS: Six patients with angiographic documentation of TIPVI in subacute/chronic phase were reviewed retrospectively. Five were treated endovascularly; however endovascular treatment was aborted in one and conservative management was pursued., RESULTS: Except for one case presenting with vision loss and mild stroke, no significant neurologic deficit was present. Vascular lesions included two cases of carotid-cavernous fistulas, three traumatic aneurysms of cavernous carotid, anterior and middle cerebral arteries and a unique case of coalescing cavernous aneurysms following a through-and-through injury in which the aneurysms united within the thrombosed cavernous sinus on follow up. Fistulas were treated with covered stents, aneurysms with parent artery occlusion or flow diverters. All patients had uneventful recoveries., CONCLUSION: TIPVI may present in a delayed fashion after a seemingly benign presentation. A high index of suspicion is critical to rule out TIPVI with vascular imaging. Transcatheter angiographic techniques allow for both diagnosis and treatment of TIPVI with favorable results.

4081. Ozkan, O., et al. (2004). "Simultaneous reconstruction of large maxillary and mandibular defects with a fibular osteocutaneous flap combined with an anterolateral thigh flap." Journal of reconstructive microsurgery **20**(6): 451-455.

This article reports the simultaneous reconstruction of maxillary and mandibular defects caused by a close-range gunshot blast to the face with one fibular osteocutaneous flap combined with an anteroateral fasciocutaneous flap. A fibular osteocutaneous flap was used for both mandibular and maxillary defects, using multiple osteotomies and discarding a central bony segment and an oral floor defect. An anterolateral thigh flap was used to cover a three-

dimensional defect of both the intraoral mucosal region, as well as external skin and soft tissue defects, including some on the upper and lower lips. The results demonstrated that the method was a good choice in the reconstruction of large composite facial defects, both aesthetically and functionally.

4082. Ozkan, O., et al. (2018). "Face allotransplantation for various types of facial disfigurements: A series of five cases." Microsurgery **38**(8): 834-843.

BACKGROUND: The aim of this report is to present our long-term experiences with a series of 5 face-transplanted patients in terms of surgical aspects and postoperative outcomes, and to describe possible salvage strategies in case of difficulties., METHODS: Five patients, 4 receiving full-face transplantation and 1 undergoing partial transplantation at our institution were included. The patients were aged between 19 and 54 years. Two had extensive burn scars to the face, and 3 had suffered gunshot injuries. The post-transplant induction immunosuppressive regimen included ATG combined with tacrolimus, mycophenolate mofetil, and prednisone, while maintenance was provided by the last 3. We focused on patient summaries including their etiologies, preoperative preparations, surgical techniques, immunosuppressive regimen, postoperative courses, revisional surgeries, together with challenges including acute rejection episodes, and immunosuppressive drug complications., RESULTS: No re-surgery due to vascular compromise was required in any case. One of the 5 patients was eventually lost due to complicated infectious and metabolic events at the end of post-transplantation month 11. The other 4 patients were still alive, with a mean follow-up time of 53 months and had satisfactory functional transplants and cosmetic appearance., CONCLUSIONS: Face transplantation still involves challenges and many issues including compliance and psychological maturity of patients, the risk of opportunistic infections and malignancies still need to be resolved for it to be accepted as a safe procedure. Surgical rescue procedures considering ideal timing should be kept in mind strictly as one of the most important issues in case of unexpected events. Copyright © 2017 Wiley Periodicals, Inc.

4083. Ozkan, U., et al. (2002). "Analysis of 107 civilian craniocerebral gunshot wounds." Neurosurgical review **25**(4): 231-236.

In this study, we present a retrospective analysis of 107 cases due to civilian craniocerebral gunshot wounds that were treated by the medical faculty of Dicle University during a period of 7 years (January 1993 to January 2000). Twenty patients died at the hospital, and the deaths were determined to result from direct effects of brain damage. Coma was the best prognostic guideline. Diffuse brain damage and ventricular injury, particularly infections, were associated with poor outcome.

4084. Ozkan, U., et al. (2006). "Spontaneous migration of a bullet into the brain." Clinical neurology and neurosurgery **108**(6): 573-575.

We report the case of a 20-year-old man with a gunshot injury as an example of spontaneous migration of a metallic foreign body within the brain. Computed tomography (CT) showed the bullet in the left temporoparietal region. At 10 days follow-up, CT revealed that the bullet had migrated posteriorly, due to the effect of gravity, lodging in the occipital lobe. Although there are a few literature reports of spontaneous migration of a bullet within the brain, this case was unique as the patient was fully conscious without any neurological deficit.

4085. Ozoilo, K. N., et al. (2012). "The conundrum of polytrauma on the jos plateau." West African journal of medicine **31**(1): 52-57.

BACKGROUND: The leading cause of morbidity and mortality from the end of the first year of life to the forty fifth is trauma. This is true worldwide but especially so in our environment. In no other situation are the complexities of the management of trauma more manifest than in the context of polytrauma. For this we undertake to study the problem of polytrauma in Jos., AIMS AND OBJECTIVES: To determine the frequency and pattern of occurrence of poly trauma in Jos university teaching hospital., PATIENTS AND METHODS: Consecutive patients presenting with polytrauma to the casualty department were prospectively studied. Data regarding demographics and a detailed description of injuries were entered into a proforma and collated over a one-year period., RESULTS: A total of 131 patients were studied. There were 103 males and 28 females giving a male to female ratio of 3.7:1. The ages ranged from 2 to 61 years with a mean of 28.4 +/- 12.4 years. Road traffic accident was the most common aetiology in 113 (86.3%) patients, while

falls 7 (5.3%), gunshots 5 (3.8%) and assaults 2 (1.6%) were observed. The most frequently encountered injuries were head, extremity and chest in 71.8%, 68.5% and 29.2% respectively. The combinations most frequently observed were head\extremity (43.5%), head\chest (17.6%) and chest\extremity (10.7%) injuries. Complications were observed in 20.6% while death occurred in 7.6%., CONCLUSION: Polytrauma occurs with sufficient frequency to warrant serious attention. As majority follow RTA, there is a need to intensify measures aimed at improving road safety. There is also a need to establish pre-hospital care\ambulance services. It is suggested that improved orthopaedic and neurosurgical care will lead to improved polytrauma care and most importantly, the establishment of dedicated trauma teams in tertiary institutions is proposed as a prelude to the establishment of regional trauma centers.

4086. Özsoy, S. and H. Tugcu (2016). "The keyhole lesion." Romanian Journal of Legal Medicine **24**(4): 257-260.

Determining the entrance and exit wounds in gunshot injuries is important for forensics. Although the gunshot wounds have a round or oval image, there might also be atypical entrance wounds as well. When the firearm bullet hits the cranium with an acute angle or in a tangential manner, there might occur fractures in the bevelled-out hole on the outer table; and the defect called “keyhole lesion”, which is rare, might occur. In this paper, the autopsy findings of a case with a gunshot wound that had atypical entrance wound in the shape of “keyhole lesion” have been presented. The bone flaps extracted with craniectomy are stored either in the body of the patients (by placing in the stomach or below the quadriceps) or in deep freezers. Especially in cases that have bone defects due to gunshot wounds, the bone flap must be stored after being photographed in detail in order to prevent the findings from being lost. In cases that have bone defects due to gunshot wounds, the distinction of the entrance and exit wounds may be performed after the examination of the bones.

4087. Pabon, M. M., et al. (2016). "Brain Region-Specific Histopathological Effects of Varying Trajectories of Controlled Cortical Impact Injury Model of Traumatic Brain Injury." CNS neuroscience & therapeutics **22**(3): 200-211.

AIMS: Traumatic brain injury (TBI) occurs when the head is impacted by an external force causing either a closed or penetrating head injury through a direct or accelerating impact. In laboratory research, most of the TBI animal models focus on a specific region to cause brain injury, but traumatic injuries in patients do not always impact the same brain regions. The aim of this study was to examine the histopathological effects of different angles of mechanical injury by manipulating the trajectory of the controlled cortical impact injury (CCI) model in adult Sprague-Dawley rats., METHODS: The CCI model was manipulated as follows: conventional targeting of the frontal cortex, farthest right angle targeting the frontal cortex, closest right angle targeting the frontal cortex, olfactory bulb injury, and cerebellar injury. Three days after TBI, brains were harvested to analyze cortical and hippocampal cell loss, neuroinflammatory response, and neurogenesis via immunohistochemistry., RESULTS: Results revealed cell death in the M1 region of the cortex across all groups, and in the CA3 area from olfactory bulb injury group. This observed cell death involved upregulation of inflammation as evidenced by rampant MHCII overexpression in cortex, but largely spared Ki-67/nestin neurogenesis in the hippocampus during this acute phase of TBI., CONCLUSION: These results indicate a trajectory-dependent injury characterized by exacerbation of inflammation and different levels of impaired cell proliferation and neurogenesis. Such multiple brain areas showing varying levels of cell death after region-specific CCI model may closely mimic the clinical manifestations of TBI.

4088. Pabuscu, Y., et al. (2003). "A different approach to missile induced head injuries." Computerized medical imaging and graphics : the official journal of the Computerized Medical Imaging Society **27**(5): 397-409.

Missile induced head injuries can be influenced by the anatomical location of the injury, i.e. type of tissue and by the ballistic properties such as the design of the weapon and the mass, shape and construction of the projectile, as well as its velocity characteristics and trajectory angle. In the diagnostic work up of the patients with missile induced head injuries, every available modality can be used. It is important, however, to recognize that CT scan is the primary and most efficacious diagnostic tool in such patients. In this article we have identified risk factors for both morbidity and mortality in patients with missile induced head injury with excluding the patients who had also extracranial serious trauma and systemic disease.

4089. Padalino, P., et al. (2006). "[Analysis of quality in a first level trauma center in Milan, Italy]." Analisi di qualita di un trauma center di I livello nella citta di Milano. **77**(2): 97-106.

BACKGROUND: In Italy there isn't a State Trauma System. Many attempts have been done to increase the quality of trauma care in prehospital and hospital phases, but only by local resources. In Mila (Italy)o Emergency Medical System is organized by Regional rules and five Hospitals warrant high level of care for trauma patients. There isn't an official registry for trauma. Creating a Trauma Registry is the prerogative to analyse the quality of assistance and to propose new solutions., OBJECTIVES: To analyse major trauma patients admitted to Ospedale Maggiore Policlinico IRCCS; to evaluate diagnostic and therapeutic protocols in order to identify preventable deaths., PATIENTS: We have observed trauma patients admitted to Ospedale Maggiore from January to December 2004. We collected demographic data, informations about the traumatic event and prehospital rescue, emergency room examination, diagnostic exams, surgical operations and results of treatment. We selected patients admitted among 6917 trauma patients observed in this period. We have calculated RTS, ISS and TRISS. Patients were followed during their staying at the hospital to record length of staying, lenght of ICU and mortality rate. We collected the autopsy of the all death patients., RESULTS: We selected 299 patients, 207 males and 92 females. Mean age was 42.4 +/- 19.5 for males (range 15 - 99) and 57.7 +/- 22.5 for female (range 7 - 101). Motorvehicle and road incident were the main cause of trauma (55.5%). A penetrating injury was observed only in 5% of cases. Mean RTS was 7.5 +/- 1. ISS and TRISS were (mean +/- SD) 13 +/- 9 and 94.9% +/- 11.5, respectively. Patients with ISS = 16 were 109 (36.4%). Forty five patients (15%) required a surgical treatment during the first 48 hours. Total length of staying was 8.9 +/- 11.2 (mean +/- SD) days (median of 5.5 days) and the length of ICU was (mean +/- SD) 11.7 +/- 10.3 days (median 9 days). 12 patients died (mortality rate 4.08%), 11 at Policlinico (2 in the emergency room, 3 in the operative room, 5 in ICU. One patient died in surgical ward), 1 at Ospedale Niguarda. Autopsy was available for 8 patients. In 2 cases the cause of death was established by clinical examination and in 1 case police are still investigating for poisons or other letal drugs. The main cause of death was the cerebral injury. Only for 1 patient it was impossibile to determine the cause of death so he was considered a potentially preventable death. His clinical RTS in the emergency room was 12 (7,4808 in the statistical analysis) and no severe lesions were observed during primary and secondary survey., CONCLUSIONS: Our data are typical of an urban area of a western country. Penetrating injury are very rare, 5% of incidence. Diagnostic and therapeutic protocols are similar to countries where a Trauma Center is active. The 4% of overall mortality rate is similar to Trauma Centers in USA. This result is better than other hospitals in Milan. The high number of ATLS providers in the trauma team could be one of causes of good results. Quality audit can't consider only RTS, ISS and TRISS. Scores are very practical and useful but they aren't enough. We must analyse every single case of death and Trauma Registry is the first tool to evaluate trauma care in a modern EMS.

4090. Padar, S. C. (1975). "Air gun pellet embolizing the intracranial internal carotid artery." Journal of neurosurgery **43**(2): 222-224.

4091. Padosch, S. A., et al. (2006). "Two simultaneous suicidal gunshots to the head with robbed police guns." Forensic science international **158**(2-3): 224-228.

The suicidal infliction of two gunshot wounds to the head represents a critical issue for medicolegal investigation. In principle, simultaneous infliction with two firearms or third parties' involvement, i.e. two consecutive gunshots, have to be considered. We report for the first time on a case of suicidal infliction of two simultaneous gunshots to the head (oral, temporal) with Action 4 expanding ammunition. A male had robbed two service guns and committed suicide thereafter under the influence of high-dose alcohol and cocaine. Interestingly, Action 4 ammunition had been used, leading to an uncommon gunshot wound morphology and extensive backspatter. At the scene, these findings caused confusion; moreover, the number of gunshot wounds was unclear, until autopsy revealed two gunshot wounds to the head, which had obviously been inflicted simultaneously. Expanding ammunition like QD-PEP and Action 4, used by several German federal state police forces, can cause an atypical gunshot wound morphology, most probably due to its peculiar deformation behaviour. Investigators should be careful when interpreting gunshot wound morphology at the scene after usage of such expanding ammunition. With regard to reconstruction in cases of two gunshot wounds to the head and two guns at the scene, two simultaneous gunshots should be taken into consideration.

4092. Padosch, S. A., et al. (2004). "[Medicolegal aspects of witnessed suicide due to gunshot to the head. Part 1: Circumstances and psychopathology]." Rechtsmedizinische Aspekte des Suizides durch Kopfschuss vor Zeugen. Teil I: Umstande und psychopathologische Befunde. **214**(3-4): 65-76.

In the USA the frequency of witnessed suicide, i.e. suicide committed in the presence of at least one further individual, is reported to range between 5 and 15%. As up to now no detailed analysis of this special issue has been given in the medicolegal literature, this article presents and discusses a number of cases including 8 males and 1 female (age 19-58 years, mean 41.2 years) who had all committed suicide by inflicting a gunshot to the head. In 3 cases post-mortem blood alcohol concentrations of 1.73, 1.88 and 2.23 g/kg respectively were observed. Toxicological tests produced negative results. 5 cases had a medical history of psychiatric disorder with endogenous depression in 3, chronic alcohol abuse and drug abuse with concomitant psychosis in one case each. As far as the motives were known, domestic arguments were of prevailing importance. With one exception the suicides were committed at home. In 6 cases one witness was present, in 2 cases 2 individuals and in one case 22 persons witnessed the suicide. The reported cases are discussed in comparison with the psychiatric-psychological classification according to McDowell et al. with the aim to provide a solid and comprehensive medicolegal method to distinguish between homicide and suicide. Furthermore aspects of psychiatric sequelae and psychological support of the witnesses, which are also of importance for the forensic pathologist called to the scene, are discussed.

4093. Padosch, S. A., et al. (2003). "Planned complex suicide by self-poisoning and a manipulated blank revolver: remarkable findings due to multiple gunshot wounds and self-made wooden projectiles." Journal of forensic sciences **48**(6): 1371-1378.

A remarkable case of complex suicide with poisoning and multiple self-inflicted gunshot wounds to the head is reported. After ingestion of a liquid insecticide, the victim shot himself twice in the head, once in each temple. Self-manufactured wooden dowels were used as projectiles in combination with conventional blank cartridges. The dowels had been glued on top of the blank cartridges and expelled by propellant gases. Moreover, the blank revolver used had been extensively manipulated in a rarely observed manner. Several occlusive devices had been removed from the barrel and the cylinder chamber to enable the expulsion of the wooden projectiles. The investigation of the methods used and the circumstances found at the scene pointed towards a planned complex suicide. A remarkable case with unusual projectiles, i.e., wooden dowels, fired by an extensively manipulated blank gun is reported, emphasizing the importance of close collaboration between the police firearm laboratory and forensic pathology in practical casework.

4094. Padure, A., et al. (2015). "Homicide committed by a person with mental disorders." Rechtsmedizin **25**(4): 411-412.

Assessment of legal responsibility of persons who commit crimes against other human life is absolutely necessary in order to guarantee the protection of human rights and society in general. It is well known that people with mental disorders could have unpredictable reactions and crimes committed by them often exceed limits of the imagination, as it is illustrated by the following case. According to the prosecution data on February 4, 05:00, the cadaver of 56 years-old-woman was found at her own home with multiple injuries caused by a sharp object. The eyeballs were enucleated and placed in a glass of water. During the body examination the following were established: two metal knives were stuck in the orbit of the right eye and left ear duct; enucleation of the both eyeballs and removal of eyelids; stab wound at the right orbit level, penetrating into the cranial cavity with meningeal and brain damage; stab wound with the entrance orifice in the left ear duct and the exit orifice below the right auricle lobe; a cut wound of the throat with anatomical damage of all structures; 114 stab wounds penetrating the chest, the abdomen and the back with injuries of the lungs, heart, liver and small intestine; posthumous cut wound of the abdomen going to external genitals and anus with the small intestine evisceration; posthumous amputation of both hands and left foot; signs of hemorrhagic shock. It was concluded that death occurred as a result of hemorrhagic shock caused by cut wound of the throat and stab wounds of the body. The criminal investigation identified the victim's husband as perpetrator. Psychiatrists considered him being without discernment at that moment when crime took place. Crimes committed by the people with mental disorders are usually characterized by a special cruelty. Hospitalization of a patient with mental disabilities who presents a danger to himself or others, or those who have committed crimes against other people is made coercively. This enters in accordance with the instruments of international law because the individual's right to life prevails over the right of mentally ill people to selfdetermination.

4095. Pagni, C. A. and F. Zenga (2006). "Prevention and treatment of post-traumatic epilepsy." Expert review of neurotherapeutics **6**(8): 1223-1233.

Post-traumatic epilepsy is reported after 2-5% of closed head injuries but up to 50% or more following penetrating head injury. Despite several studies, no drug strategy has been able, to date, to quench the biochemical events leading to epileptogenesis. One possibility is that treatment with available antiepileptic drugs has been implemented too late, and thus, ultra-early treatment might still be able to stop the neurochemical epileptogenic cascade dead in its tracks. However, currently drug therapy should be instituted only after the first late unprovoked seizure.

Penetrating injury of the skull and brain are relatively uncommon events, representing about 0.4% of all head injuries. Transorbital penetrating brain injury is an unusual occurrence in emergency practice and presents with controversial management. We report the case of a 10-year-old boy who fell forward on a bamboo stick while playing with other children, causing a penetrating transorbital injury, resulting in meningitis. We performed a combined surgical approach with neurosurgeons and ophthalmogic surgeons. Upon discharge, the patient had a Glasgow Coma Scale score of 15, no motor deficit and no visual loss. We discuss the management of this case and review current literature. © 2010 Paiva et al.

INTRODUCTION: Penetrating injury of the skull and brain is relatively uncommon, representing about 0.4% of head injuries. In this paper the Authors describe a case of patient victim of transorbital stab with brain injury with good recovery and review the literature about cranial stab wound., CASE REPORT: A 23-year-old man was involved in an altercation which resulted in the patient sustaining wounds to the head, with penetrating in left transorbital, affecting the eye. At arrival to the first trauma center the patient was conscent and complete responsive with 15 points in Glasgow Coma Scale, and motor deficit grade III. CT scan demonstrated left periventricular brain hematoma and supraorbital fracture. A four-vessel cerebral angiogram demonstrated no abnormality. In this evolution patient presented good neurologic outcome., CONCLUSION: In patients conscents with no surgical lesion like our patient, the hospital discharge must occur after the angiogram have excluded intracranial vascular lesion.

Reversible myocardial dysfunction is known to occur in patients with cerebrovascular accidents and brain death. Several mechanisms for transient myocardial dysfunction have been proposed, including increased sympathetic activity, hormone depletion, and a reduction in coronary perfusion pressure. The relative importance of each of these mechanisms remains controversial. We report the case of a 19-year-old man who suffered traumatic brain death

associated with reversible myocardial dysfunction despite elevated cardiac enzymes. Myocardial recovery occurred after correcting his hemodynamic instability and hypothermia emphasizing the importance of normalization of coronary perfusion pressure and core body temperature. The mechanisms for reversible myocardial dysfunction and their implications for heart transplantation following traumatic brain death are reviewed. A diagnostic strategy is proposed that would allow early recognition of reversible myocardial dysfunction in brain-dead patients.

INTRODUCTION: No national recording systems for knife injuries exist in the UK. Understanding the true size and nature of the problem of knife injuries is the first stage in reducing the burden of this injury. The aim of this study was to survey every knife injury seen in a single inner city emergency department (ED) over a one-year period., METHODS: A cross-sectional observational study was performed of all patients attending with a knife injury to the ED of a London major trauma centre in 2011. Demographic characteristics, patterns of injury, morbidity and mortality data were collected., RESULTS: A total of 938 knife injuries were identified from 127,191 attendances (0.77% of all visits) with a case fatality rate of 0.53%. A quarter (24%) of the major trauma team's caseload was for knife injuries. Overall, 44% of injuries were selfreported as assaults, 49% as accidents and 8% as deliberate self-harm. The highest age specific incident rate occurred in the 16-24 year age category (263/100,000). Multiple injuries were seen in 19% of cases, of which only 81% were recorded as assaults. The mean length of stay for those admitted to hospital was 3.04 days. Intrathoracic injury was seen in 26% of cases of chest trauma and 24% of abdominal injuries had a second additional chest injury., CONCLUSIONS: Violent intentional injuries are a significant contributory factor to the workload of the major trauma team at this centre. This paper contributes to a more comprehensive understanding of the nature of these injuries seen in the ED.

4104. Palm, H. G., et al. (2011). "[Vacuum-assisted closure of head and neck wounds]." Vakuumversiegelungstherapie im Kopf-Hals-Bereich. **59**(8): 819-830.

OBJECTIVE: Since the early 1990s, vacuum-assisted closure (VAC) therapy has been used to treat acute and chronic wounds in almost all disciplines of surgery in Germany. Taking this into consideration, the use of vacuum therapy in the area of head and neck surgery was examined., METHODS: A literature review using MEDLINE (with PubMed) and EMBASE as well as a Cochrane search was performed on 15 December 2010. Search terms included "vacuum therapy", "vacuum-assisted closure", "V.A.C.", "VAC", "(topical) negative pressure (wound therapy)"., RESULTS: There were 1,502 peer-reviewed articles about "vacuum therapy" concerning all medical fields in literature. There were a total of 37 publications from the discipline of head and neck surgery (538 patients). Although benefits for the patients are consistently reported, these results are usually presented only in case reports or case series (evidence level IV and V). Positive results are mainly observed for the treatment of lifting defects in reconstructive surgery and for the treatment of acute and chronic soft tissue defects of the neck. Only little experience exists in the vacuum therapy of war wounds in the head and neck region., CONCLUSION: Due to its advantages (i.e., hygienic temporary wound care with support of the continuous decontamination, wound drainage, promotion of granulation tissue formation, and effective wound conditioning), VAC is an integral and indispensable part of modern wound treatment. Analogous to this general experience, a benefit must also be assumed for head and neck wounds. High-quality and reliable studies on the use of VAC must be performed to verify this observation and the future reimbursement of in- and outpatient wound VAC treatment.

4105. Palmer, J., et al. (2017). "Successful management of a gun shot wound to the mandibular condyle by removal of the condylar head with no hard tissue reconstruction - Lessons for blunt trauma management?" British Journal of Oral and Maxillofacial Surgery **55**(10): e129.

Introduction: The decision to operatively fix the mandibular condyle in closed blunt trauma is frequently discussed within the management of complex craniofacial reconstruction. Gunshot injuries to the condylar region are rare due to the site and size of the TMJ. Reconstruction of the resected condyle would be conceptually required to restore both the length of the posterior mandible and the articular surface. We present a case where the entire mandibular condyle was removed, and following intermaxillary fixation required no further management. Case report: A 23-year-old male presented following a low energy gunshot wound to his left preauricular region. The patient was unable to open his mouth and CT scans demonstrated a destroyed left mandibular condyle and neck of condyle with a retained metallic fragment. At surgery the metal casing and bone fragments were removed via a preauricular approach. Access was gained to the superficial infratemporal fossa by means of an eminectomy. Hewas placed inIMFand at fourteen days post operatively was found to have 42mm inter-incisal mouth opening and a normal dental occlusion. Discussion: This patient has achieved a functional, painfree occlusion with good mouth opening despite a missing condyle and neck. There is likely to have been considerable functional compensation of the neuromuscular apparatus in order to achieve this, but the fact remains that he has achieved a surprising result. This case teaches us the principles of gunshot injuries of the TMJ, but in addition reminds us that anatomical reconstruction of the TMJ is not always required.

4110. Panata, L., et al. (2017). "A crossbow suicide." Forensic science international **281**: e19-e23.

The crossbow is an ancient ranged weapon originally conceived for war and hunting. Although nowadays its use in warfare has been surpassed by firearms, it continues to be used in hunting, sports and recreation. The authors present the case of a 40-year-old man who suffered from severe depression. When his condition further deteriorated, doctors ordered a forced hospitalization but, just a few hours before the measure became effective, the man committed suicide using a crossbow. The autopsy and police investigation showed possession of the crossbow darts which the man used to shoot himself in the head. The forensic pathologist found the dart stuck in the skull: the entry wound was in the suprahyoid region while the arrow tip emerged in the left parietal region meaning the arrow crossed the tongue, the middle fossa, the brain and the cranial wall. All the wounds presented a three-pointed star shape consistent with the three sharp blades of the dart. An extensive blood infiltration affected the subdural and subarachnoid space, particularly where the dart had passed. The severe brain injury, extensive subdural and subarachnoid bleeding and brain swelling following the trauma caused the death. Even though the use of the crossbow is only permitted in sporting/hunting

contexts, the reported case highlights the sharp contrast between its potential for harm and the easy access to this kind of weapon, even for those affected by mental illness.

A perforating head injury is a type of an injury wherein the projectile passes entirely through the cranium leaving both entrance and exit wounds. It is considered less prevalent than other kinds of head trauma such as closed or penetrating head injuries carry a worse prognosis among other varieties of head injuries. Having unique mechanism and pathophysiology it is considered a significant challenge for the practicing neurosurgeon mandating high precaution and novel approach to minimize further damage. Here, we presented a case of a 5-year-old boy who suffered from perforating brain injury by a fallen rusty steel bar.

4114. Pandya, J., et al. (2017). "Temporal and regional changes in brain mitochondrial bioenergetics following penetrating ballistic-like brain injury in rats." Journal of neurotrauma **34**(13): A22.

Mitochondria play a pivotal role in the secondary pathophysiological sequelae following traumatic brain injury (TBI) and thus are leading targets for therapeutic interventions. The current study is designed to characterize the temporal and regional post-injury responses of mitochondrial energy crisis up to 14 days following penetrating ballisticlike brain injury (PBBI) in rats. Adult male rats were subjected to either 10% unilateral PBBI or Sham craniotomy (n = 6/group). At 30 min, 3 h, 6 h, 24 h, 3 d, 7 d and 14 d post-PBBI, mitochondria were isolated from the ipsilateral hemisphere of two brain regions: the injury core, i.e. frontal cortex + striatum (FC+ST) and a region distant from the injury core, i.e. hippocampus (HIP). Mitochondrial bioenergetics parameters were measured using a high-throughput procedure of the Seahorse Flux Analyzer. The time-course of FC+ST mitochondria showed a biphasic energy dysfunction response, indicated by a decline in ATP synthesis and maximum respiratory capacity. The first phase of energy crisis started immediately at 30 min (-42%; $p < 0.05$ vs. Sham) and attained baseline levels between 3 h to 6 h (nonsignificant vs. Sham), followed by a second phase of more robust energy crisis observed between 24 h to 14 d post-injury (-55% to-90%; $p < 0.05$ vs. Sham). In contrast, the HIP mitochondria showed a significantly delayed decline in mitochondrial bioenergetics parameters at 7 d (-74%; $p < 0.05$ vs. Sham) and 14 d (-51%; $p < 0.05$ vs. Sham) post-PBBI. Collectively, PBBI produced temporal and regionspecific alterations in mitochondrial bioenergetics that are unique to the penetrating, temporary cavity mechanism. More importantly, the results underscore an extended therapeutic window (between 3 h to 24 h post-injury) for mitochondria targeted intervention following PBBI.

4115. Pandya, J., et al. (2016). "Identification of preferred substrates of mitochondrial energy metabolism following penetrating ballistic-like brain injury." Journal of neurotrauma **33**: A118.

Mitochondria constitute a central role in brain energy metabolism, and play a pivotal role in the development of secondary pathophysiology and subsequent neuronal cell death following traumatic brain injury (TBI). Under normal circumstances, brain consumes glucose as the preferred energy source for adenosine triphosphate (ATP) production over ketones. However following TBI, the ATP synthesis rates of glucose intermediate metabolites (i.e. pyruvate, glutamate and succinate) and ketones (i.e. bhydroxybutyrate) have not been individually compared. We hypothesize that TBI leads to an overall decline or metabolic shift in the utilization of these substrates for the ATP production. Adult male rats were subjected to either 10% unilateral penetrating ballistic-like brain injury (PBBI) or Sham craniotomy (n = 5

per group). At 24 hours post-injury, mitochondria were isolated from pooled brain regions (frontal cortex and striatum) of the ipsilateral hemisphere. MitochondrialATP synthesiswas measured usingClark-type oxygen electrode in the presence ofmetabolic substrates pyruvate +malate (PM), glutamate + malate (GM), succinate (Succ) and b-hydroxybutyrate + malate (BHBM). As compared to Sham group, the PBBI group showed a reduction in ATP synthesis with PM (-43%, $p < 0.05$); GM (-42%, non-significant); Succ (-50%, $p < 0.05$) and BHBM (-44%, $p < 0.05$). Next, we compared the ATP synthesis rates of the four substrates within the experimental group. In the Sham group, the BHBMshowed significantly less ATP synthesis than the other substrates (PM = GM = Succ > BHBM, $p < 0.05$). In the PBBI group, the ATP synthesis of PM, Succ and BHBM were significantly distinct amongst each other (PM > Succ > BHBM, $p < 0.05$). Additionally, the ATP synthesis of PM and GM were identical, and were the highest amongst the four substrates tested. Collectively, PBBI leads to an overall reduction and metabolic shift in the intermediate substrates utilization for the ATP production. These results provide a strong basis for the use of neutraceuticals as “alternative biofuels” for higher energy production following brain trauma.

4116. Pandya, J., et al. (2022). "IMPAIRMENT OF MITOCHONDRIA TARGETED POSTINJURY MECHANISMS IN THE RAT MODEL OF PENETRATING TBI." Journal of neurotrauma **39**(11-12): A42.

Mitochondrial dysfunction is a commonality among various severity of traumatic brain injury (TBI) that leads to secondary injury progression. Abnormal mitochondrial function following TBI includes impaired energy, Ca2+ and redox homeostasis. Oxidative stress further causes irreversible oxidative modifications of biomembrane components, alters membrane integrity and triggers apoptosis. The current study evaluates the mitochondria targeted post-injury mechanisms following penetrating TBI (PTBI). Anesthetized adult male rats were subjected to either 10% unilateral PTBI or uninjured Sham craniectomy (n = 6/group). Animals were euthanized at 24h post-PTBI, and mitochondria isolated from the injury core and perilesional frontal cortex and striatum regions. At 24hr post-injury, a significantly higher free radicals production, elevated lipid and protein oxidative markers were observed following PTBI vs. Sham. Together, mitochondrial antioxidants such as glutathione, peroxiredoxins-3, thioredoxins, NADPH, superoxide dismutase expression/levels were significantly decreased following PTBI. The PTBI mitochondria displayed significant loss of Ca2+ homeostasis, early opening of mitochondrial permeability transition pore and increased Ca2+ induced mitochondrial swelling. Mitochondrial membrane integrity markers such as VDAC and cytochrome c expression were significantly decreased following PTBI. This may further exacerbate apoptotic cell death as evidenced by decreased anti-apoptotic protein BCL-2, and increased apoptotic GAPDH protein expression following PTBI. Overall, the PTBI group showed increased oxidative stress, decreased antioxidants, decreased Ca2+ load capacity at 24h post-injury. The significant loss of mitochondrial membrane integrity and elevated apoptosis indicators may contribute to non-salvageable acute-phase effects following PTBI. Collectively, the current results suggest that, mitochondria targeted neuroprotective intervention is crucial for preserving brain functions during acute-phase of PTBI.

4117. Pandya, J. D., et al. (2018). "Time-course evaluation of oxidative stress parameters following penetrating TBI." Journal of neurotrauma **35**(16): A212.

Mitochondria play a pivotal role in maintaining brain energy and redox homeostasis and represent one of the leading factors contributing to the cell death following traumatic brain injury (TBI). Our time-course analysis of brain mitochondrial bioenergetics study following penetrating ballistic-like brain injury (PBBI) revealed that mitochondrial bioenergetics impairment manifests early during the acute period up to 14d post-injury. To understand the vital role of redox homeostasis during acute severe penetrating TBI, we evaluated the temporal changes of brain mitochondrial oxidative stress parameters in the PBBI model. Anesthetized adult male rats were subjected to either 10% unilateral PBBI or sham craniotomy (n = 3-6/group x 7 injury time-points). Animals were euthanized at 30min 3h 6h 24h 3d 7d and 14d post-PBBI, and brain samples i.e. homogenates, mitochondria and cytosol fractions were collected from the ipsilateral hemisphere of the injury core, i.e. frontal cortex + striatum regions. The oxidative stress measures such as protein oxidation adducts (i.e. 3-nitrotyrosine and protein carbonyl levels) and anti-oxidant capacity (i.e. total glutathione (GSH) and peroxiredoxin (PRX3) contents) were quantified using Western-blot and microplate-based analytical methods. Overall, the PBBI group showed increased oxidative stress and decreased antioxidant capacities between 30min to 14d post-PBBI period vs. sham. The mitochondrial 3-nitrotyrosine content was increased significantly (25- 73%; $p < 0.05$ vs. sham) from 30min to 3d post-injury; whereas no change was reported at 6h and 7d post-injury. The PBBI homogenates had significantly elevated (10-58%; $p < 0.05$ vs. sham) protein carbonyl level from 30min to 7d time-points. Results of antioxidant measures showed a significant injury-induced reduction in GSH content (15-58%, $p <$

0.05 vs. sham) in all fractions from 30min to 7d post-PBBI. Furthermore, the PRX3 contents were significantly decreased (16-52%; $p < 0.05$ vs. sham) from 24h to 14d post-PBBI period. This ongoing study has identified the overlapping trends of altered redox homeostasis with energy metabolism as we reported earlier. Collectively, the temporal profile of elevated oxidative stress responses may be unique to the penetrating injury mechanism following brain trauma. In the acute post-injury period, the mitochondria targeted anti-oxidants therapeutics are recommended for management of redox homeostasis following severe penetrating TBI.

4118. Pandya, J. D., et al. (2021). "Time-Course Evaluation of Brain Regional Mitochondrial Bioenergetics in a Pre-Clinical Model of Severe Penetrating Traumatic Brain Injury." Journal of neurotrauma **38**(16): 2323-2334.

Mitochondrial dysfunction is a pivotal target for neuroprotection strategies for traumatic brain injury (TBI). However, comprehensive time-course evaluations of mitochondrial dysfunction are lacking in the pre-clinical penetrating TBI (PTBI) model. The current study was designed to characterize temporal responses of mitochondrial dysfunction from 30 min to 2 weeks post-injury after PTBI. Anesthetized adult male rats were subjected to either PTBI or sham craniectomy (n = 6 animals per group x 7 time points). Animals were euthanized at 30 min, 3 h, 6 h, 24 h, 3 days, 7 days, and 14 days post-PTBI, and mitochondria were isolated from the ipsilateral hemisphere of brain regions near the injury core (i.e., frontal cortex [FC] and striatum [ST]) and a more distant region from the injury core (i.e., hippocampus [HIP]). Mitochondrial bioenergetics parameters were measured in real time using the high-throughput procedures of the Seahorse Flux Analyzer (Agilent Technologies, Santa Clara, CA). The post-injury time course of FC + ST showed a biphasic mitochondrial bioenergetics dysfunction response, indicative of reduced adenosine triphosphate synthesis rate and maximal respiratory capacity after PTBI. An initial phase of energy crisis was detected at 30 min (-42%; $p < 0.05$ vs. sham), which resolved to baseline levels between 3 and 6 h (non-significant vs. sham). This was followed by a second and more robust phase of bioenergetics dysregulation detected at 24 h that remained unresolved out to 14 days post-injury (-55% to -90%; $p < 0.05$ vs. sham). In contrast, HIP mitochondria showed a delayed onset of mitochondrial dysfunction at 7 days (-74%; $p < 0.05$ vs. sham) that remained evident out to 14 days (-51%; $p < 0.05$ vs. sham) post-PTBI. Collectively, PTBI-induced mitochondrial dysfunction responses were time and region specific, evident differentially at the injury core and distant region of PTBI. The current results provide the basis that mitochondrial dysfunction may be targeted differentially based on region specificity post-PTBI. Even more important, these results suggest that therapeutic interventions targeting mitochondrial dysfunction may require extended dosing regimens to achieve clinical efficacy after TBI.

4119. Pandya, J. D., et al. (2019). "Comprehensive profile of acute mitochondrial dysfunction in a preclinical model of severe penetrating TBI." Frontiers in neurology **10**(JUN).

Mitochondria constitute a central role in brain energy metabolism, and play a pivotal role in the development of secondary pathophysiology and subsequent neuronal cell death following traumatic brain injury (TBI). Under normal circumstances, the brain consumes glucose as the preferred energy source for adenosine triphosphate (ATP) production over ketones. To understand the comprehensive picture of substrate-specific mitochondrial bioenergetics responses following TBI, adult male rats were subjected to either 10% unilateral penetrating ballistic-like brain injury (PBBI) or sham craniectomy (n = 5 animals per group). At 24 h post-injury, mitochondria were isolated from pooled brain regions (frontal cortex and striatum) of the ipsilateral hemisphere. Mitochondrial bioenergetics parameters were measured ex vivo in the presence of four sets of metabolic substrates: Pyruvate+malate (PM), glutamate+malate (GM), succinate (Succ), and β-hydroxybutyrate+malate (BHBM). Additionally, mitochondrial matrix dehydrogenase activities [i.e., pyruvate dehydrogenase complex (PDHC), alpha-ketoglutarate dehydrogenase complex (α-KGDHC), and glutamate dehydrogenase (GDH)] and mitochondrial membrane-bound dehydrogenase activities [i.e., electron transport chain (ETC) Complex I, II, and IV] were compared between PBBI and sham groups. Furthermore, mitochondrial coenzyme contents, including NAD(t) and FAD(t), were quantitatively measured in both groups. Collectively, PBBI led to an overall significant decline in the ATP synthesis rates (43-50%; $*P < 0.05$ vs. sham) when measured using each of the four sets of substrates. The PDHC and GDH activities were significantly reduced in the PBBI group (42-53%; $*p < 0.05$ vs. sham), whereas no significant differences were noted in α-KGDHC activity between groups. Both Complex I and Complex IV activities were significantly reduced following PBBI (47-81%; $*p < 0.05$ vs. sham), whereas, Complex II activity was comparable between groups. The NAD(t) and FAD(t) contents were significantly decreased in the PBBI group (27-35%; $*p < 0.05$ vs. sham). The decreased ATP synthesis rates may be due to the significant reductions in brain mitochondrial

dehydrogenase activities and coenzyme contents observed acutely following PBBI. These results provide a basis for the use of "alternative biofuels" for achieving higher ATP production following severe penetrating brain trauma.

4120. Panourias, I. G., et al. (2006). "Penetrating craniocerebral injury caused by a pneumatic nail gun: an unsuccessful attempt of suicide." Clinical neurology and neurosurgery **108**(5): 490-492.

Nail guns are powerful tools commonly used in the building industry. As a result of their improper use, many accidents of bodily injury, including death, have already been reported over the last 50 years; their use in suicide attempts, however, is rare. In this paper, an unusual case of unsuccessful suicidal craniocerebral penetrating injury committed with a pneumatic nail gun by a 23-year-old man is presented. The particular findings that suggest a suicidal attempt are also discussed.

4121. Panteleichuk, A., et al. (2020). "Composite chitosan/polyethylene oxide film for duraplasty in traumatic brain injury model in rats." Cell and Organ Transplantology **8**(1).

The duraplasty is a standard procedure during neurosurgery for injuries and diseases of the brain. The hermetic closure of the dura mater is not always possible with the application of autologous tissues. Synthetic, allogeneic and xenogenic implants, which are currently used, have disadvantages, so the search for the material that would best meet the requirements for a dura mater scaffold continues. The purpose is to study the physical and chemical properties of the composite chitosan/polyethylene oxide (PEO) film and determine the effectiveness of its application for duraplasty in the experiment in vivo; to analyze its ability to biodegradation; to evaluate the effect of chitosan/PEO scaffold on the regeneration of dura matter. Materials and methods. The experiment used 10 white rats aged 12 months with a penetrating traumatic brain injury model. Postoperative material was examined by macroscopy, optical microscopy and infrared spectroscopy. Results. According to the analysis of infrared absorption, spectral markers of scar tissue, regenerating and intact dura mater were determined. Oscillation spectroscopy data indicate degradation of the chitosan film and repair of normal dura mater. Histology data also indicate biological degradation of the chitosan film and its replacement by newly formed normal connective tissue. Conclusion. The data of morphological and spectroscopic studies show the ability of chitosan/PEO film to biodegradation in vivo with followed replacement not by scar but by normal connective tissue.

4122. Panteleichuk, A. B., et al. (2021). "Quantitative Evaluation of the Regenerated Dura Mater in a Decompressive Skull Trepanation Model in Rats." International Journal of Morphology **39**(6): 1731-1736.

Regeneration of the dura mater following duraplasty using a collagen film, a chitosan film, or a combination of both with gelatin, was studied in a craniotomy and penetrating brain injury model in rats. Collagen autofluorescence in the regenerated dura mater was evaluated using confocal microscopy with excitation at λem = 488 nm and λem = 543 nm. An increase in regeneration of the extracellular matrix of connective tissue and an increase in matrix fluorescence were detected at 6 weeks after duraplasty. The major contributors to dura mater regeneration were collagen films, chitosan plus gelatin-based films, and, to a much lesser extent, chitosan-based films. By using autofluorescence densitometry of extracellular matrix, the authors were able to quantify the degree of connective tissue regeneration in the dura mater following duraplasty.

4123. Papa, A., et al. (2021). "Neurogenic pulmonary edema in trauma: A case report and systematic review." Critical care medicine **49**(1 SUPPL 1): 663.

