Operation Brain Trauma Therapy (OBTT) is a consortium of investigators using multiple pre-clinical models of traumatic brain injury (TBI) to bring acute therapies to clinical trials. To screen therapies, we used three rat models (parasagittal fluid percussion injury [FPI], controlled cortical impact [CCI], and penetrating ballistic-like brain injury [PBBI]). We report results of the third therapy (cyclosporin-A; cyclosporine; [CsA]) tested by OBTT. At each site, rats were randomized to treatment with an identical regimen (TBI + vehicle, TBI + CsA [10 mg/kg], or TBI + CsA [20 mg/kg] given intravenously at 15 min and 24 h after injury, and sham). We assessed motor and Morris water maze (MWM) tasks over 3 weeks after TBI and lesion volume and hemispheric tissue loss at 21 days. In FPI, CsA (10 mg/kg) produced histological protection, but 20 mg/kg worsened working memory. In CCI, CsA (20 mg/kg) impaired MWM performance; surprisingly, neither dose showed benefit on any outcome. After PBBI, neither dose produced benefit on any outcome, and mortality was increased (20 mg/kg) partly caused by the solvent vehicle. In OBTT, CsA produced complex effects with histological protection at the lowest dose in the least severe model (FPI), but only deleterious effects as model severity increased (CCI and PBBI). Biomarker assessments included measurements of glial fibrillary acidic protein (GFAP) and ubiquitin C-terminal hydrolase-L1 (UCH-L1) in blood at 4 or 24 h after injury. No positive treatment effects were seen on biomarker levels in any of the models, whereas significant increases in 24 h UCH-L1 levels were seen with CsA (20 mg/kg) after CCI and 24 h GFAP levels in both CsA treated groups in the PBBI model. Lack of behavioral protection in any model, indicators of toxicity, and a narrow therapeutic index reduce enthusiasm for clinical translation.

1410. Dixon, C. E., et al. (2014). "Dose-response evaluation of simvastatin in the controlled cortical impact model: Operation brain trauma therapy consortium." Journal of neurotrauma 31(12): A107.

The 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor simvastatin reduces serum cholesterol but also has potent inhibitory effects on neuro-inflammation and possible effects on brain edema, Akt, CBF and trophic factor production. Simvastatin was screened in the Operation Brain

Trauma Therapy (OBTT) consortium for efficacy as a sustained therapy to improve neurobehavioral and neuropathological outcomes in the controlled cortical impact (CCI) model. Forty male Sprague-Dawley rats were anesthetized and surgically prepared for CCI injury (4 m/sec, 2.5-mm deformation) or sham surgery. Rats were randomized into four groups: CCI + vehicle (3% methylcellulose in distilled water), CCI + simvastatin (1mg/kg), CCI + simvstatin (5 mg/kg), and sham. Simvastatin was given PO with the first dose at 3 h after injury and subsequent doses daily for 14 d. Motor function (beam balance and walking) were evaluated on d1-5 and Morris water maze (MWM) (acquisition and probe trial) on d14-20. Rats were sacrificed on d21 to assess lesion and hemispheric volumes. In the beam balance test, the CCI + vehicle and CCI + simvastatin (1mg/kg) performed significantly worse than sham while the CCI + simvastatin (5 mg/kg) did not differ from sham. In the beam walking test and MWM acquistion, all of the CCI groups performed significantly worse than sham and neither simvastatin-treated group differed vs. vehicle. In the MWM probe trial (% time in target quadrant), there were no differences between CCI groups. Neither lesion volume nor hemispheric volume loss were reduced by treatment. Surprisingly, our study did not replicate the benefit of simvastatin shown in previous work. Similar to the fluid percussion and penetrating ballistic-like brain injury models also used in OBTT, modest benefit was limited to motor performance after CCI. Support: US Army, W81XWH-10-1-0623.

1411. Dixon, C. E., et al. (2013). "Operation brain trauma therapy consortium: Dose-response evaluation of cyclosporine a in the pittsburgh controlled cortical impact model of traumatic brain injury." Journal of neurotrauma 30(15): A159.

Introduction Cyclosporine A (CsA) is a clinically-used immunosuppressant that has shown beneficial effects in several animal models of TBI. CsA was screened in the Operation Brain Trauma Therapy consortium. We assessed the therapeutic efficacy of post-injury administration of CsA on neurobehavioral and neuropathological outcomes in the controlled cortical impact (CCI) model. Methods Thirty-nine male Sprague-Daley rats were anesthetized and surgically prepared for CCI injury (4 m/sec, 2.5mm deformation) or sham surgery. Rats were randomized into four groups: CCI + vehicle (Cremophor), CCI + CsA (10mg/kg), CCI + CsA (20mg/kg), and sham. CsA was given IV at 15 min and 24 h after injury. Blood sampling (0.7mL whole blood) via the tail artery was obtained at 4 h, 24 h, and at sacrifice from each rat to measure the neuronal biomarker UCH-L1 and the glial biomarker GFAP levels. Motor function (beam balance and beam walking) were evaluated on days 1-5 and Morris water maze (MWM) (acquisition and probe trial) on days 14-20. The rats were sacrificed on day 21 to assess lesion and hemispheric tissue volumes. Results In the beam balance test, there was no treatment effect vs. vehicle, although both CCI + CsA groups performed significantly worse than sham. In the beam walking test, all of the CCI groups performed significantly worse than sham, but none of the CCI + CsA groups differed vs. vehicle. For MWM acquisition, only the CCI + CsA 20mg/ kg group performed significantly worse ($P > 0.01$) than sham. In the probe trial (% time in target quadrant), there were no statistical differences between groups. Neither lesion volume nor hemispheric volume loss were significantly affected by treatment. Injury significantly increased serum GFAP levels in vehicle ($P < 0.01$ vs. sham), but high dose CsA exhibited the highest GFAP levels at 24 h ($P < 0.001$ vs. sham). However, the three CCI groups did not significantly differ from each other for GFAP levels at 24 h. Conclusions Our study did not replicate the benefit of CsA shown in previous work. In fact, the higher dose (20 mg/kg) actually impaired performance on MWM and showed the highest 24 h serum GFAP levels. Our findings in CCI are also consistent with failure of CsA in the penetrating ballistic-like brain injury model in OBTT and do not support utility of CsA in severe insults.

1412. Diyora, B., et al. (2021). "Meat Hook Injury Leading to Brain Abscess: A Rare Occurrence." Indian Journal of Neurotrauma.

Transorbital orbitofrontal penetrating injury by a nonmissile object is uncommon. The presentation of this injury varies. This injury can be easily missed during the initial clinical presentation, because the foreign body is sometimes not visible on local examination, the wound on the orbital skin is

small, and very subtle signs are present. The patient can present with delayed complications of the primary injury. Our patient was a 33-year-old male who presented with an orbitofrontal injury with a meat hook. He had minor symptoms at the time of presentation, which were overlooked. Three weeks later, he developed signs and symptoms of raised intracranial pressure (ICP). Brain imaging revealed a peripheral rim of contrast-enhancing mass lesion in the right frontal lobe, extending into the right orbit with perilesional edema suggestive of posttraumatic brain abscess. Via right frontal craniotomy, pus was drained out and abscess wall was excised. The patient made good clinical recovery. A higher index of suspicion and sound knowledge of occult penetrating injury patterns is required in the cases of orbital injuries. Appropriate radiological imaging can lead to an earlier and accurate diagnosis, and can prevent its delayed sequela like brain abscess.

1413. Diyora, B., et al. (2021). "Iron Rod Penetrating Head Injury in a Child." Indian Journal of Neurotrauma 18(2): 148-149.

1414. Diyora, B., et al. (2018). "Perforating head injury with iron rod and its miraculous escape: Case report and review of literature." Trauma case reports 14: 11-19.

Civilian perforating head injury is rare. Because rarity of this injury, there is no standard management protocol. We report a case of perforating head injury with iron rod, review the literature on the subject and discuss the challenges in the management of such case. We have not found similar case in the literature. Civilian perforating head injury is rare. A 25-year-male brought to the emergency department with approximately two feet perforating iron rod in the head, entering via frontal region, left side of midline and coming out of the occipital region. He developed right sided hemiplegia and global aphasia. He underwent series of imaging for the evaluation of the course of the iron rod and injury sustained because of it. Under strict aseptic precaution, iron rod removed in the operation theater. His clinical condition improved over a period of three weeks. At one year follow up- he had almost normal speech and language functions and was able to walk without support. This case illustrates the possibility of bizarre type of such injury in the presence of protective helmet and challenges in the management. Preoperative planning on the basis of images, prophylactic antibiotics and anticonvulsant medications, cleaning of the objects with antiseptic solutions, anterograde extraction after adequate exposure around entry and exit points resulted in good clinical outcome after successful removal of the rod.

1415. Diyora, B., et al. (2022). "Life-threatening perforating brain injury by a rusty iron rod – A case report." Surgical neurology international 13.

Background: When an object traverses through the cranium leaving behind both an entry and exit wound, it is called perforating brain injury. Perforating open brain injury is rare. A paucity of published literature on such cases and a lack of a standard management protocol pose significant challenges in managing such cases. Case Description: We present a case of a 24-year-old man who worked as a carpenter at the construction site. He slipped while working and fell from a height of 13 feet onto a rusty, vertically placed 3 feet iron rod located on the ground. Iron rod entered his body from the right upper chest, came out from the neck, and again re-entered through the right upper neck medial to the angle of the mandible and finally came out from the posterosuperior surface of the right side of the head. He presented to the emergency department in a conscious state, but his voice was heavy and slow-paced, and he showed signs of lower cranial nerve palsy on the right side. He underwent numerous radiological investigations. The iron rod was removed in the operation theater under strict aseptic precautions. On day 7 after surgery, he developed right lobar pneumonia, and on day 21, he developed an altered sensorium, followed by a loss of consciousness. He did not regain consciousness and, unfortunately, succumbed after 30 days of sustaining the injuries. Conclusion: Perforating open brain injuries are rare, especially in civilian society, and are usually associated with significant morbidity and mortality. Due to a lack of standard guidelines for managing such severe injuries and limited knowledge, many patients

with these injuries do not survive. Although each case presents differently, certain management principles must be followed.

1416. Dizdarevic, K., et al. (2011). "War head injuries: Experience from sieged Sarajevo." Acta neurochirurgica 153(9): 1881.

Objectives. We aimed to analyze the war head injuries in sieged Sarajevo during the first part of Bosnian war and to present our operative strategies. Patients and methods. We conducted a retrospective study of injured patients using review of the hospital data. Results. 1,728 neurosurgical injured patients were admitted to our department. Majority of patients (84%) were admitted within 3 hours of injury and operated without any delay. The neurosurgical injuries were head injuries (80%), spine injuries (6%) and peripheral nerve injuries (14%). Over 80% of headinjured patients had penetrating injury. The patients with head injury were operated on in 70% of cases.Mortality of operated patients was 13.3%. The number patients with GCS 3 and GCS 4 who died were 143 (35%) and 122 (30 %). The GCS 4 patients were operated on only in the case of compressive intracranial haematomas. A total mortality of the patients with head injury was 30%. Over 60% of injured patients who died were under 50 years old. The most common cause of death were excessive penetrating brain injury (85%) caused by shell shrapnels and sniper bullets. Shrapnels were the cause of injury in 73% of cases. Good outcome without any focal neurological deficit was found in 42.6% of all patients with head injury. Conclusion: Our less invasive early neurosurgical operative approach in the form of intracranial haematomas evacuation, reduced brain debridment without searching for in-driven fragments and meticulous dural closure resulted in acceptable treatment outcome during the Bosnian war.

1417. Djabali, E. J. and P. T. Dziegielewski (2020). "A lucky bullet in the neck: Incidental carcinoma of unknown primary found during a gunshot wound repair." Otolaryngology Case Reports 16.

Background: The incidental finding of squamous cell carcinoma (SCC) in cervical lymph nodes during neck exploration for non-oncologic surgery is not reported in the literature. This study presents the first-ever reported incidentally found SCC in the neck during a penetrating neck trauma repair. The approach, clinical implications, and treatment are discussed. Case presentation: A 58-year-old otherwise healthy male was taken to an outside emergency department following a near-fatal gunshot wound to his neck with a large pharyngeal defect. During the neck exploration, several firm enlarged upper cervical lymph nodes were sent for frozen section pathology, which came back suspicious for SCC. A comprehensive neck dissection was completed and the remaining lymph nodes were excised. The patient underwent a pharyngoplasty and neck skin reconstruction with a bi-lobed anterolateral thigh (ALT) free flap. Final pathology identified the neck nodes to be positive for moderately differentiated human papillomavirus negative SCC. The patient underwent treatment for cancer of unknown primary with chemoradiation therapy. PET-CT imaging 1-year postoperatively was negative for persistent or recurrent disease. The patient was without signs of recurrence at his 18-month follow-up with a viable ALT flap at the site of reconstruction. Discussion: Incidental cancer diagnosis during surgery following trauma is rare. These circumstances make a case for routine examination of lymph nodes during surgery.

1418. Djalilian, H. R., et al. (2002). "Reconstruction of complicated skull base defects utilizing free tissue transfer." Skull Base 12(4): 209-213.

We managed five patients with large skull base defects complicated by complex infections with microvascular free tissue transfer. The first patient developed an infection, cerebrospinal fluid (CSF) leak, and meningitis after undergoing a translabyrinthine resection of an acoustic neuroma. The second patient had a history of a gunshot wound to the temporal bone, with a large defect and an infected cholesteatoma that caused several episodes of meningitis. The third through the fifth patients had persistent CSF leakage and infection refractory to conventional therapy. In all cases prior attempts of closure with fat grafts or regional flaps had failed. Rectus abdominis myofascial free flap, radial forearm

free flap or a gracilis muscle free flap was used after debridement of the infected cavities. The CSF leaks, local infections, and meningitis were controlled within a week. In our experience, microvascular free tissue provides the necessary bulk of viable, well-vascularized tissue, which not only assures a mechanical seal but also helps clear the local infection.

1419. Djilvesi, D., et al. (2010). "[Association of post-traumatic communication of endocranium and nasal cavity with recurrent meningoencephalitis without rhinorrhea]." Vojnosanitetski pregled **67**(11): 945-948.

INTRODUCTION: A gunshot head injury, characterized by a huge intensity of mechanical force, in addition to the direct tissue damage at the location of direct impact, may cause a skull and skull base fracture, distant from the the point of direct impact, which could be further complicated by creating a communication between endocranium and nasal/paranasal cavities. Such cases pose a great diagnostic and therapeutic challenge for every clinician., CASE REPORT: The patient is presented with the history of a perforating gunshot head injury six years ago, with recurrent attacks of meningoencephalitis subsequently, without rhinorrhea. By using high resolution CT scans, previous traumatic skull injury was verified and a fissure in the frontoethmoidal region, far from the point of direct impact, was detected. The patient underwent transnasal endoscopic surgery, in order to seal the communication on skull basis. The patient did not suffer from meningoencephalitis during the next two years., CONCLUSION: In the cases with late occurrence of posttraumatic meningoencephalitis with no signs of rhinorrhea, a possibility of an existing communication between intracranial and nasal cavities should be considered, as well. By applying modern diagnostic and therapeutic procedures such communication should be precisely located and sealed.

1420. Doctor, V. S. and D. G. Farwell (2007). "Gunshot wounds to the head and neck." Current opinion in otolaryngology & head and neck surgery **15**(4): 213-218.

PURPOSE OF REVIEW: Gunshot wounds to the head and neck result in significant bone and soft tissue loss. These defects pose a challenge to the facial reconstructive surgeon. This paper reviews the current literature on the management of ballistic injuries to the head and neck and outlines a treatment algorithm., RECENT FINDINGS: With recent advances in free tissue transfer, early definitive reconstruction of bone and soft tissue deficits with vascularized flaps has become the treatment of choice. Computed tomography angiography of the neck has been shown to be a sensitive, specific, and safe technique in screening for vascular injuries., SUMMARY: Management of ballistic injuries to the head and neck begins with advanced trauma life support protocols. Computed tomography angiography is now widely available and provides an accurate and rapid evaluation of head and neck vasculature. The initial operation aims to establish occlusion, stabilize bone and close soft tissue defects. Serial debridement of wounds with delayed reconstruction has given way to early definitive repair with vascularized tissue. This has led to improved function, fewer operations, and shorter hospital stays.

1421. Doddamreddy, P., et al. (2016). "Critical illness associated with methamphetamine exposure in the central valley of California (crime)." Chest **150**(4): 333A.

PURPOSE: The Stimulant Associated Disease Database (SADD) was established to document the health related consequences of methamphetamine exposure (ME) from a single tertiary care center in the Central Valley of California. This interim analysis focuses on critical illness associated with ME. METHODS: Data was derived from SADD, an ongoing retrospective observational registry study at our institution including all patients with a positive urine drug screen (UDS) for amphetamines, which is used as a surrogate for methamphetamine positive. Of 16,232 UDS ordered from Jan to Dec 2013, 2714 were positive (16.72%). We retrospectively reviewed 688 of these medical charts with a focus on patients with critical illness. RESULTS: Among 688 patients, 56 (8.14%) were admitted to the Intensive Care Unit (ICU). The average age was 45.28 years, and predominantly male (62.5%). 46.45% of the patients were brought to the Emergency Department (ED) for altered mental state (AMS), while 37.5% were brought for trauma. Other chief complaints included “found down” (19.64%), shortness of breath (14.29%), suicidal ideations (7.14%) and seizure (3.57%). Of note, 42.85% of the patients were hypertensive (SBP >140) upon arrival to the ED with an average blood pressure of 183/104 mmHg. Admission locations were: medical ICU (60.71%), trauma ICU (32.14%), burn ICU (5.36%), and surgical ICU (1.78%). The admitting diagnoses included AMS (16.07%), septic shock (12.5%), gunshot wound (10.7%), blunt trauma (7.14%), seizure (7.14%), cerebrovascular hemorrhage (7.14%), stab wounds (5.3%), and motor vehicle collision (5.3%). A few other included auto vs pedestrian, hypertensive emergency, acute kidney injury (AKI), train vs pedestrian, and

respiratory failure. The mean ICU length of stay (LOS) of 7.84 ± 10.78 days. 67.85% required mechanical ventilatory support with an average of 6.18 ± 10.379 ventilator days (VD). 12.5% required vasopressors and coincidentally 12.5% also were bacteremic. 16.07% of the patients had AKI while 5.35% were found to have rhabdomyolysis. However, only one patient (1.78%) required dialysis. Of the 56 ICU admissions, 6 (10.71%) expired in the ICU. Majority of these patients were male (66.67%) with an average age of 47.5 years. All these patients presented with AMS and they had an average ICU LOS of 5.17 days & 4.67 VD. The causes of death included multi-organ failure, multiple cerebral infarcts, cerebral edema, brain herniation, bacterial endocarditis and septic shock. CONCLUSIONS: 1. Amongst all UDS requested over a one year period,16.72% were positive for ME, 8% requiring ICU care. 2. ME was more predominant in young men 3. Hypertension was prevalent (>40%) upon arrival to the ED with an average SBP > 180 mmHg 4. Altered Mental State, Septic shock and Trauma accounted for > 80% of the ICU admissions with an average ICU LOS > 7 days.

1422. Dodge, G. G., et al. (1994). "Gunshot wounds: 10-year experience of a rural, referral trauma center." The American surgeon **60**(6): 401-404.

The 10-year experience of a Level II trauma center with 122 gunshot wounds referred from a large rural area was analyzed to illustrate differences from the experience of urban centers. Most frequent causes of injury were attempted suicide in 38 (31%) patients, hunting mishaps in 32 (26%), unintentional accidents in 29 (24%), and intentional assault in 18 (15%). Of weapons specified, rifles were documented in 48 (39%) instances, shotguns in 25 (21%), and handguns in 24 (20%). Body regions injured were the trunk in 47 (39%) patients, head in 35 (29%), lower extremity in 31 (25%), and upper extremity in 29 (24%). Twenty-five patients (20%) died as a result of their injuries. The cause of death was brain injury in 18 (72%), exsanguination from truncal wounds in 5 (20%), myocardial infarction in 1 (4%), and multiple organ failure in 1 (4%). We conclude that the distributions of cause and type of gunshot wounds are unique in a rural setting. These differences have profound consequences in designing effective prevention programs for our area and support the design of more efficient trauma systems for rural North America.

1423. Dodson, R. F., et al. (1978). "Cerebral tissue response to electrode implantation." The Canadian journal of neurological sciences. Le journal canadien des sciences neurologiques **5**(4): 443-446.

Tissue response to platinum electrodes was assessed after an eight-day implantation period. The regions of study included the cortical areas at the opercular gyri and at the sulcus parieto-occipitalis externus, as well as the sub-cortical white matter in these cases. Perivascular and intraparenchymal hemorrhagic lesions as well as edematous changes characterized both by extensive intra and extracellular swelling were noted. Numerous phagocytic elements and degenerative strucutres were present at the electrode/parenchymal interface. Tissue alterations were asymmetrical as observed both around and at the tip of the implanted electrode. The parenchymal alterations extended from 0.2mm to 3.5mm distance from the electrode path/parenchymal interface. Greater tissue involvement was found in the subcortical white matter as compared to the adjacent cortical gray matter.

1424. Doherty, P. F. and R. P. Rabinowitz (2004). "Gunshot wounds to the head: The role of antibiotics." Infections in Medicine **21**(6): 297-300.

Penetrating craniocerebral injuries are the leading cause of death from head trauma in the civilian population aged 35 to 75 years. In a retrospective review, we identified 19 infectious complications in 59 patients with gunshot wounds to the head who were seen at a trauma center during a period of 3.5 years. The majority of CNS infections identified were related to placement of invasive monitoring devices, specifically ventriculostomies (4 cases of ventriculitis). Most patients received antibiotics at the time of presentation, but few received CNS-specific coverage or extended-duration antibiotic therapy. No relationship could be identified between use of prophylactic antibiotics and risk of infection.

1425. Dohlman, C. H., et al. (1974). "Prosthokeratoplasty." American journal of ophthalmology **77**(5): 694-670.

1426. Dohrmann, G. J. and J. M. Rubin (1997). "Neurotraumatology: ultrasonic evaluation of the central nervous system." Neurological research **19**(3): 317-322.

In this study we describe the technique of intraoperative ultrasound imaging of brain and spinal cord in trauma patients. The images are shown and their interpretation is discussed. This intraoperative imaging allows for localization of hematomas, bone fragments and indriven foreign bodies (i.e., pieces of plastic, glass, metal, etc.). Disc material and bone fragments deep to the spinal cord can be localized with this technique. Real-time ultrasound can be used to guide instruments within the brain and, thereby, provide dynamic guidance for removal of bone fragments and foreign bodies dynamically. In summary, intraoperative real-time ultrasonic imaging is of use to the neurosurgeon in the treatment of the neurotrauma patient.

1427. Dojcinovic, I., et al. (2007). "Unusual ballistic trauma of the face with a less-lethal launcher." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **65**(10): 2105-2107.

1428. Dolachee, A. A., et al. (2019). "Factors affecting the outcome in surgically treated civilian penetrating head injury: Case series." International Journal of Research in Pharmaceutical Sciences **10**(3): 2120-2126.

Penetrating brain injury (PBI) is any injury that causes penetration of the scalp, skull, meninges, and brain. It is a traumatic brain injury caused by either low-velocity sharp objects (e.g. a knife), high-velocity projectiles (shell fragment or bullets) or blast injury is the consequence of the detonation of complex explosives with or without PBI and closed head injury. Aim of the study: To evaluate the factors (pre-operative and operative) that affect the surgical outcome of civilian PBI. This study was done from February 2017 to October 2018 prospectively & retrospectively. The study involved only the civilian patients that got a penetrating head injury and surgically treated in Neurosurgical Teaching Hospital/Baghdad/Iraq. The data include thirty-nine (39) operated patients with PBI. Data information includes the Glasgow Coma Scale (GCS), radiological investigations (computerized tomov graphy (CT-scan) and plain X-ray) the outcome determined by Glasgow Outcome Score (GOS). The patients were followed up during the time of hospitalization. The surgical outcome of the penetrating head injury in this study was assessed by GOS and was as follow, good recovery 10 patients (25.6%), moderately disabled 11 patients (28.2%), severely disabled 5 patients (12.8%), vegetative 6 patients (15.4%), Dead 7 patients (18.0%). Good outcome 21 patients 53.8% while poor outcome 18 patients 46.2%. GCS is significant factor (p-value = 0.002), time not affecting, CT-finding is significant factor (p-value = 0.000), blood pressure >= 90 mm Hg is a good predictor factor (p-value =0.001), speech difficulty is poor predictor factor (p-value = 0.004), outcome of inlet alone better than inlet and outlet. There are many factors affecting the surgical outcome in civilian penetrating head injury, and the significant factor is pre-operative GCS, CT-scan which is the best radiological investigation for pre-operative and postoperative assessment and show the details of the injury, blood pressure > = 90 mm Hg which is a good prognostic factor.

1429. Dolezalova, J., et al. (2001). "[Penetrating intraocular injuries caused by foreign bodies of organic origin]]." Penetrujici poraneni cizim nitroocnim teliskem organickeho puvodu. **57**(6): 381-386.

OBJECTIVE: To demonstrate two eyes of two patients with a penetrating injury by an organic intraocular foreign body (CNT), to outline the course of treatment and to evaluate anatomical and functional results., MATERIAL AND METHODS: During the period between May and July 1999 the authors treated at their department an 11-year-old girl and a 17-year old boy with a penetrating CNT injury of organic origin. In the girl they extracted a CNT which pierced the sclera and protruded into the vitreous body. The foreign body was extracted by means of a forceps, the site of perforation was treated by a cryosurgical procedure with a radial Silastic filling. The man was shot into the OL by a grain of pepper from an air-gun. The organic body in the vitreous body caused a violent inflammatory reaction in the vitreous body and retina. Early extraction of the CNT could not be made because of an adverse corneal finding which made surgery impossible. The progressing proliferative vitreoretinopathy (PVR) led to repeated formation of epiretinal, subretinal and cyclitic membranes which caused relapsing detachment of the retina (OS). The foreign body was extracted during pars plana vitrectomy (PPV) by the transvitreal route using a forceps. Definite adherence of the retina was achieved during the third PPV, membranectomy and implantation of silicone oil (SO). Final functional success was achieved by eliminating SO and by partial perforating keratoplasty., RESULTS: The CNT in the girl was histologically and parasitologically identified as a fibre of animal origin (animal hair or human eyelash). The follow up period is six months, VOP-5/5 nat., NOT 17 torr, bulbus undisturbed. In the second patient the cultivation finding from the vitreous body was negative. Extensive PVR developed as a result of breakdown products of the organic CNT and led to relapsing OS. Three months after the last operation the bulbus is at rest, the corneal disc clear, the retina attached, VOL-3/60 s + 8.0 D

steop., NOT 12 torr., CONCLUSIONS: The final results of treatment of severe devastating penetrating injuries by a CNT is determined by the preoperative condition of the ocular tissues. CNT of organic origin damage intraocular tissues by their breakdown products as well as by more frequent contamination with pathological microorganisms. Our experience provided evidence that penetrating injuries by non-infected CNT of organic origin have a favourable prognosis. But even relapsing and prolonged OS after extraction of the CNT of organic origin and endophthalmitis need not lead to loss of the eye or its function.

1430. Dolinak, D., et al. (2008). "Microscopic and spectroscopic features of gunpowder and its documentation in gunshot wounds in charred bodies." The American journal of forensic medicine and pathology **29**(4): 312-319.

Determining the direction and range of fire of gunshot wounds in charred bodies can be difficult because soot resulting from thermal injury can grossly be identical to soot arising from a contact or close-range firearm discharge. Two charred bodies had gunshot wounds of the head and neck region that were distorted by thermal effect, precluding determination of the direction and range of fire by gross findings alone. By microscopy, deep wound tissue from each charred body had foreign material suggestive of gunpowder. Samples of the foreign material were examined by Fourier transform infrared (FT-IR) microscopy and determined to be cellulose nitrate (nitrocellulose), a main component of gunpowder. In addition, 12 cases of suicide in well-preserved bodies with contact gunshot wounds were examined with FT-IR microscopy, confirming the presence of cellulose nitrate in 6 (50%) of the cases. Identification of cellulose nitrate in the tracks of gunshot wounds can assist in the determination of direction and range of fire when the surface features are charred.

The authors used the intracarotid and subarachnoid methods of infusion of antibiotics for treatment of purulent meningitis, brain abscesses. The methods are considered to be fairly effective.

1433. Domenicucci, M., et al. (1999). "Surgical treatment of penetrating orbito-cranial injuries. Case report." Journal of neurosurgical sciences **43**(3): 229-234.

Penetrating orbital injuries are not frequent but neither are they rare. The various diagnostic and therapeutic problems are related to the nature of the penetrating object, its velocity, shape and size as well as the possibility that it may be partially or wholly retained within the orbit. The authors present another case with unusual characteristics and discuss the strategies available for the best possible treatment of this traumatic pathology in the light of the published data. The patient in this case was a young man involved in a road accident who presented orbito-cerebral penetration caused by a metal rod with a protective plastic cap. Following the accident, the plastic cap (2.5x2 cm) was partially retained in the orbit. At initial clinical examination, damage appeared to be exclusively ophthalmological. Subsequent CT scan demonstrated the degree of intracerebral involvement. The damaged cerebral tissue was removed together with bone fragments via a bifrontal craniotomy, the foreign body was extracted and the dura repaired. Postoperative recovery was normal and there were no neuro-ophthalmological deficits at long-term clinical assessment. Orbito-cranial penetration, which is generally associated with violent injuries caused by high-velocity missiles, may not be suspected in traumas produced by low-velocity objects. Diagnostic orientation largely depends on precise knowledge of the traumatic event and the object responsible. When penetration is suspected and/or the object responsible is inadequately identified, a CT scan is indicated. The type of procedure to adopt for extraction, depends on the size and nature of the retained object. Although the possibility of non-surgical extraction has been described, surgical removal is the safest form of treatment in cases with extensive laceration and brain contusion.

1434. Domenicucci, M., et al. (1995). "Delayed post-traumatic epidural hematoma. A review." Neurosurgical review **18**(2): 109-122.

Post-traumatic acute epidural hematoma (EDH) is generally visible on the CT scan done immediately after admission: occasionally, it only comes to light at a later scan and is then termed delayed (DEDH). Since the introduction of CT, the frequency of this occurrence has gone up from 6-13% to 30%. The mechanisms responsible for the delayed appearance of the epidural hematoma a "tamponade" effect are usually increased endocranial pressure and post-traumatic arterial hypotension as well as, in a limited number of cases, coagulopathy, CSF drainage, and arterio-venous shunt. The authors report 5 of their own cases and 45 published cases and discuss the characteristics of this particular form of hematoma and its outcome.

1435. Domingo, Z., et al. (1994). "Low-velocity penetrating craniocerebral injury in childhood." Pediatric neurosurgery **21**(1): 45-49.

Fifty-four children with low-velocity penetrating injury of the skull and brain are described. The incidence of septic complications was 43%, which is significantly higher than that seen in adults. Nine percent of children developed vascular complications. Due to the high septic complication rate, a more aggressive management protocol consisting of craniectomy and dural repair under antibiotic cover is suggested.

1436. Dominguez-Gil, B., et al. (2017). "End-of-life practices in patients with devastating brain injury in Spain: implications for organ donation." Practicas clinicas al final de la vida en pacientes con dano cerebral catastrofico en Espana: implicaciones para la donacion de organos. **41**(3): 162-173.

OBJECTIVE: To describe end-of-life care practices relevant to organ donation in patients with devastating brain injury in Spain., DESIGN: A multicenter prospective study of a retrospective cohort., PERIOD: 1 November 2014 to 30 April 2015., SETTING: Sixty-eight hospitals authorized for organ procurement., PATIENTS: Patients dying from devastating brain injury (possible donors). Age: 1 month-85 years., PRIMARY ENDPOINTS: Type of care, donation after brain death, donation after circulatory death, intubation/ventilation, referral to the donor coordinator., RESULTS: A total of 1,970 possible donors were identified, of which half received active treatment in an Intensive Care Unit (ICU) until brain death (27%), cardiac arrest (5%) or the withdrawal of life-sustaining therapy (19%). Of the rest, 10% were admitted to the ICU to facilitate organ donation, while 39% were not admitted to the ICU. Of those patients who evolved to a brain death condition (n=695), most transitioned to actual donation (n=446; 64%). Of those who died following the withdrawal of life-sustaining therapy (n=537), 45 (8%) were converted into actual donation after circulatory death donors. The lack of a dedicated donation after circulatory death program was the main reason for non-donation. Thirty-seven percent of the possible donors were not intubated/ventilated at death, mainly because the professional in charge did not consider donation alter discarding therapeutic intubation. Thirty-six percent of the possible donors were never referred to the donor coordinator., CONCLUSIONS: Although deceased donation is optimized in Spain, there are still opportunities for improvement in the identification of possible donors outside the ICU and in the consideration of donation after circulatory death in patients who die following the withdrawal of life-sustaining therapy.

1439. Don Lehmkuhl, L., et al. (1993). "Factors that influence costs and length of stay of persons with traumatic brain injury in acute care and inpatient rehabilitation." Journal of Head Trauma Rehabilitation **8**(2): 88-100.