INTRODUCTION: Neurogenic Pulmonary Edema (NPE) is a rare syndrome characterized by acute pulmonary edema following a central nervous system (CNS) injury with the absence of a primary cardiogenic or pulmonary insult. There are multiple causes, however, the frequency, risk factors, morbidity and mortality of the disease remains widely unknown. First, we present a case report of NPE in a 22-year-old African-American male with a single gunshot wound to the head. Second, we perform a systematic review of NPE related to TBI in order to examine risk factors associated with mortality. METHODS: PRISMA guidelines were used to conduct the study. 1,399 articles specific to NPE were identified by searching Pubmed and Scopus. 128 records remained after applying exclusion criteria and 29 studies were included in quantitative analysis, identifying 45 patients total. Acquired patient data included admission vital signs, demographics, and mortality. Frequency data, t tests, and odds ratios were generated using IBM SPSS Version 26 to examine risk factors

for mortality. Non-numerical data, such as common radiographic imaging findings, physical exam findings, pharmacologic treatments used, and ventilation strategies were also reviewed for discussion. RESULTS: Overall mortality from NPE in traumatic brain injury was found to be 44.20%. Of the patients who survived, 63.6% (n=14) made a full recovery from NPE and 78.3% were discharged home. Median hospital stay was 11 days. Admission vitals, such as systolic blood pressure (mean [SD], 113.13 [20.17]) (P = .088) and heart rate (97.93 [19.89]) (P = .057) were not significant in predicting mortality. While the majority of patients were male (83.7%, n = 36), there was no associated significant risk in mortality based on sex; male (OR, 1.050; 95% CI, 0.248 - 7.913) female (OR, 0.750; 95% CI, 0.171 - 3.291). Median age was 19 years, however, age was not a significant risk factor for mortality (22.92 [12.61]) (P = .385). CONCLUSIONS: NPE caused by TBI is rare and carries a significant mortality and morbidity. To our knowledge this is the first systematic review of NPE associated with TBI. While the generated data may provide an idea of a typical presentation of NPE, there is insufficient evidence to establish risk factors associated with mortality.

4124. Papa, L., et al. (2015). "Biomarkers improve clinical outcome predictors of mortality following non-penetrating severe traumatic brain injury." Neurocritical care **22**(1): 52-64.

OBJECTIVE: This study assessed whether early levels of biomarkers measured in CSF within 24-h of severe TBI would improve the clinical prediction of 6-months mortality., METHODS: This prospective study conducted at two Level 1 Trauma Centers enrolled adults with severe TBI (GCS <=8) requiring a ventriculostomy as well as control subjects. Ventricular CSF was sampled within 24-h of injury and analyzed for seven candidate biomarkers (UCH-L1, MAP-2, SBDP150, SBDP145, SBDP120, MBP, and S100B). The International Mission on Prognosis and Analysis of Clinical Trials in TBI (IMPACT) scores (Core, Extended, and Lab) were calculated for each patient to determine risk of 6-months mortality. The IMPACT models and biomarkers were assessed alone and in combination., RESULTS: There were 152 patients enrolled, 131 TBI patients and 21 control patients. Thirty six (27 %) patients did not survive to 6 months. Biomarkers were all significantly elevated in TBI versus controls ($p < 0.001$). Peak levels of UCH-L1, SBDP145, MAP-2, and MBP were significantly higher in non-survivors ($p < 0.05$). Of the seven biomarkers measured at 12-h post-injury MAP-2 ($p = 0.004$), UCH-L1 ($p = 0.024$), and MBP ($p = 0.037$) had significant unadjusted hazard ratios. Of the seven biomarkers measured at the earliest time within 24-h, MAP-2 ($p = 0.002$), UCH-L1 ($p = 0.016$), MBP ($p = 0.021$), and SBDP145 (0.029) had the most significant elevations. When the IMPACT Extended Model was combined with the biomarkers, MAP-2 contributed most significantly to the survival models with sensitivities of 97-100 %., CONCLUSIONS: These data suggest that early levels of MAP-2 in combination with clinical data provide enhanced prognostic capabilities for mortality at 6 months.

4125. Papadopoulos, M., et al. (1994). "Orbital impalement by steering wheel lock." Australian and New Zealand journal of ophthalmology **22**(4): 278-279.

4126. Papavassiliou, D. (2002). "Maxillofacial trauma." Archives of Hellenic Medicine **19**(4): 427-440.

Patients with maxillofacial trauma represent a high percentage of injured patients. Maxillofacial trauma is due mainly to traffic, and especially motorcycle, accidents, but also to interpersonal violence. In descending order of frequency, falls, workplace accidents, sports injuries, shootings and dental operations ensue as etiologic factors. In Greece, based on statistical reports from trauma centers in Athens and the provinces, traffic injuries occupy the first place and, with a small difference, interpersonal violence trauma the second place. Unfortunately, this situation is not due to the reduction of traffic accidents or the improvement of the relation between road, driver and vehicle, but to the increasing trend in interpersonal violence trauma. In other European countries, on the contrary, the frequency of traffic accidents is decreasing continuously. The majority of fractures appear in the mandible, in the condylar region, the genion and also in the middle third of the face in the nasal and zygomatic bones. As regards age distribution, in children, alveolar process fractures occupy the first place whereas in the elderly, fractures of the body of an edentulous mandible are prominent. The injured patients with maxillofacial trauma are very often in need of urgent intervention because of acute respiratory problems or massive blood loss. These situations are frequently accompanied by dangerous cervical spine and/or head injuries. After stabilization of the patient's general condition, the suturing of the skin wounds and stabilization of the fractured bones maybe carried out. X-ray examinations follows the clinical examination and simply confirms the clinical diagnosis. The final rehabilitation often includes resetting of the fractures and immobilization of the bones in the desired position. In the majority of cases this is achieved by transmandibular immobilization, possibly combined with internal osteosynthesis. The most common methods in use are osteosynthesis with mini plates or use of

flaps or hallografts which helps the surgeon to repair soft tissue deficits. These methods represent a common surgical approach.

4127. Paradot, G., et al. (2008). "[Craniocerebral gunshot wounds: a study of outcome predictors]." Les plaies craniocerebrales d'origine balistique: recherche d'arguments pronostiques. **54**(2): 79-83.

BACKGROUND AND PURPOSE: A retrospective study about craniocerebral gunshot wounds was done to better identify outcome predictors., METHODS: We reported and analyzed the clinical and radiological data of 18 patients admitted to Le Kremlin-Bicetre institute for a craniocerebral gunshot wound between January 2000 and December 2005. The Glasgow Outcome Scale (GOS) was used to analyze patient outcome., RESULTS: There were 17 men and one woman, mean age 43 years (range 17-84). Fifteen patients died, two had a GOS equal to 2 and one GOS equal to 3. There were 16 suicides and two murders. All patients with areactive bilateral mydriasis and all patients with Glasgow Coma Scale (GCS) less than seven died except one. The 10 patients with intraventricular hemorrhage died. The bullet crossed the midline for 13 patients and all of them died. None of the patients underwent emergency surgery for the treatment of craniocerebral gunshot wounds because of low Glasgow Coma Scale., CONCLUSIONS: This study shows some interesting prognosis patterns: bilateral areactive mydriasis, GCS less or equal to 7 and bullet trajectory (if crossing the midline) are the most important factors predicting a fatal outcome.

4128. Paradot, G., et al. (2007). "Study of craniocerebral gunshot wounds outcome predictors: Forensic science interests." Journal de Medecine Legale Droit Medical **50**(6-7): 321-327.

We retrospectively reported and analyzed the clinical and radiological data of 18 patients admitted to Kremlin Bicetre institute for a craniocerebral gunshot wound between January 2000 and December 2005. There were 17 men and 1 woman, with a mean age of 43 (17 to 84 years old). There were 16 suicides and 2 murders. None of the patients underwent surgery in emergency for the treatment of craniocerebral gunshot wounds because of a low Glasgow Coma Scale. Bilateral areactive mydriasis, GCS ≤ 7, and bullet trajectory (if crossing the midline) are the most important factors predicting a fatal outcome.

4129. Pardini, M., et al. (2020). "Left rostrolateral prefrontal cortex lesions reduce suicidal ideation in penetrating traumatic brain injury." CNS spectrums **25**(1): 24-31.

OBJECTIVES: The objective of this study is to evaluate the relationship between suicidal ideation (SI), structural brain damage, and cognitive deficits in patients with penetrating traumatic brain injury (pTBI)., METHODS: Vietnam War veterans (n = 142) with pTBI to the prefrontal cortex (PFC) underwent combination of neuropsychological and psychiatric examinations and non-contrast CT brain scan. Patients were divided into SI positive (SI+) and SI negative (SI-) groups according to the SI item of the Beck Depression Inventory., RESULTS: Lesions to the left rostrolateral PFC (rlPFC) were associated with a lower risk of SI independent of depression and global functioning. Left rlPFC lesion also reduced abstract reasoning skills, which mediated the lesion effects on suicide ideation., CONCLUSIONS: The left rlPFC plays a crucial role in SI independently of depression and global functioning.

4130. Pardini, M., et al. (2011). "Prefrontal cortex lesions and MAO-A modulate aggression in penetrating traumatic brain injury." Neurology **76**(12): 1038-1045.

OBJECTIVE: This study investigates the interaction between brain lesion location and monoamine oxidase A (MAO-A) in the genesis of aggression in patients with penetrating traumatic brain injury (PTBI)., METHODS: We enrolled 155 patients with PTBI and 42 controls drawn from the Vietnam Head Injury Study registry. Patients with PTBI were divided according to lesion localization (prefrontal cortex [PFC] vs non-PFC) and were genotyped for the MAO-A polymorphism linked to low and high transcriptional activity. Aggression was assessed with the aggression/agitation subscale of the Neuropsychiatric Inventory (NPI-a)., RESULTS: Patients with the highest levels of aggression preferentially presented lesions in PFC territories. A significant interaction between MAO-A transcriptional activity and lesion localization on aggression was revealed. In the control group, carriers of the low-activity allele demonstrated higher aggression than high-activity allele carriers. In the PFC lesion group, no significant differences in aggression were observed between carriers of the 2 MAO-A alleles, whereas in the non-PFC lesion group higher aggression was observed in the high-activity allele than in the low-activity allele carriers. Higher NPI-a scores were linked to more severe

childhood psychological traumatic experiences and posttraumatic stress disorder symptomatology in the control and non-PFC lesion groups but not in the PFC lesion group., CONCLUSIONS: Lesion location and MAO-A genotype interact in mediating aggression in PTBI. Importantly, PFC integrity is necessary for modulation of aggressive behaviors by genetic susceptibilities and traumatic experiences. Potentially, lesion localization and MAO-A genotype data could be combined to develop risk-stratification algorithms and individualized treatments for aggression in PTBI.

4131. Pardini, M., et al. (2014). "Aggression, DRD1 polymorphism, and lesion location in penetrating traumatic brain injury." CNS spectrums **19**(5): 382-390.

OBJECTIVE: This study evaluated whether structural brain lesions modulate the relationship between pathological aggression and the dopaminergic system in traumatic brain injury (TBI). While converging evidence suggests that different areas of the prefrontal cortex modulate dopaminergic activity, to date no evidence exists of a modulation of endogenous dopaminergic tone by lesion localization in penetrating TBI (pTBI)., METHODS: This study included 141 male Caucasian veterans who suffered penetrating pTBI during their service in Vietnam and 29 healthy male Caucasian Vietnam veterans. Participants were genotyped for 3 functional single nucleotide polymorphisms (SNPs): dopamine receptor D1 (DRD1) rs686, dopamine receptor D2 (DRD2) rs4648317, and catechol-O-methyltransferase (COMT) Val158Met. Patients underwent brain CT scans and were divided into medial prefrontal cortex, lateral prefrontal cortex, and posterior cortex lesion groups. Long-term aggression levels were evaluated with the agitation/aggression subscale of the Neuropsychiatric Inventory., RESULTS: Our data showed that carriers of more transcriptionally active DRD1 alleles compared to noncarriers demonstrated greater aggression levels due to medial prefrontal cortex lesions but reduced aggression levels due to lateral prefrontal cortex lesions independently of DRD2 rs4648317 or COMT Val158Met genotypes., CONCLUSIONS: Our results suggest that the relationship between pTBI-related aggression and the dopaminergic system is modulated by lesion location. Potentially lesion location could represent an easy-to-use, widely available, para-clinical marker to help in the development of an individualized therapeutic approach to pTBI-related pathological aggression.

4132. Pardini, M., et al. (2012). "Fatty-acid amide hydrolase polymorphisms and post-traumatic stress disorder after penetrating brain injury." Translational psychiatry **2**: e75.

The past few years have seen an increase in the clinical awareness of post-traumatic stress disorder (PTSD), one of the most disabling and least understood behavioral disorders. Although the biological bases of PTSD are poorly understood, fatty-acid amide hydrolase (FAAH) activity has been linked with arousability and aversive-memories extinction, that is, two key features of PTSD. In this study, we investigated the association between the FAAH genetic polymorphisms and PTSD development and maintenance. We assessed PTSD frequency in a group of male Vietnam war veterans who suffered combat-related penetrating traumatic brain injury, that is, a relatively homogeneous population regarding the nature of the events that led to PTSD. We showed that rs2295633, a single-nucleotide polymorphism of FAAH, was significantly associated with PTSD diagnosis in subjects without lesions in the ventromedial prefrontal cortex. Moreover, the presence of the C allele was associated with more severe re-experiencing of trauma and more negative reported childhood experiences. In conclusion, our data suggest that FAAH has an important role in PTSD through modulation of aversive memories and point to both a novel therapeutic target and a possible risk marker for this condition.

4133. Pardini, M., et al. (2010). "Ventromedial prefrontal cortex modulates fatigue after penetrating traumatic brain injury." Neurology **74**(9): 749-754.

BACKGROUND: Fatigue is a common and disabling symptom in neurologic disorders including traumatic penetrating brain injury (PBI). Despite fatigue's prevalence and impact on quality of life, its pathophysiology is not understood. Studies on effort perception in healthy subjects, animal behavioral paradigms, and recent evidence in different clinical populations suggest that ventromedial prefrontal cortex could play a significant role in fatigue pathophysiology in neurologic conditions., METHODS: We enrolled 97 PBI patients and 37 control subjects drawn from the Vietnam Head Injury Study registry. Fatigue was assessed with a self-report questionnaire and a clinician-rated instrument; lesion location and volume were evaluated on CT scans. PBI patients were divided in 3 groups according to lesion location: a nonfrontal lesion group, a ventromedial prefrontal cortex lesion (vmPFC) group, and a dorso/lateral

prefrontal cortex (d/lPFC) group. Fatigue scores were compared among the 3 PBI groups and the healthy controls., RESULTS: Individuals with vmPFC lesions were significantly more fatigued than individuals with d/lPFC lesions, individuals with nonfrontal lesions, and healthy controls, while these 3 latter groups were equally fatigued. VmPFC volume was correlated with fatigue scores, showing that the larger the lesion volume, the higher the fatigue scores., CONCLUSIONS: We demonstrated that ventromedial prefrontal cortex lesion (vmPFC) plays a critical role in penetrating brain injury-related fatigue, providing a rationale to link fatigue to different vmPFC functions such as effort and reward perception. The identification of the anatomic and cognitive basis of fatigue can contribute to developing pathophysiology-based treatments for this disabling symptom.

4134. Pareja, J. M., et al. (2019). "Combined blood-based biomarker panel of major subphenotypes of pediatric traumatic brain injury and neurodevelopmental outcomes." Journal of neurotrauma **36**(13): A139-A140.

Objectives: This study correlates three major pTBI pathological mechanistic subphenotypes: contusion, cerebral hemorrhage and diffuse axonal injury (DAI) to blood-based biomarkers and neurocognitive outcomes. Methods: Subjects 0-18 years admitted to the hospital with TBI were enrolled in this study. Serial serum/plasma for 16 healthy controls and 36 subjects was collected at 0, 24 and 48h post injury. Ubiquitin-C-terminal hydrolase (UCHL-1); glial fibrillary acidic protein (GFAP), neurofilament-L (NF-L) and Tau were measured. The Pediatric Evaluation of Disability Inventory (PEDI-CAT), Glasgow Outcome Scale-Extended (GOS-E Peds), Health and Behavioral Inventory (HBI) and Pediatric Quality of Life Inventory (PedsQL) were collected at 2 weeks, 6 months, and 12 months post injury. Summary: GFAP, UCHL1, Tau, and NFL could potentially be used together to predict the presence of DAI, contusion, and/or cerebral hemorrhage when serum samples are obtained within 0-48 h post injury, ($p < 0.005$; ROC AUC of 0.879 for GFAP, 0.794 for NFL, 0.926 for TAU and 0.928 for UCHL-1). Furthermore this panel may support the prediction of mortality ($p < 0.005$; ROC AUC of 0.810 for GFAP, 0.902 for NFL, 0.973 for TAU and 0.875 for UCHL-1). GOS-E outcomes from 6-12 months post injury were calculated and correlated with the previous biomarker panel ($P < 0.05$; ROC AUC of 0.682 for GFAP, 0.764 for NFL, 0.810 for TAU and 0.815 for UCHL-1). Conclusion: This preliminary data indicates the possible ability of a biomarker panel correlated to outcome measures to provide further insight to clinicians regarding injury severity and prognosis for pTBI.

4135. Paret, G., et al. (1998). "Gunshot wounds in brains of children: prognostic variables in mortality, course, and outcome." Journal of neurotrauma **15**(11): 967-972.

A retrospective study of 51 children presenting with craniocerebral gunshot lesions was carried out to identify predictors of outcome. The patients ranged in age from 2 months to 17 years, with a mean of 14.5 years. The outcome was good in 20 patients, and seven and four were moderately and severely disabled, respectively. Twenty patients died. Statistical analysis showed prognostic significance of the admission Glasgow Coma Score (GCS), computerized tomographic findings of intraventricular hemorrhage and midline shift, and metabolic abnormalities, including hypokalemia and hyperglycemia. These prognostic factors may have implications regarding counseling of families, utilization of resources, and organ transplantation.

4136. Paret, G., et al. (1996). "Pediatric craniocerebral wounds from plastic bullets: prognostic implications, course, and outcome." The Journal of trauma **41**(5): 859-863.

OBJECTIVE: To review our experience with craniocerebral injuries caused by plastic bullets, and to delineate prognostic factors for outcome., DESIGN: Retrospective case series of 29 patients presenting with plastic bullet-induced craniocerebral lesions., SETTING: Pediatric intensive care department of a tertiary care center., MEASUREMENTS AND MAIN RESULTS: Outcome was poor in 10 patients, good in 11, and two and six patients were moderately and severely disabled, respectively. Statistical analysis showed prognostic significance of the admission Glasgow Coma Scale score, computed tomographic findings of intraventricular hemorrhage and midline shift, and metabolic studies including hypokalemia and hyperglycemia., CONCLUSIONS: Plastic bullet-induced craniocerebral injuries carry a lower morbidity and mortality rate compared with other gunshot wounds. However, plastic bullets do incur a significant risk of injury. Their use should be carefully regulated.

4137. Paris, J. J. and G. Signorello (1992). "The use of anencephalic organ donors: lesson of Baby Theresa Ann." Clinical ethics report **6**(3): 3-6.

4138. Parish, J. M., et al. (2020). "Delayed Traumatic Tension Pneumocephalus: A Case Report." The Journal of emergency medicine **59**(6): e217-e220.

BACKGROUND: Traumatic tension pneumocephalus is a rare complication after craniofacial fractures that can cause devastating neurologic deficits if not managed promptly and effectively., CASE REPORT: A 38-year-old man with no past medical history presented to the Emergency Department (ED) after a motor vehicle crash. He was noted to have an open frontal scalp laceration. Computed tomography (CT) revealed a right frontal subdural hematoma and right medial frontal contusion. There was also a frontal bone fracture extending through the frontal sinus with mild underlying pneumocephalus. He was monitored for cerebrospinal fluid (CSF) leak and was subsequently discharged on postinjury day 9. He re-presented to the ED 14 days post injury with lethargy, confusion, headache, and swelling around his scalp laceration. A CT scan was obtained that revealed a large-volume intraparenchymal pneumocephalus (pneumocerebri) with mass effect and midline shift. The patient was started on 100% oxygen and admitted to the intensive care unit. He was taken to the operating room for evacuation of the pneumocerebri, repair of dural defect, placement of a vascularized pericranial graft, and placement of a lumbar drain. His lumbar drain was removed on postoperative day 3 and he was discharged home neurologically intact on postoperative day 6. At 1 month follow-up he had no evidence of CSF leak and was neurologically intact. WHY SHOULD AN EMERGENCY PHYSICIAN BE AWARE OF THIS?: This case is presented to increase awareness among emergency physicians that traumatic tension pneumocephalus, and in this case, pneumocerebri, is a rare life-threatening neurosurgical emergency in patients with severe craniofacial fractures after blunt or penetrating head trauma. Early temporizing measures in the ED, such as 100% oxygen via nonrebreather face mask, and urgent neurosurgical consultation are indicated to prevent neurologic deterioration. Copyright Published by Elsevier Inc.

4139. Park, H., et al. (2012). "Mortality and penetrating traumatic brain injury: Analysis of a 10 year cohort." Neurology **78**(1).

Objective: To study annual mortality rates and explore the link between Glasgow Coma Scale (GCS), surgical intervention and mortality. Background Civilian penetrating traumatic brain injury (pTBI) remains a cause of significant mortality and often is excluded from studies of traumatic brain injury. Design/Methods: Using a prospective trauma registry at a tertiary academic level I trauma center, we identified patients with penetrating injuries to the head presenting to Shock Trauma from January 1, 2000 to December 31. Those without dural penetration on computed tomography (CT) were excluded. Admission GCS, surgical intervention, and mortality were abstracted from the registry and medical record. Analysis of annual rates of surgical intervention and mortality were performed using Pearson's correlation coefficient. GCS was analyzed using a mild (13-15), moderate (9-12), and severe (3-8) scheme. An additional analysis of GCS was used with GCS=3 as a separate category. All analyses also factored in dead on arrival (DOA) patients. Results: 508 patients met inclusion criteria. 337 patients died (66.34%). 115 patients were deemed DOA. 104 patient underwent surgical intervention (20.47%). Annual mortality and surgery rates did not vary with any significance. Analysis of GCS using a mild, moderate, and severe scheme showed mortality rates of 3.67%, 21.74%, and 87.23% respectively. GCS showed a strong linear association to mortality (r∧2=0.90). Separating out those with a GCS of 3 from the severe group strengthened the association (r∧2=0.97). Among those with GCS of 3, a correlation between surgery and mortality was suggested (r∧2=0.59). Conclusions: Mortality rates for penetrating brain injury have not significantly changed over the past decade. GCS is strongly associated with mortality. A correlation between rates of surgery and mortality has been suggested among those with severe GCS and further study is required to determine which patients would benefit most.

4140. Park, H., et al. (2012). "Penetrating traumatic brain injury: A 10-year experience." Neurology **78**(1).

Objective: There are limited studies available to understand the natural history of penetrating traumatic brain injury (pTBI). We explored the characteristics associated with poor outcome in pTBI. Background Civilian pTBI is a cause of significant mortality and often is excluded from studies of traumatic brain injury. Design/Methods: Using a prospective trauma registry at a tertiary academic level I trauma center, we identified patients with penetrating injuries to the head presenting from January 1, 2000 to December 31, 2009. Those without dural penetration on computed tomography (CT) were excluded. Demographics, clinical features on admission, laboratory data, initial CT findings, medical and surgical interventions, and mortality were abstracted from the registry and medical record. The primary

outcome was 30-day mortality. Descriptive statistics were computed and associations with outcome were determined using t-test and Wilcoxon rank sum. A p-value below 0.05 was considered statistically significant. Results: Among 508 patients with pTBI, 336 patients (66.1%) died by 30 days. 115 patients were considered dead on arrival. Predictors of 30-day mortality included older age (p=0.003), male gender (p<0.001), GCS (p<0.001), transfer status (p<0.001), pupil reactivity (p<0.001), gunshot wound as the mechanism of injury (p<0.001), and self-inflicted injury (p<0.001). Laboratories associated with increased mortality included INR (p<0.001) and lactate (p<0.001). Radiographic characteristics associated with 30 day mortality included perforating trajectory (p<0.001), bilateral trajectory (p<0.001), ventricular involvement (p<0.001), presence of any hemorrhage (p<0.001), intraventricular hemorrhage (p<0.001), obliteration of basal cisterns (p<0.001), and multiple penetrating injuries (p=0.02). ICP monitoring and surgical intervention were associated with improved outcome (p<0.001). Conclusions: This is one of the largest series of patients of civilian pTBI reported to date. Several clinical, laboratory and radiological features of pTBI can identify those patients at highest risk for poor outcome. Surgical intervention and ICP monitoring were associated with improved outcome.

4141. Park, M., et al. (2005). "Penetrating civilian craniocerebral gunshot wounds: A protocol of delayed surgery. Comments." Neurosurgery **57**(2): 298-299.

4142. Park, S., et al. (2021). "P47.08 A Phase II, Single-arm, Multicenter, Efficacy of 80 mg Osimertinib in Patients With Leptomeningeal Metastases Associated With EGFR Mutated NSCLC." Journal of Thoracic Oncology **16**(10): S1099.

Introduction: Leptomeningeal metastases (LM) are severe, an aggressive complication of cancer, characterized by tumor cell spread to the cerebrospinal fluid (CSF) and leptomeninges. The higher incidence of LM in EGFR mutated non-small cell lung cancer (NSCLC) has been observed, especially after treated with 1st or 2nd generation EGFR TKI. The Osimertinib, the third generation irreversible EGFR TKI, has been developed to target T790M mutation. Unlike other EGFR TKIs, Osimertinib showed homogenous distribution to the brain suggesting high penetration of blood-brain barrier, and clinical efficacy in intracranial lesions has been demonstrated from the retrospective analyses. In addition, from prospective study, double dosage (160mg) of osimertinib demonstrated meaningful clinical efficacy in LM by extending progression-free (PFS) and overall survivals (OS). However, despite the approval of Osimertinib as 1st line treatment option by the FDA in EGFR mutated NSCLC, many other countries are still in use of Osimertinib as a subsequent treatment option in selected patients. This study is designed to evaluate the clinical efficacy and safety of Osimertinib in patients with LM who failed from the previous first- or second-generation EGFR TKI. Methods: This study (BLOSSOM) is a Phase II, open-label, single-arm, multicenter study to evaluate the clinical efficacy of 80mg Osimertinib in patients with LM in EGFR mutated, either exon 19 deletion or L858R, NSCLC. From the 5 sites across South Korea and first or second-generation EGFR TKI pre-treated patients will be recruited. A total of 80 patients, 40 patients with T790M positive and 40 patients with T790M negative, will be recruited and treated with 80mg of Osimertinib until disease progression or intolerable adverse event. All the patients will be required to have at least one site of LM as identified by the radiologists from the central site that can be assessed by MRI which is suitable for repeat assessment. If the patient has no T790M mutation, the extracranial lesion must be stable following previous EGFR TKI treatment. The primary endpoint is OS. The secondary endpoints are blind independent committee review assessed RANO-LM criteria to evaluate the LM-objective response rate, LM-duration of response, LM-disease control rate, LM- PFS and this will be assessed based on the T790M mutation status. The RECIST 1.1 response assessed by investigator, CSF cytology clearance rates, disease-related symptom, and pharmacokinetics in plasma and CSF will be evaluated. The first patient received treatment in Dec. 2020, and the expected timeline for the final analyses is Q3, 2023. This study is conducted under an applicable regulatory requirement and supervision of the institutional review board (NCT04563871). Results: ▪▪▪ Conclusion: ▪▪▪ Keywords: leptomeningeal metastases, EGFR, osimertinib

4143. Park, S.-H., et al. (2006). "Penetrating craniofacial injuries in children with wooden and metal chopsticks." Pediatric neurosurgery **42**(3): 138-146.

Penetrating craniofacial injuries with chopsticks in children are peculiar accidents in the Oriental culture. All 10 cases previously reported were caused by wooden chopsticks that required surgical operations. However, there are no reported injuries with metal chopsticks in the past literature which should have been as common as that of wooden chopstick injuries in Asia. We evaluated the difference of injury patterns and clinical observations between wooden and metal chopstick injuries. We reviewed 6 treated children with penetrating craniofacial injuries from chopsticks: one

wooden and five metal chopsticks. One child who had penetration through the nasal cavity presented with temporary rhinorrhea, another with mild hemiparesis, and one child with temporary upward gaze limitation of the left eye. Radiological examination revealed 1 patient with epidural hemorrhage, 1 patient with minimal subdural hemorrhage, and 4 with intracerebral hemorrhage that were fortunately too small to receive surgery. We performed surgical procedure only for a child who had a wooden chopstick that had impacted into the temporal cortex. We followed up all 6 children for more than 1 year, and found that all had fully recovered to near-normal neurological status. We observed that penetrating craniofacial injuries with metal chopsticks rarely require surgical intervention and usually results in good outcome because the resultant wound is usually small without broken fragments compared to injuries with wooden chopsticks. 4144. Park, S. J. and M. Chi (2018). "Transorbital Penetrating Intracranial Injury by a Battery." The Journal of craniofacial surgery **29**(1): e61-e64.

The authors report a patient of transorbital penetrating intracranial injury by a battery. A 59-year-old man presented with a foreign body in the left orbital region after an explosion during waste combustion. Physical examination revealed his left eyelid had been punctured and the eyeball ruptured by what appeared to be a battery, which was lodged in the left orbit. The patient was neurologically intact. Facial computed tomography showed a ca. 6.2 x 1.7 cm sized metallic foreign body, probably an electric battery, penetrating through the left orbit and orbital roof and terminating in the left anterior cranial fossa. Clinical presentation, treatment course, and follow-up are discussed.

4145. Park, S. K., et al. (2012). "Traumatic true aneurysm of the superficial temporal artery." Aesthetic plastic surgery **36**(4): 934-937.

BACKGROUND: Aneurysms of the superficial temporal artery (STA) usually are pseudoaneurysms and occur after blunt or penetrating trauma to the head or after surgery in the temporal region. However, true aneurysms of the STA are very rare. This report describes the case of a true aneurysm of the STA that appeared after trauma and discusses several relevant studies about the development and mechanism of this aneurysm., METHODS: A 57-year-old woman was referred to the neurosurgery department due to a slowly growing mass on her left parietal scalp. She reported a history of trauma to the head 3 months before the consultation. However, examination showed the scar located far from pulsatile mass. Imaging studies showed a fusiform aneurysmal dilation of the parietal branch of the STA. The frontal branch likely was occluded due to the previous injury., RESULTS: Surgical removal was performed, and the proximal STA was ligated. Histologic examination showed all three layers of the arterial wall to be intact and only luminal dilation. No sign of atherosclerosis or inflammation was detected., CONCLUSION: The aneurysm in this case was a true aneurysm. The mechanism underlying the spontaneous development of this true aneurysm is not fully understood, although it is possible that insensible minor blunt trauma weakened the arterial wall or reduced the elasticity of the artery. Increased blood flow of the parietal branch due to occlusion of the frontal branch can facilitate aneurysmal dilation. It is speculated that the real incidence of traumatic true STA aneurysms has been underreported. Thus, the authors recommend histologic examination in all traumatic aneurysm cases., LEVEL OF EVIDENCE V: This journal requires that authors assign a level of evidence to each article. For a full description of these Evidence-Based Medicine ratings, please refer to the Table of Contents or the online Instructions to Authors www.springer.com/00266.

4146. Parker, M. and S. D. Shemie (2002). "Pro/con ethics debate: should mechanical ventilation be continued to allow for progression to brain death so that organs can be donated?" Critical care (London, England) **6**(5): 399-402.

Organ transplants continue to redefine medical frontiers. Unfortunately, current demand for organs far surpasses availability, waiting lists are long and many people die before the organ they desperately need becomes available. One proposed way to increase organ availability is to admit patients to the ICU with severe neurological injuries, for a trial of therapy. If the injury is irretrievable, discussions would then focus on extending ventilation for potential brain death/organ donation if a prior wish to donate is known or if the substitute decision maker consents. The following debate discusses the ethical dilemmas of waiting for brain death.

4147. Parkinson, J. (1982). "The ballistics of craniocerebral gunshot wounds." Journal of neurosurgical nursing **14**(5): 232-238.

The wounding capability of missiles is produced by the tremendous energy absorbed by the tissue. This energy can effect significant injury to structures distant from the wound tract as well as the destruction of neural tissue within the tract. Retained bullets and fragments are hazards both in their removal by increasing neural damage and in their retention by migration or as an inflammatory locus. Careful observation and clear description of the wounds prior to the disruption of surgical procedures and careful handling of possible evidence are the medical professionals' responsibilities in addition to the care of the victim. The mortality and morbidity of gunshot wounds to the head are very high. At present there seems to be little hope of either improving the prognosis of head wounds or of limiting the availability of firearms.

4148. Parmar, G. S., et al. (2019). "Stenciling-Based "Prick and Print" Technique for Harvesting Shaped Corneal Grafts for Management of Peripheral Corneal Perforations." Cornea **38**(1): 105-109.

PURPOSE: To evaluate a new surgical technique ("prick and print") for harvesting shaped donor corneal grafts in cases with perforated peripheral ulcerative keratitis (PUK)., METHODS: We conducted a retrospective case series at a tertiary center. Medical records of 13 patients with perforated PUK, who underwent tectonic eccentric keratoplasty using the stenciling-based prick and print technique during the past 1 year, were reviewed. All patients (15 eyes of 13 patients) received grafts of varying sizes and shapes (14 crescentic and 1 biconvex). Factors evaluated were tectonic integrity, graft apposition, and complications, if any. Surgical success was defined as maintenance of corneal integrity and healing of PUK., RESULTS: Mean age of patients was 40.6 +/- 19.4 years. Mean follow-up was 10 months. We achieved surgical success in 80% (12/15 eyes) of cases. Two eyes had graft infection, and regrafting (large circular graft) was performed for both. One eye developed new-site PUK, which was managed medically, and the graft remained viable tectonically. After surgery, 9 eyes achieved a best-corrected visual acuity of logarithm of the minimum angle of resolution +0.3 or better. No cases had graft rejection or peripheral anterior synechiae by final follow-up., CONCLUSIONS: The stenciling-based prick and print technique for making shaped donor corneal grafts may offer a simple, easy-to-learn surgical technique that can be used to make any shape or pattern of donor corneal grafts without involving the optical center, even in extensive peripheral corneal lesions.

4149. Parrado Sanchez, L., et al. (2017). "[Pediatric traumatic brain injury due to civil gunshot wounds at a General Hospital in Cali, Colombia]." Traumatismo craneoencefalico pediatrico secundario a heridas por arma de fuego en un Hospital General en Cali, Colombia. **30**(1): 50-56.

OBJECTIVES: Traumatic brain injury (TBI) due to gunshot-wounds (GSW) is a critical situation in the pediatric population. The aim of this study is to characterize TBI in this population since there are few reports that describe it especially in Colombia where its incidence is high, also to determine which were the main mortality predictor within our population., MATERIAL AND METHODS: We conducted a retrospective cross-sectional study in which we reviewed pediatric medical records of patients that had consulted at the Fundacion Valle del Lili pediatric Emergency Room between January of 2011 and December of 2015 because of TBI due to GSW. A descriptive statistical analysis was performed., RESULTS: In our sample of 32 patients the average age was of 13.3 (SD +/- 5.4) and with 75% male patients. In our sample the Glasgow Coma Scale (GCS) at entry was less than 8 in 59.38%, a 15.6% needed craniotomy and 81.2% were admitted to the Intensive Care Unit (ICU). Death occurred in 43.75% of cases. The following mortality predictors were obtained: GCS at entry, pupillary exam and light reflexes, ISS, Marshal Score, absence of basal cisterns and presence of subarachnoid hemorrhage in CT scan, and APACHE II., CONCLUSIONS: TBI due to GSW is a devastating entity, especially in the pediatric population, they are responsible of high mortality and disability rates. There were no significant findings regarding infection rates and the use of surgery as a preventive method, therefore there's a chance it might not be indicated.

4150. Parroni, E., et al. (2002). "Suicide with two guns represents a special type of combined suicide." The American journal of forensic medicine and pathology **23**(4): 329-333.

Suicide by simultaneous gunshots with two firearms is rare. The case of a 90-year-old man who killed himself with two 6.35 mm pistols fired at the temples at the same time is presented. The victim was found dead on the terrace of his home; two guns and two cartridges were present near the corpse. Cases of suicides with two guns published in the literature are compared, and the Italian cases are illustrated briefly. The authors describe the circumstances and autopsy findings that permitted the assertion that it was a case of suicide and to exclude an homicide and show, by figures, the

three-dimensional reconstruction of cranial shooting injuries. The use of two guns is considered a representation of a special type of "combined suicide" or "planned complex suicide."

4151. Paschall, A. and A. H. Ross (2017). "Bone mineral density and wounding capacity of handguns: implications for estimation of caliber." International journal of legal medicine **131**(1): 161-166.

Methodologies that improve estimation of caliber from cranial bone defects are necessary to meet the ever increasing admissibility standards. The relationship between caliber, wound diameter, and bone mineral density (BMD) was examined. The formation of the permanent cavity is influenced by bullet yaw, velocity, distance, and tissue properties. The hypothesis was that including BMD, wound diameter could be explained by differences in caliber. The sample consists of 68 autopsy sections and 101 specimens from Phelps (1898). A subsample of 18 was scanned using dual energy x-ray absorptiometry (DEXA) for BMD measurement to test whether an increase in BMD affects wound diameter. Pearson product-moment correlations of the subsample indicate the strongest correlation is between BMD and minimum diameter (r = 0.7101), followed by a correlation between minimum diameter and caliber (r = 0.6854). Despite the previous use of thickness as a proxy for BMD, no correlation was found between BMD and thickness (r = 0.0143). A multivariate analysis of variance (MANOVA) detected a significant influence of BMD and minimum diameter on caliber size (Prob > F = 0.0003). The logistic regression shows that caliber can be estimated from minimum diameter. Using the subsample, the results show that the inclusion of BMD strengthens the model for estimating caliber from entrance gunshot defects.

4152. Pascual, J. M., et al. (2009). "Penetrating ballistic-like frontal brain injury caused by a metallic rod." Acta neurochirurgica **151**(6): 689-691.

Penetrating non-missile intracranial injuries caused by metallic foreign bodies are very rare among the civilian population. We present a unique instance of a severe, high-energy, penetrating orbitocranial injury caused by a solid metallic rod that corresponded to the spray valve lever handle of a kitchen sink pre-rinse spray tap, which was fractured and projected at high speed for an unknown reason. To our knowledge, this is the first report of a high-energy, penetrating brain injury caused by such an object. After careful radiological evaluation of the shape and position of the foreign object, a combined right frontal craniotomy and supraorbital osteotomy was performed in order to achieve safe removal of the metal bar. Successful surgical treatment of an orbitocranial injury caused by a similar object has not previously been reported.

4153. Pascual-Castroviejo, I., et al. (2006). "Diplegia due to transcranial knife-blade injury in a 20-month-old child." Journal of child neurology **21**(4): 340-341.

Transcranial stab wounds are uncommon among both adults and adolescents and rarely occur in children, particularly when caused by another child. A 20-month-old girl was injured by a 3-year-old cousin, who introduced a knife blade into the brain through the left parietal region. The trajectory of the wound penetrated at least 5 cm, crossed the falx cerebri, and involved both motor cortical areas. The clinical sequela was a severe symmetric spastic diplegia.

4155. Pashinian, G. A., et al. (1992). "[The pathomorphological characteristics of the vascular plexuses and ependyma of the cerebral ventricles in human craniocerebral trauma]." Patomorfologicheskie osobennosti sosudistykh spletenii i ependimy zheludochkov golovnogo mozga cheloveka pri cherepno-mozgovoi travme. **35**(4): 9-12.

The morphology of the studied substrates was analyzed in lethal craniocerebral injuries of various origins and in various periods after it was suffered. The data on the pattern and time course of pathomorphologic shifts and functions extend the general notions on the role of the liquor circulation system in the pathogenesis of craniocerebral injury. These results may serve as additional expert criteria of the mechanisms of brain injury.

4156. Pashinian, G. A., et al. (2003). "[Evaluation of disorders in the liquor circulation in craniocerebral trauma]." Otsenka porazheniia sistemy likvoroobrashcheniia pri cherepno-mozgovoi travme. **46**(5): 24-27.

The modern methods of complex examinations of the brain in craniocerebral trauma are addressed and the possibilities of the topographic-and-anatomic substantiation in the forensic-medical (expert) evaluation of traumatic lesions of liquor-circulation structural elements are elucidated in the paper. Morphometry data characterizing the dislocation manifestations are presented with respect to the dislocation intensity and severity.

4159. Pataraia, E. (2016). "Language localization by magnetoencephalography." Clinical Neurophysiology **127**(3): e22.

Identification of the brain regions mediating language has always been the most urgently sought after due to its practical applications: advanced knowledge of the language-specific zones can facilitate surgical planning and reduce the morbidity associated with resection of eloquent cortex. Currently the Wada-test is considered the gold standard for preoperative language lateralization, while direct cortical stimulations are necessary to provide information on the exact intra-hemispheric language localization. The disadvantage of both of these methods lies in the invasiveness of each procedure. Magnetoencephalography (MEG) takes advantage of the fact that neuromagnetic signals penetrate the skull and scalp without distortion. The magnetic source image (MSI) is created when the MEG data is superimposed on a magnetic resonance image (MRI). MEG performs noninvasive functional imaging by recording the magnetic flux on the head surface associated with electrical currents in activated sets of neurons. MEG is now the imaging modality of choice where a precise and high degree of localization is required and can be used for localization of areas involved with receptive language function, its organization and reorganization under different conditions, i. e. brain injury. MEG can be used to complement structural and metabolic imaging techniques.

4160. Pate, J. W. and M. Casini (1980). "Penetrating wounds of the neck: explore or not?" The American surgeon **46**(1): 38-43.

While routine formal exploration for all neck wounds penetrating the platysma remains a safe policy, our experience indicates that it is not necessarily the best policy in large, well-staffed teaching hospitals with extensive trauma services. Careful and repeated physical examinations and observations supplemented by simple radiograph examinations allowed selection of a large group of patients who were satisfactorily treated by simple wound closure and clinical observations. Aggressive emergency room management and adequate exposure and repair of vascular injuries prevented cerebral damage so common in previous reports.

4161. Patel, A. A., et al. (2014). "Laser treatment of trismus after gunshot wound to face: A case report." PM and R **6**(9): S232.

Case Description: A 39-year-old woman with no significant past medical history presented to a level 1 trauma center after sustaining a gunshot wound to the face resulting in a right mandibular ramus, left mandibular body, right maxillary sinus and right inferior orbital wall fractures. Patient was stabilized by oral and maxillofacial surgery and underwent maxillo-mandibular fixation of unstable fracture segments with wire placement. After 6 weeks, wire was removed with continual limitation of mouth opening resulting in trismus. Patient had approximately 5-6mm opening

with manual exercises completed twice weekly with oral surgery. Due to extensive damage from initial injury, patient was scheduled for maxillary prosthesis. Patient was sent to Physical Medicine & Rehabilitation for further management of trismus. Lowlevel laser treatment (LLLT) was used for 80 seconds extraorally in five locations (submandibular, masseter, and anterior cervical strap muscles; soft tissue of posterior neck; temporomandibular joint) causing the most restriction. Setting: Level I trauma center and academic hospital. Results or Clinical Course: After 6 weeks of treatment, patient was observed to have 1-2mm/week improvement in opening size. Patient advanced to approximately 12-14mm within 6 weeks after starting laser treatment. The patient is set to have maxillary dental prosthesis in the near future. Discussion: This is the first reported case, to our knowledge, of using laser to treat trismus secondary to a gunshot wound. Trismus may develop after facial trauma such as irradiation and oral surgery. In prior studies, LLLT targeting only the insertion points of the masseter muscle has yielded mixed results. It is conceivable that the unique etiology of our patient's trismus contributed to the effectiveness of treatment-perhaps the minimal relaxation of multiple muscles achieved by LLLT summated to yield a clinically significant improvement in jaw opening, while LLLT may not achieve adequate relaxation when targeting a single trismic locus. Other modalities adjuvant to physical therapy including ultrasound, corticosteroids and botulinum toxin will be reviewed. Conclusions: LLLT can be an effective adjuvant treatment for trauma-related trismus when combined with physical therapy.

4162. Patel, J., et al. (2020). "Vascular trauma in the head and neck and endovascular neurointerventional management." Journal of Clinical Imaging Science **10**(1).

Traumatic vascular injuries of the head and neck can pose life-threatening emergencies, and therefore, the detection and accurate characterization of these injuries by the radiologist is essential. Computed tomographic angiography (CTA) is commonly performed as part of the initial imaging work-up of patients who have sustained blunt or penetrating craniocervical injuries and are suspected to have or are at risk for vascular injuries. This pictorial essay reviews the CTA and conventional angiographic imaging appearance of various vascular injuries that can occur from trauma in the head and neck and also explores the neurointerventional management of these types of injuries.

4163. Patel, K. and K. Cao (2016). "Clostridium subterminale sepsis in an immunocompetent patient without other risk factors: A case report." Chest **150**(4): 421A.

INTRODUCTION: Clostridium subterminale is an anaerobic, spore-forming, gram-positive bacteria normally found in soil. It is a rare pathogen that has only been described in 10 prior cases, with only two presenting as septicemia in immunosuppressed patients. A prominent risk factor is deep tissue injury. Other cited presentations were empyema, soft tissue infection, and meningitis after craniocerebral arrow injury. We present a case of Clostridium subterminale in an immunocompetent patient without penetrating injury. CASE PRESENTATION: 52 year old male with diabetes, chronic kidney disease, pulmonary emboli, and diastolic dysfunction was found down at home and brought in by EMS. On arrival, patient was intubated in severe shock with high anion gap metabolic acidosis (AG 26), hyperglycemia (1720), and acute renal failure (Cr 8.0). Physical exam was remarkable for mild abrasions on his knees and cool skin. Chest x-ray was unremarkable, pan cultures were ordered and patient started on vancomycin and zosyn. Despite four pressors, our patient decompensated with ventricular tachycardic arrest, but was revived. Bedside echo revealed EF 40-45%. Given worsening status and chest imaging with ARDS, antibiotics broadened. Dialysis was initiated for anuric kidney failure and worsening acidosis. On hospital day (HD) 3, patient developed DIC and shock liver. Large bullae appeared on bilateral lower extremities where previous abrasions were noted by HD4. Our patient continued to decompensate and patient's family decided to focus on comfort measures only. Patient passed by HD 5 and two days later cultures revealed Clostridium subterminale. DISCUSSION: C. subterminale is rarely virulent and does not typically present as an isolated pathogen. There are only 10 cases in the literature, of which most are after penetrating or deep tissue injuries and only 2 cases of bacteremia in immunosuppressed patients. However, our patient was immunocompetent without risk factors. A possible source of infection was the mild abrasions on his lower extremities. CONCLUSIONS: This is the first case of C. subterminale septicemia that we know of, to present in an immunocompetent host without clear risk factors. Despite adequate antimicrobial therapy patient continued to decompensate. It is important that clinicians are aware of this pathogen and further delineation of risk factors are needed.

4164. Patel, K., et al. (2016). "Management of orbital fractures using intraoperative navigational surgery. A prospective case series." Journal of oral and maxillofacial surgery **74**(9): e28-e29.

Objectives: Reconstruction of orbital trauma is one of the most challenging areas of facial trauma surgery. To ensure optimal results with limited morbidity it is essential that orbital surgery be performed with the highest level of accuracy to ensure optimal functional and aesthetic outcomes. Computer navigation systems for reconstruction of the facial skeleton have received increased attention in recent years. This study describes repair of complex orbital fractures using a treatment protocol of computer planning with preoperative scanning, intraoperative navigation and intraoperative CT scanning to ensure optimal placement of orbital implants. Our hypothesis was that this technique improves outcomes in complex orbital fractures with decreased requirements for revisional surgery. Methods: Over an 18-month period a review of 48 consecutive orbital trauma cases was completed in a prospective manner using our protocol. An IRB approval was obtained from the review committee for the study at North Memorial Medical center which is a Level I trauma Center. Data were collected on patient characteristics; fracture severity, diplopia and globe position, complications, and need for revision surgery and most importantly repositioning of the implant after placement. Results: Our results showed that the average age of all the patients was at 39.75 years (Range 12-88 yrs.). Male to female ratio was noted to be 3:1. Themajority of fractures were related to assault (37.5%), followed by motor vehicle collisions (29.12%), and then followed by falls (11%) and gunshotwounds at 6.25%. The average time to get a patient from the time of injury to the operating room was 8 days to allow for a reduction of swelling. Single orbital injuries were noted in about 37.5% of cases, while the most common injury associated with an orbital fracture was a ZMC fracture (60%). The orbital floor was involved almost 91% of the times, with the medial wall also being involved in 50% of cases. Lateral wall involvement and medial wall involvement were fairly similar at 16.67% and 14.58% respectively. Single wall defects were noted in about 49.7% of cases, twowalled defects noted in 37.5% of cases, three-walled defects noted in 10.4% of cases and all four-wall involvement was noted in approximately 4% of cases. The median number of walls fractured in any case was 1.7. Intraoperatively, the implant was repositioned in 6.25% of the patients. Major complication rates were at 14.6% however none of the patients required any repositioning of the implant. The complications included a pseudoaneurysm of the ophthalmic artery due to a gunshot injury that was coiled, nasolacrimal duct injury, entropion and enopthalamos due to fat atrophy in four cases. No patients required repositioning of the orbital implant postoperatively. Conclusions: Intraoperative navigational surgery can improve the quality and outcomes of orbital reconstruction. This study is the first to qualitatively assess orbital surgery outcomes using intraoperative navigation at a single institution in a prospective manner. Based on significant improved outcomes in postoperative diplopia and orbital volume, as well as the decreased need for revision surgery, we demonstrate improved outcomes in complex orbital reconstruction and recommend its use for complex orbital fracture repair.

4165. Patel, K. G., et al. (2016). "Persistent pneumocephalus after gun shot wound to the head." PM and R **8**(9): S275.

Case/Program Description: A 53-year-old man suffered a gun shot wound (GSW) to the head, resulting in a significant complex injury to the head and face, including a left frontotemporal subdural hematoma and pneumocephalus after injury. The patient underwent a bifrontal craniotomy with reconstruction of the skull base for notable cerebrospinal fluid (CSF) leak. After surgery, the patient became more lethargic and was found to have tension pneumocephalus, which was treated with endovascular drain (EVD) placement. Otolaryngology (ENT) performed nasal endoscopy, but found no evidence of CSF leak, and the EVD was discontinued. Two weeks later, a follow up CT scan showed persistent large volume pneumocephalus. Plastics and ENT were again consulted, but did not find evidence for CSF leak. The patient was then started on 100% oxygen for 8 days for treatment of his pneumocephalus. A follow-up CT at both 11 days and 1 month after treatment showed resolution of the pneumocephalus. Setting: Long Term Acute Care Rehabilitation Facility. Results: Resolution of pneumocephalus. Discussion: Pneumocephalus is a known sequelae of GSW to the head, and also common after craniotomy. For small pneumocephalus, the air spontaneously resorbs, but in our case, large pneumocephalus was present more than a month after craniotomy. Symptoms of large pneumocephalus, when present, range from headache and lethargy to brain herniation and death. Such persistence of large pneumocephalus often suggests a CSF tract. However, once this is excluded, the effective treatment is 100% oxygen, which lowers the concentration of nitrogen in the blood allowing for a concentration gradient to develop by which the 80% nitrogen in the pneumocephalus can slowly diffuse away. Conclusions: Pneumocephalus is a complication of both craniotomy and GSW to the head. For cases of large volume or persistent pneumocephalus, CSF tract should be excluded, followed by treatment with 100% oxygen.

4166. Patel, M. B. (2013). "Editorial critique." Journal of trauma and acute care surgery **75**(1): 14.

4167. Patel, N. N., et al. (2002). "Penetrating injury of the cheek requiring skull base exploration." The Journal of laryngology and otology **116**(7): 548-550.

We report a case of a very unusual penetrating injury of the middle third of the face. The patient was involved in a road traffic accident, and the indicator control lever became impaled in his right cheek. There was contralateral orbital damage resulting in loss of sight. The cribriform plate was breached and a pneumoencephalocele ensued. We discuss the modern management of such injuries including injury assessment. We emphasize the importance of crash scene information gathering and analysis of injury mechanisms. Facial injury zonal classification and imaging are reviewed in the context of the case. We discuss the reasons that led us to treat this patient via the subcranial approach.

4168. Patel, P. M., et al. (2004). "Cranial blade: retained for three years." British journal of neurosurgery **18**(1): 74-75.

4169. Patel, R. J. and J. M. Sosman (2012). "My teeth won't let me eat." Journal of General Internal Medicine **27**: S456.

LEARNING OBJECTIVE 1: To recognize the differential diagnosis for a patient presenting with trismus. LEARNING OBJECTIVE 2: To distinguish disease manifestations and review management of a patient with Tetanus. CASE: A 78 year-old female presented to the ED by EMS after being found on the floor of her home by neighbors. She was found unresponsive with possible seizure-like activity. An oral airway was initially placed, but removed after improvement in her mental status. The patient lived in unsanitary conditionswith a dirt floor and each roomfilled with hoarded items. In the ED, the patient complained “my teeth won't let me eat.” She was hungry but stopped eating due to fear of choking. She also complained of weakness and sacral pain due to a fall. Her VS: BP 138/48, HR 84, RR 22, T 37.8 C. Her exam revealed episodes of interrupted speech due to clenching her jaw which lasted only a few seconds. She had no other neurologic deficits. She had no visible wounds, however her feet and toe-nails were caked with dirt. Her labs revealed WBC 12.0 K/uL, CK 2369 (N 0-175), troponin 0.29 (N 0-0.05), Ca 9.1, BUN 60, Cr 1.6. EKG showed anterolateral T wave flattening and the CXR had RML infiltrates. Initial therapy included a heparin drip for possible NSTEMI and IV Ceftriaxone for aspiration pneumonia. The differential diagnosis included Tetanus, so she was begun on IV Metronidazole and Tetanus IG which required several hours to obtain sufficient doses from other health care facilities. Subsequent tests revealed a normal TTE and EEG negative for seizure-like activity. The patient's symptoms quickly progressed with frequent episodes of trismus along with apnea and hypoxemia. She also developed spastic contractions of her upper extremities, muscle rigidity, and 1st and 2nd degree AV block with 5 second pauses. The patient was given muscle relaxants, and 3000 units of IM Tetanus IG. She refused intubation or CPR. She developed progressive apnea and bradycardia despite atropine and died within 48 hours. Her blood cultures revealed no growth. DISCUSSION: Tetanus is a disorder caused by the toxin producing anaerobe Clostridium tetani. Now rare in the developed world, the CDC estimates an annual incidence of 1 per 10 million people in the US, and 2.3 per 10 million in those ages>65. The bacterium is ubiquitous in soil and remains a threat to all unvaccinated people. Infection occurs through penetrating injury with a foreign body, or within devitalized tissue. In 10% of cases, no cause is identified. C. tetani spores produce tetanospasmin that irreversibly binds to receptors of anterior horn cells. This results in autonomic instability, increased muscle tone, and severe spasms. Tetanus is a clinical diagnosis with 50% of cases presenting with trismus, a forceful spasm of the masseter muscle. Differential diagnosis includes Strychnine poisoning, drug-induced dystonias, neuroleptic malignant syndrome, and Stiff-person Syndrome. Treatment includes wound care and antibiotics to halt toxin production, neutralizing unbound toxin with Tetanus IG, sedatives to control spasms, and intubation with paralysis for weeks. Though the majority of patients survive with optimal management, mortality is as high as 50% in those who are treated conservatively. Unfortunately, our patient had not received health care or vaccinations for over two decades. This case underscores the importance of continued tetanus vaccination even during a time of advanced medical care.

4170. Patel, S. J., et al. (2021). "Sociodemographic Factors and Outcomes by Intent of Firearm Injury." Pediatrics **147**(4).

BACKGROUND AND OBJECTIVES: Firearm injuries are a leading and preventable cause of morbidity and mortality among youth. We sought to explore differences in sociodemographic factors and youth firearm injury outcomes by injury intent (unintentional, assault, and self-harm)., METHODS: We conducted a repeated cross-sectional analysis of emergency department (ED) visits among youth aged 21 and younger presenting to an ED with a firearm injury between 2009 and 2016 using the Nationwide Emergency Department Sample. We performed multivariable logistic regression to measure the strength of association between (1) patient-level factors, (2) visit-level characteristics, and (3) clinical

outcomes and intent of firearm injury., RESULTS: We identified 178 299 weighted visits for firearm injuries. The mean age was 17.9 (95% confidence interval 17.8-18.0) years; 89.0% of patients were male, 43.0% were publicly insured, 28.8% were admitted, and 6.0% died. Approximately one-third of the injuries were categorized as unintentional (39.4%), another third as assault (37.7%), and a small proportion as self-harm (1.7%). Unintentional firearm injuries were associated with younger age, rural hospital location, Southern region, ED discharge, and extremity injury. Self-harm firearm injuries were associated with older age, higher socioeconomic status, rural hospital location, transfer or death, and brain, back, or spinal cord injury. Firearm injuries by assault were associated with lower socioeconomic status, urban hospital location, and requiring admission., CONCLUSIONS: We identified distinct risk profiles for youth with unintentional, self-harm-, and assault-related firearm injuries. Sociodemographic factors related to intent may be useful in guiding policy and informing tailored interventions for the prevention of firearm injuries in at-risk youth.

4171. Patel, S. N., et al. (2012). "Diagnostic value of clinical examination and radiographic imaging in identification of intraocular foreign bodies in open globe injury." European journal of ophthalmology **22**(2): 259-268.

PURPOSE: To evaluate the diagnostic accuracy of clinical eye examination and radiographic imaging in the identification of intraocular foreign bodies (IOFBs) in open-globe traumatic injuries., METHODS: This was a retrospective chart review of open-globe traumatic injuries with IOFBs presenting to University Hospital (UH) at New Jersey Medical School between 1998 and 2008., RESULTS: A total of 527 patients with traumatic open globe injuries presented to UH, Newark, New Jersey, USA, between 1998 and 2008. Of these, 74 patients had surgically confirmed IOFBs. Mean age of patients with traumatic open globe injury and an IOFB was 33 years (range, 8-69 years); mean follow-up was 17.6 months (range, 1 day-90 months). Foreign bodies were identified as glass (13), metal (58), wood (1), plastic (0), and other (2). There were 24 anterior segment (AS) IOFBs, 45 posterior segment (PS) IOFBs, and 5 noted in both segments. Clinical eye examination at presentation identified an IOFB in 34 (45.6%) of 74 patients. B-scan echography revealed an IOFB in 14 (51.9%) of 27 cases. Computed tomography scan of the orbits identified IOFBs in 56 (94.9%) of 59 cases. Clinical eye examination was performed in all (100%) patients. B-scan was performed only when posterior segment pathology was suspected. Computed tomography scan was performed when an IOFB or orbital fracture was suspected., CONCLUSIONS: Computed tomography scan was the most reliable method for identifying IOFBs in patients presenting with open globe injuries in comparison to clinical eye examination and B-scan echography. This result was consistent regardless of IOFB location within the globe.

4172. Patel, T. P., et al. (2018). "Optic Nerve Avulsion After Finger-Poke Injury." Journal of neuro-ophthalmology : the official journal of the North American Neuro-Ophthalmology Society **38**(1): 57-59.

We present a case of optic nerve avulsion as a result of finger-poke injury to the eye. Spectral domain optical coherence tomography demonstrated a plunging cup indicative of the avulsion, a finding not previously described. Optic nerve avulsion is a form of anterior indirect traumatic optic neuropathy evoked by a sudden severe rotation at the junction of the optic nerve and globe induced, in this case, by penetration of the finger into the nasal orbit.

4173. Paterson, T. A., et al. (2014). "Not such a long shot: Mortality, discharge function and organ donation in penetraining brain injury." Neurocritical care **21**(1): S145.

Introduction Penetrating brain injury (PBI) is traditionally associated with high mortality. Despite the grave prognosis, it remains poorly described. The goal of this study was to observe outcomes and trends in PBI. Methods A retrospective review was performed of PBI over 5 years. The primary outcome was mortality. Secondary outcomes included organ donation and discharge GCS. Results There were 307 patients with PBI. Overall mortality was 62.9% (45 brain and 144 cardiac deaths). 36.6% of PBI presented with systolic blood pressure (SBP)< 90mmHg. 72.3% presented with a Glascow Coma Score (GCS)< 8 and 23.1% with a GCS from 13-15. Lateralizing signs were present in 12% and dilated pupils in 62.7%. Overall organ donation rate was 16%. Within the first 24 hours, mortality was 85.5%. As compared to survivors, of patients who died; 85% presented with GCS of 3(vs. 19.3%, p< 0.001), 92% with abnormal pupils (vs. 28.9%,p< 0.001), and 75.1% with SBP< 90mmHg(vs. 3.5%,p< 0.001). 53.6% of PBI survived to ICU compared to 39.4% who ultimately died in ICU. Among 61 survivors to ICU, organ donation rate was 53.6%. Amongst 113 survivors, 19.3% had a GCS of 3 on presentation. Functional outcomes were excellent in survivors; 69.9% had discharge GCS of 13-15, 93.8% had a discharge motor GCS of 6. 3.5% of the survivors were hypotensive in the Emergency Department(ED). Of

survivors, 3.5% had cardiac arrest in the ED and 3.5% arrested pre-admission. Pupillary abnormalities were often seen in survivors, with lateralizing signs in 19.6% and dilated pupils in 15%. Conclusions Despite a historically high case-fatality rate, many patients with PBI survive with good functional outcome. While attempts can be made at prognosticating survival on admission, decreased admission GCS and cardiac arrest were seen in survivors. Overall organ donation rate was low, but in those who survive the initial post-injury period, donation rates were substantial.

4175. Patil, Y., et al. (2011). "Apocrine hidrocystoma masquerading as a posttraumatic cerebrospinal fluid leak: case report and literature review." Archives of otolaryngology--head & neck surgery **137**(10): 1031-1034.

4176. Patir, R., et al. (1995). "Post-traumatic brain abscess: experience of 36 patients." British journal of neurosurgery **9**(1): 29-35.

Thirty-six patients with post-traumatic brain abscess were managed over 18 years. They constituted 9.3% of all brain abscesses encountered during the same period. The head injury was associated with an external compound fracture in 20, internal compounding in three and was closed in 13 patients. The mean interval between the time of injury to presentation with an abscess was 113 days. This did not differ significantly in patients with closed and compound head injury, and amongst patients who had wound sepsis and with clean wounds after the injury. The occurrence of focal neurological deficit was more frequent in patients with a closed injury ($p < 0.05$). Twenty patients underwent primary excision of the abscess with recurrence of the abscess in one patient. Of the 14 patients in whom the abscess was initially aspirated, eight patients required a subsequent excision. Excision was required in 18 patients (94.7%) with external compound injury, five (50%) of those with closed injury and in all patients with internally compound injuries. Two patients had 'coned' and died before they could be operated upon. The operative mortality in the absence of signs of herniation preoperatively was 12.5% in patient with compound injury and none among patients with closed head injury.

4178. Patra, B. N. (2022). "Traumatic Brain Injury." Indian Journal of Psychiatry **64**(SUPPL 3): S637.

Traumatic brain injury (TBI) is an alteration in brain function or other evidence in brain pathology caused by an external force such as head struck by an object, foreign body penetrating the brain, or force from blast or explosion. TBI is one of the major causes of morbidity and mortality in developing countries.1 TBI can be classified as primary and secondary brain injury. Acute management of TBI includes hospitalization, intensive care management, and surgery.

4179. Patten, J. T. (1975). "Penetrating transorbital foreign body with ocular preservation." Annals of ophthalmology **7**(5): 651-654.

Large penetrating transorbital foreign bodies may initially appear to be of a devastating character to the ocular tissues. However, several reports of such large foreign bodies have proved to spare the eye. A case report of a large wooden foreign body with transorbital penetration into the right frontal lobe is reported. The globe remained intact and was only displaced, with a final visual acuity of 20/40. However, complete ophthalmoplegia and ptosis persisted. A low pressure hydrocephalus ensued following intracranial debridement.

4180. Paucic-Kirincic, E., et al. (1997). "Transorbital penetrating brain injury caused by a toy arrow: a case report." Pediatric rehabilitation **1**(3): 191-193.

A case of a 9-year-old boy with a transorbital toy-arrow injury to the brain is presented. At admission he was in coma (Glasgow Coma Scale of 6) with right hemiparesis and had a completely prolapsed left eye. Computerized tomography revealed intracranial haemorrhage and fracture of the orbital wall, which were treated conservatively. His left eye was enucleated due to massive injury. At the 6-month check-up the boy still show neurological signs of latent right hemiparesis. Disturbances, mostly cognitive, were noted on his psychological tests. A survey of the literature reveals no report of this nature in the paediatric age group. The necessity of continuous monitoring of new environmental risks as they occur, and the requirement for the prevention of recreational brain injuries in children, is stressed.

4181. Paul, A. M. and T. Grundmann (2010). "[Intraorbital wooden foreign body undetected on CT]." Computertomographisch nicht beschriebener intraorbitaler holzerner Fremdkorper. **58**(12): 1237-1240.

We present the case of an orbital fracture and a wooden foreign body found during surgery. The patient had undergone a pre-operative computed tomography scan but the foreign body had not been seen on these images. We discuss the difficulties in demonstrating wooden objects on CT and describe indicators in patient history, examination findings and radiological signs that might suggest the presence of a wooden object. We emphasise the necessity to explore any orbital injury if there are clinical signs suggesting an intraorbital foreign body.

4183. Paula, A., et al. (2021). "Traumatic extracranial internal carotid arteryaneurysm as a cause of ischemic stroke." European Stroke Journal **6**(1 SUPPL): 497.

Background and Aims: Extracranial internal carotid artery (EICA) aneurysms are rare and frequently asymptomatic. However, they may manifest with neurological symptoms due to ischemic stroke, transient ischemic attack or Horner's syndrome. Atherosclerosis is the main cause, but other causes include infections, congenital conditions and trauma.We describe a case report of an ischemic stroke caused by a traumatic EICA aneurysm. Methods: Clinical course and imaging are described. Results: A 30-year-old male, who had suffered abdominal and cervical trauma caused by gunshot projectiles 6 years ago, presented with acute onset neglect, left homonymous hemianopia, right oculocephalic deviation, left central facial palsy and left hemiparesis. Brain CT scan revealed infarction of the right middle cerebral artery territory. CT angiography showed right M1 segment occlusion and an extracranial aneurysm of the right ICA. He underwent endovascular treatment with partial recanalization (TICI2c). Carotid ultrasound also revealed the aneurysm and identified a hypoechoic heterogeneous and fibrous structure compatible with intra-aneurysm thrombus. Later, he presented clinical and imaging worsening which led to a decompressive craniectomy. At discharge, the patient maintained important motor deficits. Antiplatelet therapy was started and the aneurysm will be reevaluated. Surgical treatment is being considered. Conclusions: We report a traumatic EICA aneurysm as a rare cause of ischemic stroke. It highlights the importance of keeping follow-up of these patients to prevent serious complications.

4184. Păun, M. A., et al. (2020). "Complex facial trauma caused by self-shooting: A case report." Romanian Journal of Legal Medicine **28**(1): 63-67.

Trauma caused by firearms is complex, often fatal, especially when addressing certain anatomical regions such as the face and neck. The causes range from attempted murder to attempted suicide or accident. Their differentiation is important both legally and due to the fact that they can trans-late certain psychiatric sufferings of the patient that will have to be considered in the subsequent management. This kind of trauma is often characterized by significant loss of soft tissue and bone, which, for the survivors, will mean numerous reconstructive interventions in a multidisciplinary approach, lasting recovery and difficult social reintegration. The severity of these wounds is mainly related to the type of weapon used, the firing distance and the mass and velocity of the bullet. We will present the successful management regarding the treatment and rehabilitation of a patient with complex trauma caused by auto-shooting at the face level.

4186. Pavelites, J. J., et al. (2010). "Death by black powder revolver: a case report." Forensic science, medicine, and pathology **6**(4): 298-303.

Deaths resulting from the use of black powder handguns are relatively uncommon compared to other firearms. We report the case of a 48 year-old woman who sustained a lethal gunshot wound to the face from a black powder revolver. Autopsy revealed extensive soot and powder deposition around the entrance wound between the right eye and nose with perforation of the skull and brain. The exit wound also contained evidence of soot. Discussion of this characteristic pattern of discharge deposition from black powder weapons is presented.

4187. Pavelites, J. J., et al. (2011). "An unusual case of lead snowstorm caused by fragmentation of buckshot." The American journal of forensic medicine and pathology **32**(3): 223-226.

This article reports the unusual radiographic findings of 2 cases of a shotgun shooting incident involving the homicide of a plant manager and the subsequent suicide of the assailant. Radiologic examination of wounds produced by the no. 00 copper-plated buckshot used in the incident revealed images with striking similarity to the lead snowstorm appearance generally associated with high-velocity, soft-point rifle bullets.

4188. Pavlidis, P., et al. (2016). "Traumatic Brain Injury Due to Screwdriver Assaults: Literature Review and Case Report." The American journal of forensic medicine and pathology **37**(4): 291-298.

Penetrating head injuries due to the use of screwdrivers as wounding agents in acts of interpersonal violence seldom occur. The aim of this article is to update and summarize the relevant literature on penetrating craniocerebral screwdriver stab wounds and to report a new case of screwdriver assault. A number of studies were reviewed to investigate the incidence, distribution, common findings, mechanism of injury, differential diagnostic criteria, complications, treatment, and prognosis of craniocerebral screwdriver stab injuries. It was observed that the degree of traumatic severity depends on the cross-sectional area of the screwdriver and the anatomical region of injury. Craniocerebral screwdriver injuries are mainly cases of interpersonal violence and the mortality rate is approximately 47.6%. In 23.8% of the incidents, the trauma is overlooked on admission because of the small entry wound and, thus, the severity of the injury is not initially appreciated.

4189. Pavlidis, P., et al. (2018). "Is the Garden Gun (Flobert 9 mm) Capable of Inducing Fatal Injury?: Literature Review and Comparative Presentation of Two Cases." The American journal of forensic medicine and pathology **39**(1): 18-22.

This article presents both a fatal suicide incident by Flobert 9 mm-type smoothbore weapon with a single-shot projectile and a nonfatal case of a suicide attempt by the same weapon type with a dispersion cartridge from the authors' forensic record. A retrospective study was conducted examining 84 cases involving cases of headshots inflicted by all kinds of weapons deriving from the broader region of Eastern Macedonia and Thrace (Northern Greece) between 2000 and 2015, among which only 1 involved lethal wounding by a Flobert 9 mm (1.19%). Only a single case report of a fatality with such a weapon has been described throughout international literature. A comparative study also follows between the 3 incidents. The authors argue that a prerequisite for the lethal outcome of the shooting is the absolute contact of the weapon to the head as well as its placement at an anatomical point where the bone resistance is relatively lower, so that the intracranial entry of the projectile is possible. It is also more harmful if the cartridge contains a single-shot projectile rather than multiple projectiles of smaller diameter.

4190. Pavlova, O. Y., et al. (2020). "Computed tomography in concomitant gunshot injury of facial skeleton." Russian Electronic Journal of Radiology **10**(2): 223-237.

Purpose. Demonstration of computed tomography (CT) possibilities in a patient with combined damage to the facial and brain parts of the skull due to a gunshot wound. Materials and methods. A male patient, 36 years old, was admitted to the hospital in May 2016 after an accident. The diagnosis was combined gunshot injury, penetrating shot wounds of the skull, brain, facial skeleton with damage to the orbits, upper and lower jaws. Upon admission to the hospital, primary surgical treatment of facial wounds and tracheostomy were performed, reposition of the lower jaw fragments with metallic osteosinthesis, enucleation of the right globe. In May 2018 the patient was hospitalized at the

maxillofacial surgery clinic №4 at the Sechenov University in order to conduct reconstructive surgical treatment of the facial skeleton. At the Russian-Japanese imaging center, Clinical University Hospital №1, the patient underwent multispiral computed tomography (MSCT) to assess the damage to bone and soft tissue structures of the face and determine the tactics of surgical treatment. MSCT was performed on a Toshiba Aquilion ONE 640-slice computer tomograph (Japan), with a slice thickness of 0.5 mm, in a spiral mode, with capture of the facial and brain parts of the skull, in the mode of bone and soft tissue reconstruction. The study was supplemented by multi-planar and three-dimensional reconstructions. Results. According to the results of MSCT, multiple post-traumatic defects and deformations of the facial skeleton were revealed. In the area of the facial skeleton, both orbits, the left eyeball and the brain, multiple foreign bodies were determined. Using MSCT data, virtual planning was carried out to determine the volume of reconstructive treatment and the choice of autografts. The first step was surgical repair of the upper jaw with an autograft from the scapula. The second stage was the reconstruction of the lower jaw with an autograft from the fibula. As a result of surgical treatment, the anatomical and topographic relationship of the bone structures of the facial skeleton was restored. The patient's condition at discharge was satisfactory. In the future, it is planned to carry out reconstructive operations in the area of the facial skeleton in order to fill the deficit of face soft tissues and restore the aesthetic appearance of the patient. Conclusion. This clinical observation demonstrates the importance of high-quality and timely diagnosis of patients with gunshot injuries of the facial skeleton both at the stage of the initial examination and the preoperative stage, and during monitoring in postoperative stages. Performing MSCT in this category of patients helps to obtain complete information about the condition of the bone and soft tissue structures of the facial skeleton, brain, reveal all the associated injuries, as well as plan the course and volume of surgery..

4191. Pavon, J. J., et al. (2019). "In situ Study Unravels Bio-Nanomechanical Behavior in a Magnetic Bacterial Nano-cellulose (MBNC) Hydrogel for Neuro-Endovascular Reconstruction." Macromolecular bioscience **19**(2): e1800225.

Surgical clipping and endovascular coiling are well recognized as conventional treatments of Penetrating Brain Injury aneurysms. These clinical approaches show partial success, but often result in thrombus formation and the rupture of aneurysm near arterial walls. The authors address these challenging brain traumas with a unique combination of a highly biocompatible biopolymer hydrogel rendered magnetic in a flexible and resilient membrane coating integrated to a scaffold stent platform at the aneurysm neck orifice, which enhances the revascularization modality. This work focuses on the in situ diagnosis of nano-mechanical behavior of bacterial nanocellulose (BNC) membranes in an aqueous environment used as tissue reconstruction substrates for cerebral aneurysmal neck defects. Nano-mechanical evaluation, performed using instrumented nano-indentation, shows with very low normal loads between 0.01 to 0.5 mN, in the presence of deionized water. Mechanical testing and characterization reveals that the nano-scale response of BNC behaves similar to blood vessel walls with a very low Young's modulus, E (0.0025 to 0.04 GPa), and an evident creep effect (26.01 +/- 3.85 nm s-1). These results confirm a novel multi-functional membrane using BNC and rendered magnetic with local adhesion of iron-oxide magnetic nanoparticles.

4192. Pawar, S. S., et al. (2015). "Reconstructive and rehabilitation challenges following a cranio-orbital gunshot wound." Ear, nose, & throat journal **94**(1): E21-26.

We present a case of a 26-year-old man who sustained a close-range gunshot wound to the head. His injuries included significant left orbital injury resulting in a ruptured, blind eye and severely comminuted fractures of the left orbital roof, superior and inferior orbital rims, and orbital floor. Associated injuries included left frontal lobe injury, anterior and posterior table fractures of the left frontal sinus, and a comminuted left zygomaticomaxillary complex fracture. We employed an interdisciplinary surgical approach with collaboration among the Otolaryngology, Neurosurgery, and Oculoplastic Surgery services performed in two stages. Management of such extensive craniofacial injuries can be challenging and requires a coordinated, interdisciplinary approach.

4193. Pawsey, S. C., et al. (2020). "Suicide by Close-Range Gunshot Wound to the Bridge of the Nose." Journal of forensic sciences **65**(3): 984-986.

Suicidal gunshot wounds to the nasal bridge are rare, particularly at close range (defined as muzzle of the weapon not touching the skin surface, but near enough to deposit soot and stippling). Previously reported suicidal gunshot wounds to the nose have been through the left nostril (Forensic Sci Int 1995;71(1):25-31; J Forensic Radiol Imag

2013;1(2):63-7). The death of a 26-year-old man with a close-range gunshot wound to the bridge of the nose was deemed suicide due to history, scene, and autopsy findings. These findings included previous suicidal ideation, texted and written notes, the decedent's cross-legged position seated on the floor, the trajectory of the bullet through his head and into the ceiling fan and roof above him, and acute alcohol intoxication. This decedent may have been intending a hard contact forehead location but inadvertently fired the gun into the bridge of his nose while bending forward, prior to contact.

4194. Peabody, J. L. (1992). "Reflections on the Loma Linda University experience." Clinical ethics report **6**(3): 1-2.

4195. Pearce, C. W. and P. G. Young (2014). "On the pressure response in the brain due to short duration blunt impacts." PloS one **9**(12): e114292.

When the head is subject to non-penetrating (blunt) impact, contusion-type injuries are commonly identified beneath the impact site (the coup) and, in some instances, at the opposite pole (the contre-coup). This pattern of injury has long eluded satisfactory explanation and blunt head injury mechanisms in general remain poorly understood. There are only a small number of studies in the open literature investigating the head's response to short duration impacts, which can occur in collisions with light projectiles. As such, the head impact literature to date has focussed almost exclusively on impact scenarios which lead to a quasi-static pressure response in the brain. In order to investigate the response of the head to a wide range of impact durations, parametric numerical studies were performed on a highly bio-fidelic finite element model of the human head created from in vivo magnetic resonance imaging (MRI) scan data with non-linear tissue material properties. We demonstrate that short duration head impacts can lead to potentially deleterious transients of positive and negative intra-cranial pressure over an order of magnitude larger than those observed in the quasi-static regime despite reduced impact force and energy. The onset of this phenomenon is shown to be effectively predicted by the ratio of impact duration to the period of oscillation of the first ovalling mode of the system. These findings point to dramatically different pressure distributions in the brain and hence different patterns of injury depending on projectile mass, and provide a potential explanation for dual coup/contre-coup injuries observed clinically.

4196. Peariso, K., et al. (2018). "Presenting characteristics and outcomes in moderate to severe pediatric traumatic brain injury: Blunt versus penetrating trauma." Annals of neurology **84**: S328.

Objective: While adult TBI studies suggest penetrating TBIs have worse outcomes, the spectrum and intent of penetrating TBI in the pediatric population is inherently different. The primary objective of this study is to compare the clinical presentation and outcome of pediatric patients with moderate and severe TBI resulting from blunt trauma versus those with penetrating trauma. Methods: We performed a retrospective review of pediatric patients with moderate and severe TBI including both blunt and penetrating mechanisms. Patients 0-18 years, excluding non-accidental traumas, presenting to Cincinnati Children's Hospital and the University of Cincinnati Medical Centers were included. Outcomes were mortality, Pediatric Functional Independence Measures (wee-FIM), and the Glasgow Outcome Scale-Extended (GOS-E) pediatric scores at 12-18 months post-injury. Results: Records from 60 patients were reviewed. Patients with hypotension, coagulopathy and non-reactive pupils on presentation had higher mortality, and this was not different between the two groups. Initial GCS scores negatively correlated, while Rotterdam scores positively correlated with GOS-E pediatric scores in both groups. Penetrating TBI had a higher mortality rate than blunt TBI in this cohort. However, the survivors of penetrating TBI had higher wee-FIM scores on admission to inpatient rehab. There was no significant difference between ICU length of stay or inpatient rehabilitation length of stay. Conclusions: This study suggests that presenting features predictive of poor outcome in adult TBI are potentially applicable in early prognostication in pediatric TBI. The data also show increased mortality in pediatric penetrating TBI, but the survivors have better functional status on admission for rehabilitation.

4197. Pearl, P. L., et al. (2013). "Results of phase II levetiracetam trial following acute head injury in children at risk for posttraumatic epilepsy." Epilepsia **54**(9): e135-137.

Posttraumatic seizures develop in up to 20% of children following severe traumatic brain injury (TBI). Children ages 6-17 years with one or more risk factors for the development of posttraumatic epilepsy, including presence of

intracranial hemorrhage, depressed skull fracture, penetrating injury, or occurrence of posttraumatic seizure were recruited into this phase II study. Treatment subjects received levetiracetam 55 mg/kg/day, b.i.d., for 30 days, starting within 8 h postinjury. The recruitment goal was 20 treated patients. Twenty patients who presented within 8-24 h post-TBI and otherwise met eligibility criteria were recruited for observation. Follow-up was for 2 years. Forty-five patients screened within 8 h of head injury met eligibility criteria and 20 were recruited into the treatment arm. The most common risk factor present for pediatric inclusion following TBI was an immediate seizure. Medication compliance was 95%. No patients died; 19 of 20 treatment patients were retained and one observation patient was lost to follow-up. The most common severe adverse events in treatment subjects were headache, fatigue, drowsiness, and irritability. There was no higher incidence of infection, mood changes, or behavior problems among treatment subjects compared to observation subjects. Only 1 (2.5%) of 40 subjects developed posttraumatic epilepsy (defined as seizures >7 days after trauma). This study demonstrates the feasibility of a pediatric posttraumatic epilepsy prevention study in an at-risk traumatic brain injury population. Levetiracetam was safe and well tolerated in this population. This study sets the stage for implementation of a prospective study to prevent posttraumatic epilepsy in an at-risk population.

4198. Pearl, R. M., et al. (1988). "An approach to mandibular reconstruction." Annals of plastic surgery **21**(5): 401-417.

Mandibular reconstruction requires the restitution of both form and function. Proper preoperative planning, vascularized bone grafts, rigid fixation, flexibility of donor site choices, and restoration of labial, buccal, and lingual sulci lead to optimal reconstruction. We have used this approach in 38 patients; bony survival resulted in 37 and primary union in 35. A main limiting factor exists with individuals who have lost extensive amounts of soft tissue and muscle at the time of tumor resection or trauma. Only by attention to details in the preoperative, intraoperative, and postoperative phases can the best functional and aesthetic results be achieved.

4199. Pearson, I. Y. (1993). "The potential organ donor." The Medical journal of Australia **158**(1): 45-47.

The source of most organs for transplantation is the brain-dead cadaveric donor. The realistic potential donor is one for whom mechanical ventilation and other support, to the point of brain death, is provided in the best interests of that patient, and not solely for the purpose of organ donation. Brain death secondary to spontaneous intracranial haemorrhage now exceeds traumatic head injury as a source of organ donors in Australia. There are now few medical exclusions to organ donation. Age limits rise constantly. No patient should be excluded without referral to the transplant coordinator. Adequate medical support of the potential donor is no more than should be provided to the severely brain-injured patient. Haemodynamic and other organ support are as logically appropriate as ventilation and must be continued until confirmation of brain death. Support should cease only if organ donation will not occur. Australian State laws define brain death as irreversible cessation of all function of the brain of the person, but do not dictate the methods of confirmation. The prospect of organ donation should not be raised until brain death is confirmed. The over-riding principle is that the family always has the right to be asked. There is no other way for the family's and patient's wishes about organ donation to be known and respected. It is vital that the person who will ask be experienced, competent and committed. A dedicated medical, nursing and allied health team providing care of the family throughout the period is essential.

4200. Pease, M., et al. (2013). "Diagnosis and surgical management of traumatic cerebrospinal fluid oculorrhea: case report and systematic review of the literature." Journal of neurological surgery reports **74**(1): 57-66.

Background Oculorrhea, or cerebrospinal fluid leakage developing from a cranio-orbital fistula, is a rare development following traumatic injury. Case Report A 22-year-old man involved in a motor vehicle accident developed a blowout fracture of the left orbital roof penetrating the frontal lobe, inducing oculorrhea. He underwent a supraorbital craniotomy for removal of the bony fragment and skull base reconstruction using a pericranial flap. Methods A systematic review of the database was performed to identify all prior cases of traumatic oculorrhea. Results Twenty-two reported cases met inclusion criteria for subsequent analysis. Oculorrhea developed due to blunt and penetrating head injury in 14 (64%) and 8 patients (36%), respectively. The most common mechanisms were car accidents, stab wounds, falls, and gunshot wounds. Ocular signs and symptoms-including visual loss, ophthalmoplegia, and pupillary dysfunction-were commonly associated findings. Initial conservative management was successful in four patients. Thirteen patients underwent initial surgical intervention, and three additional patients required operative intervention following failed

conservative treatment. Conclusion Although oculorrhea rarely develops following severe orbital trauma, suspicion should nevertheless be maintained to facilitate more prompt diagnosis and management. The decision for conservative versus surgical management often depends on the severity of the fracture and dural injury.

4201. Pechernikova, T. P., et al. (1993). "[The forensic psychiatric expertise of victims who received craniocerebral trauma in a criminal situation]." Sudebno-psikhiatricheskaia ekspertiza poterpevshikh, poluchivshikh cherepno-mozgovuiu travmu v kriminal'noi situatsii. **36**(3): 33-36.

Thirty victims of criminal situations with craniocerebral injuries were examined. Clinical picture and time course of changes in the mental disorders, that are the most important for practical forensic medical expert evaluation, were analyzed, and approaches to the choice of the correct expert conclusion in assessment of the severity of injuries and of the victims' abilities discussed.

4202. Peduzzi, J., et al. (2011). "Functional improvement in tbi using syngeneic olfactory mucosa stem cells in inbred rat." Journal of neurotrauma **28**(6): A124-A125.

INTRODUCTION: The safest and most effective treatment for traumatic brain injury (TBI) may be autologous stem cells delivered into the cerebrospinal fluid (CSF). CSF-injected stem cells home to the injured area which would be critical in diffuse axonal injury that damages several areas. These CSF-injected stem cells penetrate the brain and induce recovery. Olfactory mucosa (OM) stem cells can be obtained from the nose and their normal fate is neurons, making them safer to use. METHODS: Adult inbred Lewis rats (345-395g) received a sham surgery or severe TBI using the Marmarou model (450g weight dropped 2 meters). Two weeks later, 3 groups (6/group) received CSF injections of saline or iron-oxide-labeled OM stem cells. Blinded functional testing (1-7 weeks post-injury) included the Beam Balance, Inclined Plane, 8-Arm Radial Maze and Barnes Table tests. RESULTS/DISCUSSION: In the Beam Balance at one week posttreatment, the stem cell-injected injured group was similar to the sham group while significantly different from the vehicle-injected injured group ($p=0.017$). At later times, performance was similar. For the Inclined Plane, Radial Arm Maze and Barnes Table tests, the stem cell-injected injured group performed similarly to the sham group and consistently performed better than the saline-injected injured group at 3 and 4 weeks after treatment. In the Radial Arm Maze, this difference reached significance level at week 4 after treatment ($p=0.041$). In Barnes Table test, the sham was significantly different from the vehicle- treated injured group at week 4 after injury ($p=0.047$). CONCLUSIONS: OM stem cells caused no adverse effects and resulted in functional improvement when evaluated in experimental TBI producing diffuse axonal injury. Clinical translation is facilitated by the fact that OM stem cells can be obtained and delivered in a minimally- invasive manner.

4203. Peduzzi, J. D., et al. (1999). "The expression of TAPA (CD81) correlates with the reactive response of astrocytes in the developing rat CNS." Experimental neurology **160**(2): 460-468.

During the development of the brain, astrocytes acquire the ability to become reactive and form a scar. This change in the astrocytes occurs at approximately the same time that there is a decrease in the regenerative capacity of the CNS. Previous work from our laboratory had revealed that TAPA (Target of Anti-Proliferative Antibody, also known as CD81) is associated with reactive gliosis and the glial scar. TAPA is a member of the tetraspan family of proteins that appears to be associated with the regulation of cellular behavior. In order to define the role of TAPA in relation to the developmentally regulated CNS response to injury, we examined the levels of TAPA and GFAP immunoreactivity in rat pups that received a penetrating cerebral cortical injury. All of the animals injured at postnatal day 9 (PND 9), PND 18, or as adults, exhibited reactive gliosis scar formation when they were sacrificed 10 days after the cortical injury. Of the nine animals injured at PND 2, only three displayed reactive gliosis and scar formation. The remaining six rat pups had either a modest gliotic response or no detectable gliosis. The level of TAPA at the site of injury mimicked the reactive gliosis as defined by GFAP immunoreactivity. In all of the rats with a glial scar, there was a dramatic upregulation of TAPA that is spatially restricted to the reactive astrocytes. These results suggest that the upregulation of TAPA is an integral component of glial scar formation.