This study investigated factors that influence the costs (hospital charges) and length of stay (LOS) in acute care and in rehabilitation of 301 persons with traumatic brain injury (TBI). Factors examined included initial severity of brain injury, external cause of injury, blood alcohol level, intracranial operations, and designated payor. As expected, more

severely injured persons had longer LOS and higher charges for both acute care and rehabilitation. Overall mean LOS in acute care was 27 days (standard deviation [SD] = 24) and charges (not including physicians' fees) were $66,368. Overall mean LOS in rehabilitation was 48 days (SD = 47) and charges were $51,416. The external causes of injury resulting in the largest average overall charges (acute care and rehabilitation combined) were motorcycle accidents ($165,294 per case) and gunshot wounds to the head ($164,250 per case). Ninety-five percent of persons included in the study were living in private residences just prior to the onset of their injuries, and 81% were discharged from inpatient rehabilitation to a private residence. No trends were evident regarding the LOS and type of designated payor for rehabilitation services. The results support the premise that the TBI model systems are effective in minimizing the average LOS and in achieving functional benefits that reduce the disability of persons with severe TBI.

1440. Donmez-Demir, B., et al. (2018). "Microembolism of single cortical arterioles can induce spreading depression and ischemic injury; a potential trigger for migraine and related MRI lesions." Brain research **1679**: 84-90.

Increasing epidemiological evidence suggests an association between migraine with aura (MA) and cardiovascular events. There is experimental as well as clinical evidence implying cerebral microembolism as a potential trigger for MA attacks. Microembolism may also account for some of the ischemic MRI lesions more commonly observed in MA than in general population. Limited size of clinically-silent MRI lesions suggests isolated occlusion of a small vessel. However, it is not known whether selective thrombosis of a small arteriole (e.g. single mouse penetrating arteriole - PA), can induce cortical spreading depression (CSD), the putative cause of migraine aura and, hence, trigger an MA attack. For this, we mimiced thrombosis of a small vessel caused by microembolism by selectively occluding a PA just before diving into the cortex (radius; 10-25microm) in the mouse. Clotting was induced with FeCl3 applied focally over the PA by a glass micropipette for 3 min. DC potential changes were recorded and the alterations in cortical blood flow were monitored by laser speckle contrast imaging. Mice were kept alive for 1-4 weeks and brain sections were stained with H&E or luxol-fast blue to evaluate changes induced by PA occlusion. We found that single PA occlusion consistently triggered a CSD originating from the tissue around the PA soon after occlusion and induced delayed, small ischemic lesions within territory of the affected vessel a few weeks later. These findings suggest that cerebral microembolism can lead to MA attacks and may account for some of the silent brain lesions.

1441. Dookie, S., et al. (2016). "Survivors of self-inflicted gunshot head injuries managed at a single neurosurgical unit: A 12-year review." African Journal of Neurological Sciences **35**(2).

Background and objective: Self-inflicted gunshot head injuries (SIGHIs) following suicidal intent (SI) have a high pre-hospital mortality; with survivors representing an exceptional entity. We investigated the prevalence, demographics, and characteristics of these injuries with regards to clinical presentation, computerised tomography (CT) findings, management, and outcomes at discharge. Methods This was a retrospective study of patients admitted to the Department of Neurosurgery at Inkosi Albert Luthuli Central Hospital during January 2003 to September 2014. Patients with craniocerebral gunshot injuries (CGIs) were identified and only those with a history of a SIGHI following SI were included in the study. Results A total of 499 cases of CGI were treated during this period; of which 31(6%) were SIGHI following SI. There were 28 (90%) males (M: F ratio = 9:1). The median age was 32 years, interquartile range (IQR) of 27 - 39 years, and median admission Glasgow Coma Scale (GCS) was 11 (IQR = 8 - 14). The frontal region formed the predominant entry site [12; 39%]. CT brain scan revealed intracerebral haematomas in the majority of patients [29; 93%] and eighteen patients (58%) sustained transaxial injuries. All patients were managed surgically. The median hospital stay was 10 days (IQR = 3 - 19). The median discharge GCS was 13 (IQR = 7 - 14). Seven (23%) patients demised during their stay; having a post resuscitation GCS ≤ 8 (P = 0.018) and age ≥ 39 (P = 0.026). Conclusion This single-centre review highlights the devastating clinical impact of SIGHIs following SI. The post-resuscitation GCS remains an important prognosticating factor.

1443. Dorado, E., et al. (2019). "Suicide by gunshot at the back of the head with a muzzle-loading shooting revolver and homemade ammunition." Legal medicine (Tokyo, Japan) **37**: 60-63.

The present case concerns a 29years-old male with a history of mental disorder, who committed suicide by gunshot at the posterior midline of the head. This location is very rare in suicide cases. The weapon used is the replica of a muzzle-loading Remington Revolver with homemade ammunition prepared with easily available materials such as lead fishing weights, percussion primers, and black powder from firecrackers.

1444. Dorafshar, A. H., et al. (2013). "Total face, double jaw, and tongue transplantation: an evolutionary concept." Plastic and reconstructive surgery **131**(2): 241-251.

BACKGROUND: The central face high-energy avulsive injury has been frequently encountered and predictably managed at the R Adams Cowley Shock Trauma Center. However, despite significant surgical advances and multiple surgical procedures, the ultimate outcome continues to reveal an inanimate, insensate, and suboptimal aesthetic result., METHODS: To effectively address this challenging deformity, a comprehensive multidisciplinary approach was devised. The strategy involved the foundation of a basic science laboratory, the cultivation of a supportive institutional clinical environment, the innovative application of technologies, cadaveric simulations, a real-time clinical rehearsal, and an informed and willing recipient who had the characteristic deformity., RESULTS: After institutional review board and organ procurement organization approval, a total face, double jaw, and tongue transplantation was performed on a 37-year-old man with a central face high-energy avulsive ballistic injury., CONCLUSIONS: This facial transplant represents the most comprehensive transplant performed to date. Through a systematic approach and clinical adherence to fundamental principles of aesthetic surgery, craniofacial surgery, and microsurgery and the innovative application of technologies, restoration of human appearance and function for individuals with a devastating composite disfigurement is now a reality., CLINICAL QUESTION/LEVEL OF EVIDENCE: Therapeutic, V.

1445. Doron, Y., et al. (1982). "Penetrating cranio-cerebral injuries due to unusual foreign bodies." Neurosurgical review **5**(2): 35-40.

Seven cases of penetrating cranio-cerebral injury by peculiar foreign bodies are described. The clinical-pathological picture is reported wherever possible. Lack of adequate safety measures and untrained careless handling of instruments were at the root of these tragic accidents. Greater awareness of such dangers in industry and in school might help to promote the adoption of adequate safety measures.

1446. Doroshow, R. W., et al. (1995). "Availability and selection of donors for pediatric heart transplantation." The Journal of heart and lung transplantation : the official publication of the International Society for Heart Transplantation **14**(1 Pt 1): 52-58.

METHODS: Applying generally accepted criteria for selection of adult heart donors, we conducted a retrospective study of brain-dead infants and children for assessment of suitability as donors for heart transplantation. Cardiac histopathologic studies were evaluated in all subjects undergoing autopsy., RESULTS: In 5 years there were 58 such patients, the majority of whom had head injury, near-drowning, near-miss sudden infant death syndrome, infection, or asphyxia. Of these, only five met the proposed clinical criteria. Most prospective donors were eliminated on the basis of prolonged cardiac arrest (n = 33), pressor dependency (n = 25), and/or infection (n = 10). Forty-two subjects underwent autopsy, of whom 36 would not have been excluded as donors except on the basis of ischemic cardiac insult. Of these, 18 subjects were found to have essentially normal myocardium, nine had abnormal but potentially reversible microscopic changes, and nine had myocardial infarction. The pathologic findings were not predicted by the selection criteria, but severe chest trauma was not associated with infarction, eight of the nine patients with infarction had had cardiac arrest, and most of those with infarction had drowned or had had sudden infant death syndrome., CONCLUSIONS: The supply of donor organs for pediatric heart transplantation is very limited if selection criteria used for adult donors are applied. These criteria, however, do not correlate well with myocardial pathologic findings in infants and children. More accurate predictors of donor suitability are needed.

1447. Dorsemans, A.-C., et al. (2017). "Impaired constitutive and regenerative neurogenesis in adult hyperglycemic zebrafish." The Journal of comparative neurology **525**(3): 442-458.

A growing body of evidence supports hyperglycemia as a putative contributor to several brain dysfunctions observed in diabetes patients, such as impaired memory capacity, neural plasticity, and neurogenic processes. Thanks to the persistence of radial glial cells acting as neural stem cells, the brain of the adult zebrafish constitutes a relevant model to investigate constitutive and injury-induced neurogenesis in adult vertebrates. However, there is limited understanding of the impact of hyperglycemia on brain dysfunction in the zebrafish model. This work aimed at exploring the impact of acute and chronic hyperglycemia on brain homeostasis and neurogenesis. Acute hyperglycemia was shown to promote gene expression of proinflammatory cytokines (il1beta, il6, il8, and tnfalpha) in the brain and chronic hyperglycemia to impair expression of genes involved in the establishment of the blood-brain barrier (claudin 5a, zona occludens 1a and b). Chronic hyperglycemia also decreased brain cell proliferation in most neurogenic niches throughout the forebrain and the midbrain. By using a stab wound telencephalic injury model, the impact of hyperglycemia on brain repair mechanisms was investigated. Whereas the initial step of parenchymal cell proliferation was not affected by acute hyperglycemia, later proliferation of neural progenitors was significantly decreased by chronic hyperglycemia in the injured brain of fish. Taken together, these data offer new evidence highlighting the evolutionary conserved adverse effects of hyperglycemia on neurogenesis and brain healing in zebrafish. In addition, our study reinforces the utility of zebrafish as a robust model for studying the effects of metabolic disorders on the central nervous system. J. Comp. Neurol. 525:442-458, 2017.

1448. Dos Santos, J. H. Z., et al. (2014). "Firearm injury in face: A case report." International Archives of Otorhinolaryngology **18**.

Introduction: Firearms injuries (FI) on the face usually cause great inconvenience to patients and physicians for the noble structures present; the difficulty in managing bleeding nasal, oral, facial, and airway maintenance; besides the possible esthetic and functional sequelae, corroborating high mortality and morbidity. Objectives: This article describes a case of FI occurred in polytrauma unit of the Hospital de Base do Distrito Federal (HBDF), Brazil. Case report: A 19yearold male patient, victim of FI in the face 2 hours ago, hemodynamically stable, admitted to the ENT unit of HBDF. He presented orifice of entry into branch of the right mandible, no exit hole, trismus, moderate bleeding in the right tonsil, and swelling of the retromolar trigone and cheek. He also presented neck pinjury or pain. Result: Tomography showed bone fragments in the lingual region and masticatory space right next to tooth 48 and comminuted fracture of mandible transfixation projectile fragments before the C2 region. The team of oral and maxillofacial surgery removed bone fragments and tooth 48. Cervical Doppler showed carotid and jugular without injury. The patient kept bleeding, developed somnolence, and initiated shock protocol. He opted for surgical intervention. There was extensive laceration of the soft palate, anterior, and posterior pillar, and amygdala lacerated with moderate bleeding. The resection of the amygdala was preceded with cauterizing and suturing the pharyngeal muscles with the removal of prevertebral projectile. The patient evolved with oropharyngeal pain and odynophagia without oral bleeding. Conclusion: Thirty days followup showed good healing without dysphagia or food to reflux nose, mild speech impairment with dysarthria, and referred for speech rehabilitation.

1449. dos Santos Pereira, R., et al. (2014). "Internal maxillary artery pseudoaneurysm subsequent gunshot wound in a teenager." The Journal of craniofacial surgery **25**(3): 1125-1126.

1450. Doskova, H. (2006). "[Evaluation of results of the penetrating injuries with intraocular foreign body with the Ocular Trauma Score (OTS)]." Hodnoceni vysledkiu penetrujicich poraneni s kovovym nitroocnim telesem dle Ocular Trauma Score. **62**(1): 48-52.

UNLABELLED: The goal of the study was to correlate the final functional status with the initial prediction of the OTS in the eyes following the penetrating injury with metallic intraocular body. The group consisted of 20 men (20 eyes), the average age was 35.4 +/- 10.8 years. The average follow up period was 21.0 +/- 10.7 months. In all cases, the penetrating injury with the metallic intraocular foreign body was present. To evaluate the prediction of the final functional status of the organ, the OTS tables were used, and according to their criteria, the initial clinical findings in all 20 eyes were scored. A half of the year after the injury the achieved visual acuity was compared with proportional

prediction in given group according to the final OTS table., RESULTS: In the original prediction according to the score, 6 patients were classified in group 2, 8 patients in the group 3, 4 patients in the group 4, and 2 patients in the group 5. In the final evaluating of the functional status, in the group 2, we achieved in 3 cases 13% of probability of the presumed final visual acuity, in 2 cases 26% of probability, and in one case 18% of probability. In the group 3, we achieved in 7 cases 28% of probability and in 2 cases 44% of probability of the achieved visual acuity. In the group 4, in 3 cases we achieved 21% of probability and in one case 1% of probability. In the group 5, in one case we achieved 92% of the probability and in one case 5% of probability of the final functional status. Introducing the Ocular Trauma Score evaluating system into the practice offers the possibility of simple approximation of the final functional result after six months after the injury.

1451. Dosoglu, M., et al. (1999). "Civilian gunshot wounds to the head." Neuro-Chirurgie **45**(3): 201-207.

BACKGROUND AND PURPOSE: Civilian Gunshot Wounds (GSWs) to the head are important causes of mortality. The severity of GSWs is related to several factors. Patients with GSWs tend to do very well or very poor depending on these factors., METHODS: We retrospectively reviewed 47 patients with GSWs to the head during the last 5 years. Clinical and radiological findings of cases are described. Statistical analysis was used to find the effects of all independent variables with mortality and the prognostic factors., RESULTS: Glasgow Outcome Scale results showed that 38% of patients died, 13% were moderately disabled and 49% had good recovery at discharge. Patients with respiratory depression, hypovolemia, bilateral pupil dilatation, Glasgow Coma Scale (GCS) scores of 3 to 5, central bihemispheric and transventricular injury experienced 100% mortality. The mortality rate was 58% in patients with intracerebral or subdural hematoma, 78% in multilobar injury, 14% in unilobar injury and 57% in self-inflicted wounds. The postoperative mortality was 27%., CONCLUSION: The manuscript describes the clinical experience of penetrating missile injuries in a Turkish civilian practice. Mortality and/or poor outcome are relatively high in spite of the cases wounded by low-velocity weapons. We should emphasize that following stabilization of vital signs, all patients with GCS scores of 3 to 5 should be evaluated immediately with CT and treated conservatively. If it is appropriate the patients with a GCS score higher than 8 should undergo surgery. Patients with GCS scores of 6 to 8 should be followed closely and treated with surgery when necessary even if they have poor prognosis.

1452. Dougall, D., et al. "Pharmacotherapy for chronic cognitive impairment in traumatic brain injury." (12).

Background, Traumatic brain injury (TBI) is a major cause of chronic disability. Worldwide, it is the leading cause of disability in the under 40s, resulting in severe disability in some 150 to 200 million people per annum. In addition to mood and behavioural problems, cognition-particularly memory, attention and executive function-are commonly impaired by TBI. Cognitive problems following TBI are one of the most important factors in determining people's subjective well-being and their quality of life. Drugs are widely used in an attempt to improve cognitive functions. Whilst cholinergic agents in TBI have been reviewed, there has not yet been a systematic review or meta-analysis of the effect on chronic cognitive problems of all centrally acting pharmacological agents., Objectives, To assess the effects of centrally acting pharmacological agents for treatment of chronic cognitive impairment subsequent to traumatic brain injury in adults., Search methods, We searched ALOIS-the Cochrane Dementia and Cognitive Improvement Group's Specialised Register-on 16 November 2013, 23 February 2013, 20 January 2014, and 30 December 2014 using the terms: traumatic OR TBI OR 'brain injury' OR 'brain injuries' OR TBIs OR 'axonal injury' OR 'axonal injuries'. ALOIS contains records of clinical trials identified from monthly searches of a number of major healthcare databases, numerous trial registries and grey literature sources. Supplementary searches were also performed in MEDLINE, EMBASE, PsycINFO, The Cochrane LibraryCINAHL, LILACs, ClinicalTrials.gov, the World Health Organization (WHO) Portal (ICTRP) and Web of Science with conference proceedings., Selection criteria, We included randomised controlled trials (RCTs) assessing the effectiveness of any one centrally acting pharmacological agent that affects one or more of the main neurotransmitter systems in people with chronic traumatic brain injury; and there had to be a minimum of 12 months between the injury and entry into the trial., Data collection and analysis, Two review authors examined titles and abstracts of citations obtained from the search. Relevant articles were retrieved for further assessment. A bibliographic search of relevant papers was conducted. We extracted data using a standardised tool, which included data on the incidence of adverse effects. Where necessary we requested additional unpublished data from study authors. Risk of bias was assessed by a single author., Main results, Only four studies met the criteria for inclusion, with a total of 274 participants. Four pharmacological agents were investigated: modafinil (51 participants); (-)-OSU6162, a monoamine stabiliser (12 participants of which six had a TBI); atomoxetine (60 participants); and rivastigmine (157 participants). A meta-analysis

could not be performed due to the small number and heterogeneity of the studies., Authors' conclusions, There is insufficient evidence to determine whether pharmacological treatment is effective in chronic cognitive impairment in TBI. Whilst there is a positive finding for rivastigmine on one primary measure, all other primary measures were not better than placebo. The positive findings for (-)-OSU6162 are interpreted cautiously as the study was small (n = 6). For modafinil and atomoxetine no positive effects were found. All four drugs appear to be relatively well tolerated, although evidence is sparse.

1453. Doughty, K., et al. (2005). "An unusual case of impalement of the cranium in a child." The Journal of trauma **58**(6): 1290-1293.

1454. Douis, N., et al. (2020). "Metal artifact reduction for intracranial projectiles on post mortem computed tomography." Diagnostic and interventional imaging **101**(3): 177-185.

PURPOSE: To compare the image quality of cranial post-mortem computed tomography (CT) obtained with and without projection-based single-energy metal artifact reduction (SEMAR) in cadavers with intracranial metallic ballistic projectiles., MATERIALS AND METHODS: From January 2017 to January 2018, cadavers with ballistic projectile head wounds with metal fragments and without massive head destruction were investigated using post-mortem CT. All subjects underwent CT using a conventional iterative reconstruction (IR) and SEMAR. To evaluate the impact of metallic artifacts, the total intracranial area (TA), non-interpretable zone (NIZ), disturbed interpretation zone (DZ), and artifact total surface (ATS) were delineated. Two independent readers identified extra-axial hemorrhage (EAH) and subarachnoid hemorrhage (SAH). Autopsy reports were used as the standard of reference., RESULTS: Eleven corpses (10 males, 1 female; mean age, 62.8+/-17.9 [SD] years) were evaluated. SEMAR showed a significant decrease in the ATS ratio with respect to conventional IR (72.1+/-26.1 [SD] % [range: 26.8-99.1] vs. 86.4+/-17.8 [SD] % [range: 37.2-100]; P<0.001) and NIZ/TA ratios (11.6+/-8.26% [range: 0.95-33.4] versus 42.5+/-30.5% [range: 3.86-100]; P<0.001). The interobserver reproducibility in diagnosing EAH and SAH was excellent with conventional IR (0.82) and good with SEMAR (0.75). SEMAR reduced uncertain diagnoses of EAH in 7 subjects for Reader 1 and in 6 for Reader 2, but did not influence the diagnosis of SAH for either reader., CONCLUSION: SEMAR reduces the influence of metallic artifacts and increases the confidence with which the diagnosis of EAH can be made on post-mortem CT.

1455. Dovlatian, A. A. and I. V. Cherkasov (2003). "[Injuries of the urogenital system]." Travmy organov mochepolovoi sistemy.(4): 52-57.

To analyse the results of treatment of isolated and concomitant urogenital injuries, a retrospective analysis was made of 608 case histories for patients treated in 1986-2000. Of them, 530 patients were males, 78 were females, the age ranged from 16 to 70 years, most of the patients were 20 to 50 (71.2%) years of age. Most frequently the injury was inflicted by beating. Fall from the height, transport accidents ranked second among the causes of injury (17 and 14.3%, respectively). Stab and gunshot injuries occurred in 4.4 and 8% cases, respectively. Ultrasound and x-ray methods were employed for examination. An isolated injury was found in 481 patients, the rest had urogenital injury and skeletal (53%), craniocerebral (25%), abdominal (20%) lesions. 29 patients had a severe concomitant wound: urogenital injury combined with abdominal, skeletal, cranial lesions. Surgery was performed in 267 patients. The rest patients received conservative treatment. Most of the operations were made on the kidney and urinary bladder because of rupture. In some patients these interventions were conducted during laparotomy and were combined with abdominal intervention (44 cases). 25 patients with the compound injury underwent 2-stage operations. 552 patients were cured. 56 (9.2%) lethal outcomes were due to progression of traumatic shock. This low percent of lethality may be explained by an optimal choice of treatment policy in the above patients.

1456. Dovlatian, A. A. and I. V. Cherkasov (2003). "[Results of treatment of isolated and combined trauma of urogenital system]." Rezul'taty lecheniia izolirovannoi i sochetannoi travmy organov mochepolovoi systemy.(5): 53-58.

Retrospective analysis of treatment results of 608 patients with trauma of organs of urogenital system (UGS) was carried out. Beating was the cause of trauma in 55% cases, fall from height--in 17%, transport trauma--in 14.3%, knife wound--in 4.4%, gunshort wound--in 1.3%. Isolated trauma of UGS was in 481 (79.1%) patients. In other patients

combined injury of UGS with injury of skeleton's bones (53), cranium and brain (25), abdominal organs (20) was diagnosed. In 29 patients severe combined trauma of UGS, abdominal organs, skeleton bones and cranium was seen. Surgeries were performed in 267 patients. Surgeries on kidney and urinary bladder due to their disruption predominated. In 44 patients these surgeries were combined with ones on abdominal organs. Surgery was performed in two stages in 25 patients with combined trauma of UGS and other organs. From 608 patients 552 (90.2%) cured. Lethal outcome was in 56 (9.2%) patients due to progressive traumatic shock.

1457. Dow, R., et al. (2018). "Interventional Removal of Traumatic Nail from Skull Base After Endovascular Coiling of Internal Carotid Artery and Jugular Vein." World neurosurgery **115**: 138-142.

BACKGROUND: Cases of nail gun injuries to the head and neck are rare, and treatment approach varies with each case based on location and extent of injury., CASE DESCRIPTION: We present a case of a 52-year-old male who fell off a roof holding a pneumatic nail gun and accidentally shot himself with a nail through the right frontal neck region. The nail penetrated the right sternocleidomastoid muscle and extended intracranially through the right occipital condyle with its tip embedded in the right cerebellar hemisphere. The nail coursed between the right distal cervical internal jugular vein and right internal carotid artery. There was no evidence of vascular injury on initial imaging. The barbs of the nail abutted the right sigmoid sinus, making for high risk of tear and intracranial hemorrhage on manual nail extraction. Therefore preemptive coil embolization of the right dural venous sigmoid and occipital sinuses and internal jugular bulb was performed before attempted nail removal. Using biplane fluoroscopy, orthopedic screw removal plyers were successful in snaring the head of the nail. On initial removal attempt, the head of the nail injured the distal right cervical internal carotid artery, requiring endovascular coil embolization. The nail was then successfully extracted from the neck without further immediate complications., CONCLUSION: Use of biplane fluoroscopy and preemptive endovascular embolization makes a nonsurgical approach to penetrating skull base injuries feasible. Despite improving right visual loss related to the right internal carotid artery embolization, the patient had no new focal neurologic deficits on 1-month outpatient follow-up.

1458. Dowlati, E., et al. (2020). "The Retro-Auricular Incision as a Safe and Effective Alternative for Decompressive Hemicraniectomy." Clinical neurosurgery **67**(SUPPL 1): 148-149.

INTRODUCTION: The decompressive hemicraniectomy (DHC) is used to relieve refractory intracranial hypertension to prevent fatal brainstem compression. Traditionally, the reverse question mark (RQM) incision is utilized, placing the scalp blood supply at risk of injury. METHODS: We performed a retrospective review of all DHCs over a span of 30 months (July 2017-Dec 2019) at our institution and stratified them based on incision: RQM vs. RA. Exclusion criteria included: other incisions, bilateral DHC, penetrating injury to the head, and lack of postoperative imaging. The surface areas of the cranial defect were measured. To normalize measurements and account for difference in cranium size, defect to skull diameter ratios were also measured. Additionally, a review of clinical outcomes, including complications were collected from both cohorts and analyzed. RESULTS: A total of 47 patients in the RQM group and 35 in the RA group. The average surface area for the RA and RQM incisions were 116.9cm2 and 109.2cm2 (P = .017), respectively. Average defect: skull ratio for RA incision was 0.813 compared to 0.784 for the RQM group (P = .019). Of those who survived beyond one-week, the absolute risk for wound and surgical site complications were 7.14% and 17.78% for RA and RQM group, respectively. CONCLUSION: We present a safe and effective alternative incision to the traditional RQM incision used for DHC. The RA incision provides exposure for a larger hemicranium defect and also may lead to less wound complications by preserving major arterial blood supply to the scalp.

1459. Downey, R., et al. (2010). "MDCT evaluation of acute eye pain in the ED." Emergency radiology **17**(6): 545.

Purpose: The objectives of this exhibit are to review normal orbital anatomy and to discuss the various causes of acute eye pain in the emergency department (ED) setting and their radiologic appearance on multidetector CT (MDCT), with an emphasis on the most relevant clinical findings. Materials and Methods: For patients presenting to the ED with acute eye pain, the potential for serious adverse outcome, such as loss of vision or even death, necessitates an accurate and timely diagnosis so that appropriate treatment can be initiated. MDCT is the preferred initial imaging test for the evaluation of acute eye pain in the ED setting. The radiologist must be familiar with the complex anatomy of the orbit and the MDCT findings of the different causes of acute eye pain. Results: The normal orbital anatomy by MDCT will be illustrated and reviewed, with special attention to definitions of orbital compartments. The MDCT appearance of the

orbit acutely involved by blunt or penetrating trauma, infection, inflammation and vascular disease will be discussed and representative cases provided with accompanying surgical and pathological correlation where available. Conclusion: In patients with acute eye pain in the ED, it is imperative that an accurate and timely diagnosis is rendered due to the potential for poor clinical outcome. MDCT plays an essential role in the initial evaluation and diagnosis of acute eye pain in the ED setting. Familiarity with the various pathological entities that result in acute eye pain and their imaging appearance is important to facilitate treatment and optimize clinical outcome.

1460. Downs, C., et al. (2021). "Injuries in Netball-A Systematic Review." Sports Medicine - Open **7**(1).

Background: Netball is estimated to be played by more than 20 million people worldwide, but there is evidence of high injury incidence. A thorough understanding of the types and rates of netball injuries is essential for effective injury management and prevention strategies to be developed and implemented. This systematic review summarises the published findings with respect to injury types, participant characteristics and any identified risk factors for netball injuries. Methods: A librarian-assisted computer search of seven scientific databases was conducted for studies reporting on netball injuries. Inclusion criteria were studies published in English, in peer-reviewed journals, which reported data on injuries and variables (e.g. age and competition level) that have been proposed as possibly associated with netball injury risk. Results: Forty-six studies (43.5% prospective, 37% hospital/insurance records, 19.5% retrospective) from 45 articles were included after screening. The majority of studies (74%) were conducted in Australia or New Zealand. There was little consistency in the definition of 'injury'. Elite or sub-elite level players were included in 69% of studies where the level of competition was reported. The duration of injury surveillance was generally related to the format of competition from which data were collected. Self-report questionnaires were used in 48% of studies and only 26% of studies used qualified health professionals to collect data courtside. Injuries to the ankle and knee were the most common (in 19 studies) although the incidence varied considerably across the studies (ankle 13–84% and knee 8–50% of injuries). Prevention of ankle and knee injuries should be a priority. Children sustained more upper limb injuries (e.g. fractures) compared with adults who sustained more lower limb injuries (e.g. ankle and knee sprains/strains). A large number of potential risk factors for injury in netball have been investigated in small numbers of studies. The main circumstances of injury are landings, collisions and falls. Conclusion: Further studies should be directed towards recreational netball, reporting on injury incidence in players by age and utilising high-quality, standardised methods and criteria. Specific injury diagnosis and a better understanding of the circumstances and mechanisms of injury would provide more meaningful data for developing prevention strategies.

1461. Doyon, D., et al. (1979). "[Facial artery injury from a bullet wound discovered after arteriography (author's transl)]." Decouverte arteriographique d'une plaie balistique de l'artere faciale. **80**(1): 23-25.

Signs of a fracture of the mandible and a submaxillary hematoma were present in a patient wounded by a bullet. Selective carotid arteriography by femoral catheterization revealed the presence of sectioning of the facial artery at its origin and underlying external carotid stenosis. Hemorrhagic complications or aneurysm formation could have occurred if the lesion had not been demonstrated. Though arteriography is not without risks, it is irreplaceable for investigating cervicofacial injuries when a vascular lesion is suspected.

1462. Dragojlovic, N. and S. Pandit (2014). "Bilateral bell-s palsy in the setting of traumatic brain injury: A case report." PM and R **6**(9): S334.

Case Description: Patient: A 30-year-old man undergoing inpatient rehabilitation for a traumatic brain injury. The patient sustained a gunshot wound to the right parieto-occipital region and underwent emergent surgery. Eight days later, he was transferred to inpatient rehabilitation due to left hemiparesis and spasticity. On day ten of rehabilitation, he reported numbness and tingling on the left side of his face, and the next day he developed left facial paralysis. Over the next week, his symptoms worsened and progressed to bilateral facial paralysis with dysphagia. An initial modified barium swallow study demonstrated oral but no pharyngeal weakness. Extensive work up including computed tomography (CT) scans, laboratory testing, and electrodiagnostics were unremarkable. Magnetic resonance imaging (MRI) could not be completed due to retained bullet fragments. Setting: Community rehabilitation hospital. Results or Clinical Course: Despite the progression of his facial symptoms, his left hemiparesis and spasticity continued to improve with therapy. At the time of discharge, his symptoms had improved enough to safely resume a regular diet. In outpatient follow-up, the patient-s facial weakness was slowly resolving at two months, and completely resolved by

four months. He was diagnosed with bilateral Bell-s palsy as a diagnosis of exclusion. Discussion: Delayed facial palsy in traumatic brain injury has an estimated incidence of 0.6-2.2% and is associated with basilar skull fractures. Other causes include Lyme disease, Guillain-Barre syndrome, sarcoidosis, and viral infection. Bell-s palsy can impair function by negatively affecting hygiene, feeding, and self-perception. Those with concomitant traumatic brain injury are at increased risk for functional impairment due to pre-existing limitations in self-care and activities of daily living. Conclusions: Bilateral Bell-s palsy should be considered in the setting of new bilateral facial weakness when evaluation for other diseases is negative. Diagnosis in polytrauma is made difficult by co-existing neurologic, musculoskeletal, and medical comorbidities.

1463. Dricken, J., et al. (2013). "Ventilator associated pneumonia rates in a trauma ICU: The impact of traumatic brain injury." Critical care medicine **41**(12): A275.

Introduction: Ventilator -associated pneumonia (VAP) is a common occurrence in critically-ill trauma patients. The National Healthcare Safety Network has established national benchmarks for VAP rates in trauma intensive care units (ICU). The purpose of this study is to assess the effect of traumatic brain injury on VAP rates in a trauma ICU. Methods: Retrospective data were collected from the 5-year period (1/08-12/12) through chart review on all patients ventilated greater than 48 hours in a trauma ICU. All VAPs were diagnosed with bronchoalveolar lavage with greater than 10 to the 4th CFU/ml as diagnostic criteria. Patients were divided into two cohorts: Those patients intubated for altered mental status with traumatic brain injury (TBI) diagnosed by CT scan and those without evidence of TBI. Results: During the study period, 729 patients were ventilated greater than 48 hours. 616 (84%) were blunt trauma patients and 113 (16%) were injured secondary to penetrating trauma. 407(56%) patients were diagnosed with TBI, of which 124 (30%) developed VAP. 322 (44%) patients without TBI were intubated greater than 48 hours, 75 (23%) of which developed VAP ($P<0.05$). Average vent days for TBI patients was 10.7 days and 10.3 days for non-TBI patients ($P>0.05$). VAP rate for all patients was 23.1 VAPs/1000 vent days. VAP rate for TBI patients was 28.2 VAPs/1000 vent days and 22.5 for non-TBI patients ($P<0.05$). Conclusions: The TBI population has higher VAP rates than non-TBI patients. Trauma ICUs that admit a disproportionate number of TBI patients should be expected to have higher VAP rates than current national benchmarks.

1464. Driscoll, D. M., et al. (2012). "Empathic deficits in combat veterans with traumatic brain injury: a voxel-based lesion-symptom mapping study." Cognitive and behavioral neurology : official journal of the Society for Behavioral and Cognitive Neurology **25**(4): 160-166.

OBJECTIVE: To understand better which brain regions support emotional empathy., BACKGROUND: Emotional empathy, the ability to interpret and share the affective states of others, is a key component in human social interaction. Previous research has suggested that emotional empathy relies on several distinct brain regions, although further evidence from human lesion studies is needed to determine which regions are critical., METHODS: We studied 192 male Vietnam combat veterans who had sustained focal penetrating traumatic brain injuries, and 54 non-brain-injured veterans. We used voxel-based lesion-symptom mapping on computed tomographic scans to elucidate the neural bases of self-reported emotional empathy as measured by the Balanced Emotional Empathy Scale., RESULTS: Damage in several brain regions, particularly the ventrolateral prefrontal cortex, left and right posterior temporal lobes, and insula, was associated with diminished emotional empathy., CONCLUSIONS: These findings provide further insight into the neural substrates of emotional empathy, and are consistent with the notion that emotional empathy is supported by a distributed network of brain regions. Additional work may advance our understanding of the empathic deficits commonly observed in patients with neurologic and psychiatric disorders.