4204. Peek-Asa, C., et al. (2001). "Early predictors of mortality in penetrating compared with closed brain injury." Brain injury **15**(9): 801-810.

INTRODUCTION: Although brain injury incidence rates have been decreasing, the proportion of these injuries which are penetrating has been increasing. This study compares mortality amongst persons with penetrating and closed brain injuries and explores the relationship of early predictors of mortality., METHODS: The study included 795 moderately or severely brain injured individuals identified through the UCLA Brain Injury Research Centre. Logistic regression was used to predict mortality by GCS level and brain injury type, controlling for age, gender, and presence of multiple trauma., RESULTS: Of the 795 individuals, 110 had penetrating and 685 had closed brain injury. Case fatality rates were higher for penetrating than closed injuries for all GCS, gender, age, and cause of injury categories. When controlling for GCS level at admission, age, gender, and multiple trauma, those with penetrating injuries were 6.6 (95% CI = 3.9-11.1) times more likely to die., CONCLUSIONS: As the pool of information about survival and recovery from penetrating injuries grows, decisions regarding clinical care and prevention activities can be more appropriately focused.

4205. Peiffer, K. M. Z. (2007). "Brain death and organ procurement." The American journal of nursing **107**(3): 58-68.

Patients with severe brain injuries (as can result from trauma, subarachnoid hemorrhage, or brain tumor) are monitored closely by nursing staff. It's often the nurse who first recognizes clinical signs of decompensation and begins the process of determining whether the patient is a potential organ donor. When a person is declared brain dead, it's the nurse who maintains hemodynamic stability so that donor organs remain viable. It's therefore crucial for nurses to know how brain death is determined in adults and how potential organ donors are identified, and to know the major physiologic changes that occur upon brain death, as well as essential nursing interventions.

4206. Pekala, P., et al. (2014). "An assessment of the usefulness of a coconut as a model of the human skull for forensic identification of a homicide weapon." Archiwum medycyny sadowej i kryminologii **64**(4): 199-211.

The authors made an attempt to verify if a coconut can be used as a model of human skull to determine the homicide weapon. During our experiment 27 strike attempts were performed with the use of 9 different tools. Among them there were authentic murder weapons and instruments which had been used in similar experiments conducted on human skulls in 1955. Depending on the size of an area in contact with a coconut, weapons caused dents corresponding to the shape of a weapon, irregular fractures or long linear cracks. Our results have shown that coconut can be used as an inexpensive screening model of human skull, but only to determine fractures made by tools with small striking surface.

4207. Pekny, M., et al. (1999). "Abnormal reaction to central nervous system injury in mice lacking glial fibrillary acidic protein and vimentin." The Journal of cell biology **145**(3): 503-514.

In response to injury of the central nervous system, astrocytes become reactive and express high levels of the intermediate filament (IF) proteins glial fibrillary acidic protein (GFAP), vimentin, and nestin. We have shown that astrocytes in mice deficient for both GFAP and vimentin (GFAP-/-vim-/-) cannot form IFs even when nestin is expressed and are thus devoid of IFs in their reactive state. Here, we have studied the reaction to injury in the central nervous system in GFAP-/-, vimentin-/-, or GFAP-/-vim-/- mice. Glial scar formation appeared normal after spinal cord or brain lesions in GFAP-/- or vimentin-/- mice, but was impaired in GFAP-/-vim-/- mice that developed less dense scars frequently accompanied by bleeding. These results show that GFAP and vimentin are required for proper glial scar formation in the injured central nervous system and that some degree of functional overlap exists between these IF proteins.

4208. Pelc, R. and B. Szporek (1996). "[Use of computerized tomography for localization of a foreign body impacted into the cranium]." Wykorzystanie tomografii komputerowej do lokalizacji ciala obcego wtloczonego w obreb twarzoczaski. **49**(1-6): 59-65.

A case is presented of impaction of a metal bar into the cranium i an 8-year-old child. The significant importance for the therapeutic management was radiological examination, especially CT of the head. It made easier the determination of the foreign body locality in relation to the anterior cranial fossa and could allow to do the assessment of the resolution of air accumulation in the frontal lobe.

4209. Peleg, K., et al. (2010). "Poorer outcomes for mass casualty events victims: is it evidence based?" The Journal of trauma **69**(3): 653-659.

BACKGROUND: The sudden influx of patients during mass casualty events (MCEs) may compromise the quality of care provided and possibly impact on the medical outcomes of these patients. To test this assumption, a comparison must be made between injuries sustained in MCE and non-MCE events caused by the same mechanism. The mechanism of injury selected for this study was gunshot wounds, which occur in both types of event., METHODS: A retrospective study was carried out using the Israel's National Trauma Registry data on patients hospitalized between November 1, 2000, and December 31, 2005, as a result of high-energy gunshot trauma. Descriptive statistics and bivariate analysis were used to characterize injury patterns, and multivariate analysis was used to determine factors influencing inpatient mortality., RESULTS: Of 462 patients with gunshot wounds, 120 cases (26.38%) were defined as MCE and 342 (73.62%) as non-MCE. Both populations had ~30% of severely injured patients (Injury Severity Score 16+). MCE patients had undergone significantly fewer operational procedures. No differences between MCE and non-MCE were found in intensive care units utilization. The likelihood of death as a result of MCE was 2.75 (CI 1.09-7.02) times higher than non-MCE. Factors influencing this difference are the number of injured regions and injuries to the brain, chest, and abdomen., CONCLUSIONS: MCE patients have a significantly higher mortality than non-MCE patients, not manifesting substantial differences in the severity of injuries. The absence of difference in intensive care units utilization may be related to the effectiveness of existing protocols for dealing with MCEs.

4210. Peleg, M. and Y. Sawatari (2010). "Management of gunshot wounds to the mandible." The Journal of craniofacial surgery **21**(4): 1252-1256.

The gunshot wound to the mandible is a unique traumatic injury. The resultant injury from the gunshot wound is diverse because of the variability of the projectile, motion, velocity, and tissue characteristics. When a high-velocity projectile strikes the mandible, often times the wound will consist of a severely comminuted mandible surrounded by nonvital soft tissues and the implantation of multiple foreign bodies. This represents a challenge for the treating surgeon. The anatomy and function of the mandible make it such that the care of the gunshot wound requires a combination of trauma and reconstructive surgeries. There are varying techniques advocated for the management of gunshot wound to the face. However, for the comminuted mandible fracture sustained from a gunshot wound, an approach involving the fabrication of an occlusal splint, intermaxillary fixation, aggressive debridement of hard and soft tissues, and immediate reconstruction with a titanium plate is a comprehensive approach that can restore the appropriate function and contour of the patient. At the Division of Oral and Maxillofacial Surgery, University of Miami, this approach to the comminuted mandible fracture secondary to the gunshot wound has led to the effective management of this specific subset of injury. The complication rate is comparable with the current literature and provides an advantage as a 1-stage management to restore appropriate function and cosmesis to the patient.

4211. Pellat, J., et al. (1991). "Aphemia after a penetrating brain wound: a case study." Brain and language **40**(4): 459-470.

The speech of a patient with aphemia (pure anarthria) resulting from a penetrating brain wound was studied using linguistic and acoustic observations as well as electromyographic recordings from four labial muscles. The results are discussed in relation to phonetic disintegration's syndrome and apraxia of speech which, respectively, enhance linguistic disorders and motor programming disturbance.

4212. Pellizzer, E. P., et al. (2017). "Removable Partial Denture After Gunshot Injury: Five Year Follow-Up." The Journal of craniofacial surgery **28**(4): e381-e383.

The aim of this study was to report a patient of rehabilitation with removable partial denture retained by implants in-patient who suffered injury after firearm shooting. A 19-year-old man presented to the hospital of the Val Paraiso city after being hit by a bullet in the right on the face, affecting the teeth 12 to 16. The surgery to remove the shards of teeth, and bullet was performed. Surgical team opted for installation of implants without bone grafts; however, due to extensive loss of alveolar bone, only 3 tilted implants (2 Ø3.75 x 8.5 mm and 1 Ø3.75 x 10 mm) were installed. After recovery, the patient was referred to the Aracatuba Dental School-UNESP for the rehabilitation on the affected region. The difficulty of rehabilitation with conventional fixed prostheses was verified during the prosthetic phase. This way, it was opted for rehabilitation with removable partial dentures associated with dental implant. Two

attachment system ERA (ERA, Sterngold) were positioned in the bar to make the removable partial denture. After 5 years of follow-up, the authors can conclude that the use of removable partial denture retained by implants is effective for functional and aesthetic rehabilitation, favoring socialization and self-esteem of the patient.

4213. Pendleton, C., et al. (2012). "Harvey Cushing's contributions to motor mapping: 1902-1912." Cortex; a journal devoted to the study of the nervous system and behavior **48**(1): 7-14.

This review examined Dr. Harvey Cushing's cases in the surgical records of Johns Hopkins Hospital, from 1896 to 1912. 41 patients who underwent cortical stimulation for intra-operative motor mapping were selected for further analysis. We demonstrate that Cushing used cortical stimulation to define primary motor and sensory cortices in the treatment of tumors, trauma, and epilepsy, within adult and pediatric populations. In addition, he performed stimulation of sub-cortical white matter during 4 of these surgeries, setting the stage for contemporary use of this technique in improving post-operative outcomes. This review of Cushing's early intra-operative motor mapping illuminates his contributions, and clarifies his influence on the evolution of cortical mapping from an experimental technique to a staple of contemporary neurosurgery.

4215. Penning, L. and D. Front (1974). "Scintigraphic demonstration of a bullet track in the brain." Journal of nuclear medicine : official publication, Society of Nuclear Medicine **15**(2): 140-141.

4216. Peota, C. (2005). "Invisible wounds." Minnesota medicine **88**(1): 13-14.

4217. Pepe, P. E. and V. Kvetan (1991). "Field management and critical care in mass disasters." Critical care clinics **7**(2): 401-420.

As previously discussed, the majority of injury cases do not necessarily involve dramatic life-saving actions, but rather very rudimentary, promptly applied precautions. For most victims of trauma, therefore, we offer reassurance and simple compassion in their time of need. One of the more important lessons to be learned here is that, beyond prehospital injury "management" or "treatment," we should always remember to provide the best possible prehospital injury care. By responding as soon as possible and by delivering reassurance and compassion to those who are injured and frightened, we are providing one of the most sacred aspects of the Hippocratic mission. Despite wonderful technologic advances and the need for aggressiveness in disaster management, these humanistic values must always be maintained by those to whom care is entrusted. Successful transport of disaster victims, whether in the prehospital phase or during interhospital transfer, requires careful attention to treatment priorities, such as simple measures for airway control and ventilation, and care to prevent further injuries by appropriate immobilization techniques. The use of fully equipped teams of multidisciplinary critical care specialists in mass disaster situations is in its infancy. It is clear that with properly adapted hardware and personnel trained to function in adverse environments while effectively delivering intensive care to a large number of patients with a variety of clinical syndromes, survival can be significantly increased for the most acutely ill.

4218. Pepper, T., et al. (2019). "Coalition military personnel with stabilised facial fractures are less likely to require tracheostomy: a comparison of treatment in US and UK Medical Treatment Facilities during the Iraq and Afghanistan conflicts." British Journal of Oral and Maxillofacial Surgery **57**(10): e94.

Introduction: The United States (US) and United Kingdom (UK) deployed Medical Treatment Facilities (MTF) in support of the military campaigns in Iraq and Afghanistan. The approach to treatment of patients with facial injuries differed between nations, reflecting management protocols and the capabilities of deployed surgeons. Methods: The US and UK Joint Theatre Trauma Registries (JTTR) were scrutinized for patients with facial injuries at deployed MTF between March 2003 and October 2011. An adjusted multiple logistic regression model was performed using tracheostomy as the

in-dependent variable and treatment in a US MTF, US or UK military, mandible fracture, and treatment of mandible fracture as dependent variables. Results: Facial injuries were identified in 16944 casualties (survivors and died of wounds) across both databases. The most common mechanisms of injury were explosive events (63%), motor vehicle collisions (13%) and gunshot wounds (10%). Patients with facial injuries were equally likely to undergo surgery in US MTF as UK MTF (OR: 1.06, 95% CI: 0.4603 to 1.142, p = 0.6656). US military casualties who had treatment of their mandible fracture (ORIF or MMF) were less likely to have had a tracheostomy than those not treated (OR: 0.61, 95% CI: 0.44 to 0.86; p = 0.0066). Conclusions: Stabilization of facial fractures enabled patients to maintain their own airway, reducing the need for high dependency care. We recommend that facial fractures be definitely treated in deployed MTF, reducing the need for high dependency care.

4219. Perakis, H. and T. D. Woodard (2010). "Endoscopic management of transnasal intracranial penetrating foreign bodies." The Laryngoscope **120 Suppl 4**: S242.

4220. Perciaccante, V. J., et al. (1999). "Head, neck, and facial injuries as markers of domestic violence in women." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **57**(7): 760-763.

PURPOSE: The diagnosis of domestic violence (DV) is difficult because of a lack of clearly defined signs and symptoms. The goal of this study was to confirm and refine the role of head, neck, and face (HNF) injuries as markers of DV., PATIENTS AND METHODS: A cross-sectional study design and a sample of female trauma patients treated in an inner-city hospital emergency room (Grady Memorial Hospital, Atlanta, GA) were used. The predictor study variable was injury location (HNF or other location). The outcome variable was traumatic origin (DV or other cause). A victim of DV was defined as a patient who gave a history of being injured by her spouse or sexual partner. Other data included age, nature of the injury (blunt or penetrating), and injury severity score (ISS). Descriptive, bivariate, and logistic regression statistical analyses were performed., RESULTS: The sample consisted of 100 injured women, with a mean age of 40+/-16.3 years and a mean ISS of 3.3+/-3.0. Thirty-four women were victims of DV. The mean age of the DV victims was 32.5+/-7.3 years, compared with a mean age of 43.9+/-18.2 year in the other-causes group (P = .001). The mean ISS for the DV victims was 3.4+/-3.0, and the mean ISS for the other-causes group was 3.2+/-3.0 (P = .65). DV victims were 7.5 (2.5 < RR < 22.9) times more likely to have HNF injuries than other trauma patients (P < .001). Age was associated with cause and location of injury. After controlling for age, location remained statistically associated with cause (P = .0002). Sensitivity and specificity of HNF injuries and DV were 91% and 59%, respectively., CONCLUSIONS: The data suggest that although HNF injuries and age were sensitive predictors of DV, they remain poor in their specificity as markers.

4221. Perdekamp, M. G., et al. (2003). "[Contact shot from infantry weapons with a flash-suppressor]." Zum absoluten Nahschuss aus Infanteriewaffen mit Mundungsstuck. **212**(1-2): 10-18.

The number of reports on contact shots from firearms with a flash suppressor attached to the muzzle is small. On the basis of a case report (suicidal shot to the forehead with a Kalschnikow AKMS 47 assault rifle) the morphological peculiarities (characteristics soot pattern, relatively small powder cavity and only minor skin tears in the presence of a bony support) are presented and the conclusions to be drawn from the findings regarding the flash-suppressor, the shot distance, the angle of the shot and the way of holding the weapon are discussed.

4222. Perdekamp, M. G., et al. (2005). "[Suicide with multiple graze shots]." Suizid mit multiplen Streifschussverletzungen. **216**(5-6): 150-159.

A 77-year-old man was found in his flat with a shot to the right temple. In spite of hospital treatment he died from the head injury the next day. The weapon at the scene used for committing the suicide was a pistol, make Kaba Special (calibre 6.35 mm). At autopsy, the right temporal region showed a surgically treated, originally stellate gunshot entrance wound with a powder cavity. Close to this penetrating gunshot wound there were 3 parallel graze shot injuries of the scalp. The autopsy findings were consistent with the assumption that all the shots had been fired by the victim himself with suicidal intent. The injury pattern is presented and discussed in relation to the results of the technical investigation of the weapon and the findings at the scene.

4223. Perdekamp, M. G., et al. (2005). "Contact shot with unusual soot pattern." Forensic science international **149**(1): 75-79.

In a suicidal shot to the temple two roundish zones of powder soot blackening were found above the entrance wound. The paired zones of powder soot blackening were caused by two gas outlets located on the upper side of the muzzle end of the weapon used (converted blank cartridge pistol of make Rhoner). The conclusions that can be drawn from this particular soot pattern with regard to the type of the weapon, the muzzle-to-target distance, the direction of fire and the way of holding the weapon are discussed.

4224. Perdekamp, M. G., et al. (2011). "Intracranial impalement with entrance site in the mandibular region: postmortem elucidation of an accidental fall on a wooden plant stick." Forensic science international **209**(1-3): e35-40.

A 78-year-old woman with a history of transient ischemic attacks was found in the doorway of her house in a somnolent and unresponsive condition. In the right mandibular region, a small skin wound was localized, which was surgically treated. Six days after admission to the hospital, an exploratory craniotomy was performed because of abnormal CT findings. Apart from tissue lesions and hemorrhages a small bone fragment was detected in the right cerebral cortex, which was removed. After 11 days in hospital, the patient died from failure of central regulatory functions. At the forensic autopsy, a 15 cm long wound track running upward from the skin wound in the right mandibular region through the bony skull base to the right parietal lobe of the brain was noted. Apparently, the surgically removed bone fragment had been displaced from the right middle cranial fossa. The site of the incident in the deceased's house was inspected again and a bamboo pole used to stabilize a potted plant standing on the floor was found and sent to the trace evidence laboratory. Analysis showed blood and tissue deposits from the victim. On the basis of all the findings and the circumstances of the case, a fatal impalement injury caused by an accidental fall could be assumed.

4225. Perei, S. (2018). "Retrospective study on patterns of homicidal death in western odisha." Medico-Legal Update **18**(2): 141-145.

The study is undertaken in the department of Forensic Medicine and Toxicology, VIMSAR, Burla of Odisha state to examine the pattern of homicidal death in Western Odisha considering the data from 2013 to 2017 (152 cases). Data on age and sex, period of survivability and causes death of the deceased; motive behind, weapons used and place of occurrence of homicides; and relation between the assailant and victim have been collected from the reported cases of homicidal death after doing autopsy. The bivariate and descriptive statistics has been used for data analysis. As the dominant motive for homicides is wealth, wine and woman, the study attempts to examine the motive of homicides along this line. The analysis depict that out of 6140 autopsies done during the study period 152 (2.47%) are found as homicide cases. The distribution of deceased across gender shows that 79.6% are male and 20.4% are female. Maximum of 80.3% of homicides was committed during night time, in 57.9 % cases the place of occurrences is at outside from home, 90.4 % cases death was occurred instantly, 58.6 % cases the victim is either a family member or relative, 52 % cases the weapon used is hard and blunt, 51.3 % cases the cause of death is due craniocerebral injuries, 50.7 % cases the motive behind the homicide is wealth followed by women (22.4%). The month wise distribution of homicide cases depicted that maximum number of occurrences have occurred during the month of March and June (each 13 %) followed by February, September and October (each around 11 %).

4226. Pereira, C., et al. (2012). "Gunshot wounds to the face: level I urban trauma center: a 10-year level I urban trauma center experience." Annals of plastic surgery **68**(4): 378-381.

INTRODUCTION: Gunshot wounds (GSWs) to the face are an infrequent occurrence outside of a war zone. However, when they occur, they constitute a significant reconstructive challenge. We present our 10-year experience at an urban level I trauma center to define the patterns of injury, assess the morbidity and mortality, and estimate the cost to the health care system., METHODS: A retrospective review was performed on all patients admitted to Harbor-UCLA Medical Center with GSWs to the head and neck region between January 1997 and January 2007. Those who had sustained GSWs to the face requiring operative intervention were closely reviewed., RESULTS: Between 1997 and 2007, a total of 702 patients were admitted to the Harbor UCLA Emergency Department having sustained GSWs to the head and neck region, of which 501 patients survived. Of the survivors, 28 patients (26 male, 2 female) sustained GSWs to

their face requiring operative intervention. The mean age of these patients was 28 (+/-8.3) years. They generally presented within a few hours of the injury, but 1 individual arrived over 24 hours later. Low-velocity single gunshots (from handguns) were predominantly involved, with facial fractures occurring in all cases. Fractures were of a localized shattering type without the major displacement of bony complexes seen in motor vehicle accidents. Most required wound debridement and fracture fixation. A few patients (14.2%) underwent free tissue transfer for reconstruction (3 fibular flaps, 1 TRAM). Tracheostomy was performed in 35.7% of patients. Mean length of hospital stay was 8.3 (+/-7.1) days, with 50% of cases requiring admission to the intensive care unit. Mean length of intensive care unit stay was 5.2 (+/-5.7) days. The average cost per patient exceeded $100,000.

4227. Pereira, F. J., et al. (2011). "Management of globe luxation followed by traumatic liquoric fistula: case report." Arquivos brasileiros de oftalmologia **74**(1): 58-60.

This report describes the only case in the literature of globe luxation due to traumatic cerebrospinal fluid fistula to the orbit caused by fire gun with ocular globe maintenance. E.N., female, white, 7 months, admitted with left orbitocranial injury by fire gun. Ocular globe luxation was detected with complete ocular motility restriction and absence of pupillary reflex in the left orbit. Computed tomography showed fracture of the medial orbital wall; bone fragments near the apex of the orbit and a stretched optic nerve. Surgical exploration was performed, showing liquor fistula through the ethmoid-sphenoid wall that was blocked with sponge (Gelfoam R) plus organic glue in the left orbit posterior wall, with immediate resolution of the proptosis and ocular integrity maintenance. Although controversial, maintenance of the ocular globe instead of enucleation was performed due to the integrity of the globe in this case. Despite the blindness, we considered the result to the proposed treatment excellent, once the maintenance of the ocular globe provides a good appearance and will contribute to an adequate facial bone development.

4228. Perez-Arredondo, A., et al. (2016). "Baclofen in the Therapeutic of Sequele of Traumatic Brain Injury: Spasticity." Clinical neuropharmacology **39**(6): 311-319.

Traumatic brain injury (TBI) is an alteration in brain function, caused by an external force, which may be a hit on the skull, rapid acceleration or deceleration, penetration of an object, or shock waves from an explosion. Traumatic brain injury is a major cause of morbidity and mortality worldwide, with a high prevalence rate in pediatric patients, in which treatment options are still limited, not available at present neuroprotective drugs. Although the therapeutic management of these patients is varied and dependent on the severity of the injury, general techniques of drug types are handled, as well as physical and surgical. Baclofen is a muscle relaxant used to treat spasticity and improve mobility in patients with spinal cord injuries, relieving pain and muscle stiffness. Pharmacological support with baclofen is contradictory, because disruption of its oral administration may cause increased muscle tone syndrome and muscle spasm, prolonged seizures, hyperthermia, dysesthesia, hallucinations, or even multisystem organ failure. Combined treatments must consider the pathophysiology of broader alterations than only excitation/inhibition context, allowing the patient's reintegration with the greatest functionality.

4229. Perignon, S., et al. (2008). "[Bilateral oedipism: a case report]." Oedipisme bilateral non concomitant: a propos d'un cas. **31**(6 Pt 1): 614-617.

INTRODUCTION: Oedipism (or self-enucleation) is a rare form of self-mutilation and most often described in acutely psychotic patients, less frequently among drug addicts or the mentally deficient., CASE REPORT: We report a case of a 46-year-old man, who, 3 years after having enucleated his left eye during an acute bout of delirium symptomatic of schizophrenia, mutilated his right eye in the same way. We detail the emergency medical and surgical management indicated in these circumstances., CONCLUSIONS: In most cases described, self-mutilation involves one eye and rarely both. This case of bilateral oedipism is therefore exceptional. In these circumstances, it is necessary to prevent any intracerebral complications induced by the traction exerted on the optic nerve, such as subarachnoid hemorrhage, whose signs can be masked by the patient's psychic state, and to take the neuropsychiatric precautions necessary.

4230. Perju-Dumbravá, D. (2002). "Mechanisms and vulnerant object in head trauma: Lesional morphology." Romanian Journal of Legal Medicine **10**(3-4): 270-276.

The authors presents the most frequent lesions found in neurosurgery in connection with legal medicine. A brief synopsis on lacerations and epicranium haematoma, skull fractures, cerebral trauma lesions is to be found. There are presented many of the modalities of the traumatic events (car accident, blows by fist or foot, guns lesions, etc.).

Brain metastases (BMs) concern more than 10-15% of patients with stage IV NSCLC at baseline and more than 40% during the disease course. The wider use of MRI and improvement of extra-cranial systemic disease control contribute to increase the BMs incidence. The issue of BMs is critical in the management of NSCLC patients in the perspective of the neurological consequences of brain lesions. BMs occurrence is synonymous of a poor outcome in NSCLC but reflects in fact many different situations. Establishing a therapeutic strategy needs first to assess their prognosis; the most appropriate scale is the Graded Prognostic Assessment for Lung Cancer Using Molecular Markers including as prognostic factors EGFR mutations and ALK rearrangement in addition to age, number of BMs, extra-cranial disease and Karnofsky status, with a median survival varying from 3.0 months for the worse subgroup (GPA 0.5-1) to 46.8 months for patients with oncogene addiction and good prognostic factors (GPA 3.5-4). The second step is to evaluate the indications, efficacy and side effects of available therapeutic “weapons.” Corticosteroids are active against cerebral edema and improve symptoms. Whole brain radiotherapy (WBRT) has been for decades the treatment “reflex” of BMs but the emergence of stereotactic radiosurgery (SRS) or radiotherapy (SRT) and the issue of neurocognitive complications led to deferral or omission of WBRT in an increasing number of patients. WBRT remains indicated in patients with symptomatic, large (≤3 cm) and numerous BM. However, palliative WBRT did not provide any benefit in terms of survival, quality of life and QUALYs compared to supportive care alone in the Quartz trial; the subgroup analysis suggests a benefit only in patients with better prognostic factors. Neuroprotective strategies as sparing hippocampi during WBRT are currently evaluated. SRS defined by invasive contention with sub-millimeter accuracy or noninvasive SRT with millimeter accuracy are indicated in case of 1 to 3 BMs (but now up to 10 lesions) with a diameter <3 cm, alone or as a boost on the top of WBRT. SRS/SRT alone avoids neurocognitive toxicity of WBRT and provides a similar OS to that of surgical resection when using SRS/SRT for patients with operable lesions. Radionecrosis is observed in 10-17% of patients treated with SRS/SRT, making difficult the distinction with a tumor relapse. In spite of reduction in local and distant brain failures or in death from neurological causes, adjuvant WBRT after SRS/SRT does not improve overall survival and has a detrimental effect on neurocognitive functions and quality of life. Surgical resection of BMs achieves survival and functional benefit in addition to WBRT. Surgery is indicated in case of a symptomatic lesion, larger than 2 cm, with a mass effect, allowing fast improvement of symptoms. The invasive edge of BMs explains the high local recurrence rate after resection and the need for adjuvant radiotherapy. WBRT is progressively less used in favor of SRS/SRT despite a better intracranial control rate because of a higher rate of cognitive deterioration. Systemic treatment remains critical for extracranial systemic control of the disease. Brain-blood barrier limits the brain penetration of systemic agents, especially with efflux transporters as P-gp, for which many TKIs and cytotoxic agents are substrates. BMs usually cause brain-blood barrier disruption with heterogeneous drug penetration. Cytotoxic chemotherapy provides similar response rates in BMs to those of extracranial disease. Anti-PD- 1 antibodies seem to be active in the brain but available data are scarce. First and second-generation EGFR TKIs have a low brain penetration but sufficient to obtain response rates similar to those achieved for systemic disease; duration of response might be inferior. Osimertinib has a better CNS penetration. For ALK+ disease, crizotinib is a P-gp substrate with a low blood/CSF concentration ratio and brain is the most frequent site of progression. Next-generation ALK TKIs have a better CNS diffusion; ale tinib largely decreases the cumulative incidence of BMs compared to crizotinib. Concurrent administration of TKIs with brain radiotherapy is controversial and is not recommended outside of a clinical trial. Defining an optimal multidisciplinary strategy needs to take into account many parameters, including number, location and size of brain metastases, leptomeningeal lesions, neurological symptoms, risk factors for neurocognitive alteration, extracranial metastases and their control, primary lung tumor control, and identification of a targetable oncogenic addiction. In absence of a targetable genomic alteration, BMs at baseline can benefit from systemic treatment alone in selected patients with no neurological symptoms, small intracranial tumor burden, low risk of impending neurologic issues, on the condition that they are closely monitored; brain radiotherapy can be safely deferred to intracranial progression. Symptomatic BMs require local treatment, by favoring SRS/SRT rather than WBRT; adjuvant WBRT is not recommended but further close monitoring is mandatory to detect new intra-cranial lesions. Surgery is preferred for large lesions, posterior fossa

location or diagnosis; adjuvant SRS/SRT is mandatory to avoid local recurrences. WBRT remains indicated for multiple symptomatic lesions not eligible for SRS/SRT except in poor PS patients. In case of EGFR mutations, asymptomatic patients with BMs are treated with first or second-generation EGFR TKIs but must be closely watched with repeated brain imaging. A recent retrospective study suggests that front-line SRS/SRT might improve overall survival as CNS remains a sanctuary site in oncogene-addicted disease. Symptomatic patients are locally treated, favoring SRS/SRT requiring only a short interruption of systemic treatment. For patients with ALK+ disease, the advent of alectinib as standard front-line treatment should change the management approach to BMs: the low incidence of BMs should allow spacing brain monitoring while the high intra-cranial response rate should permit to delay local treatment. For ALK+ patients developing BMs on ALK TKI, local treatment with SRS/SRT or surgery if necessary is the first option; switching to another TKI with a better brain penetration is another option for patients candidates to WBRT. The longer life expectancy of ALK+ patients leads to defer as far as possible the use of WBRT. However, improvement of intracranial control should be considered in patients at preferential risk of dying from intracranial progression, independently on mutational status.

4233. Persad, S., et al. (2012). "Saved by the orbit-two cases of penetrating facial injuries sparing the eye." West Indian Medical Journal **61**: 32.

Penetrating orbital injuries are almost always accompanied by intracranial and/or intraocular trauma and usually carry an unfavourable visual prognosis. This paper reports two rare cases of penetrating transorbital injuries with benign outcomes. Both cases involved 29-year old males who were rushed to the emergency room, after being involved in separate domestic disputes, each with a knife handle protruding from the brow area. Both patients were fully alert and oriented on presentation with Glasgow Coma Scales of 15/15, no neurological deficits and completely intact globes with no intraocular injuries. The entry wound of one patient started at the frontal bone, just medial to the right brow, traversed the orbit, following the medial wall and exited the medial aspect of the floor of the orbit, with the tip of the blade embedded in the right maxillary sinus. The entry wound of patient two also started in the frontal bone, this time superior-lateral to the left brow, traversed the orbit following the lateral wall, continued into the maxillary sinus and terminated at the base of the skull with the tip of the blade abutting the left lateral pterygoid plate. Each patient underwent emergency surgery by a multidisciplinary team where removal of the knife followed an uneventful course and led to good postoperative visual outcomes. Many factors in these two cases of transorbital penetrating injuries led to overall fortuitous outcomes. These included the initial direction and length of the penetrating foreign bodies and the orientation of these in the orbit. The anatomical positioning of the globe in its protective bony socket also played a pivotal role in protecting the intraocular contents. The energy transfer away from the globe and the protective viscoelastic properties of the sclera were also beneficial sight-saving factors. Lastly, the dissipation of residual kinetic energy away from the orbital contents by the relenting weak orbital floor was an additional protective mechanism.

4234. Persson, L., et al. (1976). "Extravasation, spread and cellular uptake of Evans blue-labelled albumin around a reproducible small stab-wound in the rat brain." Acta neuropathologica **34**(2): 125-136.

A small stab wound was made in the frontal lobe of the rat brain in order to study both the acute damage and the restitution of the blood-brain barrier to macromolecules under well-defined experimental conditions. Intravenously administered Evans blue-labelled albumin (EBA) was used as a tracer and the brain sections were observed in a fluorescence microscope. EBA leaked into the neuropil only during the first 3 days after the trauma. The maximal leakage occurred during the first day after the injury. The tracer spread from the area surrounding the stab wound in a reproducible way, initially roughly centrifugally. Nerve and glial cells close to the wound displayed a diffuse fluorescence of their cell bodies 1 to 6 h after the injury, i.e. at times with maximal extravasation of the tracer. A more granular distribution of the tracer was seen in neurons and glial cells at both very short and long times after EBA injection. Thus, the blood-brain barrier lesion induced was reproducible and reversible as judged by the pattern of EBA leakage. Some cells immediately adjacent to the injury had a diffuse cytoplasmic distribution of the tracer complex, in contrast to cells more distant from the injury, having a more granular distribution of the tracer in their cytoplasm. However, the appearance of the fluorescence in neurons and glia was to a large extent dependent upon the time after the injury, at which the cells were exposed to the tracer complex and on the time that had elapsed from the time of injection of the tracer complex to the sacrifice of the animal. Thus, it seems likely that two factors contribute to the appearance of the neuronal EBA distribution: on one hand the location and possibly extent of cellular damage of the cell, and, on the other hand, the time and amount of EBA to which the cells were exposed.

4235. Persson, L., et al. (1976). "The brain-specific S 100 protein in small cerebral stab wounds in the rat: a quantitative study." Acta neuropathologica **36**(1): 39-45.

A quantitative study of the changes in water-soluble proteins and water-soluble S 100 was made in stab-wounded rat frontal cortex as compared to unoperated controls. No great changes occurred until 30 days after the injury. At that time there was no change in the amount of water-soluble S 100 protein/g wet weight, but a large decrease in the amount of water-soluble proteins/g wet weight and thus a proportionate increase in the amount of water-soluble S 100 protein/mg of water-soluble proteins. The significance of the results is discussed.

4236. Peschel, O., et al. (2013). "Postmortem 3-D reconstruction of skull gunshot injuries." Forensic science international **233**(1-3): 45-50.

BACKGROUND: In cases of severe decomposition or skeletonization of a corpse after cerebral gun shot injury it is difficult to exactly reconstruct the bullet path in the brain. However, in case of murder or homicide this might become necessary to answer forensic questions such as the ability to move or other actions of the victim., MATERIALS AND METHODS: Therefore a method in terms of three dimensional reconstruction technique was developed by fusing computed tomography scans (CT) of the original skull and magnetic resonance images (MRI) of a normal brain of adequate size. Hereby five cases were investigated., RESULTS: In three cases an excellent concordance between the reconstructed bullet trajectory and the autopsy reports was achieved. In one case the original brain was not available for CT-scanning due to previous autopsy. However, the findings were in line with the pathology report. In one case there was a difference of about 1-2 cm between the original autopsy description and the reconstructed bullet path. This was due to only a part of the skull being available for image reconstruction., CONCLUSION: The findings suggest that this method can successfully be applied to adequately reconstruct bullet paths in cases of completely skeletonized skulls, but should carefully be used in cases of incomplete skulls.

4237. Pessoa Neto, J. V., et al. (2019). "Removal of Foreign Bodies in Orbit-Zygomatic-Maxillary Complex." The Journal of craniofacial surgery **30**(7): e598-e600.

Trauma is one of the leading causes of death worldwide. Due to its anatomy and position in the facial skeleton, the orbit becomes a region susceptible to trauma which may also involve the penetration of foreign bodies (FBs). These events can have serious repercussions depending on their extent due to the proximity of the orbit with other noble structures of the face and skull. Because of this, a system of prehospital management of traumas must be established, in order to promote a better prognosis for patients. The present study aims to report the case of a patient suffering from a motorcycle accident with multiple fragments of FBs in the region of orbit-zygomatic-maxillary complex. The emergency surgical removal of the fragments was performed by a multidisciplinary team, involving Ophthalmology and Oral and Maxillofacial Surgery and Traumatology (OMST). Wound cleansing and debridement were performed with subsequent removal of the foreign bodies by the OMST team, in addition to the reduction and fixation of related fractures. As for Ophthalmology, the evisceration of the affected eye was performed due to its anatomical and functional impairment. The patient is 12 months postoperatively, with no aesthetic or functional complaints regarding OMST. The anatomical knowledge of the traumatized region, besides the establishment of the conduct regarding the removal of possible associated foreign bodies are required so that the success of the treatment can be obtained, aiming to minimize the damages to the patient.

4238. Pessoa, T. D. B., et al. (2021). "Endovascular treatment of subclavian artery injury with a complex post-traumatic fistula: Case report." Trauma case reports **32**.

Background: Endovascular treatment in trauma is a promising strategy to reduce perioperative morbidity and mortality. We report the case of a gunshot wound causing an initially undiagnosed subclavian artery injury, with delayed progression to a complex, difficult-to-manage arteriovenous (AV) fistula. Placement of an encapsulated endovascular stent graft resolved the primary lesion, but persistent cervical arteriovenous communications were only repaired after multiple, sequential embolization procedures. Report: A 25-year-old male sustained a gunshot wound to the right neck. Initial treatment failed to identify any vascular injury, and the patient was discharged. Three weeks later, he presented to our facility with headache and a palpable right-sided cervical thrill. Arteriography showed contrast extravasation from

the right subclavian artery and an AV fistula with the ipsilateral internal jugular vein. The arterial injury was repaired with an encapsulated stent graft, but residual contrast leak persisted on follow-up angiography. Three months after the first intervention, cervical thrill was still present; a right vertebral–right internal jugular AV fistula was identified and repaired by distal coil embolization. One month later, persistent symptoms prompted repeat arteriography, which again identified contrast extravasation, now involving the thyrocervical trunk. Selective thyrocervical embolization was ultimately successful, with resolution of symptoms and no further evidence of contrast leak. Conclusion: Delayed management of neck trauma can be challenging due to neovascularization, which hinders open repair in this delicate region. Post-traumatic arteriovenous fistulas are thus a particularly fearsome complication, and can be very difficult to approach; as in our patient, multiple interventions may be required. This case highlights the importance of detecting vascular trauma as early as possible, as a delay in diagnosis can hinder treatment and eventuate challenging late complications. Further studies are needed to demonstrate the long-term benefits of endovascular management of complex vascular injuries of the neck region.

4239. Pessoa, T. D. B., et al. (2018). "Endovascular treatment of subclavian artery trauma associated with multiple arteriovenous fistulas: Case report." Vascular and Endovascular Surgery **52**(8): S38-S39.

Background: Subclavian artery injuries are frequently asso¬ciated with high mortality rates. The diagnosis is often not evident, especially in stable patient, and this can ultimately contribute to treatment delay. Surgical approach may require extensive thoracic access and be associated with injuries of other cervical structures. When these injuries are diagnosed late in the course of the disease, as in the present case, it may hamper conventional surgical access due to local tissue changes after trauma as well as association with other com-plications, such as fistula formation. The endovascular approach is an attractive option to avoid direct access to the hostile region; besides, it is associated with lower risk of bleeding and good results. Case Description: A 25-year-old male, a victim of gunshot trauma to the right supraclavicular region, was discharged from hospital without identification of his vascular lesions. Three weeks afterward, he sought med¬ical assistance again with headache and a cervical thrill. An arteriovenous fistula between the right subclavian artery (RSCA) and the right internal jugular vein (RIJV) was diag-nosed at arteriography. The patient underwent endovascular treatment with implant of a fluency stent-graft (13.5 x 80 mm) in the RSCA with important improvement in the com¬munication. A persisting late-phase overflow was detected close to where the bullet was lodged. A new arteriography was scheduled a month later to elucidate the persisting cervi¬cal thrill. A remaining fistula between the origin of the right vertebral artery (RVA) and a very dilated (RIJV) was diag¬nosed. The Willis polygon was complete and the RVA had retrograde flow. Access to the initial portion of the RVA was made impossible by the stent-graft in the RSCA, and there¬fore, we decided to access the distal portion of the RVA at the base of the skull with the help of neurosurgery and proceed with embolization with a 5 x 15 mm and 4 x 12 mm coils near to its origin. Control image showed significant reduction of flow. One month later, the patient returned still complain¬ing of cervical thrill. New arteriography evidenced another fistula between the RIJV and branches of the thyrocervical trunk, which were embolized with 7 x 20, 5x15, and 4x15 mm coils. The patient evolved with remission of symptoms and a control angiotomography demonstrated good position¬ing of the endoprosthesis and coils with no more communications. Conclusion: The treatment of late subcla¬vian traumatic injuries can be challenging and require multi¬ple approaches, especially if associated with fistulas. Longer follow-up times are warranted.

4240. Peter, H. H., et al. (2016). "Early clinical development of gnbac1 a humanized monoclonal antibody neutralizing MSRV-ENV, a neurotoxic protein, for the treatment of multiple sclerosis." Neurology **86**(16).

Objective: Early clinical development of a humanized monoclonal antibody for multiple sclerosis Background: MSRV-Env is a protein of endogenous retroviral origin. This protein is expressed in active brain lesions of multiple sclerosis (MS) patients notably on the surface of microglial cells. MSRV-Env has a TLR4 mediated effect which is pro-inflammatory and myelinotoxic by blocking oligodendrocyte precursor cell (OPC) maturation, hence inhibiting the remyelination process. Design/Method: GNbAC1 is an IgG4 humanized monoclonal antibody which neutralizes MSRV-Env and prevents cytokine release and the nitrosative stress process at the OPC level. Remyelination observed in the brain of animals treated with GNbAC1 in experimental autoimmune encephalitis models supports the in-vitro effect. Results: After a successful first-in-man study including 33 healthy subjects testing GNbAC1 up to a dose of 6 mg/kg, a high dose pharmacology study assessed safety, tolerability and cerebrospinal fluid (CSF) penetration of GNbAC1 up to doses of 36 mg/kg in 21 healthy subjects. The safety profile was good and the pharmacokinetics of the product was dose-linear with a CSF-serum ratio up to 0.4[percnt]. GNbAC1 was also tested in 10 MS patients, of which 9 were

suffering from progressive MS, in a 12-month study. Long term safety was good. The average EDSS score remained stable over one year in the cohort. From a pharmacodynamics standpoint, MSRV-Env biomarker decreased during treatment as well as TLR4 activation markers. Conclusion: The promising early clinical results of this innovative treatment pave the way for testing GNbAC1 in a Phase IIb clinical trial. GNbAC1 will be tested in 260 relapsing remitting MS patients in a randomized placebo-controlled trial testing 3 doses of GNbAC1 versus placebo during 6 months, which will be followed by a 6-month extension where all placebo patients will be re-randomized to the different active dose arms. The study will start in early 2016.

4241. Peterson, R. S., et al. (2004). "Radial glia express aromatase in the injured zebra finch brain." The Journal of comparative neurology **475**(2): 261-269.

Estrogens have neurotrophic and neuroprotective properties. The synthesis of estrogen occurs via the expression of aromatase. Previous studies have shown that injury to the vertebrate brain results in a rapid and dramatic up-regulation of aromatase expression in astrocytes around the lesion. As part of experiments examining injury-induced glial aromatization, we identified aromatase in radial glia of the zebra finch brain. Adult female zebra finches received a penetrating injury to the right hippocampus. Twenty-four hours after lesioning, birds were administered bromodeoxyuridine (BrdU) and sacrificed 2 hours, 1 day, or 7 days later. We determined the distribution of aromatase and BrdU labeling by using immunocytochemistry. Radial aromatase was localized to cells lining the lateral ventricle adjacent to the lesioned hippocampus. Injury also induced a dramatic accumulation of newly generated cells labeled with BrdU around the lesion. BrdU labeling was strongly associated with aromatase-positive radial fibers, suggesting the migration of newly generated cells along these fibers. In the songbird brain, estrogen supports neuronal recruitment and promotes the survival and addition of new neurons. The presence of aromatase in radial glia provides a mechanism of estrogen delivery to postmitotic cells. Radial aromatization may be a key feature in the repair of the vertebrate brain following neural injury. Copyright 2004 Wiley-Liss, Inc.