1465. Drosos, E., et al. (2018). "Pediatric Nonmissile Penetrating Head Injury: Case Series and Literature Review." World neurosurgery **110**: 193-205.

BACKGROUND: Pediatric nonmissile penetrating head injury (NMPHI) is usually accidental attributed mainly to the softer skulls of growing children. However, it is a rare entity, and therefore no consensus exists regarding treatment to effectively prevent immediate and long-term complications. Throughout the literature, these injuries are mostly discussed in case reviews and case series in the general population. No data originating from randomized studies are available because of ethical and practical limitations., METHODS: We retrospectively studied and present 5 cases of children with NMPHI treated in the last 6 years in the Neurosurgery Department of Children's Hospital "Aghia Sofia". We

performed a review of the literature in PubMed, using the key words "non-missile," "penetrating head injury," and "pediatric." We included case reports and case series involving pediatric cases since 2008 and selected older reports as well as certain literature reviews focusing on analysis of complications and treatment suggestions. We compared reported practice in various institutions with suggestions from the literature., RESULTS: In the last year, 4 literature reviews were published suggesting treatment algorithms of NMPHIs. Surgery timing and method as well as anticonvulsant and antibiotic therapy still remain debatable. The only review concentrating on pediatric populations dates back to 1994, based on patient outcome studies from the 1980s. In our review, treatment steps were similar among various institutions and resembled recently suggested algorithms, with better treatment outcomes than originally reported 30 years ago.

1466. Drubach, D. A., et al. (1994). "Brain SPECT in a case of cortical blindness." Stroke **25**(5): 1061-1064.

BACKGROUND: Published reports on patients with cortical blindness describe bilateral brain hemispheric lesions visualized in radiological and functional imaging studies., CASE DESCRIPTION: We present a case with a unilateral lesion on radiological studies and bilateral abnormalities on single-photon emission-computed tomographic (SPECT) scanning., CONCLUSIONS: SPECT images correlated much more closely than radiological studies with the patient's clinical status. We suggest that SPECT scanning can be a useful indicator of focal brain dysfunction in brain injury in spite of normal radiological studies. We also hypothesize that our patient's clinical and functional imaging findings could be attributed in part to the process of diaschisis.

1467. du Toit, D. F., et al. (2003). "Neurologic outcome after penetrating extracranial arterial trauma." Journal of vascular surgery **38**(2): 257-262.

PURPOSE: We undertook this study to determine factors that adversely affect outcome in patients with penetrating injury to the extracranial cerebral vasculature. Patients and methods Medical records were reviewed for all patients who had undergone surgical intervention to treat penetrating injury to the extracranial cerebral arteries between January 1989 and December 1999. Forensic autopsy findings were also reviewed for all patients who died as a result of their injury., RESULTS: One hundred fifty-one patients with injury to the brachiocephalic artery (n = 21), common carotid artery (n = 98), or internal carotid artery (n = 32) were identified. Overall mortality was 21.2%, and stroke rate in surviving patients was 15.1%. Twenty-five of 32 deaths (78.1%) were stroke-related. Brachiocephalic artery injury was associated with the highest mortality (38.1%), and survivor stroke rate was highest in patients with internal carotid injuries (22.7%). Hemodynamic instability at presentation led to both higher mortality (30.7%) and stroke rate (19.2%). Preoperative angiography did not influence mortality or stroke rate in hemodynamically stable patients. Procedural mortality associated with arterial ligation was 45% (9 of 20 patients), and no surviving patient experienced a change in pre-ligation neurologic state. Nine patients remained neurologically intact after ligation, and 2 patients with preoperative localized neurologic deficit were unchanged postoperatively. In 131 patients, mortality after arterial repair was 17.6%, and in 5 surviving patients (5.4%) an ischemic neurologic deficit developed. Twelve of 15 surviving patients (80%) with preoperative neurologic deficit who underwent arterial repair had improved neurologic status. Cerebral infarcts were confirmed at autopsy in 23 patients; 18 infarcts were ischemic (10, repair; 8, ligation), and 5 infarcts were hemorrhagic (all, repair). No factor was identified that was predictive of ischemic versus hemorrhagic infarction in patients undergoing repair., CONCLUSIONS: The presence of hypovolemic shock, internal carotid artery injury, complete vessel transection, and arterial ligation are associated with unfavorable outcome. Penetrating injury to the brachiocephalic, common carotid, or internal carotid artery should be repaired rather than ligated when technically possible. Subsequent ischemic or hemorrhagic cerebral infarction is unpredictable, but overall outcome is superior to that with ligation of the injured artery.

1468. du Trevou, M. D. and J. R. van Dellen (1992). "Penetrating stab wounds to the brain: the timing of angiography in patients presenting with the weapon already removed." Neurosurgery **31**(5): 905-902.

Angiography is always necessary in patients with penetrating stab wounds to the head, to exclude unexpected vascular lesions. The most important, since they are seldom clinically evident, are traumatic aneurysms and arteriovenous fistulae. It has previously been proposed that carotid angiography should be delayed until the start of the second week, to allow for better visualization of these complications. However, traumatic aneurysms can rupture at any time after the injury, and the mortality resulting from a second hemorrhage is unacceptably high. A prospective study

was undertaken in which 330 patients with penetrating stab wounds to the head underwent angiography as soon as possible after admission. In 250 of these patients (76%), the weapon had already been removed by the assailant, and there was radiological evidence of penetration of the dura. Of these 250, 130 patients underwent angiography within 7 days of the injury. Another 51 patients, who presented late, underwent angiography more than 7 days after the injury. The timing of angiography did not affect the identification of traumatic aneurysms, the incidence of which was 12% in both groups. Of the patients with cranial stabs and who required urgent evacuation of intracerebral hematomas, 10% had traumatic aneurysms that could be dealt with simultaneously. No patient in this series suffered a secondary hemorrhage. We conclude that it is neither necessary nor safe to delay angiography. In some patients, either because of vasospasm or "cut-off" of a vessel, a second angiogram may be necessary to further elucidate a vascular abnormality that might not have been evident originally.

1469. Duan, R., et al. (2018). "A Penetrating Facial Wound With Burn Injury." The Journal of craniofacial surgery **29**(7): 1900-1902.

A patient presented with a complex penetrating facial wound by high temperature steel. The hot steel penetrated right temple, ethmoid bone, and maxillary sinus, and then exited from his left cheek. He kept his right eye but lost his sight. For functional and esthetic considerations, treatments were provided in a staged procedure. First, the debridement was performed under the endoscope. The dead bone was removed, broken teeth were extracted, and necrotic tissue was cleaned. The exposed wounds were cleaned, and dressing was changed daily until the exudation was widely reduced. Then, a 50-mL expander was placed in the left cheek, and an 80-mL expander was put in the scalp just before the defect in the temple area. Five months later, expander inflation was accomplished. Expanders were taken out and expanded flaps were transposed to cover the defect. At the same time, an anterolateral thigh flap was harvested to repair the inner lining of the cheek and the gingiva. Thereafter, several operations were performed to revise the wound scar and the remaining deformity. Both defects in the temple and left cheek were restored with a satisfactory functional and aesthetic outcome. The temporal area was repaired with haired expanded scalp, whereas the face was repaired with an expanded facial flap with similar texture and color. The oral commissure regained balance and integrity. The defect of the gingiva was repaired. A severe penetrating wound in the cranium and face can be nicely repaired using tissue expander and microvascular reconstruction.

1470. Duane, T. M., et al. (2002). "Endovascular carotid stenting after trauma." The Journal of trauma **52**(1): 149-153.

1471. Duarte, J. N. and J. Cavaleiro (2015). "Traumatismo crânio-encefálico penetrante múltiplo por pistola de pregos: Descrição de um caso e revisão da literatura." Sinapse **15**(1): 27-30.

Introduction: Penetrating brain trauma by pneumatic nail gun is rare and is frequently associated with suicide attempts. Case report: We report a case of a 46 year old male with a self inflicted injury by 13 nails in the head caused by a pneumatic nail gun. At the admission the patient had a Glasgow Coma Scale score of 15 and didn’t have any neurological deficit. The brain CT show 13 nails in the head, 11 of which penetrating the brain. The angio-CT didn’t show any vascular damage. After these studies the patient was submitted to a surgical procedure to remove the nail, followed by a period of antibiotics and anti-epileptic drugs and was discharged without any neurological deficits. Because it was a probable suicide attempt, he was directed to psychiatric care. Discussion: Although the diagnosis is based in clinical history and physical examination, the brain CT is essential because besides the diagnosis it allows planning the treatment. Even though the occurrence of vascular lesions is rare, the angiographic studies are recommended in most cases. Conservative treatment can be an option in some patients, although in the majority the main goal is the removal of the nails. The prognosis is based in several factors, namely the neurological condition in the admission, the type of nail gun, the intentionality of the incident, the multiplicity and the local of the trauma, the presence of vascular damage and/or haemorrhages and the period between the incident and the treatment.

1472. Dubernard, X., et al. (2020). "Attempted suicide with a crossbow." European annals of otorhinolaryngology, head and neck diseases **137**(6): 493-495.

INTRODUCTION: Airway management and control of bleeding are essential aspects of the management of attempted suicide involving the head and neck. Attempted suicide using a crossbow is exceptional. The patient's

respiratory status, the position of the crossbow bolt in the head and neck, the type of bolt and its exit wound required airway management that has not been previously reported in the literature., CASE REPORT: This conscious patient had attempted suicide by shooting a crossbow bolt to the head. The radiological assessment (contrast-enhanced CT scan) did not reveal any vascular, ophthalmological or neurological lesions. The submental entry wound of the bolt avoided any damage to the lingual and ethmoidal arteries, lamina papyracea, or frontal lobe. The bolt induced mechanical trismus and its position limited access to the base of the neck, preventing orotracheal intubation. Nasotracheal intubation and primary tracheotomy were also difficult in this situation. It was therefore decided to remove the bolt while the patient was still conscious, rapidly followed by intubation, with no complications., CONCLUSION: In attempted suicide by crossbow involving the head and neck, airway management depends on the possibility of exposure of the glottis, the bolt exit wound and safe access to the anterior neck.

1473. Dubey, A., et al. (2008). "Traumatic intracranial aneurysm: a brief review." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **15**(6): 609-612.

Traumatic intracranial aneurysms are uncommon and represent fewer than 1% of all cerebral aneurysms. They may develop after blunt or penetrating head injuries and can present both diagnostic challenges and surgical difficulties. Because traumatic aneurysms are fragile and prone to rupture, early diagnosis with cerebral angiography and prompt treatment are essential. We present two patients with traumatic aneurysms and discuss their aetiology, classification, clinical presentations, diagnosis, and treatment options.

1474. Dubiel, R., et al. (2020). "Baseline Characteristics For Differences Between Men And Women With Violence-Related Etiology Using National Traumatic Brain Injury Model Systems Database: 1989-2019." Archives of physical medicine and rehabilitation **101**(12): e131.

Research Objectives: To identify differences between men and women with violence-related etiology (VRE) traumatic brain injury (TBI). Design: Cross-sectional. Setting: Inpatient rehabilitation. Participants: Individuals >16 years old with TBI VRE and enrolled in the TBI Model Systems. Interventions: None. Main Outcome Measures: TBI VRE measured by ICD-9/10 and cause of injury category. Results: Of 4,729 women, 267 (5.6%) had VRE. Of 13,049 males, 1696 (13%) had VRE. Compared to men, women with VRE were older and more educated, more often had a history of prior mental health problems, psychiatric hospitalization, and special education, but not prior TBI, were less likely to be abusing alcohol, be using illicit drugs, or to have a prior felony conviction, were less frequently employed, married, and covered by private insurance, and were less likely to have past military service ($p < .05$). Women with VRE were more often injured via gunshot wound or other violence (e.g., assault), whereas men with VRE were more likely to have been assaulted with a blunt instrument ($p < .001$). Men with VRE took longer to follow commands post-injury ($p = .027$), had poorer functional cognition at discharge ($p = .023$), and were more likely to live with a spouse/significant other vs other relatives ($p < .001$) compared to women. Conclusions: Men with VRE had more indicators of being perpetrators of violence (e.g. alcohol abuse, prior felony), whereas women with VRE had more indicators of being victims of violence (e.g. mental health history, unemployed). VRE may be missed due to participants' consciousness state upon hospital presentation post TBI or due to inability/unwillingness to divulge sensitive intimate partner violence information at intake. Standard and routine screening for VRE upon admission to the emergency setting is recommended. Author(s) Disclosures: No disclosures. Keywords: Violence, Traumatic Brain Injury, Predictors

---

1475. Dubose, J., et al. (2011). "Combat-related traumatic brain injury: A prospective study of demographics and risk for early mortality." Critical care medicine **39**: 48.

Introduction: Combat-related TBI (CRTBI) is known to be associated with significant mortality. The purpose of our present examination was to examine the demographics of CRTBI and determine the early factors associated with in-theater death after these injuries. Methods: A prospective sample of 99 consecutive CRTBI patients (GCS < 14 on admission or penetrating TBI) was collected from both Coalition casualties and injured Host Nationals presenting to level II or III facilities. Admission variables (demographics, exam, labs, imaging) were documented and correlated with theater mortality. Results: Patients were mostly male (96.0%) and had sustained injury due to explosive mechanisms (78.6%). Penetrating brain injuries occurred in 42.9%. On arrival at a hospital facility, GCS was < or = 8 in 47.7%, with abnormal admission pupillary exams in 31.6%, and abnormal motor exams in 41.7%. Hypercarbia ($paCO_2$ >45; 50%) and hypocarbia ($paCO_2$ <36; 20.3%) were common on admission. Head CT results were documented for 74 patients. The

most common findings were skull fracture (68.9%), subdural hematoma (54.1%) and cerebral contusion (51.4%). Hypertonic saline (3%) was administered to 69.7%, and Factor VIIa to 11.1%. Overall in-theater mortality was 19.4%. On univariate evaluation, significant increases of in-theater mortality after CRTBI were associated with penetrating brain injury (p = 0.003), GCS < = 8 on admission (p<0.001), hypoxia (spO2 <90%) within the first 24 hours of admission (p = 0.002), massive transfusion (p = 0.025), GCS < = 8 and an abnormal head CT (p = 0.018), GCS < = 8 and any hypotension in the first 72 hours of admission (p = 0.007), abnormal admission pupillary exam (p<0.001), and abnormal admission motor exam (p = 0.001). Conclusions: CRTBI is associated with significant mortality. Opportunities exist for the potential improvement in the pre-hospital care of CRTBI, particularly optimization of pCO2 levels and avoidance of hypoxia.

1476. DuBose, J. J., et al. (2011). "Isolated severe traumatic brain injuries sustained during combat operations: demographics, mortality outcomes, and lessons to be learned from contrasts to civilian counterparts." The Journal of trauma **70**(1): 11-18.

BACKGROUND: Severe traumatic brain injuries occurring in the context of modern military conflict are entities about which little has been reported. We reviewed the epidemiology of these injuries from the Joint Trauma Theater Registry (JTTR), contrasting these results with civilian counterparts from the National Trauma Databank (NTDB)., METHODS: Isolated severe brain injuries (defined as head abbreviated injury scale [AIS] >=3 and no other body region AIS>2) were queried from the JTTR over a period from 2003 to 2007. The demographics and outcomes of these injuries were reviewed. These results were then contrasted to findings of similar patients, age 18 years to 55 years, over the same period from the NTDB using propensity score matching derived from age, gender, systolic blood pressure, Glasgow Coma Scale, and AIS., RESULTS: JTTR review identified 604 patients meeting study criteria, with a mean age of 25.7 years. Glasgow Coma Scale was <=8 in 27.8%, and 98.0% were men. Hypotension at presentation was noted in 5.5%. Blast (61.9%) and gunshot wound (19.5%) mechanisms accounted for the majority of combat injuries. Intracranial pressure monitoring was used in 15.2%, and 27.0% underwent some form of operative cranial decompression, lobectomy, or debridement. When compared with matched civilian NTDB counterparts, JTTR patients were significantly more likely to undergo intracranial pressure monitoring (13.8% vs. 1.7%; p<0.001) and operative neurosurgical intervention (21.5% vs. 7.2%; p<0.001). Mortality was also significantly better among military casualties overall (7.7% vs. 21.0%; p<0.001; odds ratio, 0.32 [0.16-0.61]) and particularly after penetrating mechanisms of injury (5.6% vs. 47.9%; p<0.001; odds ratio, 0.07 [0.02-0.20]) compared with propensity score-matched NTDB counterparts., CONCLUSION: Patients sustaining severe traumatic brain injury during military operations represent a unique population. Comparison with civilian counterparts has inherent limitations but reveals higher rates of neurosurgical intervention performed after penetrating injuries and a corresponding improvement in survival. Many factors likely contribute to these findings, which highlight the need for additional research on the optimal management of penetrating brain injury.

1477. Duch-Samper, A. M., et al. (1998). "Endophthalmitis following open-globe injuries." Current opinion in ophthalmology **9**(3): 59-65.

Endophthalmitis following open-globe injuries is caused by a specific range of microorganisms, of which Bacillus sp. and coagulase-negative Staphylococcus are the most frequent. Risk factors include the presence of an intraocular foreign body, injury inflicted by organic material, delay in surgery, and the type of wound involved. Despite important advances in medical and surgical management, this type of endophthalmitis continues to pose a poor prognosis. In this sense, we consider prevention to be the best approach. We report our protocols for the prevention and treatment of endophthalmitis following open-globe injuries, based on recent experimental studies on the ocular pharmacokinetics of antibiotics and on multicenter studies of the treatment of endophthalmitis.

1478. Duckworth, J. L. (2012). "23.4% Hypertonic saline in the management of increased intracranial pressure associated with combat related traumatic brain injury." Neurocritical care **17**: S102.

Introduction: 23.4% hypertonic saline is used for the treatment of increased intracranial pressure (ICP) and in the prevention and reversal of brain herniation syndromes. The use of hypertonic saline in the management of combat related penetrating and severe traumatic brain injury is described. 23.4 % hypertonic saline effectively managed ICP with decreased risk of hypovolemia and secondary hypotension compared with Mannitol. 23.4% hypertonic saline also preserved cerebral blood flow, decreasing the risk for secondary cerebral ischemia in acute neurotrauma patients, where hyperventilation is contraindicated. Methods: The NATO hospital, Kandahar Afghanistan treated eleven (11)

patients with twenty-seven (27) doses of 23.4% saline from 3-March 2012 to 25-April 2012. Hypertonic saline was used to treat acute elevation in ICP, as well as to maintain an elevated serum sodium concentration during periods of cerebral edema. All patients were treated with initial conservative ICP management. External ventricular drains were placed and drainage of 5-10cc of CSF was performed in an attempt to maintain ICP before using hypertonic saline. Patients with life-threatening clinical signs of elevated ICP secondary to brain edema or acute neurologic deterioration were potential candidates for 23.4% hypertonic saline therapy. 30-60mL of 23.4% sodium chloride was administered via a central line infusion. Results: 23.4% hypertonic saline was successful in acutely reducing ICP. A 30ml bolus of 23.4% saline predictably increased the serum sodium levels allowing reliable titration and maintenance of serum sodium levels and efficient management of the patient's volume status (30cc of 23.4% = 250cc of 3%). Conclusions: Penetrating and severe closed head injuries have the potential to lead to neurologic emergency as a result of brain edema associated with primary TBI or following neurosurgical intervention. In a combat TBI population, 23.4% hypertonic saline demonstrates a clinical benefit over alternative treatments by decreasing the risk of secondary cerebral injury during the management of elevated ICP and was well tolerated.

1479. Duda, T., et al. (2020). "Outcomes of civilian pediatric craniocerebral gunshot wounds: A systematic review." The journal of trauma and acute care surgery **89**(6): 1239-1247.

BACKGROUND: Pediatric craniocerebral gunshot injuries (CGIs) occur both in the context of accidental and intentional trauma. The incidence and physiology of pediatric CGIs merit reexamination of prognostic factors and treatment priorities. This study characterizes the current understanding of mortality and prognostic factors in this patient population., METHODS: A systematic search was conducted. Selection criteria included all studies published since 2000, which described civilian isolated CGIs in pediatric patients. Data were analyzed qualitatively and quantitatively to identify factors prognostic for the primary outcome of mortality. Secondary outcomes included functional outcome status, requirement for surgery, and injury complications. Study quality was assessed with the Newcastle-Ottawa Scale. This study was registered with PROSPERO (CRD42019134231)., RESULTS: Initial search revealed 349 unique studies. Forty underwent full text screening, and eight studies were included in the final synthesis. The overall mortality rate was 44.8%. Most CGIs occurred in older teenagers. Aggressive surgical treatment was recommended by one author, while remaining studies emphasized clinical judgment. Reported prognostic factors include initial Glasgow Coma Scale, pupil reactivity, involvement of multiple lobes or deep nuclei, and bihemispheric injuries. Reported complications from CGIs included seizure, meningitis, abscess, cerebrospinal fluid leak, bullet migration, focal neurological deficits, endocrine abnormalities, cognitive deficits, and neuropsychological deficits. The Glasgow Outcome Scale was the predominant measure of function and demonstrated a moderate recovery in 17.4% and a good recovery in 27.3% of patients., CONCLUSION: This systematic review analyzed the existing evidence for prognostic factors in the context of pediatric CGIs. Significant long-term clinical improvement is possible with interventions including urgent surgical therapy. Fixed bilateral pupils and low initial Glasgow Coma Scale correlate with mortality but do not predict all patient outcomes. Patients younger than 15 years are underreported and may have differences in outcome. The literature on pediatric CGIs is limited and requires further characterization., LEVEL OF EVIDENCE: Systematic Review, level IV.

1480. Duda, T., et al. (2019). "Systematic review of civilian pediatric intracranial gunshot wounds." Canadian Journal of Neurological Sciences **46**: S42.

Background: Pediatric craniocerebral gunshot wounds occur in the context of both accidental and intentional trauma. Unique physiologic factors merited research into prognostic factors and treatment priorities in the pediatric population. Methods: A systematic search of MEDLINE, EMBASE, Web of Science, LILACS, Cochrane Registered Trials and Systematic Reviews, ISRCTN, and ClinicalTrials.gov was conducted. Selection criteria included all studies published in any language since 2000 which described intracranial isolated gunshot wounds in a civilian individual or population of pediatric age. Post-mortem and epidemiological studies were excluded. Screening was conducted through Covidence. Results: Initial database search revealed 349 unique studies for abstract and title screening. Fifty studies were selected for full text screening. Nine studies were included in the final review. Study quality was assessed with the Newcastle-Ottawa Scale. Case series noted bullet migration, pituitary deficiency, neurovascular and neuropsychological concerns. Three single-center retrospective studies of 71, 30, and 48 pediatric patients suggested multiple negative prognostic signs on initial presentation. Early aggressive surgical treatment was recommended by some authors. Conclusions: This systematic review analyzed the best current understanding of evidence for prognostic factors and treatment

considerations of intracranial gunshot wounds in the pediatric neurotrauma context. Areas for future research with larger multi-center studies were highlighted.

1481. Duda, T., et al. (2021). "Craniocerebral gunshot injury bullet migration to the cardiac right ventricle." Surgical neurology international **12**.

Background: Missile embolism is the process of slow velocity projectiles penetrating into vascular spaces followed by arterial, venous, or paradoxical embolism of the fragments. This is a rare complication in craniocerebral gunshot injuries (CGI), with only five other cases previously published demonstrating pulmonary or arterial emboli from these injuries. There is a high rate of mortality from these injuries. Case Description: A patient presented with a CGI from an occipital trajectory, causing penetrating fragments into the venous sinus system. The weapon was a Glock Model 17M 9 mm with a hollow-point bullet, fired close range. Initial chest X-ray demonstrated only atelectasis. After stabilization, 18 min from the initial chest X-ray, subsequent computed tomography (CT) imaging demonstrated extensive intracranial injuries and fragmentation of the bullet with the expected devastating intracranial injuries. Unexpectedly, chest CT revealed metallic fragments in the right cardiac ventricle which was redemonstrated on follow-up chest X-ray. Unfortunately, his extensive intracranial injuries and poor clinical status were nonsurvivable, and thus the family elected to discontinue supportive measures. Conclusion: This case demonstrates radiographic imaging of a metallic intravascular fragment from CGI through presumed transvenous mechanisms. The imaging provides a consistent timeline demonstrating migration can occur in the acute phase. This study additionally supports the presumed mechanism for pulmonary of migration through the right heart. Fragment embolization should be considered in cases of acute deterioration in this patient population.

1483. Duerr, S. and T. Cocco (1977). "Gunshot wound of the abdomen with cerebral embolization." The Journal of trauma **17**(2): 155-157.

A distinctly rare case of a bullet embolus to the internal carotid artery following an abdominal gunshot wound is reported. Unusual aspects of the case are discussed with references to the literature. Pathways the bullet may have traversed to reach its final location are proposed.

1484. Duffy, F. J., Jr., et al. (1998). "Use of bilateral folded radial forearm free flaps for reconstruction of a midface gunshot wound." Journal of reconstructive microsurgery **14**(2): 89-96.

Optimal treatment of midfacial gunshot wounds includes early definitive reconstruction of the bony scaffold to prevent soft tissue contraction. When this is not possible, secondary reconstruction is more difficult. The authors present a case of delayed reconstruction of a midface gunshot wound. Two months following a self-inflicted, submental gunshot wound and eventual rigid fixation of the remaining midfacial bony anatomy, two simultaneous radial forearm free flaps were utilized in the reconstruction. The first flap was folded onto itself to recreate the hard palate in conjunction with a split rib graft; the second flap filled the remaining soft-tissue defect and simultaneously provided lining for an eventual staged nasal reconstruction. The second stage of the nasal reconstruction was completed 5 weeks later with a calvarial bone graft and forehead flap. This dual microsurgical approach allowed for one-step reconstruction of both surfaces of the hard palate, resulting in separate oral and nasal cavities, and optimizing the patient's ability to speak and eat. Extensive soft-tissue contraction encountered in late reconstructions underscores the importance of an early, definitive, surgical approach in these difficult wounds.

1485. Duffy, G. P. and Y. S. Bhandari (1969). "Intracranial complications following transorbital penetrating injuries." The British journal of surgery **56**(9): 685-688.

1486. Dujardin, K. S., et al. (2001). "Myocardial dysfunction associated with brain death: clinical, echocardiographic, and pathologic features." The Journal of heart and lung transplantation : the official publication of the International Society for Heart Transplantation **20**(3): 350-357.

BACKGROUND: The sequelae of severe brain injury include myocardial dysfunction. We sought to describe the prevalence and characteristics of myocardial dysfunction seen in the context of brain-injury-related brain death and to compare these abnormalities with myocardial pathologic changes., METHODS: We examined the clinical course, electrocardiograms, head computed tomography scans, and echocardiographic data of 66 consecutive patients with brain death who were evaluated as heart donors. In a sub-group of patients, we compared echocardiographic findings with pathologic findings., RESULTS: Echocardiographic systolic myocardial dysfunction was present in 28 (42%) of 66 patients and was not predicted by clinical, electrocardiographic, or head computed tomographic scan characteristics. Ventricular arrhythmias were more common in the patients with, compared to those without, myocardial dysfunction (32% vs 0%; $p < 0.001$). Myocardial dysfunction was segmental in all 8 patients with spontaneous subarachnoid or intracerebral hemorrhage. In these patients, the left ventricular apex was often spared. Myocardial dysfunction was either segmental or global in 17 patients who suffered head trauma and in 3 patients who died of other central nervous system illnesses. In 11 autopsied hearts, we found poor correlation between echocardiographic dysfunction and pathologic findings., CONCLUSIONS: Systolic myocardial dysfunction is common after brain-injury-related brain death. After spontaneous subarachnoid or intracerebral hemorrhage, the pattern of dysfunction is segmental, whereas after head trauma, it may be either segmental or global. We found poor correlation between the echocardiographic distribution of dysfunction and light microscopic pathologic findings.

1487. Dujardin, R., et al. (2021). "Effect of female sex on endothelial activation and fibrinolysis in trauma patients." Intensive Care Medicine Experimental **9**(SUPPL 1).

Introduction. Premenopausal female sex is suggested to provide a survival advantage in response to traumatic injury that is attributed to protective effects of estrogen on endothelial and coagulation disturbances[1]. However, previous studies report contradictory results. Objectives. To compare markers of endothelial activation and fibrinolysis between male and female trauma patients of different age groups. Methods. This study is performed as part of the prospective, multicenter, Activation of Coagulation and Inflammation in Trauma (ACIT) trial. All trauma patients ≥ 18 years with full trauma team activation were included between January 2008 and April 2015. Exclusion criteria were penetrating trauma, traumatic brain injury (TBI) defined as an abbreviated injury score (AIS) of head and neck ≥ 3 and total other AIS < 3, administration of > 2L i.v. fluids before hospital admission, hospital arrival > 2 h after injury or burns covering > 5% of the body. Trauma patients were divided in the following three categories: male patients < 45, female patients < 45, and female patients ≥ 45 years of age. At hospital admission, blood was drawn for analysis of von Willebrand factor antigen (vWF:ag) and thrombomodulin (TM) as markers for endothelial activation and D-dimer, plasmin antiplasmin complexes (PAP) and tissue plasminogen activator (tPA) as markers for fibrinolysis. Groups were compared using a Kruskal Wallis test, followed by a Dunn's post hoc test. Results. In total, 743 patients were enrolled. Groups did not differ in injury severity or shock indices (Table 1). Compared to males, early mortality was significantly higher in the female ≥ 45 group, but not in female < 45 patients. Levels of vWF:ag and TM were lower in both the female < 45 and female ≥ 45 group when compared to men, but not different between the female age groups. Female ≥ 45 patients showed increased PAP and tPA levels compared to female < 45 patients, and increased PAP levels compared to male < 45 patients. Although D-dimer levels were also higher in female ≥ 45 patients, this increase was not statistically significant. Conclusion. This study shows that female patients ≥ 45 years of age have an increased risk of mortality compared to female and male patients < 45 years of age, associated with an increase in markers of fibrinolysis. Reduced endothelial activation as observed in women did not provide a survival benefit. Whether suppletion of estrogen in women ≥ 45 confers protection by decreasing fibrinolysis warrants further research.

1488. Dujovny, M., et al. (1995). "Transcranial cerebral oximetry and carotid cavernous fistula occlusion. Technical note." Acta neurochirurgica **133**(1-2): 83-86.

Different methods have been used in the evaluation and monitoring of the cerebral oxygen supply during neuro-interventional therapies. Attenuation of near-infrared light by the chromophores oxyhemoglobin and deoxyhemoglobin have shown to be useful in the study of the cellular oxygen metabolism and oxygen delivery to the brain. Transcranial cerebral oximetry (TCCO) has the advantage of providing real-time information regarding regional brain oxygen saturation (rSO2) by using wavelengths in the near-infrared range. We present a patient with a carotid cavernous fistula

who underwent balloon occlusion and concurrent continuous TCCO monitoring. TCCO was found to be a useful tool providing immediate rSO2 values during the angiographic and interventional procedures. Initial balloon occlusion of a carotid cavernous fistula resulted in partial occlusion of the internal carotid artery lumen causing an immediate decrease in rSO2 which correlated with angiographic findings. Subsequent reocclusion of the fistula produced a slower and smaller degree of decrease in rSO2 with clinical improvement in the patient. Changes in rSO2 were detected before any adverse clinical event was observed. TCCO was reliable, safe, sensitive, and provided a real-time assessment tool for the monitoring of brain oxygen supply in a patient undergoing a neuroendovascular procedure.

1489. Duke, J., et al. (2018). "Another case of pleural based malignancy or perhaps not: An unusual presentation of gunshot injury." American Journal of Respiratory and Critical Care Medicine **197**(MeetingAbstracts).

INTRODUCTION: This is a case of a 46 year old with high risk of malignancy with multiple pleural-based nodules found to have thoracic splenosis. DESCRIPTION: A 46 year old man with past medical history of hypertension and tobacco use (20 pack years) was referred to our institution for evaluation of multiple pleura-based nodules along the left diaphragmatic pleura which were found incidentally on a CT scan of the chest. He reported significant asbestos exposure having worked for one year in a shipyard as well as a history of a gunshot wound to the abdomen requiring an exploratory laparotomy ten years prior. Due to concern for possible neoplasm, the patient underwent video-assisted thoracoscopic surgery converted to open thoracotomy due to significant bleeding for biopsy. His post-operative course was complicated by bilateral cerebellar stroke without long-term limitations. Pathology showed lymphoid follicles lined by endothelium cells consistent with splenic tissue. DISCUSSION:: Splenosis is a term that describes the heterotopic autotransplantation of splenic tissue to another area of the body. Typically, this occurs through trauma that results in scattering of the tissue, most often in the abdominal cavity. Often the condition is found incidentally on imaging, and the history of incidents with possible splenic injury to is the key to the diagnosis. Splenosis is a benign condition but often can be mistaken for metastatic disease resulting in an invasive workup. The diagnostic imaging modality of choice for splenosis is technetium-99m heat-damaged erythrocyte nuclear scintigraphy. The damaged red blood cells are taken up by the reticuloendothelial system, helping to localize splenic tissue. Once the diagnosis is made for splenosis, no further evaluation or treatment is necessary. Therefore, in patients with prior history of splenic rupture presenting with left-sided pleural nodules, a high index of suspicion with emphasis on a detailed history is needed to adequately assess the patient for this rare mediastinal condition. Image 1: (a) (b) CT findings of pleural-based nodules initially concerning for malignancy. (c) histology consistent with lymphoid follicles lined by endothelium cells consistent with splenic tissue.

1490. Duker, J. S., et al. (1991). "Inadvertent globe perforation during retrobulbar and peribulbar anesthesia. Patient characteristics, surgical management, and visual outcome." Ophthalmology **98**(4): 519-526.

The authors report a series of 20 eyes from 20 patients in whom inadvertent perforation of the globe occurred during local anesthesia for ocular surgery. Perforation resulted from retrobulbar anesthesia in 18 eyes and from peribulbar anesthesia in 2 eyes. Nine (45%) of 20 eyes had an axial length greater than or equal to 26.00 mm. Combining this figure with axial length data for the general population and estimates for the risk of globe perforation during local anesthesia yields an approximate incidence of perforation in eyes with axial length greater than or equal to 26.00 mm of 1 in 140 injections. Proliferative vitreoretinopathy (PVR) developed in 8 of the 20 eyes (40%) in this series. Overall, 15 (75%) of the 20 eyes were successfully repaired, and, in five eyes (25%), the final visual acuity was 20/70 or better.

1491. Dulger, H. E. and M. Tokdemir (2001). "An accidental death caused by an unexploded 40-mm grenade." Military medicine **166**(6): 557-559.

Unexploded grenades are potentially dangerous materials. Numerous grenades have been found to be unexploded after wars have ended. We present an interesting case of an unexploded grenade that was found accidentally in a soldier's skull. On physical examination, the entrance wound of an unusual penetrating object was noted. This unusual physical finding led us to undertake radiographic examination. A 40-mm unexploded grenade was noticed on the radiograph of the soldier's skull.

1492. Duman, H., et al. (1999). "Reconstruction of contour and anterior wall defects of frontal bone with a porous polyethylene implant." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **27**(5): 298-301.

Frontal bone contour defects cause marked facial deformity, which is instantly obvious to the observer. The aetiology is usually post-traumatic either following a traffic accident or a gunshot injury. The contour deformity of the frontal bone was reconstructed using Medpor porous polyethylene in 12 consecutive patients during a period of 2 years. In four of the patients, we used a coronal approach, whilst using the old incision scar and laceration for access in the remainder. In two of the patients it was not necessary to fix the implant at all, but the remainder were fixed with lag screws because of implant mobility. The aetiology, the technique used, and the results obtained are presented.

1493. Duman, H., et al. (2002). "Spontaneous subfalcial transcallosal migration of a missile to the contralateral hemisphere causing deterioration in neurological status--case report." Neurologia medico-chirurgica **42**(8): 332-333.

A 26-year-old man sustained a gunshot injury. Computed tomography (CT) demonstrated the missile in the right parietal region. Twenty-four hours later, the missile had moved towards the midline. Following slight deterioration in his neurological condition one week later, follow-up CT revealed that the missile had crossed the midline through the corpus callosum and was located in the left parietal region. CT during the second week demonstrated that the missile had stopped close to the left parietal bone. Spontaneous migration of a missile to the contralateral side via a subfalcial-transcallosal route with deterioration in neurological status is unusual. The missile may have moved under the influence of the intracranial pressure and pulsatile effect of the cerebrospinal fluid.

1494. Dumbach, J., et al. (1994). "[Limits of osseous reconstruction of the mandible with autologous spongiosa, hydroxyapatite granules and titanium mesh, especially after radiotherapy]." Grenzen der knochernen Rekonstruktion des Unterkiefers mit autogener Spongiosa, Hydroxylapatitgranulat und Titangitter, insbesondere nach Strahlentherapie. **39**: 93-95.

Over the past twenty years the titanium mesh combined with autologous iliac crest spongiosa and hydroxylapatite has performed well in the restoration of mandibular discontinuity defects in 79 patients. In 14 irradiated patients with a transplant bed of inferior quality, however, complications and failures occurred more often than in the 65 not irradiated patients. The results of our investigation clearly show, that the success of mandibular reconstruction mainly depends on a well vascularized transplant bed.

1495. Duncan, K. A., et al. (2013). "Injury-induced expression of glial androgen receptor in the zebra finch brain." Journal of neurotrauma **30**(22): 1919-1924.

Astrogliosis occurs following injury to the zebra finch brain. To date, only estrogen synthase (aromatase) has been identified in injury-induced astrocytes. The expression of other steroidogenic enzymes or their receptors remains unknown in the avian brain. However, in mammals, an upregulation of androgen receptors has been identified in glial cells. The aim of this study was to determine if the androgen receptor is upregulated following injury in adult zebra finches. Finches were given a single penetrating injury and brain tissue was collected 24 or 72 h later. Expression of androgen receptor was examined using immunohistochemistry and quantified using quantitative polymerase chain reaction (qPCR) analysis. Androgen receptors were localized to astrocytes versus neurons, further solidifying the role for astrocytes in neural recovery.

1496. Duncan, N. O., 3rd, et al. (1986). "Gunshot injuries of the temporal bone." Otolaryngology--head and neck surgery : official journal of American Academy of Otolaryngology-Head and Neck Surgery **94**(1): 47-55.

Concurrent with the increase in handgun crime in the United States is a rising incidence of gunshot wounds to the temporal bone. These injuries present challenging diagnostic and management problems to the otolaryngologist. A timely multicenter review of this entity revealed 22 cases evaluated and treated by the authors between 1975 and 1984. A wide variety of injuries were encountered, involving anatomic structures within or contiguous with the temporal bone. These included: eight intracranial injuries; 11 traumatized facial nerves; seven vascular wounds; 19 mastoid, middle, or inner ear injuries; and 11 cases of damage to the external auditory canals. A rational scheme for immediate and long-

term management of each type of injury is outlined. Illustrative cases representing vascular, neural, temporal bone, and central nervous system injury are presented.

1498. Dunn, I. F., et al. (2009). "Orbitocranial wooden foreign body: a pre-, intra-, and postoperative chronicle: case report." Neurosurgery **65**(2): E383-E384.

OBJECTIVE: Intraorbital wooden foreign bodies--usually from a low-velocity puncture--are elusive and demand a low threshold for further imaging. In patients with traumatic injuries, orbital and intracranial air from fractures may be present, and it is particularly easy to overlook a wooden fragment, CLINICAL PRESENTATION: A 53-year-old equestrian was kicked in the face by the rear hoof of a horse. The event was captured on video by her husband. Although no obvious entry point in and around the eye was observed, her ocular examination was notable for superior orbital fissure syndrome and increasing intraocular pressure in the left eye. Closer inspection revealed a 5-mm laceration above her superior lid margin; imaging revealed a foreign body at the orbital apex with apparent communication with the cranial vault., INTERVENTION: We proceeded with cranio-orbital exploration because of the risk of continued ocular damage in the setting of increasing intraocular pressure and the potential for infection of both the eye and the intracranial space from a suspected foreign body. A 3.0 cm x 0.5 cm fragment was found lodged in the orbital apex and removed., CONCLUSION: The patient recovered well after surgery and a course of antibiotics and has returned to riding. This case report presents an algorithm for approaching cranio-orbital foreign objects of unclear identity and the favorable outcomes that may be achieved.

1499. Dunn, I. F., et al. (2007). "Traumatic pericallosal artery aneurysm: a rare complication of transcallosal surgery. Case report." Journal of neurosurgery **106**(2 Suppl): 153-157.

Traumatic intracranial aneurysms are rare in adults but account for up to 33% of all aneurysms encountered in a pediatric population. The most common location of such lesions in children is the pericallosal or adjacent branch of the anterior cerebral artery, where a head impact exerts sudden decelerating shearing forces on the arteries tethered on the brain surface against an immobile falx cerebri, weakening the arterial wall. This action can lead to dissection of the damaged vascular layers, with resultant expansion of the affected site into a fusiform aneurysm. Pericallosal aneurysms following a penetrating intracranial injury have also been described, and the resultant lesion in some cases can be a pseudoaneurysm. The incidence of iatrogenic pericallosal artery aneurysms, however, is extremely rare. The authors describe the first reported case of a traumatic pericallosal artery aneurysm following transcallosal surgery. This 6-year-old boy underwent resection of a hypothalamic pilocytic astrocytoma, which was approached via the transcallosal corridor. A follow-up magnetic resonance image obtained within 1 year of surgery disclosed a small flow void off the right pericallosal artery, which was initially interpreted as residual tumor. Serial investigations showed the lesion enlarging over time, and subsequent angiography revealed a round 7-mm pericallosal artery aneurysm with an irregularly shaped 2- to 3-mm lumen. The aneurysm was difficult to treat with clip reconstruction or suturing of the affected segment, and an excellent outcome was ultimately achieved with resection of the lesion and autogenous arterial graft interposition. The authors also discuss the likely pathophysiology of the aneurysm and the surgical procedures undertaken to treat it.

1500. Dunn, L. T. and P. M. Foy (1994). "Anticonvulsant and antibiotic prophylaxis in head injury." Annals of the Royal College of Surgeons of England **76**(3): 147-149.

The evidence for and against the prophylactic use of anticonvulsants and antibiotics in head injury is reviewed. There is a lack of blinded placebo-controlled trials in this area. On balance there is no compelling evidence to support the use of either anticonvulsant or antibiotic prophylaxis in head injury, with the possible exception of antibiotic prophylaxis in compound depressed skull fractures and penetrating brain injuries.

1501. Duntze, J., et al. (2009). "[Clostridial brain abscess after glioblastoma resection: case report and critical review of the literature]." Abces cerebral aClostridium perfringens apres chirurgie d'exerese d'un glioblastome: a propos d'un cas et revue de la litterature. **55**(6): 569-572.

Clostridium perfringens is rare in neurosurgery. The source of clostridial brain abscess is usually a penetrating head injury. We report the case of a 57-year-old man who had parietal glioblastoma resection with local carmustine chemotherapy and who presented a clostridial brain abscess three weeks later. Progression was especially brutal, leading to patient's death in few hours. We discuss the etiology and progression of this case compared to the data reported in the literature.

1503. Duong Dinh, T. A., et al. (2011). "[Uncommon knife injury of the neck]." Ungewohnliche Messerstichverletzung des Halses. **90**(12): 760-761.

1504. Dupoirieux, L., et al. (1994). "The role of microsurgery in salvage operations for cranio-cerebral gunshot wounds: a case report." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **22**(2): 81-85.

A case of gunshot wound of the brain associated with a scalp defect is presented. Repair of the scalp defect was primarily achieved by multiple rotation flaps. Successive complications occurred in the postoperative course related to wound breakdown and infection. The patient underwent a secondary reconstruction by a free forearm flap. Despite an infected recipient bed and poor general condition, the postoperative course was uneventful and the healing was complete within 1 month.

1505. Durand, M. L. and C. H. Dohlman (2009). "Successful prevention of bacterial endophthalmitis in eyes with the Boston keratoprosthesis." Cornea **28**(8): 896-901.

PURPOSE: To determine the influence of topical vancomycin prophylaxis on the incidence of bacterial endophthalmitis in eyes with a Boston Keratoprosthesis (KPro)., METHODS: A retrospective chart review was performed for 255 eyes of 231 patients who received a KPro between March 1990 and December 2006. Preoperative diagnoses were burn, ocular cicatricial pemphigoid (OCP), Stevens-Johnson Syndrome (SJS), and graft failure/other. Patients used topical antibiotic prophylaxis for the duration of the KPro: polymyxin-trimethoprim or a quinolone in the 1990s, or a quinolone with or without vancomycin beginning in late 1999. For each KPro eye, the follow-up interval was divided into months on or off vancomycin (vancomycin versus no-vancomycin group). The incidence of endophthalmitis was calculated with Kaplan-Meier survival curves., RESULTS: The 255 eyes were followed for 673.6 patient-years (mean, 2.64 years; range, 1 week to 13 years). There were 18 cases of bacterial endophthalmitis; 17 occurred at least 6 weeks postoperatively (range, 1.5 to 46 months). Gram-positive cocci caused over 80% of cases. Only 1 case, due to an atypical mycobacterium, occurred in a patient using vancomycin. The incidence of bacterial endophthalmitis was lower in the vancomycin group than in the no-vancomycin group: 0.35% versus 4.13% per patient-year (P = 0.001). It was also lower in SJS eyes using vancomycin versus no vancomycin: 1.76% versus 18.39% per patient-year (P = 0.009). In eyes with preoperative diagnoses of burn, OCP, or graft failure/other, the incidence in the vancomycin group was zero., CONCLUSION: Topical vancomycin plus a quinolone is effective in preventing bacterial endophthalmitis in KPro eyes.

1506. Durfort, C., et al. (2020). "Committing Suicide With Handgun Wounds in the Head Using a Defective Firearm: About 2 Unusual Autopsy Cases." The American journal of forensic medicine and pathology **41**(2): 124-127.

We report 2 unusual autopsy cases with head handgun wounds using defective firearms in a suicidal context. In the first case, a 78-year-old man was found hanged from a tree, with a Lefaucheux revolver lying on the tree. In the right temporal region, there was an entrance wound with a bullet still in place, responsible for a mild cerebral contusion, without bone defect. The main cause of death was hanging. In the second case, a 60-year-old man died at home after shooting himself in the head several times with a 22-long rifle revolver. The autopsy showed 13 entrance wounds on the scalp. Most of the bullets remained along the skull vault. In each of 2 cases, the manner of death, the feasibility of

suicidal gesture, and the consequences of a brain injury on the time to the occurrence of incapacity were questioned. These unusual autopsy cases underline how important it is to take into account the defective nature of firearms.

1507. Durmaz, O., et al. (2017). "A Rare History: an Intracranial Nail Present for Over a Half-Century." Acta medica (Hradec Kralove) **60**(3): 124-126.

We present a rare case of a patient with a persistent headache for many years found to have an intracranial nail present for nearly 65 years. The nail was found entering approximately 1 cm from the midline on the left side, passing below the superior sagittal sinus, with the tip 1.5 mm right of the frontal horn of the lateral ventricle. Treatment strategies designed to optimize outcome for intracranial foreign bodies and possible complications are discussed in this report. We also discuss the decision for surgical intervention for foreign bodies and the relevance of position of the foreign body.

1508. Durmaz, R., et al. (2003). "Lazaroid attenuates edema by stabilizing ATPase in the traumatized rat brain." The Canadian journal of neurological sciences. Le journal canadien des sciences neurologiques **30**(2): 143-149.

OBJECTIVE: The aim of the present study was to determine the potential therapeutic value of the lazaroid U-83836E on blood brain barrier (BBB) breakdown and edema with respect to the changes in the synaptosomal Na+/K+ and Mg(2+)/Ca(2+)-adenosinetriphosphatase (ATPase) activities, tissue malondialdehyde levels and the neuronal viability in the rat brain subjected to cerebral trauma., METHODS: Traumatic brain injury (TBI) was introduced by applying a 75 gm. cm force to the right parietal cortex using the weight-drop method. The first set of animals was used for determining time course changes of the synaptosomal Na+/K+ and Mg(2+)/Ca(2+)-ATPase and the malondialdehyde levels and were sacrificed 2, 6 and 24h after lesion production. A group of the animals was treated with U-83836E proir to TBI and sacrificed 24h after cerebral injury. A second set of animals was used for evaluating the alterations in BBB disruption and tissue water content and were sacrificed 2, 6 and 24h after lesion production. Two groups of animals were treated with U-83836E and sacrificed after 2 and 24h following TBI. U-83836E was given intraperitoneally thirty minutes before trauma at a dose of 10 mg/kg. Neuronal necrosis was also evaluated in the groups of U-83836E and physiological saline-treated animals., RESULTS: Extravasation of Evans blue into the traumatized hemisphere was maximum at 2h ($p<0.001$) and returned close to the control levels at 24h after TBI ($p>0.05$). Edema had developed progressively over time and reached the maximum degree of 2.1% ($p<0.001$) at 24h. U-83836E showed no effect on the BBB breakdown and the tissue water content at 2h and still had no effect on the BBB breakdown after 24h following the trauma ($p>0.05$), although it reduced edema after 24h ($p<0.01$). The losses of Na+/K+ and Mg(2+)/Ca(2+)-ATPase activities were found as 39.5% ($p<0.001$) and 29.4% ($p<0.01$) of the control value, respectively, and remained at the decreased levels throughout the experiment. Malondialdehyde level continued to increase over time reaching up to 209% ($p<0.001$) of the control value 24h after TBI. Both ATPase activities were improved to near control values ($p>.05$) by the effect of U-83836E. U-83836E inhibited the increase of lipid peroxidation ($p<0.001$) and also salvaged neuronal necrosis ($p<0.05$)., CONCLUSION: U-83836E given prophylactically after cerebral trauma appears to reduce edema, possibly by inhibiting increases in lipid peroxidation and by stabilizing ATPase. Further studies are recommended to verify the similar effects of the brain penetrating lazaroids when they are given after trauma.

1509. Durmic, T., et al. (2017). "Death related to nasal surgery: Case report and review of literature." Rechtsmedizin **27**(4): 351-352.

Background. The investigation of deaths that are suspected to be related to medical therapy present several challenges for the forensic pathologist. Material and methods. We present a case of a 55-year-old woman who underwent this elective surgical procedure and never recovered from general anesthesia. Results. An otherwise healthy 55-year-old female with a multiple nasal polyps underwent nasal polypectomy. The operation was initially considered successful; however, the patient never recovered from general anesthesia and was declared deceased within 24 hours of her surgery. At autopsy, there was evidence of basilar subarachnoid hemorrhage. Examination of the basilar skull showed an approximately 15 by 7 mm perforation of the right cribriform plate. Above the bone perforation, there was a disruption of the dura, as well as a 20 mm long penetrating wound within the right frontal lobe parenchyma of the brain, with associated interventricular haemorrhage. Subsequent sectioning of the formalin fixed brain revealed extensive parenchymal destruction. The cause of death was certified as complications of nasal/sinus surgery, with perforation of base of skull with hemorrhagic tissue destruction of brain, while the manner of death was considered accidental.

Discussion and conclusions. Nasal polypectomy represents one common, minimally invasive nasal functional endoscopic sinus surgery technique that has been used for over 20 years in its surgical removal. All complications of this surgery are divided into major and minor complications. Major intracranial complications, although rare, are of greater interest to forensic pathologists, since many of these are potentially fatal. Complications that have resulted in death include cerebral spinal fluid (CSF) leakage, meningitis, brain abscess, damage to major blood vessels in the region, subarachnoid hemorrhage, and parenchymal damage. Following the presentation of this case, the authors discuss common nasal surgical procedures and their known complications. In addition, the authors address and review the topic of deaths related to medical therapy as an extremely challenging process with an enormous potential for almost limitless clinicopathological and medicolegal exploration.

1510. Durmic, T., et al. (2019). "Two cases of firearm-related murder-suicide: Forensic implications of the ability to act." Medicine, science, and the law **59**(2): 78-82.

One of the most important tasks in forensic medicine is differentiating between a homicide and a suicide, especially in cases where more than one self-inflicted gunshot wound is present. The significance is even greater when the victim's ability to act after the first gunshot is questionable. In these cases, the only way to determine the sequence of the shots is to consider the severity of the injuries and their disabling effect. Therefore, the importance of previously mentioned facts is even greater, not only in everyday forensic practice but also in court. The questions dealing with the crime scene and interpretation of the wounds' trajectories are of the utmost importance.

1511. Dusoir, H., et al. (1990). "The role of diencephalic pathology in human memory disorder. Evidence from a penetrating paranasal brain injury." Brain : a journal of neurology **113 (Pt 6)**: 1695-1706.

A patient (B.J.) is reported who developed severe memory impairment following a penetrating brain injury caused by a snooker cue which entered through his left nostril into the basal regions of the brain. Initially, his memory disorder had the clinical features of a dense amnesic syndrome, with both anterograde and retrograde amnesia, but B.J. subsequently showed significant recovery of memory function. Formal memory testing was carried out 21 months after injury. This demonstrated marked verbal memory impairment, as severe as that seen in patients with the amnesic syndrome. On nonverbal memory tests, his impairment was relatively mild and patchy. His retrograde amnesia had regressed mainly to affect a 6 month period before the injury. On other cognitive tasks, he performed at an average or above average level, and there was no neuropsychological evidence of frontal lobe dysfunction. Neuroradiological investigations at various stages after his injury failed to demonstrate a lesion in any of the thalamic nuclei. Magnetic resonance imaging showed a lesion in the hypothalamus in the region of the mamillary bodies. Our study demonstrates that marked, relatively focal, memory disorder after diencephalic injury can occur without direct pathology to the body of the thalamus. It also indicates that structures in or adjacent to the hypothalamus, such as the mamillary bodies, may play a more important role in human memory functioning than has hitherto been considered.

1512. Dutcher, S. A., et al. (1998). "Heat-shock protein 72 expression in excitotoxic versus penetrating injuries of the rodent cerebral cortex." Journal of neurotrauma **15**(6): 421-432.

The induction of heat shock protein 72 (hsp72) has been described in various experimental models of brain injury. The present study examined hsp72 expression patterns within the rodent cerebral cortex in experimental paradigms designed to mimic two mechanisms of damage produced by penetration of the cerebral cortex: (1) tissue tearing from the missile track and (2) diffuse excitotoxicity during temporary cavitation and shock wave formation. Adult male Spaque-Dawley rats received controlled penetration (stab) or injection of the NMDA receptor excitotoxin, quinolinic acid (QA), into the frontal cortex and were killed 1-24 h later. Tissue from the lesioned, sham-operated, or contralateral uninjected cortex was processed for Western and immunocytochemical analyses of hsp72 protein expression. By 12 h, both controlled penetration and excitotoxic brain injuries produced significant increases in hsp72 immunoreactivity, which decreased toward control levels at 24 h. However, the severity and regional distribution of hsp72 expression varied between the two models. Specifically, the controlled penetration injury produced many hsp72-expressing cells near the needle track, while immunoreactive cells within the QA-injected cortex were found in the periphery of the lesion site. Morphological assessment of brain sections subjected to dual-labeling procedures demonstrated that cells expressing hsp72 were primarily neuronal in both models of injury. These results suggest that

although controlled penetration and diffuse excitotoxicity may induce similar temporal and cellular patterns of hsp72 expression, the spatial location of hsp72-immunoreactive cells may differ between the two models.

1513. Dutton, R. P., et al. (2010). "Trauma mortality in mature trauma systems: are we doing better? An analysis of trauma mortality patterns, 1997-2008." The Journal of trauma **69**(3): 620-626.

BACKGROUND: Advances in care such as damage control surgery, hemostatic resuscitation, protocol-driven cerebral perfusion management, and lung-protective ventilation have promised to improve survival after major trauma. We examined injury severity, mortality, and preventability in a mature trauma system during a 12-year period to assess the overall benefits of these and other improvements., METHODS: Using the institutional trauma registry and the quality management database, we analyzed the outcome and the cause of death for all primary trauma admissions from July 1, 1996, to June 30, 2008, and linked these data with patient demographics, hospital length of stay, time to death, predicted probability of survival, and peer review of in-hospital deaths., RESULTS: Through fiscal year (FY) 2007, primary trauma admissions increased in number, injury severity, and age. Performance benchmarked against predicted probability of survival improved. Mortality through this era ranged from 3% to 3.7% and worsened slightly overall (p = 0.04). However, among those patients admitted with Injury Severity Score 17-25, survival improved significantly (p = 0.0003). Traumatic brain injury (TBI) accounted for 51.6% of deaths; acute hemorrhage, 30%; and multiple organ failure, 10.5%. Median time to death for uncontrollable hemorrhage, TBI, multiple organ failure was 2 hours, 24 hours, and 15 days, respectively. These patterns did not change significantly over time., CONCLUSION: Survival after severe trauma and survival benchmarked against predicted risk improved significantly at our center during the past 12 years despite generally increasing age and worsening injuries. Advances in trauma care have kept pace with an aging population and greater severity of injury, but overall survival has not improved.

1514. Dworzack, D. L., et al. (1989). "Pseudallescheria boydii brain abscess: association with near-drowning and efficacy of high-dose, prolonged miconazole therapy in patients with multiple abscesses." Medicine **68**(4): 218-224.

Brain abscess caused by Pseudallescheria boydii is a highly lethal infection, usually seen in immunosuppressed patients. Five patients with P. boydii brain abscesses are described. Four of these patients acquired their infection after near-drowning; 1 patient developed an abscess after penetrating head trauma. Two patients survived their infections, which included involvement of other body sites (lung, eye, bone) as well as multiple undrained brain abscesses, after prolonged courses of high-dose parenteral miconazole (80-90 mg/kg/d). Progressive increases in miconazole dosage during the treatment periods were required to produce serum levels above the minimum inhibitory concentrations of the fungal isolates.

1515. Dwyer, B. E., et al. (1996). "Transient induction of heme oxygenase after cortical stab wound injury." Brain research. Molecular brain research **38**(2): 251-259.

Heme oxygenase (HO) exists as two isoenzymes designated heme oxygenase-1 (HO-1) and heme oxygenase-2 (HO-2). HO-1 has been identified as a heat shock or stress protein and is inducible whereas HO-2 is largely refractory to induction. HO-2 is the predominant isoenzyme in normal brain and appears to have a predominantly neuronal distribution in cerebral cortex. Cortical stab wound injury resulted in HO-1 induction as determined by Western blot analysis. Immunohistochemical analysis suggested that induced HO-1 was largely restricted to reactive astrocytes and macrophage-like cells. Enhanced HO-1 immunoreactivity was observed in hypertrophied, GFAP+ reactive astrocytes near the wound margin as early as 12 h after injury. Very rarely were HO-1+ neurons observed and then only up to 6 h after stabbing. Maximal numbers of HO-1+ astrocytes were found 3 days after stabbing. Their numbers declined thereafter. By 5 days after stab injury few HO-1+ reactive astrocytes were observed although GFAP+ reactive astrocytes were still prominent near the wound margin. HO-1+ macrophage-like cells were initially observed between 1 and 3 days after injury and they persisted in the margin of the wound for at least 14 days. The proximity of HO-1+ cells to the wound margin suggests that factors associated with injury contribute to the regulation of HO-1 in injured cortex.

1518. Ebner, Y., et al. (2009). "Penetrating injury of the maxilla by needlefish jaws." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **37**(4): 235-238.

INTRODUCTION: Needlefish penetrating injuries have become a worldwide problem, inflicting critical morbidities and even mortalities. This is the first published case of needlefish injury in the Mediterranean basin., CASE REPORT: A 29 year old man was admitted to Meir Medical Centre in Israel with a penetrating facial wound caused by elongated needlefish jaws. The severity of the wound contrasted greatly with the expected injury from collision with a fish inflicting a small penetration lesion. The rigid jaws penetrated the maxilla transversely and obliquely from the left canine-fossae, through the nasal cavity, and to the right maxillary sinus, with its tip reaching the right medial-inferior orbital wall. The needlefish jaws were completely removed using a combined endoscopic and external approach. The course of surgery and hospitalization was uneventful and the patient was discharged with no complications., CONCLUSIONS: Fish inflicted critical facial injuries might be dangerously underestimated prima facie. The impact might be energetic enough to penetrate deep facial and vital cranial structures, hence thorough examination and imaging are recommended. Needlefish species are now common in the tropical and subtropical regions of all oceans and therefore this phenomenon is of interest to worldwide trauma medical providers, fishermen, divers, and also to marine-biologists.

1519. Ebraheim, N. A., et al. (2009). "An evaluation of halo pin insertion torque on outer table penetration in elderly patients." Journal of spinal disorders & techniques **22**(3): 177-181.

STUDY DESIGN: An experimental anatomic study performed on elderly cadaveric skulls., OBJECTIVES: (1) To determine the pin penetration depths in outer table of skull at different torques in the elderly population during halo pin insertion and (2) to validate a safe range of torque for use in this population., SUMMARY OF BACKGROUND DATA: The elderly are at an increased risk of falls, which can lead to cervical fractures. The halo pins used to stabilize these injuries present unique problems in this population owing to osteoporosis, and intracranial pin penetration should always be avoided., METHODS: A halo ring was used to insert pins in 4 standard positions on 10 elderly cadaveric skulls. Incremental torques were used to drive the pin into the outer table, and the penetration of each pin was measured using computed tomography imaging at each stage., RESULTS: Eight to Twelve in-lb of torque was not sufficient to fully penetrate the outer table of the skull. Only at 16 in-lb of torque was the outer table penetrated, and only anterolaterally, hence the posterolateral outer table is more resistant to penetration than the anterolateral outer table., CONCLUSIONS: Despite age-related bone changes in the elderly, it is still safe to use 8 in-lb of torque when inserting pins for a halo vest. However, as the anterolateral outer table is weaker than the posterolateral outer table, a new pin design with broader shoulders should be used anterolaterally to ensure maximal patient safety.

1520. Ebrahimi, A., et al. (2021). "Epidemiologic patterns of maxillofacial fractures: A 5-year study in one of the referral hospitals of Iran." Trauma Monthly **26**(5): 258-264.

Introduction: Maxillofacial trauma resulting in fractures are among the most common reasons for referral to the ER. Epidemiological fracture patterns are widely dependent on cultural, environmental, and socio-economic parameters. This study aimed to assess the epidemiology and prominent patterns of maxillofacial injuries and fractures in Iran. Methods: This cross-sectional study was conducted at a trauma research center. In this study, medical records of patients with maxillofacial fractures from 2010 to 2015 were reviewed. Factors such as age, gender, GCS at admission, hospital stay, fracture cause, site of fractured bones, ocular injuries, brain injuries, trigeminal involvement, facial nerve involvement, soft tissue injuries, and upper face fractures were evaluated. Treatments rendered were also reviewed. Data analysis was performed using SPSS version 22. Results: 283 patients with a mean age of 32.48 years and a male-to-female ratio of 4:1 was seen. The most common age group was the third decade of life (38.2%). The most common causes of fracture were MVA (66.4%), falls (13.1%), and assault (9.2%). The most common fractured bones were: mandible (42.04%), orbit (39.57%), and maxilla (37.1%). The most common treatment was open reduction (94%) and internal fixation with miniplates (49.5%). The hospital stay duration was 3.4 days (average). Conclusion: In this study males in the third decade of life were the most prone to facial fractures. Associated injuries were common and must not

be neglected on physical examination. The profession, culture, and social differences in the society are influential in facial fractures and thus the pattern will differ in different nations.

1521. Eckardt, A. and A. Al-Jawadi (2011). "Cranio-maxillo-facial injuries in civilians from Iraq caused by bomb attacks and gunshots: Experience of a humanitarian project in Jordan." International journal of oral and maxillofacial surgery **40**(10): 1034.

Objectives: Combat injuries in worldwide military conflicts have been reported frequently, however publications on injuries of unprotected civilians caused by bomb attacks and bullets are rare. The present report gives an overview of the range of complex cranio-maxillofacial injuries in victims of violence inside Iraq who were treated within a humanitarian project initiated in Amman/Jordan since 2006 from the NGO-Group “Doctors without Borders” in collaboration with “Iraqi Medical Association” and “Jordan Red Crescent Society”. Due to the critical and unsafe situation in Iraq, reconstructive surgery for the large number of residual deformities secondary to the cranio-maxillo-facial war injuries is presently inadequate. Material and method: All patients who entered this project and were treated during the period from August 2006 until December 2007 were reviewed retrospectively with regard to type of injury, previous treatment, surgical treatment, complications, and postoperative outcome. A descriptive statistical analysis was performed. Results: A total number of 144 different complex cranio-maxillo-facial reconstructive procedures were done during the period August 2006 to December 2007. All cases are residual deformities that either had received inadequate treatment at the time of injury, or got a complication of the primary treatment, or had inadequate access to proper reconstructive surgery unit inside Iraq. Summary: Unprotected civilians are vulnerable to receive and express the maximum wounding capacity during armed conflicts. However, this paper is showing that there is a considerably significant chance of patients with such severe residual deformities to re-gain adequate function, that can help heal their physical and psychological trauma.

1522. Ecker, R. D., et al. (2011). "Outcomes of 33 patients from the wars in Iraq and Afghanistan undergoing bilateral or bicompartmental craniectomy." Journal of neurosurgery **115**(1): 124-129.

OBJECT: There are no published long-term data for patients with penetrating head injury treated with bilateral supratentorial craniectomy, or supra- and infratentorial craniectomy. The authors report their experience with 33 patients treated with bilateral or bicompartmental craniectomy from the ongoing conflicts in Iraq and Afghanistan., METHODS: An exploratory analysis of Glasgow Outcome Scale (GOS) scores at 6 months in 33 patients was performed. Follow-up lasting a median of more than 2 years was performed in 30 (91%) of these patients. The association of GOS score with categorical variables was explored using the Wilcoxon rank-sum test or Kruskal-Wallis analysis of variance. The Spearman correlation coefficient was used for ordinal/continuous data. To provide a clinically meaningful format to present GOS scores with categorical variables, patients with GOS scores of 1-3 were categorized as having a poor outcome and those with scores of 4 and 5 as having a good outcome. This analysis does not include the patients who died in theater or in Germany who underwent bilateral decompressive craniectomy because those figures have not been released due to security concerns., RESULTS: All patients were men with a median age of 24 years (range 19-46 years) and a median initial Glasgow Coma Scale (GCS) score of 5 (range 3-14). At 6 months, 9 characteristics were statistically significant: focus of the initial injury, systemic infection, initial GCS score, initial GCS score excluding patients with a GCS score of 3, GCS score on arrival to the US, GCS score on dismissal from the medical center, Injury Severity Score, and patients with cerebrovascular injury. Six factors were significant at long-term follow-up: focus of initial injury, systemic infection, initial GCS score excluding patients with a GCS score of 3, GCS score on arrival to the US, and GCS score on dismissal from the medical center. At long-term follow-up, 7 (23%) of 30 patients had died, 5 (17%) of 30 had a GOS score of 2 or 3, and 18 (60%) of 30 had a GOS score of 4 or 5., CONCLUSIONS: In this selected group of patients who underwent bilateral or bicompartmental craniectomy, 60% are independent at long-term follow-up. Patients with bifrontal injury fared best. Systemic infection and cerebrovascular injury corresponded with a worse outcome.