4242. Peterson, R. S., et al. (2001). "Rapid upregulation of aromatase mRNA and protein following neural injury in the zebra finch (Taeniopygia guttata)." Journal of neuroendocrinology **13**(4): 317-323.

The expression of aromatase (oestrogen synthase) within the vertebrate central nervous system (CNS) is key in the provision of local oestrogens to neural circuits. Aromatase expression appears to be exclusively neuronal under normal conditions. However, some in vitro studies suggest the presence of astrocytic aromatase in songbirds and mammals. Recently, aromatase in reactive astrocytes has been demonstrated in response to neural injury in the mammalian CNS. Since the glial aromatase expression first documented in cultures of the songbird telencephalon may reflect processes similar to those in response to mammalian neural injury, we investigated whether injury alters the pattern of aromatase-expression in the zebra finch, a species with very high levels of forebrain aromatase expression. Adult males received a penetrating neural injury to the right hemisphere and were killed either 24 or 72 h later. Controls were anaesthetized and otherwise unmanipulated. We determined the expression of aromatase mRNA and protein using in situ hybridization and immunocytochemistry, respectively. Both the transcription and translation of aromatase is dramatically upregulated around the lesion site in response to neural injury in the zebra finch forebrain. This effect is robust and rapid, occurring within 24 h of the injury itself. Cells that upregulate aromatase appear to be reactive astrocytes based upon morphology. The hemisphere contralateral to the injury and both hemispheres in control birds showed the normal, exclusively neuronal pattern of aromatase expression. The upregulation of aromatase in astrocytes may provide high levels of oestrogen available to modulate processes such as CNS repair. Injury-induced upregulation of astrocytic aromatase may be a general characteristic of the injured vertebrate brain.

4243. Petkovic, S., et al. (2011). "Complex suicide: an unusual case with six methods applied." Journal of forensic sciences **56**(5): 1368-1372.

Complex suicides (CSs) are committed by using more than one method. They account for 1.5-5% of all suicides. We present a case of CSs of a 44-year-old man, found dead in the vicinity of his car, in a deserted frozen field. Police investigation excluded homicide, and no medical data confirmed mental illnesses. Autopsy revealed wrist cuts, neck cuts, acid burns in the GI tract, multiple stab wounds to the head by a screwdriver, and several uncertain signs of hypothermia. Toxicology analysis (gas chromatography-mass spectrometry) confirmed ingestion of insecticide. We concluded that stab wounds to the head were the cause of death, while external hemorrhage and hypothermia were

contributing factors. This is the first case of CSs reviewed in the literature where six suicide methods were applied. This particular case is interesting because the victim used a screwdriver as a tool for inflicting stab wounds to the head, which is a rare suicidal method. Copyright © 2011 American Academy of Forensic Sciences.

4244. Petridis, A. K., et al. (2011). "Outcome of craniocerebral gunshot injuries in the civilian population. Prognostic factors and treatment options." Central European neurosurgery **72**(1): 5-14.

AIM: Gunshot wounds to the head are rare in Europe. They may be inflicted by low-velocity handguns, captive bolt guns and tear gas cartridges and mostly result from suicide attempts. The experience of neurosurgeons with this kind of traumatic injury is decreasing; the aim of this study was therefore to analyse prognostic factors which help to decide whether or not to operate and to discuss treatment options., METHODS: Thirty patients with gunshot head injuries treated in our hospital from 1993 to 2008 were retrospectively evaluated. Glasgow Coma Scale (GCS) score, pupil reactivity, lesion localisation, number of bone fragments, intracranial pressure (ICP), midline shift, hypotension, and dural penetration were analysed for their prognostic value. Surgically and non-surgically treated patients were evaluated separately. Complications were registered., RESULTS: A low GCS of 3-8, fixed pupils, >2 bone fragments, bilobar or posterior fossa/brainstem lesions and ICP >45 mmHg were indicators of a poor prognosis., CONCLUSION: Patients with a GCS of 3-8 and two non-reactive pupils should not be operated. If one or both of the pupils are reactive, surgery should be performed irrespective of the GCS score, except in patients with translobar/transventricular wounds. Even if there are no clear contraindications to surgery, the outcome is expected to be poor in patients with a low GCS score, midline shift >10 mm, >2 bone fragments in the brain, and a bilobar, posterior fossa/brainstem or ventricular lesion and ICP >45 mmHg. When surgery is performed the wound and the missile or bone track should be debrided meticulously, the wound and dura should be closed in a watertight fashion and antibiotic prophylaxis as well as tetanus serum should be given. 4245. Petridis, A. K., et al. (2011). "Transorbital impalement injury with massive intracranial lesion not detected by cranial CT scan." Clinical neuroradiology **21**(3): 167-170.

An extraordinary case of transorbital penetration injury is presented. A 24-year-old male patient was involved in a fight and was pushed against a shelf. He immediately lost consciousness and was brought to hospital. A cranial computed tomogaphy (CT) scan showed a hemorrhage and brain edema over the left hemisphere with orbital roof fracture. A decompressive craniectomy was performed. Intraoperatively, an orbital roof fracture with penetration of the frontobasal dura could be seen which could not be explained by the trauma mechanism. The postoperative magnetic resonance imaging (MRI) with susceptibility-weighted image (SWI) showed two injury tracks from the orbit through the brain which appeared to be penetration injuries. The forensics department was consulted and penetration by a falling candleholder was found to be the cause of the injuries. In this case, the cranial CT alone did not show any indication of a penetration injury. Only MRI revealed the penetration track, which stresses the diagnostic value of this modality and especially the SWI in cases where the trauma mechanism does not correspond to the injury shown in the CT scan.

4246. Petroff, M. A., et al. (1987). "Cranial bone grafts for post-traumatic facial defects." The Laryngoscope **97**(11): 1249-1253.

Recent interest in onlay cranial bone grafts has shown it to be a preferred technique in the reconstruction of facial defects. This paper reports seven patients in whom outer table cranial bone grafts were used to reconstruct post-traumatic facial deformities. These included orbital and zygomatic deformities (2 patients), maxillary defects (2 patients), mandibular defects (2 patients), and nasal deformity (1 patient). A brief review of the development of membranous bone grafting for maxillofacial reconstruction is given. Good cosmetic results were obtained in six of seven patients with no evidence of graft resorption. One patient required removal of the graft because of inadequate soft tissue coverage. No patient suffered any significant donor site morbidity. In summary, this technique is extremely useful in treating post-traumatic bony deformities of the facial skeleton. The excellent graft survival and ease in harvesting the graft make this technique preferable to traditional endochondral grafts taken from the iliac crest and rib.

4247. Petrone, P., et al. (2018). "To kill or be killed: the coup de grace for a warrior after multiple sword wounds." Anthropologischer Anzeiger; Bericht uber die biologisch-anthropologische Literatur **75**(4): 311-323.

Finding traumatic lesions on ancient skeletal remains offers a unique opportunity to investigate the circumstances surrounding the time of death. Here we present the unique find of a late 17th, early 18th century young male from Southern Italy with eight traumatic skull lesions. A detailed anthropological examination using X-ray and 3D CT scanning techniques was conducted in order to evaluate traumatic extent, direction and degree of severity of each skull injury. The nature, number and timing of repair of the traumata suggest that they were intentional blows inflicted in battle. Gross and radiographic evidence shows that the individual survived long after one of these traumata, most likely suffered in a previous battle. Shape, size and location, as well as different orientation and implied trajectory of the multiple wounds, suggest that they were produced by a heavy, sharp cutting weapon. The perimortem aspect of most of the traumata revealed them to be contemporary injuries, suffered in a final assault by a heavy sword during a face-to-face combat. The largest and deepest fracture penetrating the skull cavity possibly resulting in traumatic brain injury was here suggested as the fatal one, even if the victim may have survived for several days prior to death.

4249. Petrov, D., et al. (2002). "[Major respiratory tract traumas]." Travmi na magistralnite vuzdukhonosni putishta. **58**(1): 28-31.

Between 1988 and 2000 a total of 33 patients with traumatic tracheobronchial lesions were diagnosed and treated. The trauma was penetrating in 7 (stab and gun-shot), blunt in 10 (car accidents, compression and falling from heights) and iatrogenic in 16 of them (postintubational--15, after foreign body extraction--1). The main clinical and radiological features were subcutaneous emphysema, hemoptysis, respiratory insufficiency, pneumomediastinum and pneumothorax. The diagnosis was confirmed in all patients by early fiberoptic bronchoscopy. "Watch and see" tactics with massive antibiotics therapy was followed in 4 (12%) patients. A surgical treatment was carried out in 29 (88%) patients as follows: simple repair--19 (58%), left pneumonectomy--2 (6%), tracheal resection and anastomosis "end to end"--2 (6%), tracheostomy--1 (3%), thoracocenthesis and drainage--3 (9%) and cervical mediastinotomy--2 (6%). The operative mortality was 9%. The cause of death in these 3 patients were associated brain and spinal cord injuries. In the rest of patients the early and long-term postoperative results were considered very good.

4251. Phaily, A. and M. Khan (2019). "Is our current method of cervical spine control doing more harm than good?" Trauma (United Kingdom) **21**(3): 176-183.

Introduction: Early cervical spine immobilisation has long been considered the standard of care in the management of trauma patients with suspected spinal cord injury. There has been conflicting evidence regarding its benefits and risks. This article reviews the current literature and whether the continued use of routine cervical spine immobilisation is still appropriate in modern trauma care. Method: A literature search was conducted using the Medline PubMed, Google Scholar and Cochrane Library online databases. The searches were limited to full text, English language studies conducted on adults in the last 20 years (July 1997 to July 2017). Results: The entrenchment of cervical spine immobilisation in trauma management is multifactorial. In the pre-hospital setting, immobilisation is recommended whilst awaiting full assessment. Fear of missed diagnoses of spinal injuries encourages defensive medicine and over-immobilisation. Effective cervical spine immobilisation is appropriate in certain cases and reduces the risk of further spinal cord injury. However, research has shown that we are over-immobilising, and in penetrating trauma, cervical spine immobilisation increases the risk of mortality. Conclusions: The practice of routine cervical spine immobilisation for trauma patients is outdated, ineffective and results in iatrogenic injury. Routine cervical spine immobilisation is not backed up by robust evidence. It has been clearly shown that in cases of penetrating spinal injuries, cervical spine immobilisation is not only ineffective but is also linked to an increased risk of mortality. Special considerations must also be taken in patients who have pre-existing spinal conditions, impending airway compromise, or at risk of aspiration and

those with head injuries or suspected traumatic brain injuries. A selective approach to cervical spine immobilisation is recommended and should be reserved for cases deemed high risk rather than a standard rule for all trauma patients.

4252. Pham, T., et al. (2018). "Fetal gunshot brain injury leading to late postnatal hydrocephalus." Journal of neonatal-perinatal medicine **11**(4): 427-431.

A male fetus was delivered by emergent caesarean section after a term pregnant mother was caught in crossfire and sustained gunshot injury to her abdomen. Examination of the infant was unremarkable except for a small laceration of the scalp at the anterior fontanelle. Skull radiography showed a dense bullet shaped opacity in the brain. He was managed conservatively and was discharged home on full feeds with normal neurological examination. He developed seizures and progressive hydrocephalus, and underwent a ventriculoperitoneal (VP) shunt placement at 5 weeks of age. At 13 months of age the bullet was removed. To our knowledge this is the first report of fetal brain injury with intact bullet in the brain with survival. This case provides the context for a discussion about factors that contribute to survival and favorable prognosis of infants with fetal penetrating gunshot brain injury.

4253. Phillips, B., et al. (2018). "A subgroup analysis of penetrating injuries to the pancreas: 777 patients from the National Trauma Data Bank, 2010-2014." The Journal of surgical research **225**: 131-141.

BACKGROUND: This study is the first to analyze penetrating injuries to the pancreas within subgroups of severe traumatic brain injury (TBI), early deaths, and potential survivors. Our objectives were to identify national patterns of injury, predictors of mortality, and to validate the American Association for Surgery of Trauma Organ Injury Scale (AAST-OIS) pancreas injury grades by mortality. Secondary outcomes included hospital and intensive care unit length of stay and days on mechanical ventilation., METHODS: Using the Abbreviated Injury Scale 2005 and ICD-9-CM E-codes, we identified 777 penetrating pancreatic trauma patients from the National Trauma Data Bank that occurred between 2010 and 2014. Severe TBI was identified by ICD-9-CM diagnosis codes and Glasgow Coma Score (GCS; n = 7), early deaths were those that occurred within 24 h of admission (n = 82), and potential survivors included patients without severe TBI who survived longer than 24 h following admission (n = 690). We estimated multivariable generalized linear mixed models to predict mortality to account for the nesting of potential survivors within trauma centers., RESULTS: Our results indicated that overall mortality decreased from 16.9% to 6.8% after excluding severe TBI and early deaths. Approximately, 11% of patients died within 24 h of admission, of whom 78% died in the first 6 h. Associated injuries to the stomach, liver, and major vasculature occurred in approximately 50% of patients; rates of associated injuries were highest in patients who died within 6 h of admission. In potential survivors, mortality increased by AAST-OIS grade: 3.5% I/II; 8.3% III; 9.6% IV; and 13.8% V. Predictors of mortality with significantly increased odds of death were patients with increasing age, lower admission GCS, higher admission pulse rate, and more severe injuries as indicated by Organ Injury Scale grade., CONCLUSIONS: From 777 patients, we identified national patterns of injury, predictors of outcome, and mortality by AAST-OIS grade within the subgroups of severe TBI, early deaths, and potential survivors. Because AAST-OIS is not a reported element in the National Trauma Data Bank, we correlated Abbreviated Injury Scale 2005 codes to injury grade and identified an increase in mortality. After controlling for covariance, we found that greater age, lower GCS in stab wounds, higher pulse, and presence of a grade V pancreatic injury independently predicted the likelihood of death in patients surviving beyond 24 h following penetrating injuries to the pancreas.

4254. Phillips, C. D. (1992). "Emergent radiologic evaluation of the gunshot wound victim." Radiologic clinics of North America **30**(2): 307-324.

The incidence and number of victims of gunshot injury in the United States increases yearly. Rapid acute assessment of these individuals includes radiologic examinations. This article is an overview of current management practices and information relevant to the radiologist who is called upon to evaluate these patients.

4257. Philp, L., et al. (2012). "Late outcomes after grafting of the severely burned face: a quality improvement initiative." Journal of burn care & research : official publication of the American Burn Association **33**(1): 46-56.

Many approaches to surgical management of the severely burned face are described, but there are few objective outcome studies. The purpose of this study was to perform a detailed evaluation of the late outcomes in adult patients who have undergone grafting using a standardized surgical and rehabilitation approach for full-thickness (FT) facial burns to identify areas for improvement in the treatment strategy of authors. This was a prospective observational study in which patients who had undergone grafting for FT facial burns by the senior investigator at a regional burn centre between 1999 and 2010 were examined by a single evaluator. The surgical approach included tangential excision based on the facial aesthetic units, temporary cover with allograft then autografting with scalp skin preferentially, split grafts for the upper eyelid, and FT grafts for the lower eyelid. Rehabilitation included compression (uvex and or soft cloth), scar massage, and silicone gel sheeting. Of 35 patients with facial grafts, 14 subjects (age 43 +/- 16 years with 22 +/- 21% TBSA burns) returned for late follow-up at 40 +/- 33 months (range, 5-91 months). A mean of four facial aesthetic units per patient were grafted (range, 1-9 units), with six full facial grafts performed. Scalp was used as donor in 10 of 14 cases. Scalp donor sites were well tolerated with minor alopecia visible in only one case although the donor site visibly extended slightly past the hairline in two cases. Color match with native skin was rated at 8.8 +/- 0.8 of 10 when scalp skin was used compared with 7.5 +/- 1.6 with other donor sites ($P = .06$). On the lip and chin, hypertrophic scars were significantly worse compared with the rest of the facial grafts (Vancouver scar scale 8 +/- 2 vs 3 +/- 1, $P < .01$). Sensory recovery was poor with overall moving two-point discrimination at 11 +/- 3 mm (range, 4-15 mm), and monofilament light touch was 3.8 +/- 0.6. Graft borders were significantly more elevated than graft seams. On the forehead, the most notable problem was a gap between the graft and hairlines of the frontal scalp and eyebrows (range, 0-40 mm). Grafted eyelids required one or more subsequent ectropion releases in the majority of cases. The most common problem for the nose was asymmetry of the nostril apertures. The most problematic late outcomes that the authors identified after facial grafting for FT facial burns included relatively poor sensory return, elevation of graft edges, eyelid ectropion, gaps between grafts and hairline, and marked hypertrophic scarring around the mouth and chin. The results indicate that possible areas for quality improvement include greater attention to the limits of scalp harvest, more attention to pressure application to graft borders and the lip and chin during rehabilitation, greater accuracy in excision and graft placement on the forehead to avoid gaps with the hairlines, and counseling of the patient regarding the high probability of diminished facial sensation.

4258. Pia, H. W. (1979). "Head and brain injuries." Langenbecks Archiv fur Chirurgie **Vol. 349**: 247-252.

Experiences of war surgery since World War I, especially in World War II, in Germany by W. Tonnis, in Korea, Vietnam and Lebanon have proved that penetrating brain injuries require immediate operation by teams of experienced neurosurgical surgeons and nurses. Modern diagnosis by computer tomography immediately reveals every type and form of primary and secondary closed and compound injuries and excludes misinterpretations, additionally present-day neurosurgical technique have improved the prognosis of every type of head injury. Adequate training of surgeons in up-to-date neurotraumatology is absolutely essential if optimal neurotraumatological care is to be provided in case of large scale catastrophe.

4261. Piatt, J. (2018). "Penetrating spinal injury in childhood: the influence of mechanism on outcome. An epidemiological study." Journal of neurosurgery. Pediatrics **22**(4): 384-392.

OBJECTIVE: Penetrating injury of the spine in childhood commonly causes profound and life-long disability, but it has been the object of very little study. The goal of the current report is to document temporal trends in the nationwide incidence of this condition and to highlight the differences between penetrating injuries and closed injuries., METHODS: The Kids' Inpatient Database was queried for spinal injuries in 1997, 2000, 2003, 2006, 2009, and 2012. Penetrating mechanism was determined by diagnostic coding for open injuries and by mechanistic codes for projectiles and knives. Nationwide annual incidences were calculated using weights provided for this purpose. Unweighted data were used as a cross-sectional sample to compare closed and penetrating injuries with respect to demographic and clinical factors. The effect of penetrating mechanism was analyzed in statistical models of death, adverse discharge, and length of stay (LOS)., RESULTS: The nationwide incidence of penetrating spinal injury in patients less than 18 years of age trended downward over the study period. Patients with penetrating injury were older and much more predominantly male than patients with closed injuries. They resided predominantly in zip codes with lower median household incomes, and they were much more likely to have public health insurance or none at all. They were predominantly black or Hispanic. The risk of hospital death was no different, but penetrating injuries were associated with much higher rates of adverse discharge after LOS, averaging twice as long as closed injuries. Brain, visceral, and vascular injuries were powerful predictors of hospital death, as was upper cervical level of injury. The most powerful predictor of adverse discharge and LOS was spinal cord injury, followed by brain, visceral, and vascular injury and penetrating mechanism., CONCLUSIONS: Because its pathophysiology requires no elucidation, because the consequences for quality of life are dire, and because the population at risk is well defined, penetrating spinal injury in childhood ought to be an attractive target for public health interventions.

4262. Picard, A., et al. (2004). "[Reconstruction of complex loss of maxillary substance using a vascularized fibular flap after arteriovenous fistulization with a saphenous loop]." Reconstruction d'une perte de substance complexe du maxillaire par transfert de fibula vascularise apres realisation d'une fistule arterio-veineuse par boucle vasculaire saphene. **105**(5): 295-297.

INTRODUCTION: When major loss of bone stock requires a vascularized transfer, the poor quality of the receiver vessels may require complementary lengthening of the vascular pedicle. This can be achieved with venous bypasses or by preparing the recipient site with a vascular loop. We have used this later approach successfully in a patent with major tissue loss involving the maxillary bone., CASE REPORT: A 39-year-old man presented total loss of the maxillary tissues due to a firearm wound. A free fibular flap was considered. Due to the limited length of the fibular pedicle, and the scar tissue in the area of the vascular anastomoses, reconstruction was performed in two phases: first preparation of the recipient site with a saphenous loop then fifteen days later transfer of the fibular flap., DISCUSSION: This technique is an alternative to venous bypass which increases the risk of postoperative thrombosis. The objectives of the vascular loop are to position the anastomoses in a healthy area and to achieve end-to-end anastomoses. This technique has been described basically for the treatment of post-traumatic tissue loss of the limbs, but can be applicable for the face, particularly after radiation.

4263. Picardi, J. L., et al. (1975). "Clindamycin concentrations in the central nervous system of primates before and after head trauma." Journal of neurosurgery **43**(6): 717-720.

The authors measured levels of clindamycin, a drug well established as useful in the treatment of various soft-tissue and parenchymal bacterial infections, in serum, cerebrospinal fluid, and brain tissue of 14 rhesus monkeys. Penetration into brain tissue was erratic and concentrations detected were not significant. Cerebrospinal fluid levels, however, averaged 20.5% of paired serum concentrations and were higher than concentrations needed to inhibit most Gram-positive bacteria. Further studies in humans are indicated before this antibiotic may be used routinely.

4264. Pickering, A. E., et al. (2016). "The effect of presenting complaint on the risk of developing ventilator-associated pneumonia for patients intubated in an academic emergency department." Journal of Investigative Medicine **64**(1): 319-320.

Purpose of Study Ventilator associated pneumonia (VAP) increases ICU length of stay and mortality. Eckert found that 26% of trauma patients intubated in the ED develop VAP as compared to 6.5% of those intubated in the ICU. Green demonstrated that 70% of critical patients were intubated pre-hospital or in the ED and 18.2% remained in the ED for more than 4 hours. Objective To characterize the effect of presenting complaint on VAP risk and prevalence for

patients intubated in the ED. Methods Used A retrospective study was performed using a QI database of patients intubated in the ED. “At-risk for VAP” was defined as intubated >48 hours, with no significant abnormality on chest x-ray in the first 48 hours. “At-risk” patients were identified as VAP positive if they had a new persistent infiltrate on CXR with temperature outside 36-38C, and leukocyte count outside 4,000- 12,000, on chart review. Summary of Results 539 patients were included in the cohort. 244 presented with traumatic complaints, of these 25% (60) were found to be at risk for VAP and 45% (27) of these developed VAP. 295 patients had medical presenting complaints, of these 16% (47) were at risk for VAP and 17% (8) of these developed VAP. Trauma of unknown or less prevalent mechanism was categorized as Other Trauma, including TBI's and multi trauma. 28% of this group was at risk for VAP and 79% of these were VAP positive. 19% of gunshot wounds were at risk and 67% developed VAP. Conclusions Patients with traumatic injury were at higher risk for VAP and developed VAP more frequently.

4265. Pickett, G. E. and R. Vandorpe (2019). "Management of a maxillofacial, transclival penetrating injury." Canadian Journal of Neurological Sciences **46**: S42.

Background: Penetrating traumatic injuries to the clivus are rare. We describe the case of a 79-year-old man who presented to the emergency room with a butter knife protruding from his left cheek. Imaging showed the blade entering just beneath the left zygoma and transecting the clivus to terminate within the prepontine cistern. The tip of the knife abutted the right anterior inferior cerebellar artery and lower basilar artery. Methods: He was brought to the interventional neuroradiology OR with knife in place, by a combined surgical team of ENT, neurosurgery, and neuroradiology. Under local anaesthetic and intravenous sedation, vascular access to the distal left vertebral artery was obtained and a balloon positioned. Traction was applied to the knife and the knife was successfully removed avoiding any angular or rotational movements. An immediate angiogram showed no evidence of arterial injury. Results: The patient recovered uneventfully and was discharged home with no neurological deficit. Follow-up CT/CTA was performed a month later and confirmed no pseudoaneurysm or other complication. Conclusions: Management of penetrating skull base injuries by a multidisciplinary surgical team is advisable. Vascular imaging is crucial. Positioning of balloons within large vessels close to the penetrating object is recommended to control bleeding that may occur on removal.

4266. Pidlisnyi, S. S. (1998). "[Air resorption in traumatic pneumocephalus]." Rezorbtsiia povitria pry travmatychnii pnevmotsefalii.(2): 66-67.

Traumatic pneumocephalus results from severe penetrating craniocerebral injury. Resorption of air depends on its location in the cranial cavity, concurrent injury to the brain. In the subarachnoid space resorption of a small amount of air (less then 60 cm3) occurs within the shortest time possible. In substantia medullaris air is not resorbable. In all cases cranium is supposed to be air-tight in order that full resorption might take place. This will determine the choice of the treatment option to be adopted.

4267. Pienaru, M., et al. (2014). "[Treatment for penetrating wound caused by metallic intraocular foreign body]." REZOLVAREA UNEI PLAGI PENETRANTE CU CORP STRAIN INTRAOCULAR METALIC. **58**(4): 36-39.

INTRODUCTION: Penetrating wounds with intraocular foreign body are ophthalmologic emergencies due to their severity and complexity and may require multiple surgeries for final resolution., CASE REPORT: 30-years-old patient with penetrating wound and metallic intraocular foreign body in the posterior vitreous requires successive operations for IOFB extraction, lensectomy, posterior vitrectomy for rhegmatogenous retinal detachment and then silicone oil extraction with final visual acuity 0, 4 PH.

4268. Pierre, K., et al. (2022). "Blood-based Brain and Global Biomarker Changes Following Combined Hypoxemia and Hemorrhagic Shock in a Rat Model of Penetrating Ballistic-Like Brain Injury." Clinical neurosurgery **68**(SUPPL 1): 115.

INTRODUCTION: Penetrating traumatic brain injury (pTBI) often occurs with systemic insults like hemorrhagic (HS) and hypoxemic (HX) shock. METHODS: 30 rats were randomly assigned to sham, PBBI, HS+HX, and PBBI+HS+HX groups. PBBI and sham groups underwent craniotomy with and without probe insertion and balloon expansion, respectively. HX and HS was then simulated by blood withdrawal and FiO2 reduction. Biomarker serum concentrations were determined at one (D1) and two (D2) days post-injury with ELISA methods. RESULTS: Axonal injury-linked biomarkers pNF-H and NF-L serum levels in PBBI groups were higher than those in sham and HX + HS groups at D1 and

D2 post-injury. The same was true for PBBI + HX + HS compared to sham (D2 only for pNF-H) and HX + HS groups. However, pNF-H and NF-L levels in PBBI + HX + HS were not different than their PBBI counterparts. At D1, αII-spectrin levels in the HX + HS and PBBI + HS + HX groups were higher than the sham groups. αII-spectrin levels in the HX + HS group were higher than the PBBI group. This suggests HX + HS as the common insult driving αII-spectrin elevations. CONCLUSION: pNF-H and NF-L may serve as specific serum biomarkers of penetrating TBI in the presence or absence of systemic insults. αII-spectrin may be a sensitive acute biomarker in detecting systemic insults occurring alone or with pTBI.

4269. Pigadas, N., et al. (2008). "A randomized controlled trial on cross-infection control in maxillofacial trauma surgery: a comparison of intermaxillary fixation techniques." International journal of oral and maxillofacial surgery **37**(8): 716.

Glove perforations and percutaneous injuries occur commonly during the treatment of facial fractures and reveal the need for safer techniques, especially in intermaxillary fixation. The Rapid IMF device does not use any wires and may provide better cross-infection control than wiring methods. The aim of this study was to test the hypothesis that Rapid IMF is associated with fewer glove perforations/ percutaneous injuries than traditional wiring techniques. The authors carried out a randomized controlled trial which included 120 patients with fractures of the mandible requiring open reduction and fixation. The participants were allocated either to the study group and treated with intraoperative Rapid IMF or to the control group and managed with intraoperative eyelet wire ties. Analysis of the results showed that the Rapid IMF group had significantly fewer glove perforations than the traditional method (0.67 per operation compared with 1.5), (P<0.0001). The incidence of skin-penetrating injuries was the same in both groups (rate 0.02/ procedure). The application of Rapid IMF was significantly faster than wiring (P<0.0001). Minor intraoperative complications were noted in both groups, but more in the Rapid IMF group. Most concerned loosening or fracture of the anchorage ties but the surgical outcome was not affected. Rapid IMF is a safer alternative to wiring methods with significant reduction in glove perforation rates and is quicker to apply than conventional wiring techniques.

The objective of the present study was to estimate the possibility of using computer-assisted three-dimensional modeling for the solution of selected problems of forensic medical expertise. This approach is illustrated by an example of the reconstruction of the scene of action and circumstances of the injury taking into consideration blood stains.

4272. Pikus, H. J. and P. A. Ball (1995). "Characteristics of cerebral gunshot injuries in the rural setting." Neurosurgery clinics of North America **6**(4): 611-620.

The rural CGW population has not yet undergone the metamorphosis experienced by its urban counterparts. Reminiscent of a past era, suicides far outweight homicides. Although many rural firearm injuries involve hunting accidents, these comprise only a small fraction of CGW at best. Similarly, although many rural firearm injuries involve shotguns or rifles, few CGW result from these weapons. Although the number of patients is small, those with shotgun or rifle injuries manifest lower mortality rates. The authors have confirmed the notion that caliber of civilian weapons is difficult to correlate with outcome. The geographic size of the rural catchment area is an important consideration because it must select a population able to withstand transfer. The authors noted an inverse relationship between length of time before arrival at the facility and mortality. The selection phenomenon probably accounts for the reduced mortality found in the authors series versus most others. Prognostic features of individual gunshot wounds are likely to be similar among varied populations when circumstances of the injury are matched. Thus, one expects similar features on initial examination and CT scan to have similar predictive value. The authors confirmed that CGS and specific deficits were strong predictors of outcome. No patient with a GCS score of 5 or less on admission survived. Absent pupillary response, absent brain stem function, presence of respiratory drive or cough only, and posturing were strong indicators of impending death. The authors confirmed the prognostic value associated with CT evidence of intraventricular hemorrhage, transventricular trajectory, transtentorial herniation, massive edema, and bihemispheric injury. Interestingly, presence of extensive facial fractures, an indicator of trajectory, suggested better outcome. Subarachnoid hemorrhage did not reach prognostic significance. Roughly half of the authors' patients had positive serum ethanol levels, although the test was unable to discern prognosis. Abnormality of any coagulation parameter and frank disseminated intravascular coagulation were correlated with poor outcome. Likewise, thrombocytopenia occurring within the first 24 hours was an indicator of poor prognosis. Although prophylactic antibiotics were not used in all cases, the authors encountered no deep or superficial infections in surviving patients. The prevalence of seizures in the authors' series despite prophylactic AED is unusually high. This feature merits further study.

4273. Pilarczyk, K., et al. (2017). "Does Traumatic Donor Cause of Death Influence Outcome after Lung Transplantation? A Single-Centre Analysis." The Thoracic and cardiovascular surgeon **65**(5): 395-402.

Background Owing to the shortage of donor organs in lung transplantation (LuTX), liberalization of donor selection criteria has been proposed. However, some studies suggested that donor traumatic brain damage might influence posttransplantation allograft function. This article aimed to investigate the association of donor cause of death (DCD) and outcome after LuTX. Methods A retrospective analysis of 186 consecutive double LuTXs at our institution from January 2000 to December 2008 was performed. DCD was categorized into traumatic brain injury (TBI) and nontraumatic brain injury (NTBI). In addition, NTBI was sub classified as spontaneous intracerebral bleeding (B), hypoxic brain damage (H), and intracerebral neoplasia (N). Results DCD was classified as TBI in 50 patients (26.9%) and NTBI in 136 patients (73.1%): B in 112 patients (60.2%), H in 21 patients (11.3%), and N in 3 patients (1.6%). Young male donors predominated in group TBI (mean age 36.0 +/- 14.5 vs. 42.8 +/- 10.7, $p < 0.01$; 29 males in the TBI group [58.0%] vs. 48 males in the NTBI group [35.3%], $p < 0.01$). Groups of DCD did not differ significantly by recipient age or gender, recipient diagnosis, donor ventilation time, or paO2/FiO2 before harvesting. TBI donors received significantly more blood (3.4 +/- 3.8 vs. 1.8 +/- 1.9, $p = 0.03$). A chest trauma was evident only in group T (n = 7 [3.7%] vs. 0 [0%], $p < 0.001$). Mode of donor death did not affect the following indices of graft function: length of postoperative ventilation, paO2/FiO2 ratio up to 48 hours, and lung function up to 36 months. One- and three-year survival was comparable with 84.4 and 70.4% for TBI donors versus 89.4% and 69.2% for NTBI donors. Five-year survival tended to be lower in the TBI group but did not reach statistical significance (43.4 vs. 53.9%). Conclusion This study indicates that traumatic DCD does not affect outcome after LuTX. These results can be achieved with an ideal donor management combined with an individual case-to-case evaluation by an experienced LuTX surgeon. Copyright Georg Thieme Verlag KG Stuttgart . New York.

4274. Pilipenko, G., et al. (2020). "RESULTS OF BRAIN INJURY PRIMARY SURGICAL TREATMENT IN A COMPLEX CARE FOR PATIENTS WITH COMBAT-RELATED PENETRATING CRANIOCEREBRAL GUNSHOT WOUND AT A SPECIALIZED MEDICAL FACILITY." Georgian medical news(301): 13-20.

The aim of the study is to justify the "balanced" approach to brain debridement (BD) in surgical treatment of combat-related penetrating craniocerebral gunshot wound (PCGW) patients and assess immediate and long-term treatment results. The analysis of applied surgical BD techniques was performed in PCGW military personnel with admission Glasgow Coma Scale (GCS) score of 4 or above. The study included 81 injured patients. Average GCS score at

admission was 10+/-3. Blunt injuries were predominant (n=51, 62.9%). Bone fragments were removed in 78 (92.8%) and metal foreign bodies were removed in 32 (38.1%)cases. Demographic and clinical characteristics, nature of brain injury, presence of foreign bodies and depth of their location, surgery extent, and occurrence of complications in postoperative period were taken into account. The outcome data included a Glasgow Outcome Scale (GOS) score at discharge, in 6 and 12 months, grade of speech disorders, extremities strength, and occurrence of convulsive attacks from the time of admission to 12 months. Meningitis developed in 11 (13.6%) cases. 11 (13.6%) patients died. Good recovery (GOS score 4-5) in 12 months was in 8 (38.1%) patients, moderate disability (GOS score 4) in 10 (47.6%) patients. Adverse outcome (GOS score 1-3) was associated with axial dislocation (p=0.015), diametric wound (p<0.001), and purulent-septic complications (PSC) (p<0.05). Intracranial PSCs are statistically significantly associated with duration of subdural space inflow and outflow drainage of 4+ days (p<0.05), bone fragments left in the brain matter (p=0.008), and ventricular hemorrhage on HCT (p=0.016). The choice of a BD technique depended on severity of patient's condition, brain injury, and presence of foreign bodies. Availability of an equipped operating room allowed for thorough surgery. Good outcome indicators testify to appropriateness of the chosen tactic.

4275. Pillgram-Larsen, J., et al. (1992). "[Injuries from mines]." Mineskader. **112**(17): 2183-2187.

In autumn 1991, 157 patients injured by mine explosions were taken care of by a Norwegian military medical unit attached to the United Nations mission in the demilitarized zone between Iraq and Kuwait. 146 of the patients were seen during a three week period of Iraqi mine harvesting in the desert. The detachment worked according to the principles of a second echelon surgical installation. The patients were operated upon if necessary, stabilized and evacuated to Iraqi hospitals. 20 patients in all (13%) died primarily. Four of 109 patients evacuated to the field hospital died (4%). 68 patients had major amputations, in seven of them two extremities were blown off. One patient had an open chest wound, two had tracheal puncture wounds, and one had penetrating head injury. 27 patients had eye injuries, 13 of which were penetrating. 64 major surgical procedures were performed. When evacuation times are long after mine injuries, approximately six hours, almost only patients with injuries to the extremities can be expected to reach hospital for treatment. The pattern of injury was regular, with crushed extremities, amputations and damaged eyes.

4276. Pilo, B., et al. (2011). "Concentric visual field defect related to spontaneous intracranial hypotension." Neuro-Ophthalmology **35**: S70.

INTRODUCTION: Spontaneous intracranial hypotension (SIH) is a rare syndrome characterized by postural headache associated with a low cerebrospinal fluid pressure without a history of dural puncture or penetrating trauma. Cranial MRI typically shows diffuse pachymeningeal gadolinium enhancement, subdural fluid collections or dilatation of epidural veins evidence of descent of the brain. Visual signs and symptoms have been described infrequently in patients with SIH. These include sixth nerve palsy, superior nasal quadrantanopia and temporal hemianopia. OBJECTIVE: To report a case of this condition. RESULTS: A 34 year-old woman who presented with a two-year history of orthostatic headache, rhinorrhea, gait ataxia and a bilateral concentric visual field defect. She had no past history of trauma, sinus surgery or intracranial surgery. Cranial MRI was normal. Neuro-ophthalmological examination ruled out any other causes of concentric visual field defects. Lumbar puncture showed a CSF opening pressure of 9 cm of water. Radioisotope cisternography suggested a dural leak at cribiform plate. CT of the paranasal sinuses only showed a hypoplastic right frontal sinus. The cribiform plate region was repaired with improvement of all symptoms. CONCLUSION: SIH should be included in the differential diagnosis of a bilateral concentric visual field defect.

4277. Pinckers, A., et al. (1983). "The EOG in unilateral eye disease: injuries." Graefe's archive for clinical and experimental ophthalmology = Albrecht von Graefes Archiv fur klinische und experimentelle Ophthalmologie **220**(2): 87-91.

In unilateral injuries, the tap to the eye by a penetrating foreign body is sufficient to depress the electro-oculogram (EOG). Total recovery is time-consuming. During the recovery period, complications such as siderosis and detachment may arise, acting with predilection on the light-sensitive EOG component. Blunt traumata and possibly surgical opening of the eyeball predominantly decrease the light-insensitive component of the EOG.

4278. Pineda, J. A., et al. (2012). "Impact of pediatric neurocritical care on traumatic brain injury outcomes." Journal of neurotrauma **29**(10): A146.

Introduction Traumatic brain injury is a leading cause of death and disability in children. The impact of neurocritical care on outcome is largely unknown. The objective of this study was to determine whether implementation of a pediatric neurocritical care team improved outcome for children with severe traumatic brain injury. Methods Retrospective cohort study. Two 6-year intervals before and after implementation of the neurocritical care team were analyzed. Participants included children age 3 to 219 months (0-18 years) consecutively admitted to the Pediatric Intensive Care Unit with severe traumatic brain injury (Glasgow Coma Scale Score ≤ 8). Exclusion criteria:gunshot wound to the head, non-accidental trauma, cardiac arrest prior to ICU admission, and GCS = 3 + fixed and dilated pupils on admission. The primary outcome was disposition at hospital discharge. Secondary outcomes included the Glasgow Outcome Scale score at hospital discharge and length of ICU and hospital stay. Results Implementation of the neurocritical care team improved outcome despite no changes in discharge practices per degree of disability. This improvement included a 72% reduction in mortality and improved disposition at hospital discharge for survivors. There was no difference in age, gender, mechanism of injury and severity of injury between the two groups. There was no difference in secondary outcomes. Conclusions Implementation of a neurocritical care team improved outcome in children with severe traumatic brain injury. Further studies are needed to identify best clinical practices and their impact on long term outcomes.

4279. Ping, X., et al. (2014). "PEG-PDLLA micelle treatment improves axonal function of the corpus callosum following traumatic brain injury." Journal of neurotrauma **31**(13): 1172-1179.

The initial pathological changes of diffuse axonal injury following traumatic brain injury (TBI) include membrane disruption and loss of ionic homeostasis, which further lead to dysfunction of axonal conduction and axon disconnection. Resealing the axolemma is therefore a potential therapeutic strategy for the early treatment of TBI. Monomethoxy poly (ethylene glycol)-poly (D, L-lactic acid) di-block copolymer micelles (mPEG-PDLLA) have been shown to restore depressed compound action potentials (CAPs) of spinal axons and promote functional recovery after spinal cord injury. Here, we evaluate the effect of the micelles on repairing the injured cortical axons following TBI. Adult mice subjected to controlled cortical impact (CCI) were treated with intravenous injection of the micelles at 0 h or 4 h after injury. Evoked CAPs were recorded from the corpus callosum of coronal cortical slices at 2 days after injury. The CCI caused significant decreases in the amplitudes of two CAP peaks that were respectively generated by the faster myelinated axons and slower unmyelinated axons. Micelle treatment at both 0 h and 4 h after CCI resulted in significant increases in both CAP peak amplitudes. Injection of fluorescent dye-labeled micelles revealed high fluorescent staining in cortical gray and white matters underneath the impact site. Labeling membrane-perforated neurons by injecting a membrane impermeable dye Texas Red-labeled dextran into lateral ventricles at 2 h post-CCI revealed that immediate micelle injection after CCI did not reduce the number of dye-stained cortical neurons and dentate granule cells of the hippocampus, indicating its ineffectiveness in repairing plasma membrane of neuronal somata. We conclude that intravenous administration of mPEG-PDLLA micelles immediately or at 4 h after TBI allows brain penetration via the compromised blood brain-barrier, and thereby improves the function of both myelinated and unmyelinated axons of the corpus callosum.

4280. Pingarrón-Martín, L., et al. (2015). "Experience with mandibular reconstruction using transport-disc-distraction osteogenesis." Craniomaxillofacial Trauma and Reconstruction **8**(2): 117-122.

The goal of transport-disc-distraction osteogenesis (TDDO) is to restore bone continuity by using in-situ bone. It may be useful following trauma, gunshot injuries, or tumor ablation, especially when there may be contraindications at the donor site or for prolonged surgery. To the best of the authors' knowledge, this is the first time TDDO has been used for mandibular reconstruction reporting additional procedures, which include osseointegrated dental implants rehabilitation and orthognathic surgery. A retrospective study is performed analyzing all mandibular reconstruction cases that may be suitable for distraction from January 2006 to December 2011. A thorough description of the documented cases includes details about sex, gender, complications, duration of hospitalization, etiology, size, and location of the defect. Eight cases of mandibular reconstruction were included. Six cases correspond to mandibular ameloblastoma. The remaining two cases were mandibular gunshot comminuted fractures. Range of the defects was from 45 to 60 mm. Length of the transport disc was 15 to 20 mm. Protocolized technique consisted of 5 days of latency period, 19 to 45 days of activation term (average 30 days), and 8 to 12 weeks for consolidation. Mean distraction length

achieved was 40.45 mm. We can conclude that TDDO is an alternative to conventional and more invasive procedures, when we face severe segmental mandibular defects reconstruction. It shows the potential to restore a better anatomical bone regeneration, also providing soft tissues and reducing donor-site morbidity. Patients' education and awareness about the proper use of the transport-disc-distraction device is important to optimize functional outcomes.

4281. Pinna, B. R., et al. (2004). "Traumatic facial paralysis's study: Clinical and surgical review." Revista Brasileira de Otorrinolaringologia **70**(4): 479-482.