1523. Ecker, R. D., et al. (2012). "Response." Journal of neurosurgery **116**(1): 258-259.

1524. Ecklund, J. M., et al. (1999). "Cerebral abscess after presumed superficial periorbital wound." Military medicine **164**(6): 444-445.

Penetrating wounds in the periorbital region may appear superficial and minor at first glance. The unique shape and thin bony roof of the orbit give these injuries a significant risk of associated intracranial penetration. This can initially be asymptomatic, and a high index of suspicion is essential to properly diagnose and treat these injuries. We report a case of an 8-year-old female who presented with delayed seizures from a frontal abscess resulting from such an injury. This article reviews the literature and discusses the appropriate management that should be used by emergency room and military physicians.

1525. Ecklund, J. M. and P. Sioutos (2014). "Prognosis for gunshot wounds to the head." World neurosurgery **82**(1-2): 27-29.

1526. Eckstein, M. (1995). "The prehospital and emergency department management of penetrating head injuries." Neurosurgery clinics of North America **6**(4): 741-751.

The prehospital and emergency department management of the patient with a penetrating cranial injury can be summarized by the following tenets: 1. Assume any alteration in level of consciousness to be a result of the brain injury and not from alcohol or illicit drug intoxication. 2. Have a low threshold to protect the patient's airway with endotracheal intubation and chemical paralysis if a surgical lesion is suspected, there is seizure activity, or the patient is too combative to obtain the necessary studies. 3. Always protect the cervical spine and do not remove the hard collar and spine board until adequate radiographs have been obtained and the patient is lucid enough to complain of any neck pain. 4. Do not delay CT scanning to obtain other studies in the presence of lateralizing neurologic findings. 5. Do not delay in obtaining neurosurgical consultation or in arranging transfer to a facility where definitive care can be provided. 6. Remember, first do no harm. The primary brain injury has already been done. The clinician maximizes preservation of viable brain tissue by preventing secondary injury.

1527. Edem, B. E., et al. (2017). "Anaesthetic and surgical management of airway penetrating injuries in children in resource-poor setting: Case reports." International journal of surgery case reports **39**: 119-122.

INTRODUCTION: Impacted penetrating foreign body (FB) in the airway especially the postnasal space presents with management challenges. The challenges are worsened by lack of modern equipment in resource-poor settings. Two suchlike cases were managed in this report., PRESENTATION OF CASES: Case 1: A 4-year-old girl who fell on a metal rod in her mouth while playing alone. Examination revealed an agitated child in open mouth posture, with a silvery straight metallic object impacted on the hard palate and projecting from the mouth. X-ray of the post nasal space showed a radiopaque object through the hard palate impinging on the skull base. Case 2: A 5-year-old male presented with swollen neck and difficulty in breathing following a fall on a sharp pencil while at play in school. The object which pierced through the neck was immediately removed by an attendant. Examination revealed a child in obvious respiratory distress with swollen neck, face and eyes with a slit measuring 2cm over the crico-thyroid membrane (subcutaneous emphysema)., DISCUSSION: With no available fibre-optic laryngoscope, classical Macintosh laryngoscopy was infeasible. With refusal of tracheostomy, the authors employed three-man intubation technique to successfully secure the airway for excision of the FB in first patient. The second was induced with IV ketamine since he could not tolerate the supine position and facemask. Due to falling oxygen saturation, an orotracheal intubation was done before a successful mid-level emergency tracheostomy was sited., CONCLUSION: Penetrating airway injuries in children pose serious management challenges. Careful anticipation and quick intervention are helpful.

1528. Edetanlen, B. E. and B. D. Saheeb (2016). "Blood lead concentrations as a result of retained lead pellets in the craniomaxillofacial region in Benin City, Nigeria." The British journal of oral & maxillofacial surgery **54**(5): 551-555.

Patients who survive gunshot wounds often retain pellets in their bodies, which cause delayed morbidity from lead poisoning, and even death. Our aim was to find out whether there is a high concentration of lead in the blood of patients who have asymptomatic retention of lead pellets in the craniomaxillofacial region. We prospectively studied 28 patients who were admitted to our hospital with gunshot injuries to the region, and 28 control subjects. Each was originally recruited three days after injury. The control subjects were chosen from people who lived in the same household or worked in the same place as the patients. Any previous exposure to lead was excluded. Blood samples

were collected three days and three months after injury and analysed for the presence of lead by atomic absorption spectrophotometry. The mean (SD) age for both patients and control subjects was 33 (12) years. The mean (SD) and range of concentrations of lead in patients three days after injury was 0.11 (0.07), range 0.01-0.32mumol/L, while those of the control subjects were 0.03 (0.02) and 0-0.06, respectively. Three months after injury, the mean (SD) and range of concentrations of the patients were 0.30 (0.11) and 0.12-0.59mumol/L, while those of the control subjects were 0-1.25 and 0.12 (0.006) mumol/L, respectively (p= 0.000). The study showed a higher mean blood lead concentration in patients with gunshot injuries than in control subjects, but lower than the threshold values published by the Centers for Disease Control/Occupational Health and Safety Administration in the United States.

1529. Edetanlen, B. E. and B. D. Saheeb (2019). "Effect of bone fracture(s) on blood lead levels from retained lead pellets in craniomaxillofacial region." Human & experimental toxicology **38**(12): 1378-1383.

BACKGROUND: Missile-related blood lead elevations and toxicity are well documented in the literature but reports on its associated risk factor(s) are few., OBJECTIVE: To determine if bone fracture(s) contribute to an elevated lead blood level., METHOD: This is a prospective study of subjects with retained pellets in the craniomaxillofacial region following gunshot injuries who met the inclusion criteria. Blood samples were collected from the test subjects and their corresponding control subjects via venipuncture. Collected blood samples were used for blood lead measurement by the wet method of the atomic absorption spectrophotometry. Using appropriate statistical tests, $p < 0.05$ was considered significant., RESULTS: A total number of 48 subjects were studied. The mean blood lead levels (BLLs) of the study population were 6.88 +/- 1.17 microg/dl while that of the control group was 1.52 +/- 0.87 microg/dl and the mean difference was statistically significant ($p = 0.03$). The mean and standard deviation of BLL of subjects with fractures were 4.77 +/- 0.9, 5.08 +/- 1.0, and 5.22 +/- 1.0 microg/dl at days 3, 21, and 42 postinjury, respectively, while for those without bone fractures were 3.07 +/- 1.4, 3.70 +/- 0.8, and 4.33 +/- 1.7 microg/dl. The difference was statistically significant ($p = 0.04$)., CONCLUSION: Subjects with bone fractures were found to have higher BLLs than those without bone fractures, where pellets were retained in their bodies.

1530. Edetanlen, E. B. and B. D. Saheeb (2018). "A study on shotgun injuries to the craniomaxillofacial Region in a Nigerian Tertiary Health Center." Nigerian journal of clinical practice **21**(3): 356-361.

CONTEXT: Short-range shotgun wounds of the craniomaxillofacial region are life-threatening and are as devastating as military rifle wounds., AIMS: This study aimed to evaluate the pattern of presentation of craniomaxillofacial shotgun injuries, types of shotgun injuries, and the outcome of treatments in our environment., SETTING AND DESIGN: This is a prospective observational study. Materials and Methods: This is a prospective observational study conducted from February 2006 to March 2012. All patients with shotgun wounds to the craniomaxillofacial region were included in the study by convenient sampling method. Glezer's shotgun classification scheme was used to categorize the patients into short-, intermediate-, and long-range shotgun wounds. Data collected were analyzed using SPSS version 16., STATISTICAL ANALYSIS USED: Descriptive statistics were used to calculate the data. Mean and standard deviation (SD) were calculated for all quantitative variables such as age. Frequency and percentages were presented for qualitative variables., RESULTS: A total number of 28 patients were seen. Ages ranged from 19 to 64 years with a mean (+/-SD) of 32.7 (+/-11.4) years. The two most commonly used shotguns were locally made pistol (25, 42.9%) and the cut-size gun (10, 35.7%) and the least commonly used was Dane gun (1, 3.6%). Close-range injury to the face was 17 (60.7%) while that of intermediate- and long-range injuries were 6 (21.1%) and 5 (17.9%), respectively., CONCLUSION: Wounds sustained from close-range shotguns to the face were the most common in this environment. The outcome of treatment was satisfactory when treated with conservative debridement and early reconstruction.

1531. Edge, R. and S. Navon (1999). "Scleral perforation during retrobulbar and peribulbar anesthesia: risk factors and outcome in 50,000 consecutive injections." Journal of cataract and refractive surgery **25**(9): 1237-1244.

PURPOSE: To measure the frequency of scleral perforation and identify related risk factors during local anesthetic injection for intraocular surgery., SETTING: Multispecialty eye hospital., METHODS: All patients (n = 50,000) having retrobulbar (26,857) or peribulbar (23,143) injections at the King Khaled Eye Specialist Hospital were reviewed. Cases of scleral perforation were analyzed for potential technical and ophthalmic risk factors, management of injuries,

and visual and anatomic outcomes. Mean follow-up was 14.4 months (range 8 to 24 months)., RESULTS: Seven (0.014%) needlestick injuries were identified, all of which had posterior staphyloma as the only identifiable risk factor. Applying a previously measured prevalence of 10.7% for posterior staphyloma in our surgery patients gave a scleral perforation rate of 0.13% (7 of 5350) for staphylomatous eyes. All perforated globes had originally planned cataract extraction within 8 weeks of injury. Additional management consisted of observation (2 cases), cryotherapy (2 cases), and vitreoretinal procedures for retinal detachment (3 cases) and subretinal hemorrhage (1 case). At last follow-up, all retinas were attached and 3 cases (42.8%) had a visual acuity of worse than 20/160. Both cases requiring multiple retinal detachment surgeries developed proliferative vitreoretinopathy and poor visual acuity., CONCLUSIONS: Eyes with posterior staphyloma sustained needlestick injuries at a rate of 1 in 760 compared with 0 injection perforations in more than 44,000 nonstaphylomatous eyes.

1532. Edgington, B. D., et al. (2008). "Intraorbital organic foreign body in a tree surgeon." Ophthalmic plastic and reconstructive surgery **24**(3): 237-238.

A tree surgeon suffered a traumatic floor fracture complicated by multiple organic foreign bodies. CT confirmed a left floor fracture and medial wall fracture and decreased attenuation in the inferior orbit and maxillary sinus. Exploration of the orbital floor led to the removal of multiple wooden fragments up to 2.5 cm in length. Additional surgeries led to the removal of additional wooden fragments. Detection of organic intraorbital foreign bodies requires a high degree of clinical suspicion and close consultation with a radiologist.

1533. Edrich, C. L. and C. F. Kranemann (1998). "Air gun injury presenting as axial proptosis." Canadian journal of ophthalmology. Journal canadien d'ophtalmologie **33**(4): 219-220.

1534. Edwards, F. H. and R. S. Davies (1982). "Late post-traumatic obstructive jaundice secondary to a biliary tract foreign body." The Journal of trauma **22**(4): 336-338.

Post-traumatic biliary obstruction caused by a penetrating foreign body is rare. Our patient appears to be the first case in which the diagnosis was established by endoscopic retrograde cholangiopancreatography. Even though this entity is uncommon, it should be considered in patients presenting with jaundice and abdominal pain years after penetrating abdominal trauma.

1535. Efe, J. O. J., et al. (2021). "Investigating antemortem, perimortem and postmortem injuries: Forensic implication." Bangladesh Journal of Medical Science **20**(1): 50-57.

Context:Skeletal injuries discovered from human remains are classified into antemortem, perimortem and postmortem. Studies that documents injuries of various skeletal elements is of vital importance to forensic anthropologist. Aim: This study investigated antemortem, perimortem, postmortem and other injuries caused by various instruments among skeletal elements. Methodology: A total of 200 bones of unknown age and gender were studied. Injuries were interpreted based on basic features specific to them and each was described and photographed. Chisquare test was used to show association between skeletal elements and time of injuries. Statistical evaluation was done using SPSS 20 Software Version. Significance was accepted at $p<0.05$. Result: The bones from this study showed 17.50% antemortem, 24% perimortemand 57% postmortem. Findings showed that 49.50% of the bones had blunt force injury, 30.50% had sharp force while 20.00% had ballistic injuries. Basic features of antemortem injuries were smooth and round fractured edges within bones. Sharp, smooth fractured edges were observed among perimortem bones in contrast to irregular, blunt fractured edges and uneven discoloration in postmortem bones.Straight line incisions were seen in bones with sharp force injuries,presence of an entrance wound in ballistic injuries while an impact area was discovered in most bones with blunt force injury.Findings showed that there exist a significant association between ante, peri and postmortem injuries in the ulnar,radius and femur bones ($X2=25.32;13.35;10.11$. $p=0.000;0.001,0.006$) Conclusion: Bones from this study showed more post mortem blunt force injury.

1536. Eftekhar, B., et al. (2009). "Prognostic factors in the persistence of posttraumatic epilepsy after penetrating head injuries sustained in war." Journal of neurosurgery **110**(2): 319-326.

OBJECT: The goal of this paper was to investigate the long-term outcome and the possible prognostic factors that might have influenced the persistence of posttraumatic epilepsy after penetrating head injuries sustained during the Iraq-Iran war (1980-1988)., METHODS: In this retrospective study, the authors evaluated 189 patients who sustained penetrating head injury and suffered posttraumatic epilepsy during the Iraq-Iran war (mean 18.6 +/- 4.7 years after injury). The probabilities of persistent seizures (seizure occurrence in the past 2 years) in different periods after injury were estimated using the Kaplan-Meier method. The possible prognostic factors (patients and injury characteristics, clinical findings, and seizure characteristics) were studied using log-rank and Cox regression analysis., RESULTS: The probability of persistent seizures was 86.4% after 16 years and 74.7% after 21 years. In patients with < 3 pieces of shrapnel or no sphincter disturbances during seizure attacks, the probability of being seizure free after these 16 and 21 years was significantly higher., CONCLUSIONS: Early seizures, prophylactic antiepileptics drugs, and surgical intervention did not significantly affect long-term outcome in regard to persistence of seizures.

1537. Eftekhari, K., et al. (2015). "The last ride of Henry II of France: orbital injury and a king's demise." Survey of ophthalmology **60**(3): 274-278.

Jousting was a popular pastime for royalty in the Renaissance era. Injuries were common, and the eye was particularly at risk from the splinters of the wooden lance. On June 30, 1559, Henry II of France participated in a jousting tournament to celebrate two royal weddings. In the third match, Gabriel de Montgomery struck Henry on the right shoulder and the lance splintered, sending wooden shards into his face and right orbit. Despite being cared for by the prominent physicians Ambroise Pare and Andreas Vesalius, the king died 10 days later and was found to have a cerebral abscess. The wound was not explored immediately after the injury; nevertheless, wooden foreign bodies were discovered in the orbit at the time of autopsy. The dura had not been violated, suggesting that an infection may have traveled from the orbit into the brain. Nostradamus and Luca Guarico, the astrologer to the Medici family, had prophesied the death of Henry II of France, but he ignored their warnings and thus changed the course of history in Renaissance Europe.

1538. Egan, R. A. and V. K. Vijayan (1991). "Fibronectin immunoreactivity in neural trauma." Brain research **568**(1-2): 330-334.

The presence of extracellular matrix protein fibronectin (FN) at the site of neural trauma was examined using immunohistochemical methods. At 2, 4 and 7 days following a penetrating wound through the rat cerebral cortex, FN staining was detected in the neuropil and in non-neuronal cells adjacent to the wound. FN-stained cells were GFAP-negative and were identified as brain macrophages based on cell surface staining for CR3 complement receptor. Our findings suggest a role for FN in the repair of neural trauma.

1539. Egbohou, P., et al. (2019). "Epidemiology of pediatric traumatic brain injury at sylvanus olympio university hospital of lomé in Togo." Anesthesiology Research and Practice **2019**.

Introduction. Severe pediatric traumatic brain injury (pTBI) is a leading cause of disability and death in children worldwide. Children victims of pTBI are admitted to the Sylvanus Olympio University Hospital (SOUH) at the multipurpose Intensive Care Unit (ICU). We aimed in this study to describe the epidemiologic characteristics and outcomes of pTBI patients admitted in this ICU. Patients and Methods. This study was conducted at the ICU of SOUH of Lome. It was a retrospective study based on patients' records from 0 to 15 years old admitted during the period from 1 January 2012 to 30 June 2018 (5 years and 6 months). Results. We recorded 91 pTBI included in the study. The mean age was 7.7 ± 4.3 years. The male predominated with 67.0%. Road traffic accidents were the most common cause (79.1%), followed by falls (19.8%). The average pediatric Glasgow Coma Scale (pGCS) was 6.6 ± 1.4, with a mean Injury Severity Score (ISS) of 23.1 ± 8.4. The most common brain injuries found in the CT scan were brain edema (72.9%), skull fracture (69.5%), and brain contusion (55.9%). The average duration under mechanical ventilation was 2.1 ± 2.9 days, and the mean ICU stay was 4.9 ± 4.4 days. Overall mortality was 31.9% (29 cases). Factors significantly associated ($p<0.05$) with death were hypotension (51.7%), anemia (43.1%), hyperthermia (46.7%), GCS < 6 (64%), and ISS > 20 (48.9%). Conclusion. pTBI mortality remains high in SOUH ICU. Factors associated with mortality were secondary systemic insults, worse GCS < 6, and ISS > 20.

1540. Egea-Guerrero, J. J., et al. (2013). "S100B protein may detect brain death development after severe traumatic brain injury." Journal of neurotrauma **30**(20): 1762-1769.

Despite improvements in the process of organ donation and transplants, the number of organ donors is progressively declining in developed countries. Therefore, the early detection of patients at risk for brain death (BD) is a priority for transplant teams seeking more efficient identification of potential donors. In the extensive literature on S100B as a biomarker for traumatic brain injury (TBI), no evidence appears to exist on its prognostic capacity as a predictor of BD after severe TBI. The objective of this study is to assess the value of including acute S100B levels in standard clinical data as an early screening tool for BD after severe TBI. This prospective study included patients with severe TBI (Glasgow Coma Scale score [GCS] <= 8) admitted to our Neurocritical Care Unit over a 30 month period. We collected the following clinical variables: age, gender, GCS score, pupillary alterations at admission, hypotension and pre-hospital desaturation, CT scan results, isolated TBI or other related injuries, Injury Severity Score (ISS), serum S100B levels at admission and 24 h post-admission, and a final diagnosis regarding BD. Of the 140 patients studied, 11.4% developed BD and showed significantly higher S100B concentrations (p<0.001). Multivariate analysis showed that bilateral unresponsive mydriasis at admission and serum S100B at 24 h post-admission had odds ratios (ORs) of 21.35 (p=0.005) and 4.9 (p=0.010), respectively. The same analysis on patients with photomotor reflex in one pupil at admission left only the 24 h S100B sample in the model (OR=15.5; p=0.009). Receiver operating characteristics (ROC) curve analysis on this group showed the highest area under the curve (AUC) (0.86; p=0.001) for 24 h S100B determinations. The cut off was set at 0.372 mug/L (85.7% sensitivity, 79.3% specificity, positive predictive value [PPV]=18.7% and negative predictive value [NPV]=98.9%). This study shows that pupillary responsiveness at admission, as well as 24 h serum S100B levels, could serve as screening tools for the early detection of patients at risk for BD after severe TBI.

1541. Egger, C., et al. (2015). "An extraordinary case of an intracranial foreign body after a gunshot to the head." International journal of legal medicine **129**(1): 149-152.

Intermediate targets (IT) can modify the morphology of an entrance wound, the trajectory of the bullet, and contaminate the path with fragments or material from the target. The penetration into the body of big fragments or even of an entire IT is exceptional and only rarely reported in the literature. The interpretation of a gunshot wound after contact of the bullet with IT can sometimes be very tricky as the classical morphology can be missing. The presented case is a rare example of atypical entrance wound and path due to a surprising intermediate target of a gunshot fired against the head.

1542. Eghwrudjakpor, P. O., et al. (1991). "Central nervous system bioaminergic responses to mechanical trauma. An experimental study." Surgical neurology **35**(4): 273-279.

Changes in biogenic amines in the brain and spinal cord following penetrating injury were studied in male Wistar rats using high-performance liquid chromatography with electrochemical detection. Rapid increase in hemispheric concentration of these substances was noted beginning shortly after trauma. This trend continued until they were about three to four times control levels by about 24 to 48 hours postinjury. In the spinal cord, however, there was an initial sharp reduction in regional concentrations 2 hours postinjury followed by a slow rise thereafter. By 48 hours postinjury, levels of norepinephrine, dopamine, and serotonin of the cords of injured animals were still less than those of nontraumatized controls. This variation in the central nervous system bioaminergic response with the level of injury raises questions as to its precise role in neurological damage following mechanical insult.

1543. Egorova, O. A. (2011). "[Two cases of stab and slash wounds in the vitally important body regions]." Sudebno-meditsinskaia ekspertiza **54**(4): 44-45.

Two cases of severe injuries to the head and the neck are reported. Both patients recovered after the traumas.

1544. Egorova, O. A., et al. (2010). "[Assessment of injuries to the neck and dentomandibular system complicated by the infectious process]." Sudebno-meditsinskaia ekspertiza **53**(4): 15-18.

The objective of the present work was to consider problems pertaining to forensic medical examination of injuries to the neck and dentition system complicated by pyoinflammatory processes. Two clinical observations are

reported to illustrate significant difficulties encountered by forensic medical experts during assessment of the severity of harm inflicted to human health in the cases requiring differential characteristic of injuries, evaluation of opportuneness and completeness of the provided medical aid, and the role of these factors in the development of fatal pyoseptic complications. Special emphasis is laid on the analysis of possibilities to attain these goals based on the "Medical criteria for the assessment of severity of harm inflicted to human health" (2008).

1545. Ehlers, J. P., et al. (2008). "Metallic intraocular foreign bodies: characteristics, interventions, and prognostic factors for visual outcome and globe survival." American journal of ophthalmology **146**(3): 427-433.

PURPOSE: To describe metallic intraocular foreign body (IOFB) injuries and identify prognostic factors for visual outcome and globe survival., DESIGN: Interventional, consecutive, retrospective case series., METHODS: setting: Wills Eye Hospital. study population: Ninety-six eyes of 96 patients with metallic intraocular foreign bodies. procedures: Metallic IOFB injuries between January 1991 to June 2002 were reviewed for clinical characteristics, surgical intervention, and outcome. Univariate and multivariate analyses were performed to identify prognostic variables. main outcome measures: Final visual acuity and globe survival., RESULTS: The average patient age was 33.0 years with a male predominance (94%). Forty percent of eyes had a presenting vision of 20/50 or better. Following IOFB removal, 40% of patients required additional interventions. Thirty-one percent of eyes had a final acuity of 20/50 or better. Eight percent of patients ultimately required enucleation or evisceration. Excellent visual outcome (defined as > or =20/50) was associated with multiple variables, including normal lens at presentation and anterior segment IOFB (P< .003). Factors associated with poor visual outcome (defined as <20/200) included uveal prolapse and posterior segment IOFB (P < .0003). Globe loss was associated with younger age, presenting light perception (LP) or no light perception (NLP) vision, BB/pellet injury, and the presence of an afferent pupillary defect (P < .01)., CONCLUSIONS: Multiple prognostic factors were identified in this large analysis of metallic IOFB injuries, which may help predict visual outcome and globe survival. Most of these variables were independent of intervention and can be identified at the time of initial presentation.

1546. Eid, R. A. C., et al. (2017). "How trauma patients are discharge home regards to functionality?" American Journal of Respiratory and Critical Care Medicine **195**.

Introduction: Trauma patients due to its severity tends to decrease functionality during hospital stay. Physiotherapy during hospital stay may minimize this impact. But how these patients return home after hospital discharge regards to functionality? Objective: To evaluate trauma patient's functionality at hospital discharge. Methods: A retrospective study, through medical chart and a specific prospective database of trauma patients admitted to a private hospital. All patients admitted with trauma diagnosis in the hospital, and that had information regards to functionality were included. Demographic data, trauma diagnosis, patients' severity (through SAPS), mechanical ventilation time, length of hospital stay and functionality were collected. We classified functionality in 5 categories: totally independent, modified independence (patient is independent but needs help with a specific device as walking stick, walker, etc), 25% functionality dependence, 50% functionality dependence, and total dependence. Results: 26 trauma patients were admitted to the hospital in 2015 and 2016. Of these patients 42% were polytrauma patients, followed by 27% with polytrauma and brain injury associated, 11.5% firearm injury, 11.5% blunt trauma, 3.8% stab wound, 3.8% brain injury. Most patients were male (77%), with median age of 42 years old (range of 13-64), mean SAPS of 26 (±4,2), median mechanical ventilation time of 15 (range of 4-26), median length of hospital stay of 4 days (range of 1-48), most patients were sent home after hospital discharge (96%). At hospital admission, 11.5% of patients had independent functionality, 30% had 25% functionality dependence, 50% of patients had 50% functionality dependence, and 7.7% had total dependence. At hospital discharge most patients had modified independent functionality (34%), 30% were totally independent, 19.2% had 25% functionality dependence, 15.4% had 50% functionality dependence, and no patients were discharge from the hospital totally dependent, showing an improvement of patients' functionality. There was no correlation of functionality with patients' severity or hospital length of stay. Conclusion: At hospital discharge there was an improvement in trauma patients' functionality, most patients with modified independent functionality. But some patients are still dependent in some degree, they would probably benefit from post hospital rehabilitation program.

1548. Eimontaite, I., et al. (2018). "Differential roles of polar orbital prefrontal cortex and parietal lobes in logical reasoning with neutral and negative emotional content." Neuropsychologia **119**: 320-329.

To answer the question of how brain pathology affects reasoning about negative emotional content, we administered a disjunctive logical reasoning task involving arguments with neutral content (e.g. Either there are tigers or women in NYC, but not both; There are no tigers in NYC; There are women in NYC) and emotionally laden content (e.g. Either there are pedophiles or politicians in Texas, but not both; There are politicians in Texas; There are no pedophiles in Texas) to 92 neurological patients with focal lesions to various parts of the brain. A Voxel Lesion Symptom Mapping (VLSM) analysis identified 16 patients, all with lesions to the orbital polar prefrontal cortex (BA 10 & 11), as being selectively impaired in the emotional reasoning condition. Another 17 patients, all with lesions to the parietal cortex, were identified as being impaired in the neutral content condition. The reasoning scores of these two patient groups, along with 23 matched normal controls, underwent additional analysis to explore the effect of belief bias. This analysis revealed that the differences identified above were largely driven by trials where there was an incongruency between the believability of the conclusion and the validity of the argument (i.e. valid argument/false conclusion or invalid argument/true conclusion). Patients with lesions to polar orbital prefrontal cortex underperformed in incongruent emotional content trials and over performed in incongruent neutral content trials (compared to both normal controls and patients with parietal lobe lesions). Patients with lesions to parietal lobes underperformed normal controls (at a trend level) in neutral trials where there was a congruency between the believability of the conclusion and the validity of the argument (i.e. valid argument/true conclusion or invalid argument/false conclusion). We conclude that lesions to the polar orbital prefrontal cortex (i) prevent these patients from enjoying any emotionally induced cognitive boost, and (ii) block the belief bias processing route in the neutral condition. Lesions to parietal lobes result in a generalized impairment in logical reasoning with neutral content.

1549. Eisen, M. D. and L. R. Lustig (2002). "Otolaryngologic aspects of the Lewis & Clark Expedition, 1803-1806." The Laryngoscope **112**(6): 1065-1071.

Medical difficulties related to otolaryngology that occurred during the Lewis & Clark Expedition (1803-1806) are highlighted. These difficulties included ear and face frostbite, upper respiratory infections, temporal vessel laceration from an air gun accident, neck scrofula, and a pediatric neck mass. The custom of Clatsop Indian head flattening is also described. These descriptions also aim to illustrate the state of otolaryngology during the early 19th century in America.

1550. Ekong, C. E. and Y. H. Gabriel (1980). "Unusual head trauma by a rearview mirror." The Journal of trauma **20**(5): 422-423.

An unusual case of penetrating head injury by rearview mirror is reported. The case demonstrates an important mechanical principle that when a relatively small impact is applied over a small area, it is converted to a large force with potential to cause substantial tissue damage. At 1-year followup the patient showed no complications, following craniotomy and removal of the foreign body.

1551. El Chehab, H., et al. (2018). "Cephalic region war injuries in children: Experience in French NATO hospital in Kabul Afghanistan." Injury **49**(9): 1703-1705.

BACKGROUNDS: The NATO KAIA Hospital (Kabul International Airport), under French command, provided medical support for NATO forces in the Kabul region from 2009 to 2014. Medical assistance to civilians was an additional mission which included support for children who were war injured. The objective of this study was to analyze characteristics of cephalic injuries in children victims of war trauma., METHODS: A retrospective study was conducted and commenced with the hospital opening (July 2009) to March 2012 on all children (<15years) with war trauma. We distinguished cephalic lesions in cranial (neuro-surgical), ophthalmological and neck regions. We analyzed mechanism, region, severity score, surgeries and resuscitation efforts., RESULTS: 217 children were operated on with 81 war traumas (mean age 10.2years). 36 children (44.4%) had a cephalic injury. 52.9% of the injured had an ophthalmological injury, 38.2% a cranial region injury and 29.4% a neck lesion. Mortality rate was 5.6% (1 hemorrhagic shock and 1 cerebral wound) in this cephalic lesion group. Ophthalmic injuries were the most common of cephalic injuries; 19 children of which 7 had a bilateral injury (26 eyes). In this group, fragmentary injuries were the most frequent (64% of eyes). In cerebral lesion group, the lesions were linked to a bullet or a shrapnel in 9 of 13 children. This mechanism systematically caused a crania-cerebral wound. Explosion (fragmentary and shrapnel) was the most important in the neck lesions (7 children of 10)., CONCLUSIONS: The cephalic lesions were the second most common region in children during our experience in Afghanistan. Lack of protection (helmet) in children may explain the frequency of cephalic wounds.

1552. El Hajj Abdallah, Y., et al. (2019). "Devastating neurologic injuries in the Syrian war." Neurology: Clinical Practice **9**(1): 9-15.

BackgroundSince 2011, hundreds of thousands of Syrians have been displaced and injured due to the ongoing Syrian civil war. In this study, we report the prevalence of neurologic injuries in a major rehabilitation center on the Turkish-Syrian border where death and injury tolls continue to rise.MethodBased on several on-site visits from 2013 to 2016, medical practitioners collected data from patients in the major rehabilitation center on the border of Turkey and Syria. The clinical data, which included the type and cause of injury, laterality, paralysis, areas injured, and treatment offered, were analyzed.ResultsA total of 230 patients were identified as having sustained a neurologic injury, 221/230 (96.1%) male and 9/230 (3.91%) female, ranging from ages 2-52 years. A total of 305 total injuries were documented over the course of a 4-year analysis due to several patients having multiple injuries. Gunshot wounds were the dominant mechanism of injury in 125/230 (54.3%) patients. Patients more frequently sustained single injuries 152/230 (66.1%) than multiple injuries 78/230 (33.9%). Peripheral nerve injuries were the most prevalent injuries, at 92.5% of all neurologic injuries (282/305), specifically injury to the radial nerve, at 19.1% (54/282) of peripheral injuries. Patients with spinal cord injuries made up 20/230 (8.7%) of all patients, with thoracic spine injuries composing 50% (10/20). Traumatic brain injuries were the least prevalent, 3/230 (1.3%), with an equal distribution of subtypes.ConclusionThis study and critical analysis of the devastation in Syria suggests the desperate need for emergency aid.

1553. El Khatib, K., et al. (2004). "The frontal sinus: a culprit or a victim? A review of 40 cases." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **32**(5): 314-317.

PURPOSE: Frontal sinus fractures represent 2-12% of facial trauma. The purpose of this article is to discuss proper management of these fractures and to evaluate the indications for treatment, the complications and the morphologic results of surgery., MATERIAL AND METHODS: The records of 40 patients admitted to this department with a frontal sinus fracture were reviewed. Sex, age, the circumstances of injury, the imaging techniques, fracture patterns,

associated injuries, length of hospital stay, surgical approaches and the complications were analysed. The operations included 3 main options: cranialization, obliteration or reconstruction of the frontal sinus., RESULTS: There were 32 men and 8 women (average 34 years). The most common cause of injury was motor vehicle accidents. Conventional radiography of the face was complemented by computed tomography and 3D reconstructions. Isolated anterior table fractures were found in 72.5% and combined anterior/posterior table fractures in 27.5% of the cases. The treatment was surgical for 70% of the patients; the average length of hospitalization was 1 week. Postoperative complications were: 1 brain abscess, 2 cases of frontal sinusitis and 2 cases of chronic headache., CONCLUSION: Long-term complications in frontal sinus fractures are intracranial infection, sinusitis and forehead defects. To avoid these it was decided to treat all displaced fractures surgically in displaced anterior table fractures the sinus was obliterated with cancellous bone and in displaced posterior table fractures the sinus was cranialized.

1554. El Sayed, M., et al. (2018). "Undiagnosed impacted knife blade from a penetrative orbital injury: A case report." International journal of surgery case reports **53**: 254-258.

INTRODUCTION: Impacted foreign bodies in the complex maxillofacial region is uncommon and their safe removal is a challenge., CASE PRESENTATION: The authors report an unusual case of a 41 year old male patient who suffered from violence-related orbital trauma with a knife. The presence of this foreign body was not diagnosed for a period of 20 months. After proper clinical and radiologic examination it was localized and extracted in the theater in a safe controlled manner. Although the tip of the blade was left in situ, the patient had a rapid uneventful recovery and follow up., DISCUSSION: The path of penetration of the foreign body in presented case didn't follow the predicted patterns of orbital injury described in literature. A dilemma exists as to how aggressive such injuries should be managed. Thus the surgical approach implemented for retrieving the current foreign body was highlighted., CONCLUSION: Radiographs are a crucial element for early diagnosis and proper management of foreign body injuries. Rapid postoperative recovery can be achieved with simple safe surgical retrieval maneuvers. Copyright © 2018. Published by Elsevier Ltd.

1555. El-Anwar, M. W. (2018). "A rare penetrating trauma of both orbit and nasal cavity." Iranian Journal of Otorhinolaryngology **30**(6): 365-367.

Introduction: Diagnosis of orbital foreign body (FB) penetration is usually obvious when part of the FB is still attached at the entry wound (1). However, the depth and course of the FB in this case was not visible. Case Report: A 5-year old female presented with a pencil penetrating the left orbit. A computed tomography (CT) scan showed that the pencil penetrated the left orbit (extraseptal) through the lacrimal bone to the left nasal cavity, then perforated the nasal septum, crossing the right nasal cavity. Finally, the pencil penetrated the lamina paperatea to the right orbit and stopped near the right optic nerve. The pencil was gently removed under general anesthesia with close observation of the eyes. Conclusion: A case of a pencil penetrating both orbits and nasal cavities was reported, and the pencil was safely removed. This draws attention to the possible penetration power of a pencil, with the possibility of injury to the orbit and optic nerve on the opposite side of the penetration. It also demonstrates the feasibility of safe removal.

1556. Elarbi, M. (2015). "War injuries in west of Libya." International journal of oral and maxillofacial surgery **44**: e57.

Injuries to face from different weapons used during war differ from injuries caused by other means loss of both hard and soft tissue, damage to vital structures is common in these circumstances, early intervention and proper management required. Objectives: This is 4 years retrospective study of patients sustained firearm maxillofacial injuries during war in Libyan revelations and a total of 41 patients with 55 fractures and isolated soft tissue in 9 cases treated in Ali Omar Askar Center for Neurosurgery, maxillofacial surgery department Esbea Tripoli. Patients and methods: in juries involves facial bones and soft tissues such as eyes, lips cheeks and tongue. Patients and methods: From February 2011 to December 2014 a total of 41 patients with maxillofacial firearm injuries to soft and hard maxillofacial region. Patients either referred for maxillofacial injuries after had the initial treatment elsewhere or had the full management in our hospitals including the maxillofacial team, initial assessment and life saving procedures at the accident and emergency applied to all cases proper clinical and radiographic assessment antibiotic therapy, wound debridement done for all patients and closure using local flaps when required. Treatment range from immediate intervention to 5 days. Results: The pure soft tissue injuries were in 9 patients 14%, Bony fractures involves mostly the mandible in 31 cases 48%, 37 males 90% and only 4 females 10% with a ration 9:1 the youngest patient was 15 years and oldest 60 years, the age

group 21-30 years forming 44% followed by 15-20 years 29% and 31-40 were 24% with only one patient aged 55 years 2%. 31 patients with mandibular fractures mainly angle and body 26% and 23% respectively, 11 cases of maxillary fractures, 4 cases 36% in both Lefort I and Dentoalveolar Fractures with 3 cases involves lateral wall of maxillary sinus 27%. 9 cases with isolated soft tissue involvement in the soft tissue around the mandible, forehead two cases each, cheek and tongue 3 cases which forms 33%. Associated injuries such as rupture of eye globe in one case, damage to facial nerve in 2 cases, fractures of cervical spine wing, tongue injury and loss of soft tissue in two cases. Postoperative wound infection reported in two cases. Treatment: Open reduction and rigid internal fixation used in 24 patients out of total of 44 cases forming 55%, conservative treatment in 9 cases 20%, intermaxillary fixation in 3 cases 7% and four cases had foreign body removed from soft tissue in head and neck area with or without bony involvement. Conclusion: Maxillofacial gunshot injuries with various types of arms and weapons lead to severe damage to facial bones and orofacial structures requires urgent surgical intervention to avoid postoperative infections. In this study most of the patients did not showfor followup and to knowthe progress of the treatment done.

1557. Eldridge, P. R. and J. A. Punt (1988). "Transient traumatic cortical blindness in children." Lancet (London, England) **1**(8589): 815-816.

1558. Elegbede, A., et al. (2019). "Survival following Self-Inflicted Gunshots to the Face." Plastic and reconstructive surgery **144**(2): 415-422.

BACKGROUND: Self-inflicted gunshot wounds involving the face are highly morbid. However, there is a paucity of objective estimates of mortality. This study aims to provide prognostic guidance to clinicians that encounter this uncommon injury., METHODS: A retrospective review of patients presenting to R Adams Cowley Shock Trauma Center (a Level I trauma center) with self-inflicted gunshot wounds to the face from 2007 to 2016. Isolated gunshot wounds to the calvaria or neck were excluded. The data were analyzed to determine predictors of survival., RESULTS: Of the 69 patients that met inclusion criteria, 90 percent were male and 80 percent were Caucasian, with an age range of 21 to 85 years. The most frequently seen injury patterns showed submental (57 percent), intraoral (22 percent), and temporal (12 percent) entry sites. Fewer than half (41 percent) of the cohort sustained penetrative brain injury. Overall, there were 18 deaths (overall mortality, 26 percent), 17 of which were secondary to brain injury. Independent predictors of death included penetrative brain injury (OR, 17; $p < 0.0001$) and age. Mortality was 17 percent among patients younger than 65 years, compared with 73 percent for those aged 65 years or older ($p = 0.0001$). Gastrostomy placement was independently associated with 25 percent reduction in length of hospitalization ($p = 0.0003$)., CONCLUSIONS: Despite tremendous morbidity, the overwhelming majority of patients who present with facial self-inflicted gunshot wounds will survive, especially if they are young and have no penetrative brain injury. These findings should help guide clinical decisions for this devastating injury., CLINICAL QUESTION/LEVEL OF EVIDENCE: Risk, III.

1559. Elewa, H. F., et al. (2006). "Minocycline for short-term neuroprotection." Pharmacotherapy **26**(4): 515-521.

Minocycline is a widely used tetracycline antibiotic. For decades, it has been used to treat various gram-positive and gram-negative infections. Minocycline was recently shown to have neuroprotective properties in animal models of acute neurologic injury. As a neuroprotective agent, the drug appears more effective than other treatment options. In addition to its high penetration of the blood-brain barrier, minocycline is a safe compound commonly used to treat chronic infections. Its several mechanisms of action in neuroprotection -- antiinflammatory and antiapoptotic effects, and protease inhibition -- make it a desirable candidate as therapy for acute neurologic injury, such as ischemic stroke. Minocycline is ready for clinical trials of acute neurologic injury.

1560. Elgamal, E. A. (2005). "Complete recovery of severe quadriparesis caused by stab wound at the craniocervical junction." Neurosurgical review **28**(1): 70-72.

Non-missile penetrating spinal cord injuries are uncommon, and involvement of the craniocervical junction is even less frequent. The author reports a case of 42-year-old male who presented with quadriparesis immediately following stab injury inflicted with a kitchen knife to the back of his neck. The knife was retained in the patient's neck. Neurological examination revealed spastic paraplegia and severe weakness of the left upper limb and the right-hand grip, and sensory disturbance from C2 and downwards. In addition to these symptoms, cerebrospinal fluid (CSF) was

leaking from the wound. Computerised tomography (CT) scan showed the blade passed through the spinal canal and its tip reached the odontoid peg. After retrieval of the knife, his quadriparesis recovered. The management and outcome of the patient are described.

1561. Elghoura, N. F. D. (2012). "[Meningitis can resemble subarachnoid haemorrhage]." Meningitis kan ligne subaraknoidal blodning. **174**(20): 1388-1389.

A 70 year-old man was admitted under the diagnosis of subarachnoid haemorrhage and presented with a history of ear pain, followed by acute onset of severe headache, nausea, vomiting, impaired consciousness, and fever. However, a computed tomography (CT) showed an acute mastoiditis and pneumocephalus, and a lumbar puncture confirmed the diagnosis meningitis. The increased middle ear pressure relative to the intracranial pressure had caused air and bacteria to penetrate intracerebrally. This case illustrates the importance of a rapid diagnostic workup in acute onset headache including a careful anamnesis, CT and lumbar puncture.

1562. Elia, M. D., et al. (2014). "Extraction of fronto-orbital shower hook through transcranial orbitotomy." Craniomaxillofacial Trauma and Reconstruction **7**(2): 147-148.

Transorbital foreign bodies threaten both the integrity of the globe and the brain. We present an unusual case of a penetrating right frontal lobe-orbital metallic shower hook. Extensive intracranial involvement necessitated transcranial orbitotomy allowing for the removal of the object without loss of the globe. Copyright © 2014 by Thieme Medical Publishers, Inc.

1563. Elia, M. D., et al. (2013). "Extraction of fronto-orbital metallic radio antenna through Stallard orbitotomy." Orbit (Amsterdam, Netherlands) **32**(2): 141-142.

A 39-year-old man presented after falling on a radio antenna while in his yard. Computed tomography revealed that the antenna entered the right superolateral orbit, penetrating through the right orbital roof and extending into the right frontal lobe. A Stallard orbitotomy was performed to remove the antenna resulting in blepharoptosis.

1564. Elias, P. Z. and M. Spector (2012). "Characterization of a bilateral penetrating brain injury in rats and evaluation of a collagen biomaterial for potential treatment." Journal of neurotrauma **29**(11): 2086-2102.

Penetrating brain injury (PBI) encountered in both the military and civilian sectors results in high morbidity and mortality due to the absence of effective treatment options for survivors of the initial trauma. Developing therapies for such injuries requires a better understanding of the complex pathology involved when projectiles enter the skull and disrupt the brain parenchyma. This study presents a histological characterization of bilateral PBI using a relatively new injury model in the rat, and also investigates the implantation of a collagen scaffold into the PBI lesion as a potential treatment option. At 1 week post-PBI, the lesion was characterized by dense macrophage infiltration, evolving astrogliosis, hypervascularity, and an absence of viable neurons, oligodendrocytes, and myelinated axons. Histomorphometric analysis revealed that the PBI lesion volume expanded by 29% between 1 week and 5 weeks post-injury, resulting in formation of a large acellular cavity. Immunohistochemistry showed a decrease in the presence of CD68-positive macrophages from 1 to 5 weeks post-PBI as the necrotic tissue in the lesion was cleared, while persistent glial scarring remained in the form of upregulated GFAP expression surrounding the PBI cavity. Implanted type I collagen scaffolds remained intact with open pores after time periods of 1 week and 4 weeks in vivo, and were found to be sparsely infiltrated with macrophages, astrocytes, and endothelial cells. Collagen scaffolds appear to be an appropriate delivery vehicle for cellular and pharmacological therapeutic agents in future studies of PBI.

1565. Elias, P. Z. and M. Spector (2015). "Treatment of penetrating brain injury in a rat model using collagen scaffolds incorporating soluble Nogo receptor." Journal of tissue engineering and regenerative medicine **9**(2): 137-150.

Injuries and diseases of the central nervous system (CNS) have the potential to cause permanent loss of brain parenchyma, with severe neurological consequences. Cavitary defects in the brain may afford the possibility of treatment with biomaterials that fill the lesion site while delivering therapeutic agents. This study examined the treatment of penetrating brain injury (PBI) in a rat model with collagen biomaterials and a soluble Nogo receptor (sNgR)

molecule. sNgR was aimed at neutralizing myelin proteins that hinder axon regeneration by inducing growth cone collapse. Scaffolds containing sNgR were implanted in the brains of adult rats 1 week after injury and analysed 4 weeks or 8 weeks later. Histological analysis revealed that the scaffolds filled the lesion sites, remained intact with open pores and were infiltrated with cells and extracellular matrix. Immunohistochemical staining demonstrated the composition of the cellular infiltrate to include macrophages, astrocytes and vascular endothelial cells. Isolated regions of the scaffold borders showed integration with surrounding viable brain tissue that included neurons and oligodendrocytes. While axon regeneration was not detected in the scaffolds, the cellular infiltration and vascularization of the lesion site demonstrated a modification of the injury environment with implications for regenerative strategies.

1566. Elias, W. J., et al. (2009). "Sulcal and ventricular trajectories in stereotactic surgery." Journal of neurosurgery **110**(2): 201-207.

OBJECT: The authors analyzed deep brain stimulation electrode trajectories on MR images to identify risks of cerebrovascular complications associated with the number of electrode insertions, traversal of a sulcus, and penetration of the ventricle., METHODS: Pre- and postoperative MR volumes were fused to determine the proximity of electrodes to a sulcus or ventricle and whether there were cortical, subcortical, or intraventricular complications. Complications were further classified as hemorrhagic or nonhemorrhagic and symptomatic or asymptomatic. The authors examined 258 electrode implantation for deep brain stimulation. There were 4 symptomatic events (1.6% incidence): 3 hemorrhagic and 1 nonhemorrhagic, all within the cortex. Asymptomatic events included cortical hemorrhage in 1 patient, nonhemorrhagic cortical changes in 6, pallidal hemorrhage in 1, thalamic infarction in 1, and intraventricular hemorrhage (IVH) in 5 patients., RESULTS: Proximity to a sulcus was a significant risk factor for hemorrhagic and nonhemorrhagic cortical complications ($p = 0.001$). There was a complication rate of 10.1% within the trajectories penetrating or adjacent to a sulcus, and a 0.7% rate with trajectories clearly positioned within the gyrus. Asymptomatic IVH was observed in 5% of ventricular penetrations. A history of hypertension was a risk factor for cortical hemorrhage ($p = 0.019$), but not for cortical ischemic/edematous events ($p = 0.605$). The number of electrode penetrations did not differ between patients with and without complications ($p = 0.868$), and the sequence of electrode insertions was not a risk factor in bilateral surgeries., CONCLUSIONS: Symptomatic cortical complications occur when electrodes traverse close to a sulcus. Asymptomatic IVH occurs infrequently with ventricular penetration. Despite intraoperative efforts to avoid cortical sulci, a higher than expected incidence of electrode proximity to the sulci was identified on careful postoperative trajectory analysis. This finding emphasizes the importance of assiduously planning trajectories and reviewing cases with thorough MR analysis.

1567. Elkbuli, A., et al. (2020). "A rare case of pre-hospital globe enucleation after a penetrating injury to the orbit during an assault: A case report and literature review." International journal of surgery case reports **75**: 231-234.

Introduction: Ocular trauma is a common occurrence in trauma settings but often occurs with little to no effect on the vision of the patient. Traumatic enucleation is a rare but devastating injury. Case presentation: A 40-year-old male presented to our trauma center after an assault resulting in right globe enucleation. CT confirmed absence of the globe with disruption of the ipsilateral orbital contents and distal optic nerve disruption. The patient was started on intravenous antibiotics and the right orbit was packed. He was taken to the operating room for exploration of the right orbit and placement of an implant. His remaining hospital course was unremarkable. Discussion: Documented mechanisms of injury for traumatic enucleation are diverse, but often involve significant retro-ocular force to completely dislodge the globe from the orbit. Optic nerve avulsion may cause associated optic nerve chiasm damage leading to temporal hemianopia in the uninjured contralateral eye. Treatment involves stabilization and preparation for future implant placement. Conclusion: Traumatic enucleation is extremely rare. Development of a grading system applicable to traumatic enucleation may be helpful in guiding management in this complex patient population.

1568. Elkhazh, M. K., et al. (2009). "[Gunshot combined spinal and craniocerebral injuries]." Vestnik khirurgii imeni I. I. Grekova **168**(6): 56-58.

An analysis of 32 case histories of patients with gunshot wounds of the cervical part of the spine and spinal cord in combination with cranio-cerebral injuries is presented. In 11 patients with injuries of the spine and spinal cord it was shown that in 4 patients tetraplegia persisted in the postoperative period, 3 patients had Brown-Sequard syndrome, 1

patient had superior paraparesis, 3 patients had pelvis disorders. Rehabilitation procedures started as early as possible allow minimization of the neurological problems and, correspondingly, the degree of disability of the patients.

1570. Eller, K. M. and J. A. Kuller (1995). "Porencephaly secondary to fetal trauma during amniocentesis." Obstetrics and gynecology **85**(5 Pt 2): 865-867.

BACKGROUND: There has been one reported case of porencephaly diagnosed postnatally as a result of amniocentesis. We report the first antenatal diagnosis of porencephaly, which apparently resulted from penetration of the fetal skull during amniocentesis., CASE: A 37-year-old woman had genetic amniocentesis at 16 weeks' gestation. The fetal skull was penetrated during the unguided procedure. Porencephaly discovered at 28 weeks' gestation was confirmed by imaging studies in the neonatal period., CONCLUSION: Inadvertent fetal skull penetration appeared to result from amniocentesis unguided by continuous ultrasound.

1571. Ellis, E., 3rd, et al. (2003). "Treatment considerations for comminuted mandibular fractures." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **61**(8): 861-870.

PURPOSE: We sought to assess the methods of treatment used and outcomes for a large sample of patients with comminuted fractures of the mandible., PATIENTS AND METHODS: The records of all patients who were identified as having comminuted fractures of the mandible over a 10-year period with sufficient follow-up were collected and analyzed for demographic information, treatment rendered, and outcomes. Standard descriptive statistics and nonparametric statistics were used to analyze the data., RESULTS: A total of 196 patients (167 males and 29 females) with 198 comminuted fractures met the inclusion criteria. The mandibular body was the most commonly affected region. Approximately half were sustained in altercations. Gunshot wounds created fractures that were more comminuted than other causes. The comminuted regions were treated by closed reduction and maxillomandibular fixation (MMF) in 35 fractures, open reduction with stable internal fixation in 146 fractures, and 17 were treated with external pin fixation. For those patients treated with open reduction, a single reconstruction bone plate was used in the majority of cases (114). For those patients treated open, 98 were treated using an intraoral approach and 52 were treated using an extraoral approach. The mean follow-up was 140.6 days. Complications occurred in 26 fractures (13%). The complications were malocclusion in 8 fractures and nonocclusal (ie, infection, nonunion, etc) in 18 fractures. There was a statistically significant relationship between the development of complications and the degree of fragmentation ($P < .05$). There was also a significant relationship between treatment and the development of complications ($P < .05$). Patients treated with external pin fixation had a 35.2% complication rate compared with a 17.1% complication rate for patients undergoing closed treatment with MMF, or patients treated with open reduction and stable internal fixation (10.3%). However, patients treated with external pin fixation had more severe injuries., CONCLUSIONS: The results of this study show that, when possible, the use of open reduction and stable internal fixation is associated with a low complication rate. However, not all comminuted fractures are amenable to this treatment, and in those, alternatives such as closed reduction with MMF or the application of external pin fixation may be necessary.

1572. Ellis, E., 3rd and Y. Tan (2003). "Assessment of internal orbital reconstructions for pure blowout fractures: cranial bone grafts versus titanium mesh." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **61**(4): 442-453.

PURPOSE: To assess the adequacy of internal orbital reconstruction in pure blowout fractures using either cranial bone grafts or titanium mesh implants., PATIENTS AND METHODS: The preoperative and postoperative true coronal computed tomography (CT) scans of 58 patients with unilateral pure orbital blowout fractures were included in the study. Demographic data and measurements of the pretreatment size of the defects were tabulated. The accuracy of reconstruction was assessed subjectively by 1 surgeon by scoring the position of the implant/graft, repositioning of orbital soft tissues, and assessment of orbital volume using the uninjured side for comparison. The cross-sectional area of the anterior, middle, and posterior regions of the reconstructed defect was statistically compared with the same locations on the uninjured orbits by scanning the CT scans and calculating the number of pixels within the selected CT slices. A comparison of the accuracy of reconstructions for those reconstructed with cranial bone graft and those with

titanium mesh was statistically performed using parametric (for subjective analyses) and nonparametric tests (for cross-sectional area data)., RESULTS: Thirty-eight cases were classified as fractures of the orbital floor, 4 as isolated medial wall fractures, and 16 as combined floor/medial wall fractures. There was a statistically significant difference in the surgeon's subjective ratings of adequacy of reconstructions between titanium mesh and bone-grafted groups. Orbits reconstructed with titanium mesh were more accurate than those reconstructed with bone (P <.001). Overall, there was no significant difference in cross-sectional areas between the reconstructed and uninjured orbits in the middle and posterior regions of the defects, but the anterior region showed significantly smaller cross-sectional areas in the reconstructed orbits (P <.001)., CONCLUSIONS: Although there was great individual variability and both materials could be successfully used, the orbits reconstructed with titanium mesh showed better overall reconstructions than those reconstructed with bone grafts. 1573. Ellis, P. K. (2013). "Supra-aortic arterial trauma." Cardiovascular and interventional radiology **36**: S173.

Supra-aortic trauma includes injuries to the carotid, subclavian, vertebral or innominate arteries and may be blunt or penetrating. The endovascular approach offers an alternative that avoids significant morbidity associated with open surgery. Experience in this area is growing; however, publications remain limited to case reports and small series with short-term follow-ups. Carotid and vertebral pseudoaneurysms may occur following trauma, catheterisation or mycotic infection and should be treated because they are associated with poor outcomes such as haemorrhage, enlargement and distal embolisation. There have been several case series detailing treatment of these lesions using covered stents or bare stents with coil occlusion. Outcomes have been generally good with mid-term follow-up. The endovascular technique is particularly attractive near the skull base, where surgery is technically challenging, and has been associated with high morbidity and mortality rates. There is no consensus for to the ideal regimen of anti-coagulation during or following an endovascular procedure. Some series have reported the use of clopidogrel administered as a loading dose during the procedure. Alternatives include the use of heparin during the procedure or ,on occasions, the use of no anti-coagulation during the acute traumatic phase. Following the treatment, various strategies have been employed, including warfarin and dual and single antiplatelet therapy, often for variable lengths of time. There is lack of sufficient evidence for recommending a particular strategy in all patients. Arteriovenous fistulae of the vertebral arteries can occur because of penetrating injuries and are often iatrogenic. Many are asymptomatic; others present with bruit, vertigo, diplopia or tinnitus. The goal of treatment should be the closure of the arteriovenous fistula with preservation of the parent artery. If a penetrating injury of the vertebral artery results in extensive damage to the vessel, possibly a transection, the endovascular approach may not always result in preservation of the parent artery and vascular sacrifice may be necessary. In this case, a balloon occlusion test will be necessary to exclude vascular ischemic symptoms. The fistula may be excluded using detachable balloons, coils or liquid agents such as N-butyl cyanoacrylate. Supporting stents may be helpful. Axillosubclavian arterial injuries are often difficult to repair surgically in view of the wide exposure required. Literature to date describes over 30 reports of endovascular treatment of these injuries, comprising a total of 160 patients. Most injuries were penetrating (gunshot wound, stab wound and iatrogenic catheter-related injury). Injuries included pseudoaneurysm, AV fistula, occlusion, transection and perforation. In most cases covered or uncovered stents were utilised. Coils or gelfoam can be used for bleeding branch vessels. Again, mid-term results in this area have been promising, with low morbidity and mortality. CONCLUSION: Endovascular techniques show great promise in traumatic injury to the supra-aortic vessels. The presentation will describe some of the techniques and review some of the literature to date.

1574. Ellis, P. S. (1997). "Fatal gunshot injury caused by an unusual projectile--a barrel-cleaning brush as a tandem bullet." The American journal of forensic medicine and pathology **18**(2): 168-171.

The case of a man who committed suicide by shooting himself in the head is reported. The rifle used by the decedent had been cleaned with the use of a barrel-cleaning brush, which had become detached and had been retained in the barrel. The brush together with the usual projectile were propelled into the head. A highly unusual radiograph was obtained. The implantation of a barrel-cleaning brush in the skull has not been reported in the English literature. This case is reported because of its unique nature and because of possible misinterpretation of an unusual radiological appearance. The potential dangers of inadequate care during weapon cleaning are also discussed.

1575. El-Menyar, A., et al. (2015). "Traumatic brain injury in pediatric population: A single-center analysis over 5 years." Critical care medicine **43**(12): 290.

Learning Objectives: Traumatic brain injury (TBI) is a major cause of morbidity and mortality in children and adolescents worldwide. We aimed to study the trends of pediatric TBI (pTBI) in terms of the demographics, etiology, clinical patterns, and outcomes in a level I trauma center in Qatar. Methods: For the period between 2010 and 2014, we conducted a retrospective observational analysis for all pTBI. Results: Over a 5-year period, 945 patients were admitted with TBI, out of them 17.7% were ≤ 18 yr old with a mean age of 10.6 ± 5.9 and 81% were males. MVCs were significantly higher in late adolescent (77.3%), whereas, FFH was significantly higher in infants/preschoolers (59%) group. Head injuries were common in late adolescents aged 15-18 (40%) and infants/preschool age group of 0-4 yr (23%). Fatal injuries were most frequent in infants/preschool age group, in which 21% of the injuries were fatal. Almost one-third of the pTBI needed neurosurgical intervention (insertion of monitoring [15%], drainage devices [6.4%] or outright surgery [10.2%]. The mean ISS was 20.7 ± 9.8 and the highest ISS was recorded in adolescents (24.2 ± 9.8).Fifty three (41%) patients were intubated at the scene. Although AIS showed no significant differences by age groups, it was higher in infants/preschoolers and late adolescents. Only brain contusion showed significant difference by age (p=0.04); higher in early adolescents (61.5%) and late adolescents (58.6%). Hospital complications included pneumonia (25.4%), sepsis (8%) and ARDS (1.6%). Pneumonia and sepsis showed significant differences (p<0.05) by age groups. Overall mortality rate was 13%. Higher mortality was seen in infants (20.5%, p=0.43). Half of the patients died within 24 hr; 8 (36%) patients died between 1- 7 days and 3 (14%) patients died after one week. Conclusions: The overall rate of pTBI is 5-14 cases per 100,000 children per year with high mortality in Qatar. FFH is the mechanism of pTBI for small children, whereas MVC was the cause of injury in adolescents. Public education regarding safety measures, injury prevention and Law enforcement are highly recommended.

1576. El-Menyar, A., et al. (2017). "Pediatric Traumatic Brain Injury: a 5-year descriptive study from the National Trauma Center in Qatar." World journal of emergency surgery : WJES **12**: 48.

Background: The epidemiologic characteristics and outcomes of pediatric traumatic brain injury (pTBI) have not been adequately documented from the rapidly developing countries in the Arab Middle East. We aimed to describe the hospital-based epidemiologic characteristics, injury mechanisms, clinical presentation, and outcomes of pTBI and analyze key characteristics and determinant of pTBI that could help to make recommendations for policies to improve their care., Methods: We conducted a retrospective observational study in a level 1 trauma center (2010-2014) for all pTBI patients. Data were analyzed and compared according to different patient age groups., Results: Out of 945 traumatic brain injury patients, 167 (17.7%) were <= 18 years old with a mean age of 10.6 +/- 5.9 and 81% were males. The rate of pTBI varied from 5 to 14 cases per 100,000 children per year. The most affected group was teenagers (15-18 years; 40%) followed by infants/toddlers (<= 4 years; 23%). Motor vehicle crash (MVC; 47.3%) was the most frequent mechanism of injury followed by falls (21.6%). MVC accounted for a high proportion of pTBI among teenagers (77.3%) and adolescents (10-14 years; 48.3%). Fall was a common cause of pTBI for infants/toddlers (51.3%) and 5-9 years old group (30.3%). The proportion of brain contusion was significantly higher in adolescents (61.5%) and teenagers (58.6%). Teenagers had higher mean Injury Severity Scoring of 24.2 +/- 9.8 and lower median (range) Glasgow Coma Scale of 3 (3-15) (P = 0.001 for all). The median ventilatory days and intensive care unit and hospital length of stay were significantly prolonged in the teenage group. Also, pTBI in teenage group showed higher association with pneumonia (46.4%) and sepsis (17.3%) than other age groups (P = 0.01). The overall mortality rate was 13% (n = 22); 11 died within the first 24 h, 7 died between the second and seventh day and 4 died one week post-admission. Among MVC victims, a decreasing trend of case fatality rate (CFR) was observed with age; teenagers had the highest CFR (85.7) followed by adolescents (75.0), young children (33.3), and infants/toddlers (12.5)., Conclusions: This local experience to describe the burden of pTBI could be a basis to adopt and form an efficient, tailored strategy for safety in the pediatric population.

1577. El-Naaj, I. A., et al. (2006). "Gunshot wounds: reconstruction of the lower face by osteogenic distraction." Plastic and reconstructive surgery **118**(5): 1271-1272.

1578. Eloy, J. A., et al. (2012). "Salvage endoscopic nasoseptal flap repair of persistent cerebrospinal fluid leak after open skull base surgery." American journal of otolaryngology **33**(6): 735-740.

PURPOSE: Persistent cerebrospinal fluid (CSF) rhinorrhea after open skull base surgery can be challenging to manage due to the risk of meningitis, brain abscess, surgical morbidity associated with revision craniotomy, and the lack of available healthy autologous tissue after failure of a pericranial flap. Given the recent success of the vascularized pedicled nasoseptal flap (PNSF) for reconstruction after endoscopic skull base surgery, we have adopted this technique as a salvage method to treat recalcitrant CSF rhinorrhea after previous open skull base surgery in order to avoid revision craniotomy. To our knowledge, use of the PNSF in this setting has not been previously described in the literature., METHODS: A retrospective analysis was performed on 4 patients who underwent endoscopic endonasal PNSF repair of persistent CSF rhinorrhea after having undergone previous open transcranial skull base operation. Pathologies consisted of one sinonasal anterior skull base squamous cell carcinoma, one recurrent petrosal skull base meningioma, and 2 traumatic gunshot wounds to the head., RESULTS: All 4 patients underwent successful repair of CSF rhinorrhea without complications using the salvage endoscopic endonasal PNSF technique after a mean follow-up of 21.5 months., CONCLUSIONS: In patients who have undergone previous open skull base surgery as the primary approach, persistent CSF rhinorrhea can be safely repaired using the vascularized PNSF via an endoscopic endonasal approach. This minimally invasive strategy has the advantage of providing new healthy vascularized tissue for skull base reconstruction while avoiding revision craniotomy.

1579. Eloy, J. A., et al. (2013). "Early harvesting of the vascularized pedicled nasoseptal flap during endoscopic skull base surgery." American journal of otolaryngology **34**(3): 188-194.

PURPOSE: The vascularized pedicled nasoseptal flap (PNSF) represents a successful option for reconstruction of large skull base defects after expanded endoscopic endonasal approaches (EEA). This vascularized flap can be harvested early or late in the operation depending on the anticipation of high-flow CSF leaks. Each harvesting technique (early vs. late) is associated with different advantages and disadvantages. In this study, we evaluate our experience with early harvesting of the PNSF for repair of large skull base defects after EEA., METHODS: A retrospective review was performed at a tertiary care medical center on patients who underwent early PNSF harvesting during reconstruction of intraoperative high-flow CSF leaks after EEA between December 2008 and March 2012. Demographic data, repair materials, surgical approach, and incidence of PNSF usage were collected., RESULTS: Eighty-seven patients meeting the inclusion criteria were identified. In 86 procedures (98.9%), the PNSF harvested at the beginning of the operation was used. In 1 case (1.1%), the PNSF was not used because a high-flow intraoperative CSF leak was not encountered. This patient had recurrence of intradural disease 8months later, and the previously elevated PNSF was subsequent used after tumor resection., CONCLUSION: Based on our data, a high-flow CSF leak and need for a PNSF can be accurately anticipated in patients undergoing EEA for skull base lesions. Because of the advantages of early harvesting of the PNSF and the high preoperative predictive value of CSF leak anticipations, this technique represents a feasible harvesting practice for EEA surgeries.

1580. Elron, M., et al. (1997). "Suboccipital tangential gunshot wound." Acta neurochirurgica **139**(4): 377-378.

1581. Elron, M., et al. (1998). "Profuse hemorrhage from cerebral vessels in tangential missile injuries." Acta neurochirurgica **140**(3): 255-259.

Tangential missile injuries are recognized as a cause of cerebral damage by in driven bone fragments, parenchymal lacerations and intracerebral haematomas. Severe blood loss from this type of injury was not reported. Four patients are described in whom high kinetic energy missiles caused severe tangential craniocerebral injuries. Their condition was aggravated by life threatening haemorrhage. The bleeding vessels were cerebral arteries or major veins entrapped in the fracture line and bleeding extracranially. This blood loss cannot be controlled by dressing and salvage could be achieved only by immediate resuscitation, vigorous fluid replacement and very rapid evacuation to a neurosurgical center.

1582. Elserry, T., et al. (2013). "Image guided surgery in the management of craniocerebral gunshot injuries." Surgical neurology international **4**(SUPPL.6): S448-S454.