Traumatic facial paralysis is the second more common cause of facial impairment. Study design: Chart review. Material and method: A retrospective review of 82 patients with facial paralysis was conducted from January 1990 to January 1999. Results: From this group 54 were males (65.8%) and 28 females (34.2%), patients' age ranged from 2 to 75 years (mean age 30.9 y). The kind of trauma was iatrogenic in 15 (18.22%); penetrating injuries into the face in 2 (2.44%); temporal bone fractures in 50 (60.97%); gunshot injuries in 14 (17.07%) and birth injury in 1 (1.22%). There were 71 sudden paralysis (86.5%), 10 progressive paralysis (12.3%) and 1 at birth (1.22%). The beginning electrical tests were symmetrical in 32 (43.84%) and with markedly decreased response in 41 (56.16%). The symmetrical ones had complete recovery in 24, 80% of recovery in 6 and 60% of recovery in 2; the asymmetrical ones with decreased response, only 5 recoveries completely. Conclusion: 1. There was greater male incidence; 2. There were more sudden paralysis and they recovered better than the progressives; 3. There were more patients with temporal trauma with fractures and they recovery better than the others; 4. The electrical tests could give the prognoses to the facial paralysis patient; 5. The worst cases of facial paralysis received more aggressive treatment, with good results.

4282. Piotrowski, W. P. (1992). "[Results of treatment of brain gunshot injuries]." Behandlungsergebnisse nach Hirnschussen. **95**(2): 74-77.

Craniocerebral missile injuries are a relatively rare type of head injury during peacetime. In the Department of Neurosurgery of the Landesnervenklinik Salzburg 72 patients were operated on for gunshot wounds of the brain in the period 1970-1990, and 31 survived. In the same period 6763 patients were treated for other head injuries. As shown by the clinical courses and the operative results, the velocity and thus the extent of the primary brain damage determine the prospects of success in the treatment of cerebral missile injuries.

4283. Pircher, R., et al. (2014). "Muzzle imprint mark: a patterned injury which may be constituted of intradermal blood extravasations." Forensic science international **244**: 166-169.

The muzzle imprint mark in contact shots is usually regarded as a patterned pressure abrasion depicting the barrel end as well as adjacent constructional components of the weapon. Due to parching after exposure to air, the affected skin assumes a brown color, especially along the contours of the impacting structures. Apart from this well-known type of epidermal damage, the imprint mark may also be formed by intradermal hemorrhages. In some cases, these intracutaneous bleedings manifest themselves as circular, curved or straight reddish lines mirroring the surface relief of the weapon's muzzle end. To estimate the frequency of skin hematomas in muzzle imprints, 35 consecutive contact shots to the head (temple, forehead, submental and occipital region) were evaluated. In 3 cases, the muzzle imprint mark exclusively consisted of intracutaneous bruises surrounding the bullet entrance hole. In 14 cases, the muzzle imprint was composed of both excoriations and intradermal hematomas.

4284. Pircher, R., et al. (2017). "Suicide with two makes of captive-bolt guns (livestock stunners) fired simultaneously to the forehead." International journal of legal medicine **131**(6): 1557-1564.

In humans, most fatalities from slaughterer's guns are suicides committed by persons familiar with stunning devices. The great majority of cases accounts for shots to the head, especially the frontal region. Only a small number of two subsequent cranial shots from captive-bolt humane killers have been reported up to now. In the case presented by the authors, a suicide by simultaneous shots to the head fired from two different makes of captive-bolt guns (one of them having two separate outlets for the combustion gases in the muzzle plane, the other type having no additional openings) is described for the first time. One of the shooting devices remained in firm contact with the left hand and

produced patterned staining from rust corresponding to the surface relief of the gun. The medicolegal and criminalistic aspects of this unique case are discussed with reference to the pertinent literature.

4285. Pircher, R., et al. (2019). "Rearward movement of the slide in semi-automatic pistols: a factor potentially influencing the configuration of muzzle imprint marks in contact shots." International journal of legal medicine **133**(1): 169-176.

A muzzle imprint mark is a highly diagnostic finding, which indicates a contact shot. In many cases, it also provides additional information on the type of the weapon used and on the way in which it was held at the time of firing. In semi-automatic pistols, some constructional elements constituting the muzzle plane move to the rear together with the slide, which may prevent them from causing a corresponding imprint close to the bullet entrance hole. The present study comprises 30 consecutive autopsy cases of fatal contact shots to the head inflicted with semi-automatic pistols. The imprint marks accompanying the entrance wounds were compared with the muzzle ends of the respective weapons both before and after retracting the slide. It turned out that in a considerable number of cases (3 out of 30), the retractable parts were not depicted or only to a minor degree as components of the imprint mark. In order to validate the presumed correlation, experimental shots were fired to composite models using pistols in which the movable and the stationary parts forming the muzzle plane were dyed with different paints. Thus, it could be demonstrated that the muzzle imprint preferentially mirrors the front sides of the stationary parts such as the barrel end, the recoil guide, and the gun housing. Immediately after discharge, the slide and the ballooning skin of the bullet entrance site move in the same direction. The stationary parts of the weapon block the expansion of the skin bulging towards the muzzle, so that the skin gets firmly pressed against them. The dynamic interaction between the gun and the entrance region resulting in a characteristic imprint mark could be visualized by the use of a high-speed motion camera recording test shots to different composite models.

4286. Pires, M. S. M., et al. (2013). "An interesting case of gunshot injury to the temporomandibular joint." Craniomaxillofacial Trauma and Reconstruction **8**(1): 79-82.

The head and face are relatively common sites of gunshot injury, and the temporomandibular joint is often affected. These wounds usually produce major deformity and functional impairment, particularly when the temporomandibular joint is affected or when structures such as the facial nerve are damaged. Complications may include mandibular displacement at maximum mouth opening and in protrusion, limited mouth opening, limited lateral movement of the jaw, anterior open bite, and, more rarely, temporomandibular ankylosis. Projectiles that strike the mandible usually cause comminuted fractures; maxillary wounds, in turn, are most commonly perforating. The present report describes a case of gunshot injury in which the projectile lodged within the mandibular fossa but did not cause any fractures. Oral and maxillofacial trauma surgeons must be aware of the different types of gunshot injury, as they produce distinct patterns of tissue destruction due to projectile trajectory and release of kinetic energy into surrounding tissue.

4287. Pistner, H., et al. (1994). "[Microsurgical scapula transplants for reconstruction of the facial skull--experiences with 44 patients]." Mikrochirurgische Scapulatransplantate zur Rekonstruktion des Gesichtsschadels--Erfahrungen mit 44 Patienten. **39**: 122-126.

Great versatility gives composed scapular flaps a particular significance for the reconstruction of defects in face and skull: According to individual requirements one up to five separate elements may be transferred with one vascular pedicle. Anatomical studies of 120 scapulas measured a mean length of 13.4 cm and a mean diameter of 1.2 cm of the lateral margin offering sufficient bone for most indications in the visceral skull. Up to three cutaneous flaps may cover nearly every defect in the head. 44 patients were treated in the years 1989 to 1993 using scapular flaps, most of them combinations consisting of bone and skin elements. In two patients a so called 4-in-1-flap was transferred including the latissimus-dorsi-flap. All donor sites could be closed primarily. Venous thrombosis caused one loss of a flap. Infections healed without sequelae. Medical gymnastics brought full rehabilitation of the donor site within 6 months.

4288. Pitlyk, P. J. (1983). "Removal of retained bone fragments." Journal of neurosurgery **58**(4): 624-625.

4289. Pitsika, M. and V. Tsitouras (2013). "Cerebellar mutism." Journal of neurosurgery. Pediatrics **12**(6): 604-614.

Mutism of cerebellar origin is a well-described clinical entity that complicates operations for posterior fossa tumors, especially in children. This review focuses on the current understanding of principal pathophysiological aspects and risk factors, epidemiology, clinical characteristics, treatment strategies, and outcome considerations. The PubMed database was searched using the term cerebellar mutism and relevant definitions to identify publications in the English-language literature. Pertinent publications were selected from the reference lists of the previously identified articles. Over the last few years an increasing number of prospective studies and reviews have provided valuable information regarding the cerebellar mutism syndrome. Importantly, the clarification of principal terminology that surrounds the wide clinical spectrum of the syndrome results in more focused research and more effective identification of this entity. In children who undergo surgery for medulloblastoma the incidence of cerebellar mutism syndrome was reported to be 24%, and significant risk factors so far are brainstem involvement and midline location of the tumor. The dentate-thalamo-cortical tracts and lesions that affect their integrity are considered significant pathophysiological issues, especially the tract that originates in the right cerebellar hemisphere. Moderate and severe forms of the cerebellar mutism syndrome are the most frequent types during the initial presentation, and the overall neurocognitive outcome is not as favorable as thought in the earlier publications. Advanced neuroimaging techniques could contribute to identification of high-risk patients preoperatively and allow for more effective surgical planning that should focus on maximal tumor resection with minimal risk to important neural structures. Properly designed multicenter trials are needed to provide stronger evidence regarding effective prevention of cerebellar mutism and the best therapeutic approaches for such patients with a combination of pharmacological agents and multidisciplinary speech and behavior augmentation.

4290. Pittman, D. M. and L. E. Smith (1985). "Complications of colostomy closure." Diseases of the colon and rectum **28**(11): 836-843.

A series of 126 colostomy closures was analyzed to evaluate factors contributing to morbidity. There were no deaths, but there was a 33 percent complication rate. Patients with penetrating abdominal trauma and foreign-body rectal perforations had fewer serious complications following colostomy closures than patients with diverticulitis or cancer. No significant difference was found in the anastomotic leak rate, length of surgery or length of hospitalization in patients with sutured or stapled anastomoses. Most patients in this series had end colostomies that required limited resection and anastomoses. Complication rates were comparable with previous series, which consisted predominantly of loop colostomy closures. The incidence of surgical complications was not related to the time interval between colostomy formation and closure. Timing of closure, however, significantly influenced the complication rate in two specific patient groups: patients with intraperitoneal colon perforation at the initial procedure when closure was performed within four weeks, and patients with surgical complications at the time of colostomy creation if they underwent closure within eight weeks. Early closures in patients still recovering from colostomy complications were associated with the highest incidence of anastomotic leak. Wound infections at stoma sites were decreased by leaving the skin open. The average hospitalization was 11.1 days for patients without complications, 15.5 days for those with wound infection, 18.5 days for patients with ileus, and 20.4 days for patients with anastomotic leaks. This study illustrates that the optimal time for colostomy closure must be determined on an individual basis. The morbidity can be minimized by delaying closure in specific groups of patients for one to two months. Delaying closure for an arbitrary time interval in all patients, however, is not warranted.

_____

4292. Pizzoni, C. and E. Pierangeli (2008). "Traumatic Brain by gunshot wounds." Rivista Italiana di Neurobiologia **5**(2): 113-120.

Traumatic brain injury (TBI) is the fourth all cause of death in the United States and is the principal cause of death in persons aged 1-44 years. About 2 million TBIs occur each year in the United States. Analysis of the trauma literature has revealed that 50% of all trauma deaths in the United States are secondary to TBI, and gunshot wounds to the head caused 35% of these. TBIs can be divided into non-penetrating, penetrating and perforating injuries. Non-

penetrating injuries include damage of the bone and unbroken meningeal membranes. Penetrating injuries is a wound in which a projectile breaches the cranium but does not exit it, while in perforating injuries there is an exit wound. Despite the incidence of these injuries, the morbidity and mortality of penetrating and perforating head injury remain high. Improvements in the understanding of the mechanisms of TBI and aggressive medical and surgical management of patients with these injuries may conduct to improved outcomes. This work focuses on the pathophysiology of both primary and secondary mechanisms of injury, describes the treatment of patients and concludes with a list of possible complications and patient outcome.

4293. Plackett, T. P., et al. (2015). "Re-evaluating the need for hospital admission and observation of pediatric traumatic brain injury after a normal head CT." Journal of pediatric surgery **50**(10): 1758-1761.

There is no consensus on the optimal management of pediatric patients with suspected trauma brain injury and a normal head CT. This study characterizes the clinical outcomes of patients with a normal initial CT scan of the head. A retrospective chart review of pediatric blunt trauma patients who underwent head CT for closed head injury at two trauma centers was performed. Charts were reviewed for demographics, neurologic function, CT findings, and complications. 631 blunt pediatric trauma patients underwent a head CT. 63% had a negative CT, 7% had a non-displaced skull fracture, and 31% had an intracranial hemorrhage and/or displaced skull fracture. For patients without intracranial injury, the mean age was 8 years, mean ISS was 5, and 92% had a GCS of 13-15 on arrival. All patients with an initial GCS of 13-15 and no intracranial injury were eventually discharged to home with a normal neurologic exam and no patient required craniotomy. Not admitting those children with an initial GCS of 13-15, normal CT scan, and no other injuries would have saved 1.8 +/- 1.5 hospital days per patient. Pediatric patients who have sustained head trauma, have a negative CT scan, and present with a GCS 13-15 can safely be discharged home without admission. Copyright Published by Elsevier Inc.

Contracture following the successful take of a split-thickness cutaneous graft may be difficult to avoid if a force opposite to the contraction cannot be applied. In this paper, a procedure is described in which a wire-frame buried around the graft maintains it expanded during the contractile period.

4295. Plantman, S., et al. (2012). "Characterization of a novel rat model of penetrating traumatic brain injury." Journal of neurotrauma **29**(6): 1219-1232.

A penetrating traumatic brain injury (pTBI) occurs when an object impacts the head with sufficient force to penetrate the skin, skull, and meninges, and inflict injury directly to the brain parenchyma. This type of injury has been notoriously difficult to model in small laboratory animals such as rats or mice. To this end, we have established a novel non-fatal model for pTBI based on a modified air rifle that accelerates a pellet, which in turn impacts a small probe that then causes the injury to the experimental animal's brain. In the present study, we have focused on the acute phase and characterized the tissue destruction, including increasing cavity formation, white matter degeneration, hemorrhage, edema, and gliosis. We also used a battery of behavioral models to examine the neurological outcome, with the most noteworthy finding being impairment of reference memory function. In conclusion, we have described a number of events taking place after pTBI in our model. We expect this model will prove useful in our efforts to unravel the biological events underlying injury and regeneration after pTBI and possibly serve as a useful animal model in the development of novel therapeutic and diagnostic approaches.

4296. Plantman, S., et al. (2014). "A novel mouse model of penetrating TBI." Journal of neurotrauma **31**(5): A25.

A penetrating traumatic brain injury (pTBI) occurs when an object hits the head with sufficient force to penetrate the skin, skull, and meninges, and inflict injury directly to the brain parenchyma. This type of injury has been notoriously difficult to model in small laboratory animals. We recently developed a rat model for pTBI (Plantman et. al. J Neurotrauma 2012 29:1219-32). The present study describes the adaptation of this model for use with mice. Our novel pTBI model is based on a modified air rifle that accelerates a pellet, which in turn hits a small probe that then causes the injury to the animal's brain. The speed and depth of penetration is controlled by adjusting the loading pressure in the

air-rifle. The present study includes a technical characterization of issues such as the relationship between loading pressure and depth of penetration. Further, we have characterized the tissue destruction, including increasing cavity formation, neuronal degeneration, blood-brain barrier defects, and gliosis. We also evaluated basic outcome measures (survival, weight gain and performance on rotarod). We expect this model will prove useful in our efforts to unravel the biological events underlying injury and regeneration after pTBI.

4297. Platt, A., et al. (2020). "Cranial Vault Reconstruction and Evacuation of Hemorrhage After a Bifrontal Gunshot Wound to the Brain." World neurosurgery **138**: 408-410.

Civilian gunshot wounds to the brain are associated with high overall mortality; however, outcomes can vary significantly depending on bullet trajectory. This report details the outcome of a patient who sustained a bifrontal gunshot wound with multiple associated calvarial and frontal sinus fractures. Although surgery for penetrating brain injury is most frequently employed for relief of mass effect and decompression of vital structures, this case report describes a more comprehensive technique involving duroplasty, obliteration of the frontal sinus, and cranial vault reconstruction with the aim of decreasing the rate of cerebrospinal fluid leak, infection, reoperation, and readmission.

4298. Platt, S. (2005). "Evaluation and treatment of the head trauma patient." In Practice **27**(1): 31-35.

Severe head trauma is associated with high mortality, with death often resulting from progressive increases in intracranial pressure. Brain injury in dogs and cats is most frequently caused by road traffic accidents, but can also be due to falls, kicks, gunshot wounds and animal bites. Appropriate management of patients with head trauma remains a controversial area in veterinary medicine because of a lack of retrospective studies evaluating treatment approaches for dogs and cats with similar injuries. Notwithstanding, management of affected cases must be immediate if the animal is to recover to a level that is both functional and acceptable to the owner. The first veterinary surgeon to deal with an animal suffering from brain injuries following an inciting traumatic event will dictate that patient's fate! It is important to be aware of the optimal way to assess head trauma cases before making treatment decisions. Many dogs and cats can indeed recover from severe brain injuries if treatable systemic and neurological abnormalities are identified promptly. This article discusses current recommendations for optimising the chances of success for such patients.

4299. Platz, A., et al. (1995). "[Outcome after craniocerebral gunshot injury]." Outcome nach Schadelschussverletzung.(2): 118-121.

Gunshot wounds to the head have a high morbidity and mortality [1, 2, 3, 4, 5]. In our areas this kind of injury is rarely seen, being mostly due to attempted suicide [6]. To help determine the optimal management of patients with penetrating GSW to the head, retrospective experience with 47 patients from 1986 to 1993 is presented. Due to our experiences we provide the following treatment of patients with craniocerebral gunshot wounds: After a short neurological examination and the stabilization of the vital parameters, we do further examination with skull X-ray and a CT. With these informations we decide about the further treatment: We operate patients with stable vital signs, with GCS higher than 3, as long the ventricular system is not involved. 18 patients survived the injury. The currently living 16 patients were examined and checked concerning outcome after GSW to the head. 11 of 16 patients had a GOS 4 or 5. The remaining 5 patients are dependent on permanent help.

4300. Plotkin, A., et al. (2020). "Penetrating Carotid Artery Injury: Epidemiology, Predictors of Associated Injury, and Repair Technique." Journal of the American College of Surgeons **231**(4): S352.

Introduction: Penetrating carotid artery injury (PCAI) is significantly morbid and deadly, often presenting in extremis with associated injury and central nervous system (CNS) deficit. Repair may be challenging, with arterial reconstruction vs ligation role poorly defined. This study evaluates contemporary outcomes and management of PCAI. Methods: Penetrating carotid artery injury patients in the National Trauma Data Bank from 2007 to 2015 were analyzed. Outcomes were compared between repair and ligation groups after additionally excluding external carotid injury (ECI) and concomitant jugular vein injury (JVI). Primary endpoints were in-hospital mortality and stroke. Secondary endpoints were associated injury frequency and operative management. Results: There were 3,536 PCAI (58.5% gunshot wounds, 41.5% stab wounds). Gunshot wounds more frequently had associated brain (46.1% vs. 16.7%, p <0.001) and spinal cord

(8.6% vs 1.5%, p < 0.001) injury; stab wounds more frequently had JVI (18.8% vs 26.5%, p < 0.001). In-hospital mortality was 17.8% and stroke rate was 6.4%. After excluding ECI and concomitant JVI, 163 underwent ligation and 59 had operative repair. Ligation patients had lower presenting Glasgow Coma Scale scores (8 vs 14, p = 0.015). Stroke rate was equivalent (11.7% vs 10.2%, p = 0.99); however, in-hospital mortality was higher after ligation (27.4% vs 14%, p = 0.047). On multivariable analysis, ligation was not associated with an increased stroke (Table) or in-hospital mortality. Tachycardia and central nervous system deficit were associated with stroke; Injury Severity Score and Glasgow Coma Scale score were associated with in-hospital mortality. Conclusion: Penetrating carotid artery injury is highly fatal, with a high stroke rate. In this study, carotid repair was not associated with improved stroke rate or death compared with ligation, particularly in patients with high Injury Severity Score and preoperative neurological deficit. 4301. Pluisch, F. and K. Sellier (1994). "[Does a bone gunshot wound leave pure lead bullet metal residues?]." Fuhrt der Beschuss von Knochen mit Reinblei-KK-Geschossen zu Metallabrieb? **194**(5-6): 155-160.

The objective of the study was to give a survey on the possibilities and limits of reconstruction in cases of gunshot injuries of the vertebral bodies. X-ray examinations of the vertebral column hit by lead bullets of .22 rimfire ammunition regularly revealed small fragments of lead from the missile deposited along the wound track through the bone.

4302. Plurad, D. S., et al. (2021). "The Effect of Trauma Center Verification Level on Outcomes in Traumatic Brain Injury Patients Undergoing Interfacility Transfer." Academic emergency medicine : official journal of the Society for Academic Emergency Medicine **28**(3): 292-299.

BACKGROUND: Previous literature demonstrates increased mortality for traumatic brain injury (TBI) with transfer to a Level II versus Level I trauma center. Our objective was to determine the effect of the most recent American College of Surgeons-Committee on Trauma (ACS-COT) "Resources for the Optimal Care of the Injured Patient" resources manual ("The Orange Book") on outcomes after severe TBI after interfacility transfer to Level I versus Level II center., METHODS: Utilizing the Trauma Quality Program Participant Use File of the American College of Surgeons admission year 2017, we identified patients with isolated TBI undergoing interfacility transfer to either Level I or Level II trauma center. Logistic regression was performed to determine independent associations with mortality., RESULTS: There were 10,268 (71.6%) transferred to a Level I center and 4,025 (28.4%) were transferred to a Level II center. They were mostly male (61.4%) with a mean +/- SD age of 61 +/- 20.8 years. Mean Injury Severity Score was 16.3 +/- 6.3 and most were injured in a single-level fall (51.5%). Patients transferred to a Level I center were less likely to be White (82.3% vs. 84.7%, 0.002) and more likely to have sustained penetrating trauma (2.7% vs. 1.6%, <0.001). The incidence of severe TBI (Glasgow Coma Scale [GCS] = 3-8) was similar (9.3% vs. 8.3%, 0.068). On logistic regression, severity of TBI predicted death; however, there was no difference in adjusted mortality outcome with admission to a Level II versus a Level I center (0.998 [0.836-1.192], 0.985)., CONCLUSIONS: There is no mortality discrepancy in patients with isolated TBI transferred to a Level II versus Level I center despite previous contrary evidence and thus no reason to bypass a Level II in favor of a Level I. This relative improvement potentially relates to the new requirements as defined in the latest version of the ACS-COT's resources manual.

4303. Plymale, J., et al. (2010). "Corrected QT Interval in Children With Brain Death." Pediatric cardiology **31**(7): 1064-1069.

Prolongation of the QT interval is a well-documented finding in adults with severe brain injury. However, QT prolongation has not been well documented in the pediatric population with brain injury. Our objective was to determine the range of QT intervals in children with the diagnosis of brain death, hypothesizing that the QT interval corrected for heart rate (QTc) is longer in this population than in a normal population. All previously healthy children (<18 years) dying in our hospital from 1995 to 2007 with a diagnosis of brain death and at least one electrocardiogram (ECG) with normal anatomy by echocardiogram were included. Admission details, past medical and family history, demographic data, and laboratory data were collected. The QT and preceding RR intervals from three sinus beats on a standard 12-lead ECG were measured. The QTc was calculated with the Bazett method, and the values were averaged. Thirty-seven patients met inclusion criteria. Five had event histories concerning for possible underlying rhythm disturbances; data analysis was performed with and without these patients. The QTc data were normally distributed.

The mean (SD) QTc for the entire cohort was 452 (61) ms. Excluding the five patients, it was 449 (62) ms. On multivariate analysis, sex (QTc female < male) and hypokalemia were associated with QTc prolongation. QTc in children with brain death is normally distributed but significantly longer than QTc in normal children. Until rapid genetic testing for channelopathies is universally available, our findings suggest that potential pediatric cardiac donors with isolated prolongation of the QTc in this setting may be acceptable in the absence of other exclusionary criteria.

4304. Pniel, D. and T. K. Withers (2018). "A case of multiple nail gun injuries to the head and one to the heart." Surgical neurology international **9**(1).

Background: Nail gun injuries, while uncommon, can present significant treatment challenges. Many are often caused by work-related accidents, they have also been seen in suicide attempts and assaults. Case Description: A 53-year-old male was transferred from a peripheral hospital to a tertiary center after being found confused and with a left-sided weakness. Initial scans showed four nails penetrating the skull, with one additional nail in the pericardium. These all underwent surgical removal, and due to meticulous pre- and perioperative planning, the patient had a largely uneventful recovery. Conclusion: The challenging nature of these injuries requires extensive workup prior to surgical decision-making in order to minimize potential complications.

4305. Poeppl, W., et al. (2012). "Penetration of doripenem in human brain: an observational microdialysis study in patients with acute brain injury." International journal of antimicrobial agents **39**(4): 343-345.

Concentration-time profiles of unbound doripenem were determined by microdialysis in the cerebral interstitium of five patients with acute brain injury. The ratio of the area under the concentration-time curve in brain to that in plasma (AUC(brain)/AUC(plasma)) was 0.17 in one patient and 0.01 in the remaining four patients. Based on the percentage of the dosing interval during which the doripenem concentration exceeded a certain minimum inhibitory concentration (T>MIC), a value of >=35% of the dosing interval was reached for pathogens with MICs up to 0.05 mg/L. The present data indicate that breakpoints based on concentrations of doripenem in plasma may overestimate antimicrobial activity in brain parenchyma.

_____

4306. Pogorzelski, G. F., et al. (2018). "Epidemiology, prognostic factors, and outcome of trauma patients admitted in a Brazilian intensive care unit." Open Access Emergency Medicine **10**: 81-88.

Background: Trauma is a major cause of hospital admissions and is associated with manifold complications and high mortality rates. However, data on intensive care unit (ICU) admissions are scarce in developing and low-income countries, where its incidence has been increasing. Objectives: To analyze epidemiological and clinical factors and outcomes in adult trauma patients admitted to the ICU of a public teaching hospital in a developing country as well as to identify risk factors for complications in the ICU. Patients and methods: Retrospective cohort of adult trauma patients admitted to the general ICU of a public teaching hospital in southern Brazil in the year 2012. Demographic, clinical, and outcome data from the ICU were analyzed. Results: During the study period, 144 trauma patients were admitted (83% male, Acute Physiology and Chronic Health Evaluation Score II =18.6±7.2, age =33.3 years, 93% required mechanical ventilation). Of these, 60.4% suffered a traffic accident (52% motorcycle), and 31.2% were victims of violence (aggressions, gunshot wounds, or stabbing); 71% had brain trauma, 37% had chest trauma, and 21% had abdominal trauma. Patients with trauma presented a high incidence of complications, such as infections, acute renal failure, acute respiratory distress syndrome, and thrombocytopenia. The ICU mortality rate was 22.9%. Conclusion: In a Brazilian public teaching ICU, there was a great variability of trauma etiologies (mainly traffic accidents with motorcycles and victims of violence); patients with trauma had a high incidence of complications and mortality in the ICU.

_____

4307. Pogorzelski, R., et al. (2007). "Surgical treatment for thoracic injuries - One clinic's experience." Polski Przeglad Chirurgiczny **79**(10): 1157-1167.

The aim of the study was to present one clinic's experience in the treatment of thoracic injuries. Particular attention was paid to the methods for treatment of patients after thoracic injuries. Material and methods. During the years 1996-2006, 273 patients with thoracic injuries were hospitalized in the clinic; 0.9% of all patients treated during this time. There were 66 women (24.2%) and 207 men (75.8%), aged 17 to 85 years (average: 34.9). Results. Among all

of the thoracic injuries analyzed, the most common was traffic accidents, which made up 111 (40.7%) cases. Next, accidents of violence made up 87 (31.9%) cases, and accidental falls and falls from heights 62 (22.7%) cases. Rare were self-mutilations, crash traumas and gunshot traumas. Isolated injury was observed in 107 cases, and 166 (60.8%) patients had multifocal trauma and multi-organ injuries. 50 patients (18.3%) had acute, penetrating injuries, and 223 patients (81.7%) had blunt thoracic injuries. During hospitalization, other traumas were diagnosed: rib fractures in 107 cases (39.2%), pleurohematoma in 37 cases (13.6%), pneumothorax in 36 cases (13.2%), pneumohemothorax in 26 cases (9.5%), lung contusion in 43 cases (15.8%), posttraumatic aorta aneurysm in 31 cases (11.4%), and contusion of the heart or great vessels in 8 cases (2.9%). The applied treatment was: pleural cavity drainage in 86 cases (27.8%), immediate thoracotomy in 24 cases (8.8%), laparotomy in 23 cases (8.4%), stent-graft implantation in posttraumatic aneurysms in 30 cases (11%), and other specialized operations in 46 cases (16.9%). Qualified surgical treatment was performed in 176 cases (64.5%) out of 273. Multispecialized treatment was used in 46 cases (16.8%). 16 patients died (5.9%), most directly after admission to the hospital. Conclusions. 1. Over 30% of patients need no surgical treatment after thoracic trauma. 2. The most common coexisting injuries with thoracic trauma are cranio-cerebral injuries and bone fractures. 3. The main cause of death is oligovolemic shock due to heart and great vessels contusion.

4308. Pohlenz, P., et al. (2007). "Clinical indications and perspectives for intraoperative cone-beam computed tomography in oral and maxillofacial surgery." Oral surgery, oral medicine, oral pathology, oral radiology, and endodontics **103**(3): 412-417.

OBJECTIVES: Intraoperative cone-beam computerized tomography (CBCT) imaging has been introduced in oral and maxillofacial surgery. Using midfacial fractures as the pioneer model, this study describes the spectrum of further promising clinical indications for intraoperative CBCT and a clinical combination with intraoperative navigation., STUDY DESIGN: One hundred seventy-nine patients admitted for surgical treatment of the facial skeleton were included in the study. Intraoperatively, 3-dimensional images were generated with the mobile CBCT scanner Arcadis Orbic 3D, obtained from Siemens Medical Solutions, in a variety of indications., RESULTS: The acquisition of the data sets was uncomplicated, and image quality was sufficient to assess the postoperative result in all cases. In the example of a facial gunshot injury, a navigation system for intraoperative localization of the metal foreign bodies was used.

4309. Pohlmann-Eden, B. and J. Bruckmeir (1997). "Predictors and dynamics of posttraumatic epilepsy." Acta neurologica Scandinavica **95**(5): 257-262.

OBJECTIVES: The goal of our study was to identify clinical, neurophysiological and neuroradiological variables in severe head trauma (SHT) with predictive value for posttraumatic epilepsy (PTE) and to evaluate the influence of each risk factor for the dynamics of epilepsy., MATERIALS AND METHODS: We systematically compared 57 PTE patients with 50 age and sex-matched control patients with SHT and no PTE. Mean follow-up was 8 years., RESULTS: Of all PTE-patients 68.5% had their first seizure within 2 years after the trauma. Significant risk factors for PTE were focal signs in the first examination ($P < 0.01$), missile injuries ($P < 0.01$), frontal lesions ($P < 0.01$), intracerebral hemorrhage ($P < 0.01$), diffuse contusion ($P < 0.01$), prolonged posttraumatic amnesia ($P < 0.001$), depression fracture ($P < 0.01$) and cortical-subcortical lesions ($P < 0.001$). The combination of the last 3 variables conferred a particularly high risk for PTE (logistic regression analysis). Combined seizure pattern, high seizure frequency, AED-noncompliance and alcohol abuse predicted poor seizure control., CONCLUSION: The risk for PTE is clearly determined by those variables which correlate with the severity, the extent of tissue loss and the penetrating nature of the brain trauma.

4310. Policicchio, D., et al. (2018). "Delayed diagnosis of post-traumatic aneurysm of distal anterior cerebral artery." Surgical neurology international **9**(1).

Background: Traumatic intracranial aneurysms (TICA) are often associated with poor prognosis and should be diagnosed as soon as possible to prevent delayed intracranial hemorrhage and high rates of morbidity/mortality related to bleeding. Diagnosis requires a high index of suspicion. The goal of treatment is to exclude the aneurysm issue with surgical or endovascular methods. Case Description: We report the case of a 19-year-old boy who suffered a cranio-orbital trauma; 2 weeks after initial trauma he deteriorates with a new intracranial bleeding. Immediate angiography resulted negative. Delayed follow-up by magnetic resonance angiography showed an unruptured aneurysm of anterior cerebral artery that was successfully clipped. Conclusions: A TICA should be suspected in case of delayed deterioration in head-injured patient, prompt diagnosis and treatment could improve prognosis and reduce morbidity and mortality.

4311. Polin, R. S., et al. (1995). "Multivariate analysis and prediction of outcome following penetrating head injury." Neurosurgery clinics of North America **6**(4): 689-699.

Schemes for predicting outcome in craniocerebral missile injury have ranged from Cushing's analysis that was based on the physical characteristics of the injury to complex logistic analyses that incorporate radiographic, laboratory, and clinical data. Generation of predictive scales is discussed, focusing on the utility of the Glasgow Coma Scale (GCS) score at presentation, presence or absence of coagulopathy, and radiographic evidence of the volume and type of tissue damage.

4312. Polkinghorne, P. J. (1996). "Inadvertent perforation of the globe during regional anaesthesia." Australian and New Zealand journal of ophthalmology **24**(1): 43-45.

PURPOSE: This retrospective study was undertaken to review the clinical signs and management of patients with perforating eye injuries associated with regional anaesthesia for ophthalmic surgery., METHODS: Fifteen consecutive patients presenting with inadvertent perforation of the globe were evaluated. Eleven required vitreoretinal surgery. The indications were retinal detachment (six eyes), vitreous haemorrhage (four) and an epiretinal membrane (one eye)., RESULTS: Those eyes with retinal detachments generally had a poor functional outcome in spite of the retinae being attached in five of the six eyes. The operative findings of those eyes with vitreous haemorrhage but attached retina demonstrated varying retinal tear configurations., CONCLUSIONS: Eyes with perforating injuries following intraorbital anaesthesia are at risk of developing a retinal detachment. In those eyes presenting with dense vitreous but attached retina, consideration of vitrectomy and laser photocoagulation is advised.

4313. Pollak, S. and I. Wieser (1988). "[Teeth as an intermediate target--a cause for rapid disintegration of the full metal-jacketed bullets used by the military]." Zahne als Zwischenziel--eine Ursache fur die rasche Zerlegung von militarisch verwendeten Vollmantelgeschossen. **100**(22): 729-733.

Sharp-pointed full metal-jacketed bullets fired from assault rifles are expected to have a low tendency of deformation or destruction within biological tissues. In principle this also should apply to small calibre projectiles .223. If a bullet penetrates the oral region, contact with teeth can cause early break up and even total disintegration of the projectile. Under such circumstances the fragments are possibly retained within the body. A case of accidental gunshot injury to the head inflicted with an assault rifle AUG Steyr. 223 of the Austrian army serves to demonstrate and discuss the wound ballistic effects in relation to the altered behaviour of the projectile. Analogous findings were reproduced in experimental models.

4314. Pollanen, M. S., et al. (1992). "Fracture of temporal bone with exsanguination: pathology and mechanism." The Canadian journal of neurological sciences. Le journal canadien des sciences neurologiques **19**(2): 196-200.

Eight cases of basal skull fracture with transverse fracture of the petrous temporal bone with medial extension to the internal carotid artery and lateral extension of the structures of the middle ear are described. Injuries in all cases were due to major blunt impact to the head usually occurring in a motor vehicle accident. General autopsy revealed major blood loss without any obvious external or internal site of hemorrhage suggesting that exsanguination was a complication of the head injury. The internal carotid arteries at the most medial extension of the fractures were lacerated or transected in all cases. In selected cases, the cervical internal carotid arteries were perfused and perfusate escaped rapidly from the ear(s) with the majority of fluid bypassing the cerebral venous system. Magnetic resonance image reconstruction of sequential sections of the fractured base of the skull confirmed the laceration of the internal carotid arteries and disruption of the middle ear. Based on this evidence, we propose that some displaced fractures of the base of the skull produce carotid-middle ear continuities which act as arterial shunts, resulting in rapid fatal exsanguination through the ear.

4315. Pollard, Z. F. (1990). "Accommodative esotropia after ocular and head injury." American journal of ophthalmology **109**(2): 195-198.

Five children lost their ability for motor fusion after traumatic injury to either the eye or head. All patients had the onset of accommodative esotropia within two months of the traumatic episode. The ocular alignment of each child was controlled by the use of spectacles that corrected the accommodative requirements. These patients are unique because they did not show any evidence of accommodative esotropia before their injuries. One child developed accommodative esotropia with a high ratio of accommodative convergence to accommodation. The use of bifocal spectacles controlled the deviation for this child.

4316. Pollion, P., et al. (2014). "A ten years old child with ballistic type of cranial trauma." Revue de Medecine Legale **5**(4): 165-169.

A 10-year old Guadeloupean child suffered from a fall while he played with his friends during carnival time. When the rescue arrived, he had a Glasgow Coma Score 7 with hemiparetic neurological deficit, twitching and vomiting. The external review also noted a millimetre wound of the left eye inner canthus. After orotracheal intubation, he was transferred to the intensive care unit. The CT scan report revealed multiple skull fractures and the presence of two intracranial metal tone foreign bodies, all along a fronto-occipital ballistic path. Despite resuscitation, the child will die from complications of a refractory intracranial hypertension. The medicolegal autopsy confirmed bone and intracranial hemorragic lesions and allowed the removal of the occipital foreign body. By a joint work of investigators, the piece of lead could be identified as a fragment of a ballast used at the extremity of craft whips used during the festival in order to increase their visual and sound effect.

4317. Polushkin, K. D. (1968). "[A case of prolonged presence of a rifle shell casing in the brain]." Sluchai dlitel'nogo nakhozhdeniia rauzheinoi gil'zy v mozgu. **43**(5): 97-98.

4318. Pomara, C., et al. (2012). "Radiological evidence of a modern 'martyr's crown': suicide by multiple self-inflicted nail gun shots." Singapore medical journal **53**(8): e169-171.

A man attempted suicide by shooting seven nails into his head with a nail gun; five in the right temporal region and two in the left. He subsequently presented at the emergency department with complaints of headache. He was found to be oriented in space and time, with no focal neurological deficits. The patient handed the nail gun to the doctors and informed them that he had earlier attempted suicide. Radiological studies showed the presence of nails arranged like a 'martyr's crown'. The man died six days after the surgical removal of the nails. Autopsy was refused by Italian authorities. We conclude that imaging techniques are an adjuvant to forensic medical diagnosis and forensic autopsies.

4319. Pomara, C., et al. (2008). "A medieval murder." The American journal of forensic medicine and pathology **29**(1): 72-74.

On rare occasion, the body or skeleton of a murder victim may be discovered hundreds of years, or even millennia, after the crime. The murder of the 5000-year-old Stone Age man, found frozen in the ice of the Italian Alps, being the most recent example. In most of these cases too much time has passed to allow the application of modern forensic technology. We describe here a homicide that occurred between 1310 and 1390. The victim died of a crossbow injury, with a bolt passing between the 2nd and 3rd vertebrae, completely transecting the brainstem. The crossbow was, for more than 2 and one half centuries (1200-1460), the weapon of choice in European armies, and its use would not have been unusual. The choice of weapon, and other features of the crime, makes it possible to arrive at some reasonable conclusions about the circumstances of the death.

4320. Pons, J., et al. (1977). "[Destruction, of traumatic origin, of the orbito-palpebral region and of the nasal pyramid]." Destruction d'origine traumatique de la region orbito-palpebrale et de la pyramide nasale. **78**(8): 529-533.

Sequelae of nose and orbito-oculo-palpebral destructions from a traumatic origin can present on the therepeutical level under various aspects according to the lesions observed. Accidental damages must indeed be treated by surgical and prosthetic means. The loss of the ocular globe and of its annexes make of these traumatisms an essentially plastic problem, difficult indeed but bringing about satisfactory issues on the whole.

4321. Pooboni, S. K., et al. (2004). "Pneumocephalus in neonatal meningitis: diffuse, necrotizing meningo-encephalitis in Citrobacter meningitis presenting with pneumatosis oculi and pneumocephalus." Pediatric critical care medicine : a journal of the Society of Critical Care Medicine and the World Federation of Pediatric Intensive and Critical Care Societies **5**(4): 393-395.

UNLABELLED: OBJECTIVE /PATIENT: Gas-containing encephalitis is rarely associated with neonatal meningitis. We report a case of a 19-day-old baby who presented with a rapid onset of septic shock complicated by progressively increasing gas accumulation within the brain and anterior chamber of the eye. We describe the evolution of the clinical picture and the management., INTERVENTIONS: Ventilatory support, fluid resuscitation, and continuous venovenous hemofiltration were provided in view of multiple system failure. Despite effective antibiotic therapy and supportive management, the patient died with worsening accumulation of gas within the brain, resulting in brainstem death., RESULTS: Computed tomographic images were characteristic of diffuse necrotizing meningo-encephalitis. Postmortem examination showed friable brain tissue with venous infarction and extensive gas accumulation. Citrobacter koseri was identified from the blood and cerebrospinal fluid cultures., CONCLUSION: This case re-emphasises the importance of C. koseri as both a community-acquired and nosocomial neonatal pathogen. Radiologic evidence suggestive of diffuse necrotizing meningo-encephalitis in combination with pneumocephalus and pneumatosis oculi in Citrobacter infections has never been described before. Diagnostic imaging with computed tomographic scanning of the brain and initiation of broad-spectrum antibiotics with good penetration into cerebrospinal fluid are indicated as soon as infection with Citrobacter species is suspected clinically, with appearance of pneumatosis oculi as a rare, late finding.

4322. Poole, G. V., et al. (1996). "Laparoscopy in trauma." The Surgical clinics of North America **76**(3): 547-556.

Laparoscopy is a nearly century-old technique that has experienced a resurgence of interest from surgeons since the development of technology that has broadened its applications. Although laparoscopy has been used to evaluate patients with possible abdominal trauma, its use for this purpose is limited by the availability of other diagnostic procedures that may be more suitable for particular circumstances and are more accurate for certain injuries. Laparoscopy is contraindicated in patients who are hypovolemic or hemodynamically unstable and should not be performed in patients with clear indications for celiotomy. It may not be appropriate for patients with cardiac dysfunction, nor for those with significant head injuries who are at risk for intracranial hypertension. Its best applications may be in stable patients with stab wounds or those with tangential gunshot wounds of the abdomen. The likelihood of missing hollow visceral injuries depends upon the indications for conversion to celiotomy. If peritoneal violation or the presence of a small amount of blood in the peritoneal cavity is used as an indication for celiotomy, then the missed injury rate will be low but the unnecessary celiotomy rate will be diminished only slightly compared with a policy of mandatory celiotomy. Excessive enthusiasm for laparoscopy in trauma might result in its use when other diagnostic measures or simple observation are more appropriate. The desire to perform a procedure can be compelling, especially in circumstances in which the general surgeon would not operate upon a patient but simply provide postoperative care after other surgeons have operated. The use of laparoscopy for these purposes can only be condemned, as it increases the costs and risks of care without improving the outcome. The role of laparoscopy in trauma is evolving, and further research into its diagnostic role and therapeutic applications is clearly needed.

4323. Poorman, G. W., et al. (2019). "Traumatic fracture of the pediatric cervical spine: Etiology, epidemiology, concurrent injuries, and an analysis of perioperative outcomes using the kids' inpatient database." International Journal of Spine Surgery **13**(1): 68-78.

Background: The study aimed to characterize trends in incidence, etiology, fracture types, surgical procedures, complications, and concurrent injuries associated with traumatic pediatric cervical fracture using a nationwide database. Methods: The Kids' Inpatient Database (KID) was queried. Trauma cases from 2003 to 2012 were identified, and cervical fracture patients were isolated. Demographics, etiologies, fracture levels, procedures, complications, and concurrent injuries were assessed. The t-tests elucidated significance for continuous variables, and v2 for categoric values. Logistic regressions identified predictors of spinal cord injury (SCI), surgery, any complication, and mortality. Level of significance was P, .05. Results: A total of 11 196 fracture patients were isolated (age, 16.63 years; male, 65.7%; white, 65.4%; adolescent, 55.4%). Incidence significantly increased since 2003 (2003 vs 2012, 2.39% vs 3.12%, respectively), as did Charlson Comorbidity Index (CCI; 2003 vs 2012, 0.2012 vs 0.4408, respectively). Most common etiology was motor

vehicle accidents (50.5%). Infants and children frequently fractured at C2 (closed: 43.1%, 32.9%); adolescents and young adults frequently fractured at C7 (closed: 23.9%, 26.5%). Upper cervical SCI was less common (5.8%) than lower cervical SCI (10.9%). Lower cervical unspecified-SCI, anterior cord syndrome, and other specified SCIs significantly decreased since 2003. Complications were common (acute respiratory distress syndrome, 7.8%; anemia, 6.7%; shock, 3.0%; and mortality, 4.2%), with bowel complications, cauda equina, anemia, and shock rates significantly increasing since 2003. Concurrent injuries were common (15.2% ribs; 14.4% skull; 7.1% pelvis) and have significantly increased since 2003. Predictors of SCI included sports injury and CCI. Predictors of surgery included falls, sports injuries, CCI, length of stay, and SCI. CCI, SCIs, and concurrent injuries were predictors of any complication and mortality, all (P, .001). Conclusions: Since 2003, incidence, complications, concurrent injuries, and fusions have increased. CCI, SCI, falls, and sports injuries were significant predictors of surgical intervention. Decreased mortality and SCI rates may indicate improving emergency medical services and management guidelines. Level of Evidence: III Clinical Relevance: Clinicians should be aware of increased case complexity in the onset of added perioperative complications and concurrent injuries. Cervical fractures resultant of sports injuries should be scrutinized for concurrent SCIs.

4324. Pope, E. J. and O. B. C. Smith (2004). "Identification of traumatic injury in burned cranial bone: an experimental approach." Journal of forensic sciences **49**(3): 431-440.

Interpreting patterns of injury in victims of fire-related deaths poses challenges for forensic investigators. Determining manner of death (accident, suicide or homicide) using charred remains is compounded by the thermal distortion and fragmentation of soft and skeletal tissues. Heat degrades thin cranial structures and obscures the characteristic signatures of perimortem ballistic, blunt, and sharp force trauma in bone, making differentiation from thermal trauma difficult. This study documents the survivability and features of traumatic injury through all stages of burning for soft tissue reduction and organic degradation of cranial bone. Forty cadaver heads were burned in environments simulating forensic fires. Progression of thermal degradation was photographically documented throughout the destructive stages for soft tissues and bone to establish expected burn sequence patterns for the head. In addition to testing intact vaults, a percentage were selectively traumatized to introduce the variables of soft tissue disruption, fractures, impact marks, and incisions throughout the cremation process. Skeletal materials were recovered, reconstructed, and correlated with photographs to discern burn patterns and survivability of traumatic features. This study produced two important results: (1) Identification of preexistent trauma is possible in reconstructed burned cranial bone. Signatures of ballistic (internal and external bevel, secondary fractures), blunt force (impact site, radiating fractures), and sharp force (incisions, stabs, sectioning) survive the cremation process. (2) In non-traumatized specimens, the skull does not explode from steam pressure but does fragment as a result of external forces (collapsed debris, extinguishment methods) and handling. The features of both results are sequentially described throughout the progression of thermal destruction.

4327. Porchet, H., et al. (2016). "Pharmacokinetic and safety study of GNbAC1, a humanized monoclonal antibody for multiple sclerosis." European Journal of Neurology **23**: 404.

Introduction: MSRV-Env is a protein of endogenous retroviral origin. This protein is expressed in active brain lesions of multiple sclerosis (MS) patients. Due to its proinflammatory and myelinotoxic effects, MSRV-Env appears as a pertinent target in MS. GNbAC1 is an IgG4 humanized monoclonal antibody (mAB) which neutralises MSRV-Env and prevents cytokine release and the nitrosative stress process in oligodendrocyte precursor cells. Methods: This randomised placebo-controlled doseescalation study evaluated the safety and pharmacokinetics in the plasma and cerebro-spinal fluid (CSF) of GNbAC1 in 21 healthy volunteers at doses of 6, 18, 36mg/kg. Lumbar punctures were

performed at Days 2, 15 and 29 postinfusion. Results: All subjects completed the study. GNbAC1 was well tolerated. All adverse events were mild or moderate in severity. There were no notable dose or treatment related trends in the number or type of adverse events. Pharmacokinetic data show a dose-linear pharmacokinetics in the plasma. The concentration of GNbAC1 in CSF was assessed after intravenous infusion at Day 2, 15, and 29. A mean CSF/serum ratio of 0.12% was observed at Day 2 increasing to 0.39% at Day 15 and 0.42% at Day 29. The pharmacokinetic profile of GNbAC1 in the CSF shows a progressive increase in this compartment up to an equilibrium. Conclusion: GNbAC1 safety at high dose was shown in this study. The CSF pharmacokinetic data show that the brain penetration of GNbAC1 is favourable compared to other mABs. These results paved the way to launch a Phase IIb trial testing GNbAC1 in MS patients.

4328. Porojan, V.-A., et al. (2019). "Traumatic Diaphragmatic Lesions - Considerations Over a Series of 15 Consecutive Cases." Chirurgia (Bucharest, Romania : 1990) **114**(1): 73-82.

Introduction: Diaphragmatic injuries are produced by blunt or penetrating thoracoabdominal trauma. They are potentially life-threatening due to the herniation of abdominal organs into the pleural cavities and severe associated lesions. The aim of this retrospective study was to analyse the clinical presentation and management of patients admitted with diaphragmatic rupture in our institution. Material and Method: We performed a 5-year retrospective study of patients admitted with acute blunt or penetrating diaphragmatic rupture in the Department of General Surgery of "Bagdasar- Arseni" Emergency Hospital. We have studied sex, age, mechanism of trauma, side-location, timeto-diagnosis, concomitant injuries, surgical treatment and outcome. Results: Fifteen patients (8 males, 7 females, mean age: 42 years) with diaphragmatic rupture (left-side: 13, right-side: 2) following blunt (8 patients) or penetrating (7) trauma were included. Patients with blunt diaphragmatic injury had larger tears and abdominal viscera herniation was observed in 6of these cases. A direct suture was performed for all 15 patients. Laparotomy was the surgical approach preferred in most of the cases. Mortality rate was 20%, mainly caused by severe associated lesions. Conclusion : Although traumatic diaphragmatic lesions are frequently associated with severe cerebral and thoraco-abdominal trauma that is also the main cause of death, a prompt diagnosis and treatment can lead to good outcome. Copyright Celsius.

4329. Poroy, C., et al. (2016). "Traumatic globe subluxation and intracranial injury caused by bicycle brake handle." Archives of Trauma Research **5**(3).

Introduction: Penetration of a bicycle brake handle into the orbit is a rare and serious type of trauma. Globe subluxation due to such trauma has not been previously reported. Case Presentation: A 10-year-old girl presented after falling from a bicycle, which resulted in the handbrake penetrating her right upper eyelid. On examination, the globe was subluxated anteriorly, there was no light perception, and the pupilla was fixed and dilated. Radiologic studies revealed orbitonasal fractures, hemorrhage, emphysema in the orbit and cranium, and rupture of the extraocular muscles. The globe was replaced into the orbit with the help of lateral cantholysis and orbital septotomy. During 22 months of follow-up, the globe remained intact, but total loss of vision, blepharoptosis, and extraocular motility restriction persisted. Conclusions: This case and previous reports show that bicycle brake handles can cause severe, penetrating orbital and cerebral traumas that can result in vision loss or fatality. Brake handles should be designed to protect bicyclists from such injuries.

4330. Porri, S., et al. (2013). "Use in rapid administration of specific antibiotic therapy in severe mycoplasma pneumoniae encephalitis." Swiss Medical Weekly **143**: 28S.

Mycoplasma pneumoniae is a well known cause of acute childhood encephalitis, accounting for a significant proportion of cases. It has been associated with a poor prognosis, neurological complications arising in 15-30% of cases and mortality rates as high as 9%. Physiopathological pathways responsible for the neurological manifestations are not clearly understood, but several different mechanisms, either coexiting or not, are most likely involved: direct invasion of the central nervous system, auto-immunity, cytokinemediated inflammatory response, neurotoxin production, vasculopathy. The role of antibiotic therapy in the management of acute Mycoplasma pneumoniae encephalitis remains uncertain. Therapeutic success might depend upon the current clinical stage of the disease, a reflection of the different underlying pathological mechanisms. We report the case of a previously healthy 7-year-old boy with a 7-day history of fever and respiratory symptoms, who presented with sudden onset severe altered level of consciousness and epileptic seizures of bitermporal origin. Evidence of Mycoplasma pneumoniae was obtained by PCR in a throat specimen. High

levels of cytokines Il-6 and Il-8 were measured in the cerebrospinal fluid. Outcome was favourable following the rapid administration of ciprofloxacine, a fluoroquinolone with high bactericidal activity against Mycoplasma pneumoniae as well as good cerebrospinal fluid penetration. The efficiency of this therapeutic strategy suggests the reduction in direct cerebral lesions by Mycoplasma pneumoniae or in the inflammatory response secondary to the elimination of the circulating pathogen. Furthermore, it could enable a reduction in the risk of subsequent indirect neurological lesions.

4331. Porta, D., et al. (2013). "The importance of an anthropological scene of crime investigation in the case of burnt remains in vehicles: 3 case studies." The American journal of forensic medicine and pathology **34**(3): 195-200.

Inspection of a crime scene is a crucial step in forensic medicine, and even the methods taught by forensic anthropology are essential. Whereas a thorough inspection can provide crucial information, an approximate inspection can be useless or even harmful. This study reports 3 cases of burnt bodies found inside vehicles between 2006 and 2009 in the outskirts of Milan (Italy). In all 3 cases, the victim was killed by gunshot, and the body was burnt in the vehicle to destroy signs of skeletal injury and prevent identification. In every case, the assistance of forensic anthropologists was requested, but only after the inspection of the body at autopsy showed that the remains were incomplete, thus making it more difficult to determine the identity, cause, and manner of death. A second scene of crime inspection was therefore performed with strict anthropological and adapted archeological methods by forensic anthropologists to perform a more complete recovery, proving how much material had been left behind. These cases clearly show the importance of a proper recovery and of the application of forensic anthropology methods on badly charred bodies and the importance of recovering every fragment of bone: even the smallest fragment can provide essential information. Thus, a precise coordination, a correct and thorough recovery of bone fragments, and an anthropological approach are crucial for many issues: analysis of the scene of crime, reconstruction of the corpse, and reconstruction of the perimortem events.

4332. Porzionato, A., et al. (2018). "The utility of plastinates in court: a case of firearm homicide." Forensic science, medicine, and pathology **14**(2): 216-220.

Plastination is a technique renowned for its use in the preservation of human tissues or organs, and is mainly employed in anatomical training and in research regarding various scientific fields. The advantages of this method are related to the natural appearance, absence of odor, and easy-handling of the plastinated products. The use of plastinates in forensic sciences, their potential role in personal identification, and their usefulness in interpretation of post-mortem findings has been described, although literature on this topic is poor. The present paper is the first report of a firearm homicide where the brain of the victim was plastinated and presented in court as documentary evidence. Three dimensional examination of the brain during the trial allowed the judge to directly evaluate the pathway of the projectile and to compare it with the information that was presented based on depositions, post mortem data and police investigations, in a more straightforward manner. The important role played by plastination in the reported case in assisting with the final verdict could be a catalyst to extend the use of this technique to other criminal cases.

4334. Potapov, A. A., et al. (1996). "Late diagnosis and removal of a large wooden foreign body in the cranio-orbital region." The Journal of craniofacial surgery **7**(4): 311-314.

The rare case of a large wooden foreign body impaled in the cranio-orbital region, and its late diagnosis and successful removal, is presented. A 26-year-old man was admitted to a regional hospital after suffering a severe penetrating craniocerebral injury from a motorcycle accident. Two months after the accident, computed tomographic examination at Burdenko Neurosurgical Institute revealed a large foreign body located in the cranio-orbital region and penetrating the right temporal lobe, with surrounding abscess development. Radiological examination, including three-dimensional computed tomography, enables one to choose the optimal surgical approach and to remove the foreign body, thereby avoiding purulent, inflammatory complications.

4335. Potapov, A. A., et al. (1992). "[Prolonged crushing of the head (the biomechanics, clinical picture, diagnosis and treatment)]." Dlitel'noe sdavlenie golovy (biomekhanika, klinika, diagnostika, lechenie).(2-3): 5-12.

Analysis of the victims of the earthquake in Armenia made it possible to distinguish a form of trauma, unique in biomechanics and pathogenesis, which was not described earlier, namely, prolonged compression of the head (PCH). Its clinical picture is characterized by superimposition and mutual aggravation of general organismic, general brain, cerebral and extracerebral focal symptomatology. Variants of the relations of the syndrome of prolonged compression of the soft tissues of the head and the craniocerebral damages proper are described. A detailed CT characterization of PCH is given. The principles of stage treatment of victims and the indications for compelled nonoperative and surgical tactics in PCH are suggested for the first time.

4336. Potapov, A. A., et al. (2015). "[Guidelines for the management of severe head injury. Part 1. Neurotrauma system and neuroimaging]." Zhurnal voprosy neirokhirurgii imeni N. N. Burdenko **79**(6): 100-106.

Traumatic brain injury is one of the main causes of mortality and disability in young and middle-aged individuals. The patients with severe traumatic brain injury who are in coma are the most difficult to deal with. Appropriate diagnosis of the primary brain injuries and early prevention and treatment of secondary damage mechanisms largely determine the possibility of reducing mortality and severe disabling consequences. The authors compiled these guidelines based on their experience in development of international and Russian recommendations on the diagnosis and treatment of mild traumatic brain injury, penetrating gunshot injury of the skull and brain, severe traumatic brain injury, and severe consequences of brain injuries, including a vegetative state. In addition, we used the materials of international and Russian recommendations on the diagnosis, intensive care, and surgical treatment of severe traumatic brain injury published in recent years. The proposed recommendations are related to organization of medical care and diagnosis of severe traumatic brain injury in adults and are primarily addressed to neurosurgeons, neurologists, neuroradiologists, anesthesiologists, and emergency room doctors, who are routinely involved in management of these patients.

4337. Potapov, A. A., et al. (2016). "[Guidelines for the diagnosis and treatment of severe traumatic brain injury. Part 2. Intensive care and neuromonitoring]." Zhurnal voprosy neirokhirurgii imeni N. N. Burdenko **80**(1): 98-106.

Traumatic brain injury (TBI) is one of the major causes of death and disability in young and middle-aged people. The most problematic group is comprised of patients with severe TBI who are in a coma. The adequate diagnosis of primary brain injuries and timely prevention and treatment of the secondary injury mechanisms largely define the possibility of reducing mortality and severe disabling consequences. When developing these guidelines, we used our experience in the development of international and national recommendations for the diagnosis and treatment of mild traumatic brain injury, penetrating gunshot wounds to the skull and brain, severe traumatic brain injury, and severe consequences of brain injuries, including a vegetative state. In addition, we used international and national guidelines for the diagnosis, intensive care, and surgical treatment of severe traumatic brain injury, which had been published in recent years. The proposed guidelines concern intensive care of severe TBI in adults and are particularly intended for neurosurgeons, neurologists, neuroradiologists, anesthesiologists, and intensivists who are routinely involved in the treatment of these patients.

4338. Potapov, A. A., et al. (2014). "[Penetrating head and brain injuries with nonmetal foreign bodies]." Zhurnal voprosy neirokhirurgii imeni N. N. Burdenko **78**(6): 101-106.

Penetrating brain injuries (PBI) are common in neurosurgical practice. Most of them are civil or war-time missile and blast injuries. This type of trauma is widely presented in neurosurgical publication, textbooks and clinical evidence-based guidelines. At the same time, PBI by non-metallic foreign bodies are very rare. All the data are limited to case reports and small series of cases. Moreover, there are no clinical consideration on diagnosis, treatment, complication, outcome and prognosis of PBI by non-metallic penetrating brain injuries. In this review all the data are summarized to provide recommendations on the diagnosis and treatment of PBI by non-metallic foreign bodies.

4339. Potapov, A. A., et al. (1996). "Removal of a cranio-orbital foreign body by a supraorbital-pterion approach." The Journal of craniofacial surgery **7**(3): 224-227.

Foreign body removal in blind, penetrating craniocerebral injuries, especially those involving craniobasal localization, could entail additional brain trauma risk. Under such conditions one can use surgical approaches for tumor removal or clipping of intracranial aneurysms. In this report, we present a case of blind, penetrating craniofacial injury in which a supraorbital-pterion approach for foreign body removal was used. Craniography, carotid angiography, and computed tomography data, including three-dimensional imaging, were taken into consideration while planning the operation.

4340. Potoka, D. A., et al. (2000). "Impact of pediatric trauma centers on mortality in a statewide system." The Journal of trauma **49**(2): 237-245.

BACKGROUND: Regional pediatric trauma centers (PTC) were established to optimize the care of injured children. However, because of the relative shortage of PTC, many injured children continue to be treated at adult trauma centers (ATC). As a result, a growing controversy has evolved regarding the impact of PTC and ATC on outcome for injured children., METHODS: A retrospective analysis of 13,351 injured children entered in the Pennsylvania Trauma Outcome Study between 1993 and 1997 was conducted. Patients were stratified according to mechanism of injury, injury severity, specific organ injury, and type of trauma center: PTC; Level I ATC (ATC I); Level II ATC (ATC II); or ATC with added qualifications to treat children (ATC AQ). Mortality was the major outcome variable measured., RESULTS: Most injured children were treated at a PTC or ATC AQ. The majority of children below 10 years of age were admitted to PTC. Patients treated at PTC and ATC had similar injury severity as determined by median Injury Severity Score, mean Revised Trauma Score, and Glasgow Coma Scale. Overall survival was significantly better at PTC and ATC AQ compared with ATC I and ATC II. Survival for head, spleen, and liver injuries was significantly better at PTC compared with ATC AQ, ATC I, or ATC II. Children who sustained moderate or severe head injuries were more likely to undergo neurosurgical intervention and have a better outcome when treated at a PTC. Despite similar mean Abbreviated Injury Scores for spleen and liver, significantly more children underwent surgical exploration (especially splenectomy) for spleen and liver injuries at ATC compared with PTC., CONCLUSION: Children treated at PTC or ATC AQ have significantly better outcome compared with those treated at ATC. Severely injured children (Injury Severity Score > 15) with head, spleen, or liver injuries had the best overall outcome when treated at PTC. This difference in outcome may be attributable to the approach to operative and nonoperative management of head, liver, and spleen injuries at PTC.

4341. Pottker, T. I., et al. (1997). "Suicide with an air rifle." Annals of emergency medicine **29**(6): 818-820.

We report the case of a 14-year-old boy who committed suicide with the use of an air rifle. We include a brief description of his clinical presentation and course, as well as radiography and autopsy findings. This case represents an uncommon mechanism of suicide with an instrument commonly possessed by adolescents and demonstrates the potential lethality of air rifles. Today's air rifles employ one of three gas-compression systems: pneumatic, spring-air or gas compression. They are capable of generating velocities between 200 and 770 feet/second, enabling pellets or BBs to penetrate skin, soft tissue, and bone. This case also highlights the need for preventive measures, including public education and legislation.

4342. Potts, F. L., 3rd, et al. (1987). "Penetrating head trauma by a boat cleat." North Carolina medical journal **48**(1): 21-22.

4343. Poulos, C. K. and B. L. Peterson (2012). "Two cases of firearm grip impressions on the hands of suicide victims." The American journal of forensic medicine and pathology **33**(1): 61-63.

Many factors are used to help distinguish firearm suicides from homicides and accidents, including range of fire, location of entrance defects, wound path trajectory, backspatter (blowback), and gunshot residue. Specifically, authors have discussed examination of the hands for backspatter, gunshot residue, cylinder gap effects, iron staining, and trauma as means of supporting a person having held a firearm while committing suicide. Here, we discuss 2 cases where suicidal gunshot wounds were accompanied by unique firearm grip impressions on the hands of the decedents. In 1 case, a "negative"[impression of a grip pattern was left in a decedent's hand and in another case a grip pattern was left on the decedent's hand in dried blood. Such impressions can be used to provide support for establishing suicide as the manner of death.

4344. Powers, D. B. and R. I. Delo (2013). "Characteristics of ballistic and blast injuries." Atlas of the oral and maxillofacial surgery clinics of North America **21**(1): 15-24.

Ballistic injury wounds are formed by variable interrelated factors, such as the nature of the tissue, the compositional makeup of the bullet, distance to the target, and the velocity, shape, and mass of the of the projectile. This complex arrangement, with the ultimate outcome dependent on each other, makes the prediction of wounding potential difficult to assess. As the facial features are the component of the body most involved in a patient's personality and interaction with society, preservation of form, cosmesis, and functional outcome should remain the primary goals in the management of ballistic injury. A logical, sequential analysis of the injury patterns to the facial complex is an absolutely necessary component for the treatment of craniomaxillofacial ballistic injuries. Fortunately, these skill sets should be well honed in all craniomaxillofacial surgeons through their exposure to generalized trauma, orthognathic, oncologic, and cosmetic surgery patients. Identification of injured tissues, understanding the functional limitations of these injuries, and preservation of both hard and soft tissues minimizing the need for tissue replacement are paramount.

4345. Powers, D. B., et al. (1998). "Stereolithography: a historical review and indications for use in the management of trauma." The Journal of cranio-maxillofacial trauma **4**(3): 16-23.

BACKGROUND: Stereolithography (SL) is a new adjunct for treatment planning in complex maxillofacial trauma. It uses an argon/ion laser to polymerize acrylic resin models of reformatted computerized tomographic radiographs. SL provides superior anatomical detail and translucency, and it can be sterilized and transported to the operative field, if necessary., DISCUSSION: A review of the historical development of SL technology is presented, along with three clinical cases, showing the advantages of SL models in the treatment of patients with complex maxillofacial trauma., CONCLUSION: SL technology provides superior understanding of anatomic relationships, the ability to perform presurgical simulation of the proposed procedure, preoperative adaptation of biomaterials, decreased time in the operating room and associated patient morbidity, and improved residency training and patient education. The primary disadvantages of SL are availability and cost.

4346. Powitzky, R., et al. (2008). "Spectacular impalement through the face and neck: a case report and literature review." The Journal of trauma **65**(6): E53-57.

4347. Powner, D. J., et al. (1992). "Changes in serum catecholamine levels in patients who are brain dead." The Journal of heart and lung transplantation : the official publication of the International Society for Heart Transplantation **11**(6): 1046-1053.

Prospective blood samplings from 15 patients admitted with a Glasgow Coma Score of less than 7 were obtained to observe and compare epinephrine, norepinephrine, and dopamine serum levels in patients with brain injury before, after, and in the absence of brain death. Nine of the patients developed or were admitted after brain death. Wide variations in catecholamine blood levels over time were documented, and subgroup analysis precluded useful statistical comparison or inference of the data. The data are presented therefore as descriptive observations only. No apparent differences were noted between similarly injured patients in whom brain death did not develop and patients before brain death or between patients with penetrating versus nonpenetrating brain injury. Brain death was preceded by hypertension and corresponding elevations in serum catecholamine levels in one patient with complete data. Catecholamine levels appeared to fall after brain death in most patients. Only minimal changes in myocardial histology were present in three donor hearts, and the two transplanted hearts functioned satisfactorily. Serum catecholamine measurement or monitoring does not provide a precise method of determining potential injury to the donor heart before or after brain death. Other experimental data and clinical observation indicate that some hearts may be injured in the donor during the evolution of brain death. Pharmacologic intervention may prevent such injury in experimental animals but must be used before brain death is induced. Such interventions should be studied in selected human donors before brain death to determine whether cardiac function is improved in the donor or recipient.

4348. Pradeep, N., et al. (2015). "Treatment of post-traumatic carotid-cavernous fistulas using pipeline embolization device assistance." BMJ case reports **2015**.

This report describes two cases of post-traumatic, high flow carotid-cavernous fistulas that demonstrated residual shunting after initial embolization with coils and Onyx, and that were successfully closed with pipeline embolization devices. Following their combined endovascular treatments, the patients experienced clinical improvement of symptoms with durable obliteration of the fistulous communications. 4349. Prahlow, J. A. and J. J. Barnard (1999). "Contact gunshot wound of the head: Diagnosis after surgical debridement of the wound." Journal of clinical forensic medicine **6**(3): 156-158.

A case of homicidal contact gunshot wound of the head is described. The victim survived approximately 1 day and one-half following the shooting, during which time the bullet was recovered during surgery the injuries were 'well-documented', and surgical debridement of the wound destroyed any visible evidence of gunshot residue on the scalp or underlying bone. Autopsy revealed a skull fragment with soot deposition within the depths of the injured brain, allowing an accurate determination of range-of-fire. The case reiterates the importance of performing autopsies on all homicides.

4350. Praneeth, K., et al. (2019). "Synchondral Fracture of the Posterior "Hemiarch" of Pediatric Atlas with Cerebrospinal Fluid Fistula following a Penetrating Neck Injury." Pediatric neurosurgery **54**(6): 424-427.

INTRODUCTION: As such, the incidence of spinal fractures in young children is less than that of adults due to an increased pliability of the immature bones. The presence of unfused synchondroses in these children predisposes them to an infrequent pattern of fractures that traverse through ossification centers. Such synchondral injuries are uncommonly reported in the C1 and C2 vertebrae. Those that have been occasionally described in C1 involved the anterior synchondrosis. Furthermore, penetrating injuries to a pediatric spine are relatively rare., CASE PRESENTATION: In this context, we present a 4-year-old child in whom a penetrating injury to an immature atlas led to an unusual disjunction of the posterior synchondrosis with fracture displacement of the posterior "hemiarch" of the atlas that plunged into the dura, resulting in a cerebrospinal fluid fistula., CONCLUSION: We discuss the possible mechanism and considerations in the management of this unique presentation. Such an atypical fracture pattern involving the posterior hemi ring of the pediatric atlas is previously unknown. Copyright © 2019 S. Karger AG, Basel.

4351. Prasad, C., et al. (2021). "Healthcare-associated infections in pediatric patients in neurotrauma intensive care unit: A retrospective analysis." Indian Journal of Critical Care Medicine **25**(11): 1308-1313.

Background: Healthcare-associated infections (HAIs) can impact the outcome following traumatic brain injury (TBI) in children. We undertook a retrospective observational study to see the incidence, risk factors, and microbiological profile for HAIs in pediatric TBI. We also studied the impact of baseline patient characteristics, HAIs on patient outcome, and antibiotic resistance of different types of bacteria. Methods: Data on pediatric TBI patients of age up to 12 years were collected via a computerized patient record system (CPRS) from January 2012 to December 2018. Descriptive Chi-square test and Wilcoxon signed rank test were used to characterize baseline parameters. General linear regression models were run to find an unadjusted and adjusted odds ratio (OR). Results: HAIs were found in 144 (34%) out of 423 patients. The most commonly seen infections were of the respiratory tract in 73 (17.26%) subjects. The most predominant microorganism isolated was Acinetobacter baumannii in 188 (41%) samples. A. baumannii was sensitive to colistin in 91 (48.4%) patients. Male gender (OR 0.630; p-value 0.035), fall from height (OR 0.374; p-value 0.008), and higher injury severity scale (ISS) (OR 1.040; p-value 0.002) were independent risk factors for development of HAIs. Severe TBI, higher ISS and Marshall grade, and HAIs were significantly associated with poor patient outcome. Conclusion: Severe TBI poses a significant risk of HAIs. The most common site was the respiratory tract, predominately infected with A. baumannii. HAIs in pediatric TBI patients resulted in poor patient outcome.

4352. Prasetyo, E., et al. (2020). "Management of transorbital penetrating intracranial injury by a homemade metal arrow: Serials case report." Open access Macedonian journal of medical sciences **8**(C): 30-35.

BACKGROUND: Transorbital penetrating intracranial injury (TOPI) is rare lesions, representing about 0.4% of traumatic brain injury. This uncommon injury has potentially severe and fatalities brain damage with high mortality rate

if not promptly treated. CASE REPORT: We presented three patients with TOPI following penetration by a homemade metal arrow; unfortunately, two patients (cases 1 and 2) death on arrival at our hospital. As a survival patient (case 3), a 15-year-old boy presented with a homemade metal arrow entered through a right superior orbital fissure into the right cerebral hemisphere. Plain skull radiograph showed that the tip of the shaft was located in the right of the posterior cerebral hemisphere and confirmed by computerized tomography (CT) and three-dimensional CT of his brain. Injury to the right middle cerebral arteries was apparent on non-contrast CT angiography. Using a right occipital craniotomy approach with C-arm radiography fluoroscopy guidance, we successfully removed the arrow. Follow-up studies confirmed an excellent outcome. CONCLUSIONS: Pre-operative imaging is mandatory to evaluate the trajectory, brain, and vascular injury for appropriate surgical planning and post-operative care of patients with TOPI.

4353. Prasetyo, E., et al. (2020). "Transorbital-penetrating intracranial injury due to a homemade metal arrow: A case report." Annals of Medicine and Surgery **57**: 183-189.

A transorbital-penetrating intracranial injury (TOPI) is an unusual traumatic brain injury. This rare injury has the potential to result in serious and fatal brain damage with a high mortality rate and requires prompt multidisciplinary surgical intervention. Here, we describe an interesting case in which a patient who presented with accidental penetrating injuries of the brain was found to have a transorbital-penetrating intracranial injury (TOPI). We chose an anterior approach to the foreign body above the entrance wound for removal in a retrograde manner with fluoroscopic guidance. The patient remained well with no complications and was discharged on postoperative day 10. Reasonable diagnostic imaging, surgical planning, and careful post-surgery management can increase patients successful outcomes.

4354. Prassinos, N. N. (2006). "Fractures combination of the proximal antebrachium in an immature dog that resembles Monteggia fracture." Veterinary and comparative orthopaedics and traumatology : V.C.O.T **19**(3): 184-186.

A 5-month-old German shepherd dog with a combination of a proximal radial physeal fracture and a proximal ulnar diaphyseal comminuted fracture, with cranial displacement of their distal fragment, was presented. This fractures combination resembles type I Monteggia fracture. After surgical reduction of the fractures, three full-cerclage wires were used to stabilize the ulnar fracture, and two positional screws were placed across the radius and ulna immediately distally to the growth plate to hold these bones in apposition. Four weeks post-operatively, the screws were removed since sufficient callus had been formed and the dog was free of lameness. It seems that if the appropriate conditions for a type I Monteggia fracture develop in an immature dog, proximal radial physeal fracture instead of radial head luxation may accompany ulnar diaphyseal fracture.

4355. Prat, D., et al. (2021). "Ocular injuries incurred by Israeli defense forces during low-intensity conflicts." Injury **52**(2): 292-298.

BACKGROUND: To describe ocular injuries sustained by Israeli Defense Forces (IDF) soldiers during low-intensity conflicts from 1998 to 2017, and to evaluate the use of protective eyewear., METHODS: Retrospective analysis of data retrieved from two tertiary Israeli medical centers and the military trauma registry. The analysis included all IDF soldiers with ocular injuries who were referred to these centers between 1998 and 2017. Data on injury type, the use of protective eyewear, and interventions were retrieved and analyzed. Additional data regarding the use of protective eyewear and ocular injuries in 108 patients with head and neck injuries in one operation was analyzed., RESULTS: A total of 126 soldiers, all males, mean age 22 (SD 5.3) years, sustained ocular injuries during low-intensity conflicts and treated at one of the two participating medical centers. Blast was the most common type of injury (n = 70/126, 56%), followed by shrapnel (n = 37/126, 29%) and gunshot wound (n = 12/126, 9%). The Birmingham Eye Trauma Terminology System (BETTS) injury pattern disclosed lamellar laceration (n = 34/126, 27%), intraocular foreign body (n = 27/126, 21%), penetrating (n = 10/126, 8%), and perforating (n = 7/126, 6%) injuries. Average VA improved from 20/140 at presentation to 20/60 after surgical or conservative intervention, the median VA improved from 20/40 to 20/30 ($P < 0.001$). Forty-nine patients (49/126, 39%) had poor visual outcome. The mean follow-up lasted 22 (SD 31) months. The use of protective eyewear was correlated with better initial VA(20/30 vs 20/217, $P = 0.07$). Among 108 patients with head and neck injuries, there was a higher rate of ocular injuries in the group of patients who did not use protective eyewear (n = 26/73, 36% vs n = 4/35, 11%, $P = 0.016$)., CONCLUSIONS: Ocular injuries are common occurrences in low-intensity conflicts. The use of protective eyewear significantly reduces these injuries and should be mandatory., LEVEL OF EVIDENCE: III, prognostic.

4356. Pratt, L. W. (1985). "Chain saw injuries of the head and neck." Ear, nose, & throat journal **64**(5): 215-222.

4357. Prayer, D. and C. Rametsteiner (2001). "[Acute head trauma: diagnostic imaging]." Schadelhirntrauma: Radiologische Akutdiagnostik. **151**(21-23): 496-501.

Computed tomography (CT) ist the primary modality of choice for imaging patients with acute head trauma. Lesions of the soft tissues and of the bones can be assessed more precisely than with other imaging modalities. With magnetic resonance imaging (MRI) additional information may be gained especially in subacute and chronic posttraumatic conditions. Urgent indication to perform a CT examination depends on the patient's history and on the mechanism of trauma. Image interpretation has been performed in the context of typical pathologic effects of trauma and with respect to potential therapy.

4358. Prein, J., et al. (1996). "[Gunshot injuries of the mandible]." Schussverletzungen des Unterkiefers. **41**: 160-165.

43 patients with gunshot wounds of the mandible were treated in Tubingen and Basel between 1968 and 1995. Among them were 31 patients (= 72.09%) with bone loss and defect fractures. Over that time period the treatment principles of gunshot wounds have not changed. They are based on an early soft tissue closure and an approach from the inside to the outside. Besides that modern techniques in maxillofacial reconstructive surgery, which include the application of biocompatible plates and screws and the introduction of microvascular reconstructive techniques, have enlarged the therapeutical options. Every patient needs an individual approach to his special medical condition, which is illustrated in three exemplary cases. The combination of the above mentioned modern reconstructive techniques prevents long and multiple hospital stays and invalidity. Furthermore it is the basis for social reintegration as well as functional and esthetic rehabilitation.

4359. Prendergast, D. M., et al. (2004). "The use of a marked strain of Pseudomonas fluorescens to model the spread of brain tissue to the musculature of cattle after shooting with a captive bolt gun." Journal of applied microbiology **96**(3): 437-446.

AIMS: The aim of this study was to use a marked strain of Pseudomonas fluorescens to model the spread of central nervous system (CNS) tissue in cattle following captive bolt stunning., METHODS AND RESULTS: The marked organism was introduced by injection through the captive bolt aperture immediately after stunning and was subsequently detected in a wide range of derived tissues, including blood, organs, and the musculature of the entire forequarters of test animals. This was dependent on the use of high concentrations of the organism that were recovered sufficiently and rapidly to minimize the bactericidal properties of the circulatory system. These results suggest that a marked organism could potentially be used to model the effects of captive bolt stunning on the dissemination of CNS tissue from the brain., CONCLUSIONS: These results indicate that current commercial methods of captive bolt stunning may induce widespread and significant mobilization of CNS tissue within beef carcasses. This may lead to the widespread dissemination of such materials within meat destined for human consumption., SIGNIFICANCE AND IMPACT OF THE STUDY: In the absence of rapid, simple and sufficiently sensitive methods for the direct detection of prion in commercially slaughtered animals, marked organisms can provide useful models in studies of the dissemination kinetics of prion disease in captive bolt stunned animals.

4360. Prgomet, D., et al. (1998). "Mortality caused by war wounds to the head and neck encountered at the Slavonski Brod Hospital during the 1991-1992 war in Croatia." Military medicine **163**(7): 482-485.

From July 1, 1991, until January 1, 1993, a total of 7,720 patients (soldiers and civilians) with war wounds were treated at Dr. Josip Bencevic General Hospital in Slavonski Brod, Croatia. Treatment was provided for 7,043 patients, whereas 677 individuals (8.8%) killed in action (KIA) were examined at the Forensic Department. There were 1,456 patients (18.9%) with head and neck wounds: 1,176 soldiers and 280 civilians. The mortality rate was significantly greater in patients with head and neck wounds (N = 271, 40.0%) than in those with injuries to the thorax (N = 163, 24.1%) and abdomen (N = 62, 9.2%; $p < 0.01$ for both). During treatment, 188 patients (2.4%) died of wounds (DOW). The DOW mortality was 5.2% (61 of 1,185), 4.0% (41 of 1,026), and 2.9% (25 of 867) for wounds of the head and neck,

thorax, and abdomen, respectively. There was no significant difference in the mortality rate between head and neck and thorax wounds: however, the former exceeded the mortality rate recorded for abdominal wounds ($p < 0.05$). No significant differences were observed between soldiers and civilians with head and neck injuries either in the KIA (205 of 1,176, 17.4% vs. 66 of 280, 23.5%, respectively) or the DOW group (51 of 971, 5.3% vs. 10 of 214, 4.7%, respectively. According to the mechanism of head and neck wounding, there were 1,046 explosive (71.9%), 226 gunshot (15.5%), and 184 other (12.6%) wounds. Lethal outcome was significantly more common in gushot than in explosive wounds (79 of 226, 35% vs. 243 of 1,046, 23.2%; $p < 0.01$). The proportion of head and neck injuries did not differ significantly from literature reports on recent conventional wars. The site of wounding, i.e., at the battlefield or elsewhere, had no effect on the prognosis of wounds to the head and neck. Gunshot head and neck injuries showed a significantly higher mortality rate.

4362. Pricola, K. L., et al. (2011). "Successful repair of a gunshot wound to the head with retained bullet in the torcular herophili." World neurosurgery **76**(3-4): 362.e361-364.

BACKGROUND: Nonlethal missile injuries to the dural venous sinus system are rare. To date successful repair of isolated penetrating injury to the torcular herophili has not been reported without significant associated morbidity. We report the case of a gunshot wound injury to the occipital region with retained bullet fragment in the confluence of the sinuses causing traumatic sinus venous thrombosis., METHODS: Occipital and suboccipital craniotomy for removal of bullet in the torcula, repair of sinus defect, and repair of depressed skull bone fragments was performed., RESULTS: The procedure resulted in restoration of proximal and distal flow across the dural sinus system and preservation of torcular sinus patency with excellent neurological outcome. Technical considerations in the repair of penetrating torcular injuries are discussed., CONCLUSIONS: Gunshot wounds with retained bullet fragments in the torcula can be successfully repaired with preservation of neurological function after retrieval of metallic foreign body and restoration of venous sinus patency.

4363. Pringle, C., et al. (2021). "Manchester Arena Attack: management of paediatric penetrating brain injuries." British journal of neurosurgery **35**(1): 103-111.

PURPOSE: The Manchester Arena bombing on 22 May 2017 resulted in 22 deaths and over 160 casualties requiring medical attention. Given the threat of modern- era terrorist attacks in civilian environments, it is important that we are able to anticipate and appropriately manage neurological injuries associated with these events. This article describes our experience of managing paediatric neurosurgical blast injuries, from initial triage and operative management to longer-term considerations., MATERIALS AND METHODS: Case study and literature review., RESULTS: Paediatric traumatic and penetrating brain injury patients often make a good neurological recovery despite low GCS at time of injury; this should be accounted for during triage and operative decision making in major trauma, mass casualty events. Conservative management of retained shrapnel is advocated in view of low long-term infection rates with retained shrapnel and worsened neurological outcome with shrapnel retrieval. All penetrating brain injuries should receive a prolonged course of broad-spectrum antibiotics and undergo long term follow-up imaging to monitor for the development of cerebral abscesses. MRI should never be utilised in penetrating brain injury cases, even in the absence of macroscopically visible fragments, due to the effect of MRI ferromagnetic field torque on shrapnel fragments. Anti-epileptic drugs should only be prescribed for the initial seven days after injury, as continuing beyond this does not incur any benefit in the reduction of long term post-traumatic epilepsy., CONCLUSION: All receiving neurosurgical units should become familiar with optimum management of these thankfully rare, but complex injuries from their initial presentation to long term follow up considerations. All neurosurgical units should have well-rehearsed local plans to follow in the event of such incidents, ensuring timely deliverance of appropriate neurosurgical care in such extreme settings.

4364. Pringle, C. and I. D. Kamaly-Asl (2019). "Managing paediatric ballistic brain injuries." British journal of neurosurgery **33**(4): 457-458.

Objectives: Improvised explosive devices cause ballistic penetrating traumatic brain injuries (PTBIs). Most UK trained neurosurgeons will not have managed these complex injuries. Given the increasing frequency of terrorist attacks in civilian environments, it is important that we are able to anticipate and appropriately manage these injuries. Design: We present our experience of managing paediatric PTBIs sustained from the Manchester Arena blast. Subjects: Paediatric ballistic brain injury patients. Methods: Literature review. Results: Children with PTBIs and GCS <5 at presentation or prolonged traumatic coma can make an acceptable neurological recovery (up to 40% and 70%); this should be considered at triage. Tempered debridement and conservative management of retained shrapnel is associated with improved neurological outcomes and similar infection rates when compared to aggressive management. PTBIs should receive minimum 5 days broad spectrum antibiotics, with longer courses and regular surveillance imaging for retained shrapnel. Delayed cerebral abscesses have been reported up to 7 years post injury. Persistent CSF leak is associated with increased infection rate. Victims should be screened and vaccinated against blood borne viruses. There is no benefit of prophylactic anti-epileptics beyond 7 days post injury when considering late seizure occurrence. Late seizure occurrence is associated with low GCS, shrapnel, haematomas and infection. Conclusions: PTBIs create management challenges at time of presentation and throughout treatment.

4365. Procaccio, F., et al. (2001). "Deaths with acute cerebral lesion and heart-beating potential organ donors in the Veneto region." Minerva anestesiologica **67**(1-2): 71-78.

BACKGROUND: The study was aimed at describing the clinical characteristics of dead patients with acute cerebral lesion and analyzing reasons of the shortage of heart-beating potential organ donors in the Intensive Care Units (ICUs) in the Veneto Region., METHODS: Data have been prospectively recorded in 23 ICUs over six months for deceased patients with acute cerebral lesion (clinical data, death diagnosis) and for any potential organ donor (medical suitability, family interview, organ retrieval)., RESULTS: In the ICUs of the Veneto Region in 1998 deceased patients with acute cerebral lesion were 187 per million population (p.m.p.); 317 cases have been studied. Median age was 64 years (range 7-93). Heart-beating death was legally confirmed only in 98/317 cases (31%) against a clinical diagnosis of brain death in 203/317 (64%). Only 82/317 (26%) were considered eligible donors and 48/317 (15%) became real donors (22.8 p.m.p.). Among the remaining 235 cadavers, 105 were over 70 years old. In the group of 130 under 70 years absolute contraindications were present only in 30 and problematical clinical situations were reported in 100., CONCLUSIONS: The number of deaths with acute cerebral lesion represents a sensible index and a key factor for evaluating the potential organ donor pool in small regions and in the single intensive care unit. Collected data demonstrate that in the Veneto Region the efficiency of solid organ retrieval can be improved and that organ donor shortage may depend, beyond family refusal, on clinical and cultural factors that hamper stabilized heart-beating deaths. Most potential donors with age over 70 or problematical clinical situations are preventively excluded by ICUs physicians. To improve organ donation all the patients who die in spite of neuro-intensive treatment should be prevented from circulatory arrest to permit legal declaration of death. Thus more potential organ donors without absolute contraindications could be recovered and time would exist for discussing any problematical situation with experts in organ procurement, particularly in respect to existing urgencies in the waiting list.

4366. Procaccio, F., et al. (2015). "Deaths with acute cerebral lesions in ICU: does the number of potential organ donors depend on predictable factors?" Minerva anestesiologica **81**(6): 636-644.