Background: A craniocerebral trauma caused by firearms is a complex injury with high morbidity and mortality. One of the most intriguing and controversial part in their management in salvageable patients is the decision to remove

the bullet/pellet. A bullet is foreign to the brain and, in principle, should be removed. Surgical options for bullet extraction span from conventional craniotomy, through C-arm-guided surgery to minimally invasive frame or frameless stereotaxy. But what is the best surgical option? Methods: We prospectively followed up a cohort of 28 patients with cranio-cerebral gunshot injury (CCHSI) managed from January to December 2012 in our department of neurosurgery. The missiles were extracted via stereotaxy (frame or frameless), C-arm-guided, or free-hand-based surgery. Cases managed conservatively were excluded. The Glasgow Outcome Score was used to assess the functional outcome on discharge. Results: Five of the eight stereotactic cases had an excellent outcome after missile extraction while the initially planned stereotaxy missed locating the missile in three cases and were thus subjected to free hand craniotomy. Excellent outcome was obtained in five of the nine neuronavigation cases, five of the eight cases for free hand surgery based on the bony landmarks, and five of the six C-arm-based surgery. Conclusion: Conventional craniotomy isn't indicated in the extraction of isolated, retained, intracranial firearm missiles in civilian injury but could be useful when the missile is incorporated within a surgical lesion. Stereotactic surgery could be useful for bullet extraction, though with limited precision in identifying small pellets because of their small sizes, thus exposing patients to same risk of brain insult when retrieving a missile by conventional surgery. Because of its availability, C-arm-guided surgery continues to be of much benefit, especially in emergency situations. We recommend an extensive long-term study of these treatment modalities for CCGSI. © 2013 Elserry T.

1583. Elshafei, A. M. K., et al. (2017). "Clinical profile and outcomes of management of orbital cellulitis in Upper Egypt." Journal of Ophthalmic Inflammation and Infection **7**(1).

Background: The purpose of this paper is to study the etiology, clinical findings, and outcomes of management of cases of orbital cellulitis treated in Minia University Hospital in Upper Egypt over the period of 6 years from July 2009 to July 2015. One-hundred two patients diagnosed to have orbital cellulitis were admitted to the hospital and treated on inpatient basis from July 2009 to July 2015. All patients were subjected to full ophthalmological examination, systemic evaluation, and ear, nose, and throat (ENT) consultation. Axial and coronal CT scan and orbital echography were done for all patients. All patients received medical treatments, and 20 patients needed surgical intervention. Results: The source of infection was paranasal sinusitis in 66 patients, trauma in 14 cases, panophthalmitis in 6 patients, and dental infection in 2 cases, and no definite source was detected in 14 cases. Subperiosteal abscess (SPA) developed in 16 patients. The final best corrected visual acuity improved in 58% of the cases, decreased in 4%, and remained unchanged in 38% of cases. No intracranial complication was recorded. Conclusions: Good presenting visual acuity and appropriate medical treatment together with early surgical intervention in cases of SPA are important factors to achieve favorable outcomes in orbital cellulitis. All cases with SPA had paranasal sinusitis, and contrary to previous studies, superior SPA location was the most common followed by the medial location.

1584. El-Shoura, E. A. M., et al. (2018). "Perindopril ameliorates lipopolysaccharide-induced brain injury through modulation of angiotensin-II/angiotensin-1-7 and related signaling pathways." European journal of pharmacology **834**: 305-317.

Localized tissue renin-angiotensin system (RAS) is an interesting pathway of organ damage. Here, the effect of the brain-penetrating angiotensin converting enzyme (ACE) inhibitor perindopril was studied on lipopolysaccharide (LPS)-induced brain damage, with and without exogenous angiotensin (Ang)-II administration. Animals were divided into 6 groups; a normal control group, an LPS control group (LPS, 3mg/kg, i.p., single dose), two treatment groups receiving perindopril (1 and 2mg/kg/day, i.p.) for 7 days before LPS administration, and two Ang-II/perindopril/LPS groups receiving perindopril and LPS, followed by a single dose of Ang-II solution (5 microl, i.c.v.). Brain tissue Ang-II, Ang-1-7, and NADPH oxidase were estimated using ELISA technique. Nuclear factor kappa-B (NF-kB-p65) was estimated using real time PCR technique, while phosphorylated NF-kB-p65 (p-NF-kB-p65), phosphorylated and non-phosphorylated protein kinase B (p-Akt and Akt) and phosphorylated inhibitor of kappa-B (p-IkBa) were estimated by western blot analysis. Malondialdehyde (MDA), glutathione (GSH), superoxide dismutase (SOD), glutathione-S-transferase (GST), catalase, nitrite and myloperoxidase (MPO) were estimated colorimetrically. Brain tissue inducible and endothelial nitric oxide synthases (iNOS and eNOS) were estimated immunohistochemically, confirmed by a histopathological study. LPS-intoxicated rats showed significantly elevated Ang-II, NADPH oxidase, NF-kB-p65, p-NF-kB-p65, p-IkBa, p-Akt, Akt, p-Akt/Akt ratio, MDA, nitrite, MPO and iNOS levels, coupled with significantly suppressed Ang-1-7, GSH, SOD, GST, catalase, and eNOS levels, which were all corrected by pre-treatment with perindopril in both doses by varying degrees. Exogenous Ang-II significantly ameliorated the protective effects of perindopril. Conclusively, perindopril ameliorates

LPS-induced brain damage through modulation of RAS, iNOS/eNOS, p-Akt/Akt and NF-kB signaling pathways.

1585. Elterman, J., et al. (2011). "Independent predictors of 28-day survival in patients with severe traumatic brain injury." Journal of the American College of Surgeons **213**(3): S75.

INTRODUCTION: Traumatic brain injury (TBI) remains the leading cause of death after trauma. Normal saline has been shown to be equivalent to hypertonic saline=dextran for the treatment of severe TBI in a recent trial. While this trial showed no difference in outcome, we sought to identify independent predictors of mortality in this cohort. METHODS: A retrospective review was conducted on data collected prospectively as part of a multicenter, randomized, clinical trial within the Resuscitation Outcomes Consortium.We modeled the association between 28-day survival and fluid use with multivariable logistic regression using robust standard errors adjusting for age, sex, ISS, initial GCS, initial SBP, highest field HR, penetrating injury and study site. RESULTS: 1158 patients were enrolled in the study. The volume of pre-hospital crystalloid - odds ratio (OR) 0.85 per liter increase (95%CI [0.64, 1.13] p=0.27) and hospital crystalloid infused in the first 24 hours - OR 1.05 per liter (95%CI [0.98, 1.12] p=0.18) were not associated with a difference in 28-day survival. However, volume of PRBC in the first 24 hours - OR 0.76 per liter (95%CI [0.6,0.97] p=0.03) and volume of FFP in the first 24 hours - OR 0.59 per liter (95%CI [0.38,0.93] p=0.02) were both independently associated with decreased 28-day survival. CONCLUSIONS: In patients with severe TBI, volume of red blood cells and fresh frozen plasma transfused were independently associated with a statistically significant decrease in 28-day survival while volume of pre-hospital crystalloid and volume of initial 24-hour resuscitation were not.

1586. Elzayat, S. G. and A. A. Ameen (1986). "Incidence of post-traumatic epilepsy." Journal of Neurological and Orthopaedic Medicine and Surgery **7**(1): 69-70.

The incidence of early epilepsy in 200 consecutive patients with penetrating missile head injuries was studied and compared with that in non-missile head injuries. The points emphasized are that neither dural tears with brain penetration, nor the presence of retained metallic fragments, increase the incidence of early epilepsy. Also, it is apparent that anticonvulsants should be reserved for patients under real threat of status epilepticus.

1587. Emamhadi, M. R. and D. Mahmoudi (2015). "Recovery of facial nerve paralysis after temporal nerve reconstruction: A case report." Trauma Monthly **20**(4).

Introduction: Facial paralysis is common following accidents, trauma, viral infection or tumors. Case Presentation: A 24-year-old male patient was referred to us with a history of sharp penetrating trauma to the right temporal region causing unilateral paralysis of the muscles of the right forehead. He was unable to scowl or elevate his right eyebrow and there were no folds on his right forehead. Anastomosis of branches of the temporal nerve was done one month after trauma following regular physical therapy sessions, outcome was good and paralysis of the muscles of the right forehead improved after several months. Conclusions: Immediate repair of the facial nerve injury will improve the process of recovery and rehabilitation of the face and forehead muscles and may play a very important role in the patient's mental satisfaction and improve their quality of life.

1588. Emami, P., et al. (2012). "Case report: surviving a tiger attack." Neurosurgical review **35**(4): 621-624.

Attacks on humans by large predators are rare, especially in Northern Europe. In cases of involvement of the craniocervical compartment, most of the attacks are not survived. We report on a case where the patient survived a tiger attack despite severe head trauma and discuss the circumstances leading to the patient's survival and excellent outcome. The patient we report on is a 28-year-old tamer, who was attacked by three tigers during an evening show. A bite to the head resulted in multiple injuries including left-sided skull penetration wounds with dislocated fractures, dural perforations, and brain parenchyma lesions. The patient recovered without neurological deficits after initial ICU treatment. No infection occurred. In order to understand the mechanism of the tiger's bite to the patient's cranium, a simulation of the attack was performed using a human and a tiger skull put together at identical positions to the bite marks in a CT scan. It seems that during the bite, the animal was not able to clamp down on the patient's skull between its canine teeth and therefore reduced bite forces were applied. Survival of an attack by a large predator that targeted the cervical-cranial compartment with an excellent outcome is not described in the literature. We were surprised to find

only minor lesions of the brain parenchyma despite the obvious penetration of the skull by the tiger's canines. This seems to be related to the specific dynamics of the cranial assault and the reduced forces applied to the patient's head demonstrated in a 3D bite simulation.

1589. Emanuelson, I., et al. (1996). "Rehabilitation and follow-up of children with severe traumatic brain injury." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **12**(8): 460-465.

We studied the outcome of 25 patients [12 girls and 13 boys; mean age 13.7 (SD 3.9 years)] with severe traumatic brain injury (TBI). The Glasgow Coma Scale (GCS) score 6 h after the injury was (mean) 4.5 (SD 2.7), and the mean duration of unconsciousness was 15.8 (SD 10.6) days. Being the most severely brain-injured children in the health care region, they were all referred to its only regional pediatric rehabilitation center during 1986-1990. At discharge, 1 patient was healthy, 1 was in a vegetative state and 18 had multiple impairments. Motor problems were present in 22, epilepsy in 7 and speech impairment in 14. It was not possible to assess cognition in 3 of the children, and 15 of the remaining 22 fell in the normal range. At follow up 2-6 years after trauma, all 23 survivors reported at least one sequela, and 21 had multiple sequelae. As many as two-thirds had normal I.Q. and only 3 were non-ambulatory, but behavioral and personality disturbances were so disabling that none of the patients in this group had been able to readjust to a normal life in society after the trauma.

1591. Empey, P. E., et al. (2012). "Probenecid coadministration increases N-acetylcysteine concentrations following experimental pediatric traumatic brain injury." Clinical and translational science **5**(2): 193.

OBJECTIVES/SPECIFIC AIMS: Oxidative stress plays an important role in the pathophysiology of traumatic brain injury(TBI) but antioxidants have not shown clinical efficacy possibly due to poor brain penetration. Xenobiotic transporters are well known to impact entry of drugs into the brain. We hypothesized that coadministration of the transporter inhibitor, probenecid(PB), would increase plasma levels of the antioxidant, N -acetylcysteine (NAC), in a preclinical model of pediatric TBI. Th is study aimed to determine if this approach has the potential for direct clinical application to improve outcomes in pediatric TBI patients. METHODS/STUDY POPULATION: Juvenile rats (16-18 days old; ≥5/group) received a controlled cortical injury (2.5 mm deformation at 4 m/s) and intraperitoneal doses of NAC (163 mg/kg), PB (150 mg/kg), or the combination 10 min postinjury. Novel liquid chromatography tandem mass spectrometry assays were developed for both drugs and serial plasma concentrations were quantified. RESULTS/ANTICIPATED RESULTS: Drug assays were linear (NAC: 100-10000 ng/mL, R 2 = 0.9991; PB: 25-800μg/mL, R 2 = 0.9926), accurate(inter-/intra-assay variation ≤7.2%), and precise (inter-/intra-assay variation ≤8.4%). Coadministration of PB and NAC increased plasma NAC exposure ∼2-fold (AUC 1-6h : 1.16 ± 0.21×10 5 vs. 2.13 ± 0.40×10 5 ng/mL∗h; p = 0.006); PB levels were unchanged. DISCUSSION/SIGNIFICANCE OF IMPACT: PB coadministration increases systemic NAC exposure in juvenile rats following experimental TBI; suggesting that NAC is a transporter substrate and that brain levels may also increase. Transporter inhibition is a promising therapeutic strategy for future studies in pediatric TBI patients.

1592. Englot, D. J., et al. (2010). "Removal of nail penetrating the basilar artery." Neurosurgical review **33**(4): 501-504.

Nail-gun injuries have become an increasingly prevalent source of penetrating intracranial trauma. Few cases of intracranial nail-gun injuries disturbing major cerebrovascular structures have been reported, and none entailing basilar artery involvement. We report here the case of a 51-year-old male with an intracranial nail-gun injury involving penetration of the distal basilar artery. Operative removal was accomplished under direct vision using a double concentric cranioorbital zygomatic osteotomy for a trans-Sylvian approach. We highlight the principles involved in removing foreign bodies penetrating critical neurovascular structures.

1593. Engrav, L. H., et al. (1986). "Excision of burns of the face." Plastic and reconstructive surgery **77**(5): 744-751.

Sequential excision of burns is now a common technique. Nevertheless, standard texts, when describing the treatment of facial burns, recommend allowing spontaneous separation of the eschar and then grafting on granulation

tissue if healing does not occur. This method yielded disappointing results for us and the reconstructive procedures required were of great magnitude. Therefore, in January of 1979, we began primary excision and grafting of those face burns not essentially healed at 10 days. We have now treated 16 consecutive patients (approximately 5 percent of all face burns) in this manner who are at least 12 months postinjury. Three were lost to follow-up, leaving 13 for evaluation. This method yields better appearance and function than that obtained by allowing spontaneous healing over more than 3 weeks or grafting on granulation tissue and decreases the magnitude of subsequent reconstruction.

1594. Engum, S. A., et al. (2000). "Prehospital triage in the injured pediatric patient." Journal of pediatric surgery **35**(1): 82-87.

BACKGROUND/PURPOSE: Identifying major trauma patients in the prehospital setting is essential in determining management, destination, and best utilization of emergency department resources. Few methods of trauma triage have been accepted unanimously. This study prospectively evaluates the efficacy of comprehensive field triage using 12 criteria (simplified version of the American College of Surgeon's guidelines) in 1,285 pediatric trauma patients., METHODS: Major trauma was defined as occurring in those who died in the emergency room, had major surgery (penetrating injury involving surgery of the head, neck, chest, abdomen, or groin), or were admitted directly to the intensive care unit. The correlation between trauma triage criteria, hospital disposition, and triage accuracy were determined prospectively and compared in the pediatric patients (36 months) with an adult cohort of patients (12 months)., RESULTS: A total of 1,285 pediatric trauma patients were evaluated and compared with 1,326 adult trauma patients. The most accurate trauma triage criterion for major injury was a blood pressure < or = 90 mmHg (systolic) with an accuracy of 86%. This was followed by burn greater than 15% total body surface area (79%), Glasgow Coma Scale score < or = 12 (78%), respiratory rate less than 10/min or greater than 29/min (73%), and paralysis (50%). Less accurate criteria included a fall from greater than 20 feet (33%); penetrating injury to head, neck, chest, abdomen, or groin (29%); ejection from vehicle (24%); pedestrian struck at greater than 20 mph (16%); paramedic judgement (12%); rollover (3%); and extrication (0%). The Glasgow Coma Scale score was a more accurate indicator of major injury in children than adults, and paramedic judgement was less accurate in children when compared with adults. Of the 379 major pediatric trauma victims, the Revised Trauma Score and Pediatric Trauma Score missed 36% and 45% of these major trauma victims, respectively. The overtriage rate for children was 71% with a sensitivity of 100% (no missed major trauma patients)., CONCLUSIONS: Physiological variables, anatomic site, and mechanism of injury provide a sensitive and safe system of triage. Continued education of prehospital personnel regarding pediatric trauma and stratification of the current triage tools are necessary to minimize overtriage in an era of shrinking resources.

1595. Enicker, B. and T. E. Madiba (2014). "Cranial injuries secondary to assault with a machete." Injury **45**(9): 1355-1358.

BACKGROUND: Assaults with a machete cause compound skull fractures which present as a neurosurgical emergency. We aimed to profile cranial injuries caused by a machete over a 10 year period in a single neurosurgical unit., MATERIALS AND METHODS: Retrospective data analysis of cranial injuries following assault with a machete, admitted to the neurosurgery ward, from January 2003 to December 2012 was performed. Medical records were analyzed for demographics, clinical presentation, CT scan findings, surgical treatment and Glasgow Outcome Scale (GOS) at discharge. Management involved wound debridement with antibiotic cover., RESULTS: Of 185 patients treated 172 (93%) were male. Mean age was 31+/-11.4 years. Mean GCS on admission was 13+/-2. Presenting features were focal neurological deficit (48%), brain matter oozing from wounds (20%), and post traumatic seizures (12%). Depressed skull fractures were found in 162 (88%) patients. Findings on CT brain scan were intra-cranial haematoma (88%), pneumocephalus (39%) and features of raised intra-cranial pressure (37%). Thirty-one patients (17%) presented with septic head wounds. One hundred and fifty seven patients (85%) were treated surgically. The median hospital stay was 8 days (range 1-145). The median GOS at discharge was 5 (range 1-5). Twelve patients died within the same admission (6.5%)., CONCLUSION: Machetes cause complex cranial injuries with associated neurological deficit and should be treated as neurosurgical emergency. Timeous intervention and good surgical principles are advocated to prevent secondary infection and further neurological deterioration.

1596. Eolchiian, S. A., et al. (2011). "[Reconstructive surgery of cranio-orbital injuries]." Zhurnal voprosy neirokhirurgii imeni N. N. Burdenko **75**(2): 25-40.

The aim of study was to optimize evaluation and surgery of cranioorbital injuries in different periods after trauma. Material and methods. We analyzed 374 patients with cranioorbital injuries treated in Burdenko Neurosurgery Institute in different periods after trauma from January 1998 till April 2010. 288 (77%) underwent skull and facial skeleton reconstructive surgery within 24 hours - 7 years after trauma. Clinical and CT examination data were used for preoperative planning and assessment of surgery results. Stereolithographic models (STLM) were applied for preoperative planning in 89 cases. The follow-up period ranged from 4 months up to 10 years. Results . In 254 (88%) of 288 patients reconstruction of anterior skull base, upper and/or midface with restoration of different parts of orbit was performed. Anterior skull base CSF leaks repair, calvarial vault reconstruction, maxillar and mandibular osteosynthesis were done in 34 (12%) cases. 242 (84%) of 288 patients underwent one reconstructive operation, while 46 (16%)--two and more (totally 105 operations). The patients with extended frontoorbital and midface fractures commonly needed more than one operation--in 27 (62.8%) cases. Different plastic materials were used for reconstruction in 233 (80.9%) patients, of those in 147 (51%) cases split calvarial bone grafts were preferred. Good functional and cosmetic results were achieved in 261 (90.6%) of 288 patients while acceptable were observed in 27 (9.4%). Conclusion . Active single-stage surgical management for repair of combined cranioorbital injury in acute period with primary reconstruction optimizes functional and cosmetic outcomes and prevents the problems of delayed or secondary reconstruction. Severe extended anterior skull base, upper and midface injuries when intracranial surgery is needed produced the most challenging difficulties for adequate reconstruction. Randomized trial is required to define the extent and optimal timing of reconstructive surgery in patients with severe traumatic brain injury and craniofacial injury in acute period of trauma.

1597. Erbayraktar, S., et al. (2001). "Intracranial penetrating injury associated with an intraoperative epidural haematoma caused by a spring-laden pin of a multipoise headrest." British journal of neurosurgery **15**(5): 425-428.

Lack of an intermediary piece that should have been placed between the pin and spring resulted in skull penetration due to a rapid waste in the spring's compensatory capacity. Checking integrity of internal pieces should be performed regularly. Designing intermediary piece and spring as a single piece might increase safety.

1598. Erdogan, E., et al. (2002). "Craniocerebral gunshot wounds." Neurosurgery Quarterly **12**(1): 1-18.

Cranial gunshot wounds frequently produce devastating injuries to central nervous system (CNS) structures. Surgical therapy and primary and secondary debridement, including repair of dural defects and removal of retained intracranial bone and metal fragments, were applied to 374 cranial gunshot wound victims at Gulhane Military Medical School in Turkey from 1992 to 1999. Dural defects were closed primarily or with temporalis fascia, pericranium, and cadaver grafts. Central nervous system infections were mostly observed in cases with cerebrospinal fluid (CSF) fistulas. All patients underwent computed tomography (CT) scans periodically. In 119 of 374 (32%) patients, bone and metal fragments were determined on control CT scans. We also performed angiography in some patients to reveal traumatic vascular pathologic findings. Most of the deaths in this group of patients were attributed to the direct effects of brain injury and occurred within the first month after injury. Fragments retained after the first debridement were followed periodically by CT scan. Surgery was not performed until infection developed. Retained fragments did not increase the infection risk, but high rates of infection did occur in cases with CSF fistulas. The presence of diffuse brain damage, brainstem injury, CNS infection, or ventricular injury was associated with a poor outcome.

1599. Erdogan, E., et al. (2004). "Ventricular injury following cranial gunshot wounds: clinical study." Military medicine **169**(9): 691-695.

Gunshot wounds to the head are usually fatal injuries, despite all medical and surgical interventions. Ventricular injury is a poor prognostic factor-for penetrating cranial gunshot wounds. Intraventricular hemorrhage and ventricular lacerations are the main components of such injuries. The incidence, management, and outcomes of cases of ventricular injury secondary to cranial gunshot wounds that were treated during a 9-year period at Gulhane Military Medical Academy were examined. The study group consisted of 67 consecutive patients who were admitted to the Department of Neurosurgery with the diagnosis of ventricular injury, with different penetration sites. The patients had been injured by either bullets or shrapnel. Surgical treatment was performed for all patients with ventricular injuries and 22 (32.8%) died. Ventricular injury in cranial gunshot wounds is a complex severe type of trauma that requires serious treatment. Early radiological diagnosis and accurate treatment frequently had lifesaving roles for these patients.

1600. Eren, B., et al. (2013). "An unusual case of penetrating intracranial injury due to scissors." Soudni lekarstvi **58**(2): 29-30.

Craniocerebral penetrating non-missile injuries caused by metallic foreign bodies are uncommon events. Healthy 10 year-old boy applied to the hospital emergency service with his parents. Family members stated that the scissors have been stalled his head accidentally by his sister when they had played together. During physical examination the scissors located on left parietal region of the head was examined. There was no loss of consciousness and oriented with normal vital signs. Radiological investigation demonstrated a hyper dense foreign body (scissors) penetrating cranial cavity and ended before reaching posterior region of the left parietal lobe. To our knowledge, the presented was rare case of intracranial penetrating scissor, which was not removed until, injured, reached the hospital. Our goal was to discuss the rare case of penetrating non-missile foreign body cranial injury from medico legal aspect.

1601. Eren, B., et al. (2012). "Cranial injury caused by penetrating non-missile foreign body: an autopsy case." Soudni lekarstvi **57**(4): 62-63.

UNLABELLED: Presented case was 32-year-old male marble worker, who underwent industrial accident at workplace. On gross physical examination; on forehead region round skin wound in 0.9 cm diameter was detected, radiological examination showed the image of metallic object. in the skull cavity. Brain dissection showed obvious brain injury, haemorrahge explaining the pattern of injury caused by the metallic bodys path, from left frontal lobe to the left cerebellar hemisphere was identified. We presented rare case of penetrating injury of the cranial region caused by non-missile foreign body., KEYWORDS: cranial injury - non-missile foreign body - autopsy.

1602. Erickson, B. P., et al. (2015). "An Unexpected Intraorbital Foreign Body." Ophthalmic plastic and reconstructive surgery **31**(5): e140.

1603. Erickson, N. A., et al. (2016). "A typical foreign body disease in an atypical location." Journal of Comparative Pathology **154**(1): 83.

Introduction: Foreign body-associated encephalitis is a rare condition and can be observed mainly after severe, penetrating trauma of the skull, nose or ears. Materials and Methods: A 2-year-old Hungarian vizsla dog was presented with multiple epileptiform seizures approximately 6 weeks after hyperthermia of unknown origin. Magnetic resonance imaging revealed intra-axial changes in the right occipital lobe. Analysis of the cerebral spinal fluid (CSF) identified severe, neutrophilic to mixed cellular pleocytosis and highly increased protein, suggestive of meningoencephalitis. Bacterial culturing of the CSF and 16S rRNA gene sequencing failed to reveal bacterial involvement. The dog was humanely destroyed because of the poor prognosis. Results: A 1.75 cm long, linear, plant-like foreign body, penetrating 1.45 cm into the cerebral parenchyma was associated with a severe and focally extensive chronic pyogranulomatous meningoencepha-litis. Further histopathological lesions included unilateral rhinitis with focally extensive fibrosis on the right. The perineural connective tissue of the left optic nerve had mild multifocal lymphoplasmacytic infiltrates accompanied by macrophages and few multinucleated giant cells. Conclusions: Despite the size of the foreign body, a migration tract was not identified. Non-traumatic routes of entry may involve nasal migration, the inner otic canal, perforation of the pharyngeal soft tissue, the Foramen magnum or a periocular pathway, for which, in this case, the histological findings in the nasal and perineural tissue may be consistent. Encephalitis due to migrating plant material, most frequently involving a grass awn, with or without bacterial infection, is an unusual lesion, presenting a challenging ante-mortem diagnosis.

1604. Erikson, A. B., et al. (2010). "Evidence of perimortem trauma in free-ranging mountain gorillas (Gorilla beringei beringei) from Volcanoes National Park, Rwanda." American journal of physical anthropology **141**: 101-102.

Analyses of trauma and pathology in skeletal collections derived from wild great apes can provide unique insight and improve our understanding of mortality in living populations. Here we focus on perimortem trauma associated with a modern skeletal sample of Virunga mountain gorillas. The most common cause of death reported previously for mountain gorillas is trauma, resulting from conspecific aggression (most notably infanticide) or poaching-related incidents. Individuals also succumb to respiratory disease, another common source of fatality. The application of a

forensic perspective can aid in clarifying the circumstances of death from analyses of skeletal remains, when records are incomplete or cause of death unknown. We examined evidence of perimortem trauma in a skeletal collection comprised of 78 mountain gorillas (43 adults; 35 infants/juveniles) from Rwanda. Availability of associated veterinary and life history records for many individuals in this collection provides a unique opportunity to clarify the manner in which circumstances surrounding death leave their mark on the skeleton. Analysis of 66 crania and 57 postcrania revealed that blunt force trauma was most common, and regularly found on infants, corresponding with known incidents of conspecific aggression. Trauma associated with infanticide was preferentially distributed in the cranial vault, ribs, and pelvis. Sharp force trauma, inflicted by bladed instruments, was documented on four individuals. No clear skeletal evidence of gunshot wounds exists. Overall, a wide range of perimortem trauma is documented within this assemblage, providing many possible avenues of comparison with similar primate populations and skeletal collections from other parts of the world.

1605. Eriş, S., et al. (2009). "Factors affecting mortality in patients with gunshot injuries." Marmara Medical Journal **22**(3): 181-191.

Objective: We planned this study in order to determine the factors affecting mortality in patients with gunshot injuries in more than one organ. Methods: We retrospectively reviewed the hospital records of 714 patients admitted to the Emergency Department of Dicle University, between January 2000 and December 2004. The factors that we considered would affect mortality such as age, sex, attempts suicide, long barrelled gun injuries, pellet injuries, contact/near contact shot, delayed admission time, presence of serious anemia and shock during admission, more than four entrance wounds, injury areas, serious cranial, thorax and abdominal injuries, vascular injuries in the extremities, administration of multiple transfusion, and trauma scores as GCS, RTS, PATI were analyzed. Results: As a result of unvaried statistical analyses, we determined that suicide attempts (p=0.001), presence of serious anemia (p=0.001) and shock (p=0.001) during admission, presence of serious cranial (p=0.001), thorax (p=0.001) and abdominal (p=0.001) injury, femoral artery injury (p=0.001), multiple blood transfusion (p=0.009), , GCS 0-7, GCS 8-12 (p=0.001) and low RTS (p=0.001)were significant factors affecting mortality. Conclusion: Multivariate analysis showed that serious anemia during admission, serious cranial injury, serious abdominal injury and low RTS were independently significant in predicting mortality (p<0.05).

1606. Erkutlu, I., et al. (2011). "Unusual penetration of a construction nail through the orbit to the cranium: a case report." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES **17**(1): 79-82.

Penetrating head and neck trauma with construction nails are uncommon life-threatening injuries and an important problem in developing countries. Assessment of the neurovascular and systemic physical status is a first requirement, and the decision concerning which surgical approach to perform for the removal of the nail is of critical importance. A 10-year-old girl was presented one hour after a fall injury with complaint of a swelling and foreign body lodgment on the left forehead. Neurological and systemic physical examinations were normal except for weak direct pupillary light reflex on the left side and the patient's state of uneasiness. Radiological investigations showed that the head of the nail had entered from the left infra-orbital region and become lodged through the orbital roof, below the frontal bone. Surgical extraction of the nail in the operating room was performed successfully using left pterional craniotomy and lateral orbitotomy technique, and there was no complication after surgery. Here, we report a case with a rare craniocerebral penetrating wound and type, with the head of the nail lodged in the anterior fossa through the orbital roof, which may be defined as 'reverse penetration of the nail'.

1609. Erol, B., et al. (2004). "Maxillofacial fractures. Analysis of demographic distribution and treatment in 2901 patients (25-year experience)." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **32**(5): 308-313.

INTRODUCTION: The aim of this study was to analyse retrospectively the demographic distribution, treatment modalities, and complications of maxillofacial fractures in 2901 patients treated in this department in Southeast Anatolia between 1978 and 2002. In addition, the use of internal fixation was evaluated in an effort to determine whether there were changes in using internal fixation techniques., PATIENTS AND METHODS: Two thousand nine hundred and one cases of facial trauma were assessed according to age, sex, and aetiology, in addition to the distribution of the fractures relating to facial bones and seasons., RESULTS: It was found that facial fractures were most frequent in males (77.5%) and in the 0-10 year age group; they tended to be more frequent during summer (36.3%); and traffic accidents were the most common aetiological factor (38%). 77.9% of cases were treated with conservative methods, and 22.1% with one or more internal fixation techniques. The most favoured technique was miniplate osteosynthesis; the complication rate associated with internal fixation was 5.7%., CONCLUSION: Currently there are many techniques to be used in treating maxillofacial trauma. However, the experience of the surgical team is also an important factor in achieving satisfactory functional and aesthetic results, and in minimizing complications.

1610. Errando, C. L. (2005). "[Severe injury in the obstetric patient: considerations for anesthesiologist and critical care specialist]." La paciente gestante con traumatismo grave. consideraciones para el medico especialista en anestesiologia y reanimacion. **52**(6): 336-366.

In spite of the high incidence of moderately severe or severe injury in obstetric patients, the anesthesiology literature contains few references to their diagnosis and treatment. We review the epidemiology, etiology, treatment, and prognosis of severe or moderately severe injuries in obstetric patients.

1611. Ersahin, Y., et al. (1994). "Transorbital stab wound: a case report." The Turkish journal of pediatrics **36**(1): 71-75.

Stab wounds of the skull are uncommon. They are usually accidental in children. An apparently trivial wound may cause death due to vascular damage or infection. A 5-year-old boy presented with a nail in the left intraorbital region. He fell with a nail in his hand five hours prior to hospital admission. Computed tomographic scans displayed the nail penetrating the cranium through the left orbital roof and extending towards the left anterior clinoid process. The nail was removed under general anesthesia in the operating room. Meningitis developed two days after the removal of the penetrating object and responded well to antibiotics. The pertinent literature was reviewed.

1612. Ersahin, Y., et al. (1996). "Pediatric depressed skull fractures: analysis of 530 cases." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **12**(6): 323-331.

Depressed skull fractures (DSFs) account for 7-10% of children admitted to hospital with a head injury and 15-25% of children with skull fractures. We reviewed the records of 530 patients operated on for DSF from January 1, 1973, to December 31, 1993. This group was made up of 357 boys (67%) and 173 girls (33%) whose ages ranged from 1 day to 16 years (mean age 6.1 years). Fall was the most common cause of injury. Of the 530 patients with DSF, 66% had compound fractures. The incidence of compound fractures increased with age. Compound fractures caused more brain lacerations (29%) than simple fractures (15.5%) did. We also classified DSFs radiologically as true, flat, or ping-pong ball fractures. Associated intracranial lesions were found to be a bad prognostic factor. There were 13 deaths (2.5%) in this series. Satisfactory results were achieved in over 95% of the patients. Compound fractures are associated with a worse outcome and a higher incidence of intracranial lesions and cortical laceration. Unilateral pupillary dilatation and an admission GCS score of 8 or less are ominous signs in regard to mortality. We also found that the deeper the depressed bone, the higher the risk of both dural tear and cortical laceration and the worse the prognosis. A conservative approach should be followed in cases of simple DSF without associated intracranial hematoma and in cases in which the bone depression is not deeper than 1 cm.

1613. Ersahin, Y., et al. (1999). "Transorbital stab wound from a speargun: A case report." Turkish neurosurgery **9**(3-4): 133-136.

Penetrating stab wounds of the skull rarely occur in civilians. In the absence of direct injury to the brainstem or laceration of a major intracranial vessel, the prognosis for these injuries is good. Transorbital stab wounds causing intracranial complications are more common in children than in adults, and are reported more often in boys than girls. A 9-year-old girl presented with a spear penetrating her left orbita. A cranial computed tomographic scan confirmed that the tip of the spearhead had passed through the left orbital roof and was penetrating the left temporal lobe. The barbed spearhead was removed via craniotomy after cutting off three of the spear's prongs. The child recovered completely after surgery and was neurologically intact 1 year following the injury. Postoperative magnetic resonance angiography (MRA) was also normal. Barbed objects should not be removed by retracing their route of entry. MRA can be used to screen for important potential vascular complications.