BACKGROUND: As the potentiality of deceased organ donation mostly depends on the number of brain deaths (BDs), the aim of this study is to quantify rates and probabilities of BD declaration in Italy., METHODS: Deaths with acute cerebral lesion (ACLDs) in the Italian ICUs have been prospectively collected. A total of 27,490 ACDLs occurred in 5 years. Age, gender, etiology, timing of death and ICU Region have been utilized for multivariate analysis., RESULTS: The global ratio of BD declarations to ACLDs was 39.9%. The rates of ACLDs, BD declarations and actual donors were 93.5, 37.3 and 19.7 pmp respectively. Wide variability resulted among Regions, with 148.2 ACLDs, 77.8 BD declarations and 42 donors pmp as benchmark. The probability of being BD declared was significantly higher in stroke compared with head injury (OR 1.6, P<0.001) and in females (OR 1.5, P<0.001), with half the Regions missing around 50% of BD declarations compared with the benchmark, particularly in elderly patients., CONCLUSION: Predictable factors associated with BD declaration can be identified in ACLD management. Positive factors leading to the identification of potential organ donors, i.e., the capacity of declaring BD in all the patients fulfilling BD criteria irrespective of age and etiology, could be captured in the best performing regions and reproduced throughout the Country. The implementation of simple

indicators based on prospective ACLD monitoring, i.e. the declared BDs to ACLDs in ICU ratio, may be helpful in achieving efficiency targets and reliable comparisons of outcomes in the identification of BD potential organ donors.

4367. Prockop, L. D. (2006). "Weapons of mass destruction: Overview of the CBRNEs (Chemical, Biological, Radiological, Nuclear, and Explosives)." Journal of the neurological sciences **249**(1): 50-54.

The events of September 11, 2001, made citizens of the world acutely aware of disasters consequent to present-day terrorism. This is a war being waged for reasons obscure to many of its potential victims. The term "NBCs" was coined in reference to terrorist weapons of mass destruction, i.e., nuclear, biological and chemical. The currently accepted acronym is "CBRNE" which includes Chemical, Biological, Radiological, Nuclear, and Explosive weapons. Non-nuclear explosives are the most common terrorist weapon now in use. Nuclear and radiological weapons are beyond the scope of this publication, which focuses on the "CBEs", i.e. chemical, biological and explosive weapons. Although neurologists will not be the first responders to CBEs, they must know about the neurological effects in order to provide diagnosis and treatment to survivors. Neurological complications of chemical, biological and explosive weapons which have or may be used by terrorists are reviewed by international experts in this publication. Management and treatment profiles are outlined.

4368. Promsopa, C. and U. Prapaisit (2019). "Removal of intraconal bullet through endoscopic transnasal surgery with image-guided navigation system 8 months after injury: a case report." Journal of medical case reports **13**(1): 65.

BACKGROUND: Lodgment of a bullet within the orbit is uncommon. The decision to remove these objects poses a challenge to surgeons due to a high risk of complications. Currently, endoscopic transnasal surgery with navigator assistance facilitates the localization of foreign bodies allowing their safe removal with minimal surrounding tissue damage or optic nerve injury., CASE PRESENTATION: We describe a case of a 26-year-old Thai woman with a chronic intraorbital foreign body located within her medial intraconal space. The chronic intraorbital foreign body was successfully removed by endoscopic transnasal surgery, combined with assistance from a navigation system, 8 months after injury without any damage to her eye or disturbance in vision., CONCLUSION: Intraconal foreign bodies, such as bullets, are a chronic problem and should be observed in the long term; prompt surgical removal should be performed if indicated.

4369. Provenzale, J. (2007). "CT and MR imaging of acute cranial trauma." Emergency radiology **14**(1): 1-12.

A wide variety of imaging findings can be seen in the setting of acute head trauma. The purpose of this manuscript is to review the major computed tomography and magnetic resonance imaging findings of various types of traumatic head injuries with the intent of providing the reader with a means to diagnose these lesions quickly and accurately.

4372. Puentes, K., et al. (2011). "Non-fatal gunshot wounds in the context of intimate partner violence. The importance of a multidisciplinary approach: a case report." Journal of forensic and legal medicine **18**(5): 221-224.

According to Portuguese law, if a case of intimate partner violence is noticed or suspected by a professional working in public services, reporting it to the police, medico-legal services or directly to the public prosecutor is mandatory. However, in most cases, reporting does not take place, despite its vital importance in triggering the multidisciplinary intervention that will ensure the correct and timely diagnosis and protection of the victim. In the present case, the victim, a 37 year-old woman, was sexually and physically abused by her husband in their home, and was physically abused again at the victim's mother's house. The victim mentioned that her husband struck her in the

head with a hammer and shot a handgun while in her mother's house. However, she denied having a gunshot wound. The couple's daughter was also slapped in the face by her father. The police took the victim to the emergency room of a central hospital to receive medical attention, while the medical examiner on duty was called to the same emergency room to perform a medico-legal evaluation in the context of the intimate partner violence reported to the police. Medico-legal assessment revealed scalp injuries that had not been detected during the first inspection by the emergency room attending physicians who had performed a neurological examination, which revealed no neurological dysfunction. A cranial computed tomography with three-dimensional reconstitution and virtual dissection, requested by the medical examiner, revealed two projectiles trapped in between the inner and the outer table of the cranium, with linear fractures only in the inner table and no brain injuries. Gynecological examination with the collection of biological evidence, also performed by the medical examiner, made it possible to identify a male DNA profile matching her husband's. The victim was subjected to neurosurgery and a follow-up, and was released one month after the traumatic event. A forensic psychological evaluation, performed one month after the traumatic event, revealed the presence of reactive symptoms to the occurrence. This multidisciplinary intervention and the use of modern diagnosis imaging techniques allowed for a timely diagnosis and treatment, adequate protection of the victim and her family, as well as the identification of the aggressor, who was arrested.

4373. Puffenbarger, M. S., et al. (2019). "Reduction of Computed Tomography Use for Pediatric Closed Head Injury Evaluation at a Nonpediatric Community Emergency Department." Academic emergency medicine : official journal of the Society for Academic Emergency Medicine **26**(7): 784-795.

OBJECTIVE: The purpose of this study was to determine if implementation of a Pediatric Emergency Care Applied Research Network (PECARN)-based Closed Head Injury Assessment Tool could safely decrease computed tomography (CT) use for pediatric head injury evaluation at a nonpediatric community emergency department (ED)., METHODS: A quality improvement project was initiated at a nonpediatric community ED to implement an institution-specific, PECARN-based Pediatric Closed Head Injury Assessment Tool. Baseline head CT use at the participating ED was determined for children with closed head injury through retrospective chart review from March 2014 through November 2015. Head injury patients were identified using International Classification of Disease (ICD)-9 codes for head injury, unspecified (959.01) and concussion with and without loss of consciousness (850-850.9) until October 2015, after which ICD-9 was no longer used. To identify eligible patients after October 2015, lists of all pediatric patients evaluated at the participating ED were reviewed, and patients were included in the analysis if they had a physician-assigned discharge diagnosis of head injury or concussion. Exclusion criteria were age >= 18 years, penetrating head trauma, history of brain tumor, ventriculoperitoneal shunt, bleeding disorder, or presentation > 24 hours postinjury. Medical history, injury mechanism, symptoms, head CT use, and disposition were recorded. Implementation of the Pediatric Closed Head Injury Assessment Tool was achieved through provider education sessions beginning in December 2015 and ending in August 2016. Head CT use was monitored for 12 months postimplementation, from September 2016 through August 2017. Patients were classified into low, intermediate, or high risk for clinically important traumatic brain injury (ciTBI) by chart review. ED length of stay (LOS), disposition, and ED returns within 72 hours were recorded. Categorical variables were compared using chi-square test or Fisher's exact test, and continuous variables, using Kruskal-Wallis test., RESULTS: A total of 252 children with closed head injury were evaluated preimplementation (March 2014 through November 2015), 132 children were evaluated during implementation (December 2015 through August 2016), and 172 children were evaluated postimplementation (September 2016 through August 2017). Overall CT use decreased from 37.7% (95% confidence interval [CI] = 31.7-43.7) preimplementation to 16.9% (95% CI = 11.3-22.5) postimplementation ($p < 0.001$). Only 1% (95% CI = 0%-2.9%) of low-risk patients received a head CT postimplementation compared to 22.6% (95% CI = 16.1%-29.1%) preimplementation ($p < 0.001$). CT use among patients >= 24 months decreased from 42.9% (95% CI = 36.5%-49.6%) to 19.6% (95% CI = 13.1%-26.1%; $p < 0.001$) and remained low and unchanged for patients < 24 months. Transfers to a pediatric trauma center and ED returns within 72 hours were unchanged, while median ED LOS improved from 1.5 to 1.3 hours ($p = 0.03$). There were no missed ciTBIs after implementation of the guideline., CONCLUSION: Implementation of the PECARN-based Pediatric Closed Head Injury Assessment Tool reduced head CT use in a nonpediatric ED. The greatest impact was seen among children aged >= 24 months at very low risk for ciTBI.

4374. Puffenbarger, M. S., et al. (2018). "Implementation of a pediatric minor head trauma guideline at a community emergency department." Academic emergency medicine **25**: S128.

Background: Head trauma is a common complaint among children in the ED. The Pediatric Emergency Care Applied Research Network (PECARN) guideline identifies children at very low risk for clinically important traumatic brain injury (ciTBI) and has safely reduced head CT use at pediatric EDs. Most children first present to non-pediatric EDs where they are more likely to receive a head CT. The purpose of this study was to determine if implementation of a PECARNbased minor head trauma guideline could safely decrease head CT use at a non-pediatric community ED. Methods: A retrospective chart review of 384 patients determined the baseline head CT use at a non-pediatric community ED. Patients were identified by ICD-9 codes for head injury, unspecified (959.01) and concussion with and without loss of consciousness (850-850.9). Exclusion criteria were age ≥18 years, penetrating head trauma, history of brain tumor, ventriculoperitoneal shunt, or bleeding disorder, or presentation >24 hours post-injury. Medical history, injury mechanism, symptoms, head CT use, and disposition were recorded. The head trauma guideline was implemented and CT use monitored among 172 patients identified by discharge diagnosis. Patients were classified into low, intermediate, and high ciTBI risk based on physician documentation. ED length-of-stay (LOS), disposition, and ED returns within 72 hours were recorded. Categorical variables were compared with the Chi-Square test or Fisher's Exact test, and the Kruskal-Wallis test was used for continuous variables. Results: Seven patients were excluded for co-morbidities and 69 patients were excluded for presenting >24 hours post-injury. Overall CT use decreased to 16.9% post-implementation from 30.5% pre-implementation (p <0.001). CT use among patients ≥24 months decreased to 19.6% from 36.3% (p <0.001), and remained low and unchanged for patients ≤24 months. Only 0.95% of low risk patients received a head CT post-implementation compared to 18.4% preimplementation (p <0.001). Median ED LOS, transfers to a pediatric trauma center, and ED returns within 72 hours were unchanged with no missed ciTBIs after implementation of the guideline. Conclusion: Implementation of the PECARN-based minor head trauma guideline safely reduced head CT use in a non-pediatric ED. The greatest impact was seen among older children at very low risk for ciTBI.

4375. Pugh, M. J., et al. (2021). "Emergence of post-traumatic epilepsy in post-9/11 veterans: Traumatic brain injury severity, deployment and multimorbidity." Journal of neurotrauma **38**(14): A46-A47.

Objective: To identify predictors of epilepsy in Post-9/11 Veterans. Background: The association of traumatic brain injury (TBI) and epilepsy in Veterans has been examined among those with combat deployments due to the high TBI prevalence. We hypothesized that epilepsy would be more likely in those with a history of TBI and deployment where blast injury/military exposures are common. Design/Methods: Retrospective observational study using merged Veterans Health Administration (VHA) and Department of Defense health data (2002-2019) for Veterans who entered VHA care 2002-2014. We identified epilepsy using ICD9/10 codes and use of antiseizure medications. We identified TBI severity using ICD9/10 codes and TBI screening data, and mental/physical health comorbidities using ICD9/10 codes before the index date (EPILEPSY: date of the first antiseizure medication after epilepsy-consistent diagnosis; No EPILEPSY: median time from first DoD care to epilepsy [2625 days]). We excluded individuals with verified psychogenic non-epileptic seizures and used logistic regression to identify predictors of epilepsy. Results: In this cohort (N = 1,226,280), 30,993 (2.53%) met epilepsy criteria. After controlling for mental/physical health comorbidities, odds of epilepsy were significantly lower for deployed (vs. non-deployed; adjusted odds ratio [AOR] 0.76; 0.73-0.79) and those without TBI were less likely than those with mTBI (AOR 1.60; 1.55-1.66), moderate/severe TBI (AOR 2.84; 2.36-2.61), penetrating TBI (AOR 5.13; 4.71-5.58). Other strong predictors included other neurological conditions such as ALS, MS, Parkinson's disease (OR 6.73; 6.38-7.10), stroke (OR 3.61; 3.45-3.77), headache/migraine (OR 2.34; 2.28-2.40), and cardiac disease (OR 1.91; 1.84-1.98). Conclusions: TBI, including mTBI, was associated with epilepsy, but those deployed were LESS likely to develop epilepsy. Chronic physical and mental health conditions that preclude deployment were associated with epilepsy and may be of equal concern to clinicians caring for patients with epilepsy and/or TBI; however more sophisticated statistical models are needed to better understand the interactions among TBI, deployment and chronic mental/physical comorbidities.

4376. Pugh, M. J., et al. (2021). "Risk factors for epilepsy among post-9/11 veterans: Traumatic brain injury and deployment status." Neurology **96**(15 SUPPL 1).

Objective: To identify predictors of epilepsy in Post-9/11 Veterans. Background: The association of TBI and epilepsy in Veterans has been examined among those with combat deployments. We hypothesized that individuals with epilepsy would be more likely than those without epilepsy to have history of TBI and a history of deployment where

blast injury/military exposures are more common. Design/Methods: Retrospective observational study using merged Veterans Health Administration (VHA) and Department of Defense health data (2002-2019) for Veterans who entered VHA care 2002-2014. We identified epilepsy using ICD9/10 codes and use of antiseizure medications. We identified TBI severity using ICD9/10 codes and TBI screening data, and mental/physical health comorbidities using ICD9/10 codes before the index date (EPILEPSY: Date of the first anti-seizure medication after epilepsy-consistent diagnosis; No EPILEPSY: Median time from first care in DoD to epilepsy [2625 days]). We excluded individuals with verified psychogenic non-epileptic seizures. We used logistic regression to identify predictors of epilepsy. Results: In this cohort (N=1,226,280), 30,993 (2.53%) met criteria for epilepsy. After controlling for mental/physical health comorbidities, odds of epilepsy were significantly lower for deployed (vs. non-deployed; AOR 0.76; 0.73-0.79). Compared to individuals without TBI, those with mTBI (OR 1.60; 1.55-1.66), moderate/severe TBI (OR 2.84; 2.36-2.61), penetrating TBI (OR 5.13; 4.71-5.58) had significantly higher odds of epilepsy. Other strong predictors included other neurological conditions such as ALS, MS, Parkinson's disease (OR 6.73; 6.38-7.10), stroke (OR 3.61; 3.45-3.77), headache/migraine (OR 2.34; 2.28-2.40), and cardiac disease (OR 1.91; 1.84-1.98). Conclusions: TBI, including mTBI, was associated with epilepsy, but those deployed were LESS likely to develop epilepsy. Chronic physical and mental health conditions that preclude deployment were associated with epilepsy and may be of equal concern to clinicians caring for patients with epilepsy and/or TBI; however more sophisticated statistical models are needed to better understand the interactions among TBI, deployment and chronic mental/physical comorbidities.

4377. Pugh, M. J., et al. (2014). "The prevalence of epilepsy and association with traumatic brain injury in veterans of the Afghanistan and Iraq wars." Brain injury **28**(5-6): 807.

Objective: While studies from prior wars and civilians have linked traumatic brain injury with epilepsy, little evidence is available for Veterans of the Afghanistan and Iraq (OEF/OIF/OND) wars. A recent investigation by the DoD indicated that epilepsy incidence increased 52% from 2006 to 2010, with ∼8% of those with epilepsy having a previously diagnosed TBI. However, those with more severe and penetrating TBI, who are at highest risk of post-traumatic epilepsy and more frequently discharged from the military, were underrepresented in that active duty population. The purpose of this study was to determine the prevalence of epilepsy in the population of OEF/OIF Veterans who receive VA care and to determine if TBI exposure was associated with epilepsy. Methods: This cross-sectional observational study utilized national inpatient and outpatient data. Participants included individuals who received care from the Veterans Health Administration (VA) in fiscal years 2009-2010. Algorithms developed for use with ICD-9-CM codes were used to identify patients who met criteria for epilepsy (VA algorithm), traumatic brain injury (TBI; Armed Forces Health Surveillance Center) and other risk factors for epilepsy (e.g. stroke, substance use disorder). TBI was divided into penetrating TBI (pTBI) and other TBI. TBI and other risk factors were identified prior to the index date (date of first seizure or 1 October 2009 for those without seizure). Results: Among 256 284 OEF/OIF veterans who received VA care in 2009-2010, 2719 met criteria for epilepsy. Epilepsy prevalence was 10.6 per thousand with an age-adjusted prevalence of 6.1. In addition, 29 297 veterans were diagnosed with TBI prior to the index date. Statistically significant associations were found between epilepsy and prior TBI diagnosis (pTBI: adjusted odds ratio (AOR) 18.77 (95% CI=9.21-38.23); other TBI AOR 1.64 (1.43-1.89)). Younger veterans (18-49 years vs 65 and older; AOR 2.22 [1.55-2.59] and those with prior stroke (AOR 5.50 [4.04-7.49]) were also significantly more likely to meet epilepsy criteria. Conclusions: Among OEF/OIF veterans, epilepsy was associated with a previous TBI diagnosis and pTBI had the strongest effect. Studies of war-related epilepsy in Vietnam War veterans with TBI have shown additional new cases of epilepsy accruing over decades post-war. A detailed prospective study is needed to understand the evolving relationship between epilepsy and TBI in OEF/OIF veterans.

4378. Pugh, M. J. and A. Van Cott (2021). "Risk for early onset Dementia among Veterans: The contributions of TBI and Epilepsy." Archives of physical medicine and rehabilitation **102**(10): e18.

Research Objectives: To identify the impact of TBI and epilepsy on subsequent diagnoses of early onset dementia (EOD) in a cohort of post-9/11 era Veterans as both are associated with dementia in older individuals and are more common in Post-9/11 Veterans than the general population. Design: Retrospective observational study of Post-9/11 Veterans in VA care FY02-FY18. Setting: National longitudinal data from Departments of Defense and Veterans Affairs. Participants: Post-9/11 Veterans 3 years of care. Interventions: N/A. Main Outcome Measures: EOD was operationalized using ICD-9-CM/10 diagnoses for diagnoses previously identified as reliable for EOD (Alzheimer's and frontotemporal dementia). TBI severity was identified using self-reports from the VA Comprehensive TBI Evaluation and

ICD-9-CM/10 codes. Epilepsy was identified using a previously validated algorithm requiring ICD-9-CM/10 codes and anticonvulsant medications. Covariates included socio-/military demographics, prior deployment and comorbid conditions associated with dementia. We conducted logistic regression analysis predicting EOD to identify associations for epilepsy and TBI severity controlling for potential confounders. Results: Among the 1,055,873 Veterans who met inclusion criteria, 923 had EOD (7.4/1000 epilepsy; 0.7/1000 no epilepsy). Epilepsy (aOR 2.41 [1.98-2.93]) and TBI of all severity (aORs: mTBI 1.67 [1.40-1.99]; moderate/severe TBI 2.31 [1.80-2.98]; penetrating TBI 2.87 [2.08-3.97]) were significantly associated with EOD. Other significant predictors (aORs >1.5; p <.001) included age 50-64 and 40-49 (vs. 30-39), other neurological conditions, stroke, schizophrenia, depression, and bipolar disorder. Conclusions: Epilepsy and TBI (of all severities) were associated with EOD. While there was a near linear association of TBI severity and EOD which is consistent with prior research, there was no significant interaction between TBI and epilepsy. This suggests that each condition contributes to EOD. However, those with more TBIs have higher risk for epilepsy and EOD suggesting the mechanism of added impact of TBI severity may work through other neurological/neurodegenerative conditions. Indeed, other strong predictors of EOD (e.g., stroke, other neurological conditions) supports this hypothesis and the idea that multimorbidity associated with TBI may reveal phenotypes of neurodegenerative outcomes that require further evaluation. Author(s) Disclosures: None.

4379. Pugh, M. J., et al. (2021). "Early onset dementia in post-9/11 veterans: Traumatic brain injury, epilepsy, and chronic disease." Journal of neurotrauma **38**(14): A79-A80.

Research Objectives: To identify the association of TBI and epilepsy on diagnoses of early onset dementia (EOD) in a cohort of post-9/11 era Veterans as both are associated with dementia in older individuals and are more common in Post-9/11 Veterans than the general population. Design: Retrospective observational study of Post-9/11 Veterans in VA care FY02-FY18 using national longitudinal data from Departments of Defense and Veterans Affairs. Participants: Post-9/11 Veterans <65 years at VA care entry and >3 years of care. Main Outcomes: EOD was operationalized using ICD-9-CM/10 diagnoses for diagnoses found reliable in prior research (Alzheimer's and frontotemporal dementia). TBI severity was identified using selfreports (VA Comprehensive TBI Evaluation) and ICD-9-CM/10 codes. Epilepsy was identified using ICD-9-CM/10 codes and anticonvulsant medications. Covariates included socio-/military demographics, prior deployment and comorbid conditions associated with dementia. Logistic regression analysis identifie associations with EOD for epilepsy and TBI severity controlling for potential confounders. Results: Among the 1,055,873 Veterans who met inclusion criteria 923 met criteria for EOD (7.4/1000 epilepsy; 0.7/1000 no epilepsy). Epilepsy (aOR 2.41 [1.98-2.93]) and TBI of all severity was associated with EOD (aORs: mTBI 1.67 [1.40-1.99]; moderate/severe TBI 2.31 [1.80-2.98]; penetrating TBI 2.87 [2.08-3.97]). Other significant predictors (aORs >1.5; p <.001) included age 50-64 and 40-49 (vs. 30-39), other neurological conditions, stroke, schizophrenia, depression, and bipolar disorder. Conclusions: Epilepsy and TBI (of all severities) were associated with EOD. Consistent with prior research there was a near linear association of TBI severity and EOD, but no significant interaction between TBI and epilepsy. Thus, each condition contributes to EOD. However, those with more severe TBIs have higher risk for epilepsy and EOD suggesting the mechanism of added impact of TBI severity may work through other neurological/neurodegenerative conditions. Indeed, other strong predictors of EOD (e.g., stroke) supports this hypothesis and the idea that multimorbidity associated with TBI may reveal phenotypes of neurodegenerative outcomes that require further evaluation.

4380. Pugh, M. J. V., et al. (2015). "The prevalence of epilepsy and association with traumatic brain injury in veterans of the Afghanistan and Iraq wars." The Journal of head trauma rehabilitation **30**(1): 29-37.

OBJECTIVE: To examine the association of epilepsy with traumatic brain injury (TBI) in Afghanistan and Iraq (Operation Enduring Freedom [OEF]/Operation Iraqi Freedom [OIF]) Veterans., DESIGN: Cross-sectional observational study., PARTICIPANTS: A total 256 284 OEF/OIF Veterans who received inpatient and outpatient care in the Veterans Health Administration in fiscal years 2009-2010., MAIN OUTCOME MEASURES: We used algorithms developed for use with International Classification of Diseases, Ninth Revision, Clinical Modification, codes to identify epilepsy, TBI (penetrating TBI [pTBI]/other TBI), and other risk factors for epilepsy (eg, stroke). TBI and other risk factors were identified prior to the index date (first date of seizure or October 1, 2009) for primary analyses., RESULTS: Epilepsy prevalence was 10.6 per 1000 (N = 2719) in fiscal year 2010; age-adjusted prevalence was 6.1. Of 37 718 individuals with a diagnosis of TBI, 29 297 Veterans had a diagnosis of TBI prior to the index date. Statistically significant associations were found between epilepsy and prior TBI diagnosis (pTBI: adjusted odds ratio = 18.77 [95% confidence interval, 9.21-38.23]; other TBI: adjusted odds ratio = 1.64 [1.43-1.89])., CONCLUSIONS: Among OEF/OIF Veterans, epilepsy was

associated with previous TBI diagnosis, with pTBI having the strongest association. Because war-related epilepsy in Vietnam War Veterans with TBI continued 35 years postwar, a detailed, prospective study is needed to understand the relationship between epilepsy and TBI severity in OEF/OIF Veterans.

4381. Punjabi, S. K., et al. (2012). "Associated injuries with facial trauma - A study." Journal of the Liaquat University of Medical and Health Sciences **11**(2): 60-63.

Objectives: The objectives of the study were to determine the incidence of associated injuries with maxillofacial fractures and to enlist the age and gender distribution of maxillofacial trauma and also to find out cause, bone most frequently affected with it. Material and Methods: History was taken from patients affected with facial trauma along with 2 diagnostic radiographs. Age, gender, cause, type of injury and fractures elsewhere in the body were recorded. Study was carried out at Emergency Department of Liaquat University Hospital Hyderabad in a period of 1 year i.e. from 1st January 2011 to 30 December 2011. Results: Total of 680 patients was included in this study. Out of these males were predominantly affected (72%), mean age was found to be 36.4 years. Road traffic accident (RTA) was the most common cause of injury (51%) and mandible was the most common bone involved (51%). Out of associated injuries tibia (12.35%) and ulna (11.23%) were most common injuries. Conclusion: Our study showed a high frequency of trauma in males in 3rd decade of life. Road traffic accident (RTA) was the most common cause and mandible the most common bone affected. Tibia and ulna were common associated injuries with facial trauma.

4382. Punt, J. (1978). "Chronic extradural hematoma presenting 33 years after penetrating cranial trauma. Case report." Journal of neurosurgery **49**(1): 103-106.

A case is reported of a 53-year-old normotensive man who presented, 33 years after a penetrating cranial war injury, with dysphasia of 10 month's duration, which proved to be due to a chronic extradural hematoma. The pathogenesis and symptomatology are discussed, and it is proposed that the lesion had been present since the original injury.

4383. Puntaric, D., et al. (2000). "Neurologic recovery after penetrating craniocerebral war injury." Neuroepidemiology **19**(3): 149-152.

From June 1, 1991, until December 31, 1992, 116 patients with penetrating craniocerebral war injuries inflicted at the east Slavonian front were treated at the Osijek University Hospital. There were 26 (22.4%) gunshot wounds and 90 (77.6%) wounds inflicted by explosive devices and projectiles. Four years after the injury, a study of the survivors' condition was carried out. No difference was recorded in the survival rate between the patients with gunshot wounds compared with explosive wounds. Rehabilitation produced good results in the survivors, in the prevention of both acute and chronic complications and permanent damage. Older age, lower Glasgow Coma Scale, and level of consciousness were found to be prognostic indicators of outcome. Copyright 2000 S. Karger AG, Basel

4386. Puri, P., et al. (1999). "Management of ocular perforations resulting from peribulbar anaesthesia." Indian journal of ophthalmology **47**(3): 181-183.

PURPOSE: To analyze the clinical presentation and outcome of treatment for globe perforation secondary to peri-bulbar anaesthesia., METHODS: Eight patients (3 females and 5 males) aged 66-84 years were included in the study. Ocular perforations were suspected in 3 cases before or during surgery, in 4 cases diagnosis was established within one week and in one case at 3 weeks. Three patients underwent indirect argon laser photocoagulation to seal the retinal break, one patient had cryotherapy, 3 patients underwent a pars plana vitrectomy with fluid gas exchange and endo-

laser; and one patient refused any further treatment., RESULTS: The final visual acuity after a mean follow up of 14 months was better than 6/9 in 2 patients, between 6/9-6/12 in 4 patients, and perception of light in 2 patients., CONCLUSION: If diagnosed early and treated adequately, a majority of patients with globe perforation during periocular anaesthetic could be saved.

4387. Purushothuman, S., et al. (2013). "The response of cerebral cortex to haemorrhagic damage: experimental evidence from a penetrating injury model." PloS one **8**(3): e59740.

Understanding the response of the brain to haemorrhagic damage is important in haemorrhagic stroke and increasingly in the understanding the cerebral degeneration and dementia that follow head trauma and head-impact sports. In addition, there is growing evidence that haemorrhage from small cerebral vessels is important in the pathogenesis of age-related dementia (Alzheimer's disease). In a penetration injury model of rat cerebral cortex, we have examined the neuropathology induced by a needlestick injury, with emphasis on features prominent in the ageing and dementing human brain, particularly plaque-like depositions and the expression of related proteins. Needlestick lesions were made in neo- and hippocampal cortex in Sprague Dawley rats aged 3-5 months. Brains were examined after 1-30 d survival, for haemorrhage, for the expression of hyperphosphorylated tau, Abeta, amyloid precursor protein (APP), for gliosis and for neuronal death. Temporal cortex from humans diagnosed with Alzheimer's disease was examined with the same techniques. Needlestick injury induced long-lasting changes-haem deposition, cell death, plaque-like deposits and glial invasion-along the needle track. Around the track, the lesion induced more transient changes, particularly upregulation of Abeta, APP and hyperphosporylated tau in neurons and astrocytes. Reactions were similar in hippocampus and neocortex, except that neuronal death was more widespread in the hippocampus. In summary, experimental haemorrhagic injury to rat cerebral cortex induced both permanent and transient changes. The more permanent changes reproduced features of human senile plaques, including the formation of extracellular deposits in which haem and Abeta-related proteins co-localised, neuronal loss and gliosis. The transient changes, observed in tissue around the direct lesion, included the upregulation of Abeta, APP and hyperphosphorylated tau, not associated with cell death. The findings support the possibility that haemorrhagic damage to the brain can lead to plaque-like pathology.

4388. Puschel, K., et al. (2001). "[Once again: risk of injury caused by blank pistols]." Noch einmal: Verletzungsgefahren durch Schreckschusswaffen. **207**(1-2): 26-32.

The nature and extent of the use of blank pistols in Hamburg (according to the Hamburg crime statistics about 300 to 400 such cases per year; 34 cases involving head and neck wounds from 1989 to 1999 were investigated at our institute; among these 8 suicides, no homicide) as well as patterns of injuries caused by close distance blank pistol shots were analysed. 7 of these cases are described in detail. The results of our studies corroborate the warning statements made by many criminological and medico-legal experts regarding the danger inherent in these allegedly harmless weapons. Blank cartridge pistols can, when shot from a close distance, cause most severe injuries involving penetration into body cavities and bodily organs (especially in the head and neck), and even perforation of the skull. Therefore, we call for a much stricter control of weapons of this kind.

4389. Puspitasari, V., et al. (2019). "Glial Fibrillary Acidic Protein Serum Level as a Predictor of Clinical Outcome in Ischemic Stroke." Open access Macedonian journal of medical sciences **7**(9): 1471-1474.

BACKGROUND: Glial Fibrillary Acidic Protein (GFAP) is a protein produced by astrocytes in response to brain injury, which then penetrates the cerebrospinal fluid and the blood stream., AIM: We sought to determine whether GFAP serum level in acute ischemic stroke could predict clinical outcome., METHODS: As much as 64 patients with first-ever ischemic stroke had their GFAP serum level measured at 72 hours after onset. The National Institute of Health Stroke Scale (NIHSS) was assessed during the 72 hours of onset, the seventh day, and followed up 1 month after., RESULTS: There were 46 men and 18 women included in the study. Mean age was 58.3 years old, and nearly half of them (46.9%) were between 50-59 years old. More than half (58.7%) presented with moderate to a severe stroke and mean GFAP serum level was 0.113 +/- 0.029 ng/mL. GFAP serum levels had a significant correlation with NIHSS after 1 month (p = 0.04, r = 0.259)., CONCLUSION: There is a significant correlation between GFAP serum levels with stroke severity scale after 1 month of stroke onset.

4390. Puybasset, L., et al. (2014). "Critical appraisal of organ procurement under Maastricht 3 condition." Annales francaises d'anesthesie et de reanimation **33**(2): 120-127.

The ethics committee of the French Society of Anesthesia and Intensive Care (Sfar) has been requested by the French Biomedical Agency to consider the issue of organ donation in patients after the decision to withdraw life-supportive therapies has been taken. This type of organ donation is performed in the USA, Canada, the United Kingdom, the Netherlands and Belgium. The three former countries have published recommendations formalizing procedures and operations. The French Society of Anesthesia and Intensive Care (Societe francaise d'anesthesie et de reanimation [Sfar]) ethics committee has considered this issue and envisioned the different aspects of the whole process. Consequently, it sounded a note of caution regarding the applicability of this type of organ procurement in unselected patients following a decision to withdraw life-supportive therapies. According to French regulations concerning organ procurement in brain-dead patients, the committee stresses the need to restrict this specific way of procurement to severely brain-injured patients, once confirmatory investigations predicting a catastrophic prognosis have been performed. This suggests that the nature of the confirmatory investigation required should be formalized by the French Biomedical Agency on behalf of the French parliamentarians, which should help preserve population trust regarding organ procurement and provide a framework for medical decision. This text has been endorsed by the Sfar.

4392. Qi, H. and K. Li (2021). "Civilian gunshot wounds to the head: a case report, clinical management, and literature review." Chinese Neurosurgical Journal **7**(1).

Background: Civilian gunshot wounds to the head refer to brain injury caused by projectiles such as gun projectiles and various fragments generated by explosives in a power launch or explosion. Gunshot wounds to the head are the deadliest of all gun injuries. According to literature statistics, the survival rate of patients with gunshot wounds to the head is only 9%. Due to the strict management of various types of firearms, they rarely occur, so the injury mechanism, injury and trauma analysis, clinical management, and surgical standards are almost entirely based on military experience, and there are few related reports, especially of the head, in which an individual suffered a fatal blow more than once in a short time. We report a case with a return to almost complete recovery despite the patient suffering two gunshot injuries to the head in a short period of time. Case presentations: We present a case of a 53-year-old man who suffered two gunshot injuries to the head under unknown circumstances. On initial presentation, the patient had a Glasgow Coma Scale score of 6, was unable to communicate, and had loss of consciousness. The first bullet penetrated the right frontal area and finally reached the right occipital lobe. When the patient reflexively shielded his head with his hand, the second bullet passed through the patient's right palm bone, entered the right frontotemporal area, and came to rest deep in the lateral sulcus. The patient had a cerebral hernia when he was admitted to the hospital and immediately entered the operating room for rescue after a computed tomography scan. After two foreign body removals and skull repair, the patient recovered completely. Conclusions: Gunshot wounds to the head have a high mortality rate and usually require aggressive management. Evaluation of most gunshot injuries requires extremely fast imaging examination upon arrival at the hospital, followed by proactive treatment against infection, seizure, and increased intracranial pressure. Surgical intervention is usually necessary, and its key points include the timing, method, and scope of the operation.

OBJECTIVE: To explore the changes of cerebral microvasculature in cats with missile brain wound., METHODS: The microvascular corrosion casts of the brain were examined by scanning electron microscopy, and the ultra-thin slices of the brain were inspected by transmission electron microscopy., RESULTS: The brain microvasculature showed evidently abnormal morphological changes, with both vasospasm and vasodilation as well as concurrent bleeding and ischemia. Strong pathological contraction of vascular sphincter, rupture of some microvessels, and increased microvilli

and vacuoles in the endothelial cells were observed. Loosening of the intercellular tight junction and basal membrane rupture occurred along with perivascular swelling and neural cell damages., CONCLUSION: Morphological or functional changes occur in the cerebral microvasculature leading to secondary brain injury after missile brain wound in cats.

4395. Qiu, W. W., et al. (1999). "Neurotologic evaluation of facial nerve paralysis caused by gunshot wounds." Ear, nose, & throat journal **78**(4): 270-passim.

Facial nerve injury is one of the most common neurotologic sequelae of a gunshot wound (GSW) to the head or neck. However, few neurotologic studies have been performed on the nature and time course of such facial nerve impairments. This study was designed to characterize the neurotologic manifestations and time course of facial nerve paralysis caused by GSWs to the head and neck. We conducted a battery of electrodiagnostic tests on 10 patients who had experienced traumatic facial paralysis due to a GSW to the head or neck. The etiologies of facial nerve paralysis--including direct injury, compression, fracture, and concussion of the temporal bone--were demonstrated by audiologic, radiologic, and surgical findings. Hearing loss and other cranial nerve injuries were also seen. Six of the 10 patients experienced a complete paralysis of the facial nerve and a poor recovery of its function. We also present a comprehensive case report on 1 patient as a means of discussing the evaluation of facial nerve function during the course of management.

4396. Quatrehomme, G., et al. (2016). "Bone beveling caused by blunt trauma: a case report." International journal of legal medicine **130**(3): 771-775.

The authors report a fatal case of blunt trauma to the skull caused by a rib of a beach umbrella. The skull displayed a round hole in the right temporal bone with typical internal beveling. Blunt trauma mimicking a gunshot wound (round perforation of the skull with internal beveling) is very rarely reported in the forensic literature.

4397. Quattrocchi, K. B., et al. (1990). "Traumatic aneurysm of the superior cerebellar artery: case report and review of the literature." Neurosurgery **27**(3): 476-479.

Less than 10% of the 250 reported cases of traumatic intracranial aneurysms have involved the posterior circulation. Traumatic aneurysms of the superior cerebellar artery are extremely rare, with only three cases previously reported. This is the first report of a traumatic superior cerebellar artery aneurysm in which the diagnosis was suggested by computed tomographic scan. The potential for a good outcome suggests the value of early angiography when the history and diagnostic imaging studies suggest the possibility of a traumatic aneurysm.

4398. Queiroz, A. B., et al. (2017). "Endovascular treatment of traumatic injuries of the vertebral artery: Initial experience of a teaching hospital." Vascular **25**(3): 48.

Background: Trauma of the vertebral artery with subsequent formation of a pseudoaneurysm is an uncommon clinical situation and is associated with a high mortality rate, due to either further bleeding or occurrence of neurological complications. Its incidence is most often related to penetrating cervical trauma. The clinical presentation is varied, being asymptomatic or presenting signs and symptoms as pulsatile mass, vertigo, diplopia or headache. The management of these lesions aims mainly to restore the habitual flow of this artery, free of cerebral events with the preservation of life. The endovascular treatment of these lesions is a viable option and presents good clinical results according to the literature. Aim: To describe the initial clinical and angiographic results of endovascular therapy in the treatment of posttraumatic vertebral artery pseudoaneurysms in a teaching institution. Materials and Methods: Two cases of post-traumatic vertebral artery pseudoaneurysms were reported and treated in the year 2016 at the Endovascular Surgery Department of the Ana Nery Hospital, in Salvador-Bahia. The mean age was 19 years (16-22 years), all the patients were male with injuries secondary to penetrating gun shot wound in the cervical region. All cases underwent arterial embolization with coils. Results: In both patients, endovascular therapy resulted in an immediate occlusion of the pseudoaneurysms with good clinical and angiographic results. Conclusion: In this initial sample, the

endovascular approach of post-traumatic vertebral artery pseudoaneurysms proved to be safe and effective, presenting as an important option for the therapeutic arsenal of the modern vascular surgeon.

4400. Quencer, R. M., et al. (1976). "Jugular venography for evaluation of abnormalities of the skull base." Journal of neurosurgery **44**(4): 485-492.

Jugular venography done to evaluate abnormalities at the base of the skull demonstrated three distinctly different patterns depending on whether there is occlusion, invasion, or growth with in the internal jugular vein. Improper technique results in a lack of intracranial dural sinus filling which may masquerade as venous occlusion. This problem is avoided by adequate neck compression along with proper volume and rate of delivery of contrast. Radiographically, an abnormal jugular vein at the base of the skull will show a concave defect in true occlusion, constriction or invasion of the vein by tumor, or tumor growth within the vein.

4401. Quenzer, F., et al. (2021). "Self-Inflicted Gun Shot Wounds: A Retrospective, Observational Study of U.S. Trauma Centers." The western journal of emergency medicine **22**(3): 518-524.

INTRODUCTION: Intentional self-harm (suicide) by firearms is a growing problem in the United States. Currently, there are no large studies that have identified risk factors for patients who die from self-inflicted gunshot wounds. Our objectives are to 1) identify risk factors for patients with the highest morbidity and mortality from self-inflicted gunshot wounds (SIGSWs) at trauma centers 2) present the outcomes of victims of SIGSW by handguns (HG) versus all other specified guns (AOG) and 3) compare the presentations and outcomes of victims with head or face (HF) injuries to other regions of the body., METHODS: We performed a retrospective analysis from the National Trauma Database (NTDB) data between 2012 and 2013 of all SIGSW patients who presented to trauma centers. Categorical data included patient characteristics upon presentation and outcomes which were compared between patients with HG injury versus AOG injury using the Chi-Squared test, where AOG includes shotguns, hunting rifles, and military firearms. Additionally, analysis of head and face (HF) injuries versus other bodily injuries (OBI) were compared between the HG group versus AOG group using Chi-squared test., RESULTS: There were 7,828 SIGSWs, of those, 78% (6,115) were white and 84.3% (6,600) were male. There were 5,139 HG injuries, 1,130 AOG injuries, and 1,405 unidentified gun injuries. The HG group was likely to be older (>55 years old), hypotensive (systolic blood pressure < 90), have a lower Glasgow Coma Score (GCS < 9), use illegal, or use prescription drugs. In comparing HF injuries (4,799) versus other bodily injuries (OBI) (3,028), HF group was more likely to use handguns, expire in ED, require ICU, and have a higher percent of overall mortality. Of the total OBI, the thorax, upper extremities, and abdomen were the most commonly injured., CONCLUSION: In our retrospective study of SIGSWs, we were able to demonstrate that SIGSW by handguns are associated with higher rates of mortality versus all other types of firearms. SIGSWs in older white males with handguns are the most at-risk for severe complications. Future efforts should improve screening methods for handguns in suicidal patients and at developing prevention programs.

4402. Quesada, L. M., et al. (2018). "PBBI lesion, axonal injury reduced while improving motor outcome with human neural stem cell transplants." Journal of neurotrauma **35**(16): A113-A114.

Penetrating traumatic brain injury(PTBI) is common in the USA and worldwide, outcome remains poor in survivors. In the absence of ''neuroprotective'' therapies, progressive secondary tissue loss after PTBI underlies disability among survivors. This study tests transplantation of human neural stem cells (hNSCs) as a treatment to mitigate lesion in penetrating ballistic-like brain injury (PBBI), a rat PTBI model. One-week post PBBI male Sprague Dawley rats (7-10/ group) were randomized to: (1) injured treated with vehicle (media, no cells), (2) uninjured (sham+hNSCs), two PBBI groups (PBBI+hNSC) either (3) into surrounding (peri) or (4) within lesion core(intra), one million cells were stereotactically microinjected into brains of immunosuppressed group 2-4. Motor function was assessed on grid walk prior to euthanization at 12 weeks post-transplantation. Lesion size, axonal injury was quantitated with Matlab based scripts of brain sections stained with histochemical stains. Lesion size and remote secondary axotomy were significantly reduced in transplant groups. Engraftment or neuronal differentiation did not differ between groups 3 and 4, despite

being higher than in sham. On the grid walk test, sham animals had fewer foot faults than vehicle group as expected. Compared to vehicle, groups 3 and 4 had significantly reduced foot faults but still significantly higher than control. A two-way ANOVA of the rat brain cortical tissue quantity between +3.72mm and -0.28mm bregma (rat motor cortex) there was significant interaction between bregma levels and treatment. There was reduction in lesion size in both transplant groups ($p < 0.05$). Lesion seize reduction was due to significant increase in tissue sparing in the perilesional transplant group compared to vehicle ($p < 0.01$). One-way ANOVA revealed no statistically significant differences in spared tissue between two transplant groups but greater sparing of the motor cortex in perilesional transplantation. The concomitant reduction in lesion area and increased cortical tissue sparing suggests that transplantation of hNSCs reduced the progression of PBBI induced cortical atrophy, spared motor cortex reduced secondary axotomy may be associated with improved motor performance in transplant groups. This data provides a rationale for use of hNSC transplants to mitigate PTBI induced secondary tissue loss. Perilesional rather than intralesional transplantation conferred greater neuroprotection.