1615. Escudero, D., et al. (2022). "Clinico-radiological related to early brain death factors." Medicina intensiva **46**(1): 1-7.

OBJECTIVE: To identify clinical and radiological factors associated to early evolution to brain death (BD), defined as occurring within the first 24h., DESIGN: A retrospective cohort study was made covering the period 2015-2017., SETTING: An adult Intensive Care Unit (ICU)., PATIENTS/METHODS: Epidemiological, clinical and imaging (CT scan) parameters upon admission to the ICU in patients evolving to BD., RESULTS: A total of 166 patients with BD (86 males, mean age 62.7 years) were analyzed. Primary cause: intracerebral hemorrhage 42.8%, subarachnoid hemorrhage 18.7%, traumatic brain injury 17.5%, anoxia 9%, stroke 7.8%, other causes 4.2%. Epidemiological data: arterial hypertension 50%, dyslipidemia 34%, smoking 33%, antiplatelet medication 21%, alcoholism 19%, anticoagulant therapy 15%, diabetes 15%. The Glasgow Coma Score (GCS) upon admission was 3 in 68.8% of the cases in early BD versus in 38.2% of the cases in BD occurring after 24h (p=0.0001). Eighty-five patients presented supratentorial hematomas with a volume of 90.9ml in early BD versus 82.7ml in BD>24h (p=0.54). The mean midline shift was 10.7mm in early BD versus 7.8mm in BD>24h (p=0.045). Ninety-one patients presented ventriculomegaly and 38 additionally ependymal transudation (p=0.021). Thirty-six patients with early BD versus 24 with BD>24h presented complete effacement of basal cisterns (p=0.005), sulcular effacement (p=0.013), loss of cortico-subcortical differentiation (p=0.0001) and effacement of the suprasellar cistern (p=0.005). The optic nerve sheath measurements showed no significant differences between groups., CONCLUSIONS: Early BD (>24h) was associated to GCS<5, midline shift, effacement of the basal cisterns, cerebral sulci and suprasellar cistern, and ependymal transudation.

1616. Escudero, D. and J. Otero (2015). "Intensive care medicine and organ donation: exploring the last frontiers?" Medicina intensiva **39**(6): 373-381.

The main, universal problem for transplantation is organ scarcity. The gap between offer and demand grows wider every year and causes many patients in waiting list to die. In Spain, 90% of transplants are done with organs taken from patients deceased in brain death but this has a limited potential. In order to diminish organ shortage, alternative strategies such as donations from living donors, expanded criteria donors or donation after circulatory death, have been developed. Nevertheless, these types of donors also have their limitations and so are not able to satisfy current organ demand. It is necessary to reduce family denial and to raise donation in brain death thus generalizing, among other strategies, non-therapeutic elective ventilation. As intensive care doctors, cornerstone to the national donation programme, we must consolidate our commitment with society and organ transplantation. We must contribute with the values proper to our specialization and try to reach self-sufficiency by rising organ obtainment.

1617. Escudero, D., et al. (2017). "Organ Donation and Elective Ventilation: A Necessary Strategy." BioMed research international **2017**: 7518375.

Organ transplantation is the sole treatment to improve or save the life of patients with final-stage organ failure. The shortage of available organs for transplantation constitutes a universal problem, estimating that 10% of patients on waiting lists die. Brain death is an undesirable result; nevertheless, it has beneficial side-effects since it is the most

frequent source of organs for transplantation. However, this phenomenon is relatively uncommon and has a limited potential. One of the options that focuses on increasing organ donation is to admit patients with catastrophic brain injuries (with a high probability of brain death and nontreatable) to the Intensive Care Unit, with the only purpose of donation. To perform elective nontherapeutic ventilation (ENTV), a patient's anticipated willingness to donate organs and/or explicit acceptance by his/her relatives is required. This process should focus exclusively on those patients with catastrophic brain injuries and imminent risk of death which, due to its acute damage, are not considered treatable. This article defends ENTV as an effective strategy to improve donation rate, analyzing its ethical and legal basis.

1618. Eskildsen, J. F., et al. (2016). "Airway Management of a 3-Year-Old Child With a Penetrating Oropharyngeal Foreign Body Risking Vascular Injury." A & A case reports **7**(12): 256-259.

Management of anesthesia for a child with an upper airway foreign body is fraught with particular challenges. We present the case of a 3-year-old girl who presented to the emergency department with a 12-cm sewing needle protruding from her mouth and unknown vascular involvement. We were faced with establishing a secure airway despite exclusion of mask ventilation or use of a laryngeal mask airway. Moreover, peripheral intravenous access was lost before adequate sedation. Ultimately, we were able to safely induce anesthesia and achieve endotracheal intubation. The penetrating foreign body was removed with no perioperative complications.

1619. Esmaeilzadeh, M., et al. (2010). "One life ends, another begins: Management of a brain-dead pregnant mother-A systematic review." BMC medicine **8**: 74.

BACKGROUND: An accident or a catastrophic disease may occasionally lead to brain death (BD) during pregnancy. Management of brain-dead pregnant patients needs to follow special strategies to support the mother in a way that she can deliver a viable and healthy child and, whenever possible, also be an organ donor. This review discusses the management of brain-dead mothers and gives an overview of recommendations concerning the organ supporting therapy., METHODS: To obtain information on brain-dead pregnant women, we performed a systematic review of Medline, EMBASE and the Cochrane Central Register of Controlled Trials (CENTRAL). The collected data included the age of the mother, the cause of brain death, maternal medical complications, gestational age at BD, duration of extended life support, gestational age at delivery, indication of delivery, neonatal outcome, organ donation of the mothers and patient and graft outcome., RESULTS: In our search of the literature, we found 30 cases reported between 1982 and 2010. A nontraumatic brain injury was the cause of BD in 26 of 30 mothers. The maternal mean age at the time of BD was 26.5 years. The mean gestational age at the time of BD and the mean gestational age at delivery were 22 and 29.5 weeks, respectively. Twelve viable infants were born and survived the neonatal period., CONCLUSION: The management of a brain-dead pregnant woman requires a multidisciplinary team which should follow available standards, guidelines and recommendations both for a nontraumatic therapy of the fetus and for an organ-preserving treatment of the potential donor.

1620. Esme, H., et al. (2006). "Blunt and penetrating traumatic ruptures of the diaphragm." The Thoracic and cardiovascular surgeon **54**(5): 324-327.

BACKGROUND: The difficulties in diagnosing traumatic diaphragmatic rupture (TDR) at the first admission are the most common causes of morbidity and mortality. The purpose of this study was to review our experience with the management of TDR in order to identify the factors contributing to diagnostic delay and associated morbidity and mortality., METHODS: Fourteen patients with TDR were treated in our hospital between January 2000 and June 2005. They have been investigated retrospectively., RESULTS: The study identified 9 men (64 %) and 5 women (36 %), with ages ranging from 19 to 65 years (mean 35.3 years). Rupture of the diaphragm was left-sided in 10 (71 %) and right-sided in 4 (29 %) of the patients. Blunt trauma accounted for the injuries of 11 patients (79 %). Early diagnosis was obtained in 9 patients (64 %). The diagnosis was established preoperatively in 8 patients (57 %), and intraoperatively in 4 (29 %). The diagnosis was missed in 2 (14 %) patients in the first operation. Multiple associated injuries were observed in 12 patients (85 %). Postoperative complications were encountered in five patients (35 %), and the overall mortality was 7 %., CONCLUSIONS: Diaphragmatic rupture should be suspected in all blunt or penetrating traumas of the thorax and abdomen, and the presence of such an injury should be excluded before terminating the exploratory procedure.

1621. Espaillat, A., et al. (1998). "Intraorbital metallic foreign body." Archives of ophthalmology (Chicago, Ill. : 1960) **116**(6): 824-825.

1622. Esposito, D. P. and J. B. Walker (2009). "Contemporary management of penetrating brain injury." Neurosurgery Quarterly **19**(4): 249-254.

Penetrating brain injury includes all traumatic brain injury that is not the result of a blunt mechanism. Concerning these injuries, gunshot wounds are by far the most prevalent. Despite law enforcement efforts, these injuries unfortunately continue to be commonplace in large trauma centers as well as in metropolitan and large community emergency departments. Great efforts have been undertaken to standardize the medical and surgical management of these patients. The authors review the Guidelines of Penetrating Brain Injury published in 2001 and performed an updated literature search concerning this topic. There is evidence to suggest based upon current data that aggressive antibiotic prophylaxis and avoidance of aggressive debridement of deep-seated bone and bullet fragments has improved morbidity and mortality over the last 35 years.

1623. Essex, R. W., et al. (2004). "Post-traumatic endophthalmitis." Ophthalmology **111**(11): 2015-2022.

OBJECTIVE: To establish risk factors for the occurrence of post-traumatic endophthalmitis, to observe the efficacy of prophylaxis, and to describe the clinical features of post-traumatic endophthalmitis., DESIGN: Partially prospective consecutive case-control study., PARTICIPANTS: A total of 250 consecutive patients admitted to a single ophthalmic hospital with open globe injuries during a 3-year period were included., METHODS: Patients with post-traumatic endophthalmitis were identified prospectively and added to an endophthalmitis database. All open globe injuries during the same time period were identified through a retrospective search of inpatient admissions, and their charts were reviewed. Information collected from all patient files included patient age; gender; injury setting (indoor/outdoor); wound contamination; nature of injury (site on eye, lens involvement, retained intraocular foreign body); mechanism of injury (penetration/perforation/rupture/ruptured surgical wound); prophylactic antibiotic administration, including route and timing; timing of primary repair; lensectomy at the time of primary repair; and depot corticosteroid at the time of primary repair. Any association between these parameters and the subsequent development of endophthalmitis was investigated. Any association between endophthalmitis and final visual acuity (VA) and also enucleation was evaluated., MAIN OUTCOME MEASURE: Development of endophthalmitis., RESULTS: The frequency of endophthalmitis after open globe injury was 6.8%. The following factors were associated with the subsequent development of endophthalmitis by univariate analysis: dirty wound (14.3% vs. 4.1%, P = 0.01), retained intraocular foreign body (13.0% vs. 4.4%, P = 0.02), lens capsule breach (12.8% vs. 3.2%, P = 0.01), delayed primary repair (> or =12 hours) (11.3% vs. 2.9%, P = 0.02), and rural address (10.1% vs. 4.3%, P = 0.07). Risk factors identified after multivariate analysis were dirty injury (odds ratio [OR], 5.3; 95% confidence interval [CI)], 1.5-18.7), breach of lens capsule (OR, 4.4; 95% CI, 1.2-15.6), and delay in primary repair (per hour: OR, 1.013; 95% CI, 1.002-1.024). None of the following factors was found to be associated with post-traumatic endophthalmitis: patient age, gender, injury setting, site of injury on eye, mechanism of injury, antibiotic administration, lensectomy at the time of primary repair, and depot corticosteroid at the time of primary repair. Final VA tended to be worse in eyes with endophthalmitis (P = 0.08). Endophthalmitis did not significantly influence the frequency of enucleation/evisceration (5.9% vs. 4.3%, P = 0.55)., CONCLUSIONS: Delay in primary repair, ruptured lens capsule, and dirty wound were each independently associated with the development of post-traumatic endophthalmitis. Patients with > or =2 of these 3 risk factors had a particularly high frequency of infection.

1624. Estebanez, G., et al. (2014). "Penetrating orbital-cranial injuries management in a limited resource hospital in Latin America." Craniomaxillofacial Trauma and Reconstruction **8**(4): 356-362.

Penetrating orbital-cranial injuries (POCIs) are difficult cases especially in hospitals in low-middle-income countries (LMIC) where resources are limited. We present a case series of POCI managed in a university hospital in such scenario. A retrospective case series was conducted including patients with POCI in 2011. Mechanism of injury, Glasgow Coma Scale score, imaging, medical and surgical management, complications, and Glasgow Outcome Scale (GOS) score were analyzed. A total of 30 patients with penetrating orbital injuries were admitted from March 2011 to December 2011. Of this group, only four patients were diagnosed with cranial penetration. Computed tomography (CT) angiography revealed orbital fractures and injury to frontal, temporal, or occipital lobes. Urgent craniotomy with

isolation of ipsilateral carotid artery was performed. GOS score at discharge was 5 in three patients and 4 in one patient. POCIs are not uncommon in hospitals of LMIC. In such scenarios, a standard approach with CT angiography and early neurosurgical intervention results in good outcome.

1625. Estébanez Montiel, B., et al. (2018). "Brain dead donors (BDD) following cerebral gunshot wounds: Renal allografts validity." Intensive Care Medicine Experimental **6**.

INTRODUCTION. Severe brain injury, after cerebral gunshot wounds, may release large amounts of tissue factor to the circulation, may develop disseminated intravascular coagulation (DIC) and it can lead to renal dysfunction. OBJECTIVES. Analyse the validity for transplantation of kidneys harvested from BDD following cerebral gunshot wounds and the outcome of the transplanted renal grafts. METHODS. Retrospective descriptive study of renal allografts harvested from BDD following cerebral gunshot wounds, at a single center, between January 1, 2007 and May 31, 2017. Donorś data (patientś characteristics, blood tests, associated injuries) and recipients (graft survival, rejection) were collected. RESULTS. We analysed data from six BDD following cerebral gunshot wounds (age 40.3 ± 9.6 years) without any cardiovascular risk factors, except one patient who had hypertension. All patients presented brain death in the first 24 hours of hospital admission. None of them had any associated injuries. One patient suffered a cardiopulmonary arrest (during 20 minutes) prior to ICU admission. One of the patients had elevated creatinine levels in the blood tests when he was admitted to the hospital. But, during the ICU length of stay, up to 50% of the patients presented acute renal failure. Fifty percent of the patients presented compatible or suggestive criteria for DIC. Four kidney grafts were not valid for transplantation because: acute renal failure (two kidney grafts), poor graft perfusion (one case) and complex vascular anomalies (one case). Eight kidney grafts (66.67%) were transplanted. Seven kidney grafts were transplanted in our center. One of them was explanted, in the first 24 hours after transplantation, due to cortical necrosis (pathology exam: glomerular and vascular thrombotic microangiopathy lesions). Fig 1. CT scan. The donorś contralateral kidney was not implanted due to poor perfusion. The pathology exam of this kidney showed multiple fibrin trombi in glomerular capillaries and small-vessels (Figure 2). The remaining 6 grafts presented adequate function one year after the transplantation, except in one case which suffered underlying disease recurrence. CONCLUSIONS. An accurate evaluation of kidney grafts from BDD following cerebral gunshot wounds is required, because they are patients at risk for DIC and acute renal failure. Pre-transplant biopsy and reduction of ischemia time may be indicated. Almost all transplanted renal allo-grafts from BDD, following cerebral gunshot wounds, had good results in our study. Further studies with larger simple sizes are needed.

1626. Estebe, J. P., et al. (1994). "[Intracranial insertion of a nasogastric tube in a patient with severe head injuries]." Penetration intracranienne d'une sonde nasogastrique chez un traumatise cranien grave. **13**(6): 843-845.

The accident intracranial insertion of a nasogastric tube is a well known complication. We report the case of 19-year-old girl with a severe craniofacial trauma who had a nasogastric tube inserted at the site of the traffic accident. The aspiration gave issue of haemorrhagic fluid. At admission the X-ray of the skull showed the intracerebral penetration of the tube. It was removed but the patient died two days later. The various means of prevention and treatment of this complication are discussed.

1627. Eswara, J., et al. (2014). "Epidemiology of adrenal injuries requiring adrenal surgery." Urology **84**(4): S91.

Introduction and Objectives: Adrenal trauma is extremely rare and current literature is lacking in data from large case series. In this study, we analyze adrenal injuries using the National Trauma Data Bank (NTDB). Materials and Methods: We performed a retrospective analysis of the NTDB from the years 2007-2011. Patient demographics, Injury Severity Score (ISS), mechanism of injury, and blunt versus penetrating trauma, associated injuries and hypovolemic shock were assessed. Multivariable models were used to determine associations with outcomes such as need for surgery, type of surgery mean length of stay, need for ICU, and death. Results: Of the 1,766,606 trauma cases in the data set, 8683 were identified involving one or both adrenal glands. There were 7835 blunt and 663 penetrating injuries, and 184 of these injures were isolated to the adrenal glands. Of the 8683 adrenal injuries, 80 (0.9%) required surgery. However, none of the 184 isolated adrenal injures required surgery (p=0.42). Factors associated with isolated adrenal injury include lower ISS (p<0.001), younger age (p<0.001), and penetrating injury (p<0.001). No isolated adrenal injuries were associated with death (12% vs. 0%, p<0.0001). The most common associated organ injuries were ribs (50.9%), thoracic (50.0%), liver (41.6%), vertebrae (30.9%), kidney (27.8%), and spleen (22.0%). Logistic regression showed that

injures to the thorax (p=0.0014) and multiple abdominal injuries (p<0.001) were associated with a lower rate of undergoing adrenal surgery. Higher ISS score (p=0.007), penetrating injury (p<0.001), race (Black) (p=0.029) and concurrent injuries to the spleen (p<0.001) and intestines (p=0.016) were associated with a higher likelihood of requiring adrenal surgery. Older age (p<0.001), higher ISS score (p<0.001), race (Black, Other) (p=0.03, p=0.02), penetrating injuries (p<0.001) and injuries to the aorta/vena cava (p=0.008), vessels (p=0.001), thorax (p=0.03), ribs (p=0.005), stomach (p=0.02), liver (p=0.03), multiple abdominal injuries (p=0.002), and brain/spinal cord (p<0.001) were associated with a higher mortality rate. Conclusions: Adrenal injuries are rare, comprising 0.49% of all traumatic injuries. In our database, isolated adrenal injuries were not fatal and did not require surgery. Younger age, race (Black), higher ISS score, penetrating injury, and concurrent injuries to the spleen/intestines were associated with a higher likelihood of requiring an adrenalectomy.

1628. Eswara, J. R., et al. (2015). "Adrenal injuries: A national trauma data bank analysis." Journal of Urology **193**(4): e208.

INTRODUCTION AND OBJECTIVES: Adrenal trauma is extremely rare and current literature is lacking in data from large case series. In this study, we analyze adrenal injuries using the National Trauma Data Bank (NTDB). METHODS: We performed a retrospective analysis of the NTDB from the years 2007-2011. Patient demographics, Injury Severity Score (ISS), mechanism of injury, blunt versus penetrating trauma, associated injuries and hypovolemic shock were assessed. Multivariable models were used to determine associations with outcomes such as need for surgery, type of surgery mean length of stay, need for ICU, and death. RESULTS: Of the 1,766,606 trauma cases in the data set, 8683 were identified as involving one or both adrenal glands. There were 7835 blunt and 663 penetrating injuries, and 184 of these injures were isolated to the adrenal glands. Of the 8683 adrenal injuries, 80 (0.9%) required surgery. However, none of the 184 isolated adrenal injures required surgery (p=0.42). Factors associated with isolated adrenal injury include lower ISS (p<0.001), younger age (p<0.001), and penetrating injury (p<0.001). No isolated adrenal injuries were associated with death (12% vs. 0%, p<0.0001). The most common associated organ injuries were ribs (50.9%), thoracic (50.0%), liver (41.6%), vertebrae (30.9%), kidney (27.8%), and spleen (22.0%). Logistic regression showed that injures to the thorax (p=0.0014) and multiple abdominal injuries (p<0.001) were associated with a lower rate of undergoing adrenal surgery. Higher ISS score (p=0.007), penetrating injury (p<0.001), race (Black) (p=0.029) and concurrent injuries to the spleen (p<0.001) and intestines (p=0.016) were associated with a higher likelihood of requiring adrenal surgery. Older age (p<0.001), higher ISS score (p<0.001), race (Black, Other) (p=0.03, p=0.02), penetrating injuries (p<0.001) and injuries to the aorta/vena cava (p=0.008), vessels (p=0.001), thorax (p=0.03), ribs (p=0.005), stomach (p=0.02), liver (p=0.03), multiple abdominal injuries (p=0.002), and brain/spinal cord (p<0.001) were associated with a higher mortality rate. CONCLUSIONS: Adrenal injuries are rare, comprising 0.49% of all traumatic injuries. In our database, isolated adrenal injuries were not fatal and did not require surgery. Younger age, race (Black), higher ISS score, penetrating injury, and concurrent injuries to the spleen/intestines were associated with a higher likelihood of requiring an adrenalectomy.

The case of a 25 year old male with a stab wound of common carotid artery and the internal jugular vein is reported. He was admitted in severe hemorrhagic shock and immediately treated successfully by arterial reconstruction by means of a venous patch. Mild, declining neurological deficits correlated in magnetic resonance imaging with disturbances in the perfusion area of the medial cerebral artery. A survey of the literature shows that the fast repair of the carotid artery is clearly to be given preference to ligature. First can be executed successfully in exceptional emergency cases also by non-carotid surgeons, if basic vascular-surgical techniques are controlled.

1631. Euteneuer, J., et al. (2019). "Evaluation of the backspatter generation and wound profiles of an anatomically correct skull model for molecular ballistics." International journal of legal medicine **133**(6): 1839-1850.

Molecular ballistics connects the molecular genetic analysis of biological traces with the wounding events and complex forensic traces investigated in terminal ballistics. Backspatter, which originates from a projectile hitting a biological target when blood and/or tissue is propelled back into the direction of the gun, is of particular interest; those traces can consolidate and persist on the outer and inner surfaces of firearms and serve as evidence in criminal investigations. Herein, we are the first to present an anatomically correct head model for molecular ballistic research based on a polyurethane skull replica enclosing tissue-simulating sponge material that is doped with "triple-contrast" mixture (EDTA-blood, acrylic paint, and an x-ray contrast agent). Ten percent ballistic gelatin was used as brain simulant. We conducted contact and intermediate-range shots with a Glock 19 pistol (9 mm Luger), a pump-action shotgun (12/70 slugs), and blank cartridge handguns. Each shot was documented by a high-speed camera at 35,000 fps. Apart from the blank cartridge guns, all gunshots penetrated the skull model and created backspatter, which was recovered from the distal part of the barrels and analyzed. The pistol contact shots and one of three shotgun shots yielded full STR profiles. While the shotgun slugs destroyed the skulls, the remaining models could be used for radiological and optical fracture and wound channel evaluation. Known backspatter mechanisms and their respective timing could be confirmed visually by video analysis. Our complete model setup proved to be well applicable to molecular ballistic research as well as wound channel and fracture pattern investigation.

1633. Eviz, E., et al. (2013). "A case of avoidant/restrictive food intake disorder (ARFID): a new conceptual approach in DSM 5." Bulletin of Clinical Psychopharmacology **23**: S200.

Loss of appetite that may cause weight loss is a common symptom in Major Depressive Disorder. On the other hand Anorexia Nervosa is described as restriction of energy intake leading to significantly low body weight, accompanying intense fear of gaining weight or of becoming fat. Significant weight loss that does not occur exclusively during the course of anorexia nervosa or bulimia nervosa is included in the new DSM-5. Avoidant/restrictive food intake disorder (ARFID) is a new diagnostic category in DSM-5. Although described as Feeding Disorder of Infancy or Early Childhood before, it is not restricted to childhood in DSM-5. As ARFID is categorized within Feeding and Eating Disorders in DSM-5, new researches focusing prevalence and incidence in different populations will facilitate the development of innovations for this group of patients. Here in this case report, we present a patient with significant weight loss without fear of gaining weight or becoming fat. A 33-year-old, married female patient, known to have depressive symptoms for nearly 16 years without full remission and no prior psychiatric admission or treatment. She had been lost 20 kg in the last ten months' period, she has been 40.5 kg and BMI was 15.8 at the time of examination, was our case. She was hospitalized because of depressed mood, markedly diminished interest and pleasure, significant weight loss and suicidal ideation. During her first evaluation after hospitalization, she reported that she couldn't eat anything, never felt hunger and eating reminds her of 'death'. She was uncomfortable for being so thin, loosing her hair and having problems with her teeth. 'My legs look like a child's' she said and reported no binge eating, provoked vomiting or excessive exercising. Her menstruations were periodic with normal duration. In her psychiatric evaluation she was depressive with suicidal ideas and plans. Her sleep pattern was evidently affected which she reported to be increased. She had marked anhedonia and hopelessness with lack of energy and concentration. She felt guiltiness because of her incapacity of household responsibilities and diminished social functioning. Besides she had no psychotic features. This case example with ARFID illustrates the importance of differential diagnosis. We also make a revision of the topic, rare in literature, in clinical features, differential diagnosis and treatment approaches, suggesting a conceptual approach for ARFID. Key research findings and core clinical features focusing on diagnosis and treatment are highlighted. The clinicians should pay attention to the eating disorders' group that may be concealing a broader diagnosis. of Turkish Forensic Medicine between the years 2005-2010 were reviewed and 27 cases related Psychiatry were included. Results: Eight of the grievances occurred in dispensaries and military hospitals, 7 in psychiatric hospitals, 6 in emergency services and the others were in different places. 23 of the defendants were psychiatrists and 4 of them were medical doctors from other clinics. 9 of the defendants were complained together with medical doctors from other clinics or health care workers. 16 of the defendants were male, 11 of them were female. 3th Speciality Board of Institute of Forensic Medicine's decisions about the cases were as below; in 14 of the cases there were no malpractice, in 9 of the cases there was malpractice, 3 of them couldn't be evaluated and in one of the cases must be evaluated by the court because of missing file. 16 of the victims were male and 11 of them were female. The average age of the cases was 35.1, (between 19 and 66 years old)

22 of the victims were dead, 5 of them were alive and well and one of them was disabled because of sequel of encephalitis. The autopsy was performed for 16 of dead victims and not performed for the rest of them. The boards decisions about the cause of death were as below: 7 of them couldn't be determined, 3 of them were because of pneumonia, 2 of them were due to hanging, and the others were different causes ike sepsis, brain damage due to gun shot injury, gastric perforation and hemorrhage due to taking a corrosive substance, myocardial infarction, cardiac arrest due to taking haloperidol, cardiovascular disease resulting pulmonary edema, cerebral hemorrhage, blunt head-abdominal and thoracic trauma, penetrating thoracic injury, general body trauma due to jump from a height. Conclusion: Most of the victims were young adults. Most of the complaints about Psychiatric malpractice were cases with death. Therefore psychiatrists have to do a detailed evaluation, be careful and intentive about requested consultations from emergency services or other clinics, exclude the organic etiology and also be aware of the risk of suicide.

1634. Ewing-Cobbs, L., et al. (1994). "Gunshot wounds to the brain in children and adolescents: age and neurobehavioral development." Neurosurgery **35**(2): 225-233.

Neurobehavioral outcome after craniocerebral gunshot wounds was evaluated in a prospective, 3-year, longitudinal follow-up of a consecutive case series of 13 children and adolescents. The younger group was composed of seven children, ages 1.5 to 4 years, and the older group contained six children, ages 5 to 14. Outcome measures included the Glasgow Outcome Scale and neuropsychological assessment of intelligence, language, motor, memory, attention, academic achievement, and adaptive behavior. Glasgow Outcome Scale scores at baseline indicated moderate and severe disabilities in 69 and 23%, respectively. At the 3-year follow-up, 85% had moderate disabilities but only 8% were severely disabled. Significant and persistent neurobehavioral deficits varied with developmental level at the time of cerebral insult. Intellectual functioning was clearly more impaired in children younger than 5 years of age at the time of injury than in older children. Cognitive and motor factors were most closely related to deficits in the younger group. Disability in older children and adolescents was associated with impaired attention, adaptive behavior, and behavioral disturbance. Disabilities appear to be at least as severe in our sample after cerebral gunshot wounds as in our studies of severe pediatric closed-head injury. At the time of follow-up, younger children sustaining gunshot wounds had slightly lower intelligence quotient scores and similar receptive language, expressive language, and gross motor scores compared with children with severe closed-head injury. The older gunshot wound patients were significantly more impaired than patients with severe closed-head injuries on measures of adaptive behavior and attention.(ABSTRACT TRUNCATED AT 250 WORDS)

1635. Exadaktylos, A. K., et al. (2002). "The value of protocol-driven CT scanning in stab wounds to the head." The American journal of emergency medicine **20**(4): 295-297.

A prospective study involving 179 patients with cranial and orbital stab wounds was undertaken to evaluate the incidence and relationship of clinical findings, radiographs, and computed tomography (CT) findings and treatment decision. Indications for a CT scanning of the head are a of loss of consciousness, convulsions, any neurological deficit, palpable or visible fracture on the skull X-ray film after an attack with a sharp instrument, presence of an impaling weapon. A CT scan and plain radiography were performed in 179 patients. There were pathological CT findings in 128 patients (71.51%). In contrast only 35/179 (19.5%) X-ray films were positive; 11 (6.15%) patients had a palpable fracture. Approximately 80% of all cranial injuries would remain undetected if the diagnosis would be based on a visible fracture. Fifty percent of patients had an admission GCS of 15/15. The importance of a CT scan and the limited benefit of plain radiography alone in stab injuries to the head is discussed. Copyright 2002, Elsevier Science (USA). All rights reserved.)

1636. Ey, W. (1981). "[Orbital involvement in frontobasal injuries]." Mitbeteiligung der Orbita bei frontobasalen Traumen. **60**(4): 162-167.

In the mechanism of fracturing in the region of the frontobasis and of the midface there is the possibility of an orbital involvement. If the traumatic forces affect directly the frontal zone we may find a latero-orbitalfrontobasilar fracture--the socalled type IV according to the classification of frontobasilar fractures by Escher. If the middle face is more affected, the type III will result with tearing off the midface bones from the skull at the frontobasis. In a few cases there are indirect blow-out fractures of the orbital roof in communication with frontobasilar fractures especially in the ethmoidal or frontal sinus region. Penetration of foreign bodies through the orbital roof and through the lamina

cribriformis cause an open frontobasal cerebral trauma. The problem of the penetrating fronto-orbital traumata is to find the foreign body and to remove it. The danger is the infection with possible development of meningitis or brain abscess. The quota of lesions of the optic nerve in frontobasilar fractures seems to be relatively high. The pathogenesis of optic nerve injury is rather unknown. Mechanisms to be considered are discussed as well as indications and contraindications for a rhinosurgical decompression operation in the optic canal.

1637. Eze, K. C., et al. (2009). "Ultrasonic evaluation of orbito-ocular trauma in Benin-City, Nigeria." The Nigerian postgraduate medical journal **16**(3): 198-202.

AIMS AND OBJECTIVES: To find out the causes, time of presentation for ultrasound scan, pattern of eye injuries and orbital ultrasound findings in patients with orbito-ocular trauma., MATERIALS AND METHODS: Retrospective study of request cards, case notes and ultrasound reports of 67 patients who had trauma to the eye and were assessed with ultrasonography over a 3-year period (between 20th January 2000 and 19th January 2003) was done. The collected data included age, sex, presenting complaint, past medical history, duration of the injury before presentation to ultrasonographic study and ultrasound findings., RESULT: Sixty-seven patients were seen consisting of 54 males (83.58%) and 11 females (16.42%) with male to female ratio of 5:1. Age range was 4 to 91 years with mean age of 30.8 years. 44 patients (65. 67%) had blunt trauma while 23 patients (34.32%) had penetrating trauma. The causes of the ocular trauma include road traffic accidents 32 (47.76%), assaults 16 (23.88%), gunshot injuries 10 (14. 93%), sports injuries 5 (7.46%), and falls from heights 4 (5.92%) patients. 42 patients (53.73%), especially those with severe injuries presented late for ultrasonography. Those who made early presentation were cases of assault because of police involvement. Forty-five patients (67.16%) had structurally identifiable pathology in one or both eyes. Retinal detachment 18 (26.87%), vitreous haemorrhage 17 (25.37%), traumatic cataract 13 (19.40), ruptured globe 6 (8.96%) and posterior dislocation of the lens 6 (8.96) were the commonest abnormal sonographic findings. In 22 patients (32.84%) both eyes were normal., CONCLUSION: Ultrasound scan is a useful imaging modality for examination of the globe in patients with ocular trauma. Road traffic accident is the commonest cause of traumatic ocular injury affecting the globe. Retinal detachment and vitreous haemorrhage are the most frequent injuries to the globe diagnosed by ultrasound scan. Measures to reduce road traffic accidents will have far reaching positive effect in preventing blindness resulting from orbito-ocular trauma in Nigeria.

1639. Fabian, T. and K. Lohmann (1999). "Nerve transplantation: a father's final gift." Journal of transplant coordination : official publication of the North American Transplant Coordinators Organization (NATCO) **9**(3): 175-176.

Offering the option of organ and tissue donation to grieving families may seem stressful, but asking the question may provide a positive means to extend care to the bereaved family and help others in return. Many donor families have said donation was an opportunity to make some sense out of a senseless situation and to relieve some of the grief they experienced. This article presents a case that started with such a discussion by ICU nurses in one of our donor hospitals, and ended with successful organ and tissue recovery and transplantation. As "routine" as this may sound, it was anything but routine--it made history.

1640. Fabian, T. C., et al. (1991). "Factors affecting morbidity following hepatic trauma. A prospective analysis of 482 injuries." Annals of surgery **213**(6): 540-548.

During a 5-year period, 482 patients with liver injuries were studied prospectively: 65% resulted from penetrating and 35% from blunt injuries. The injuries were graded by the hepatic injury scale (grades I to VI); transfusion requirements and perihepatic abscesses correlated with increasing scores. Minor surgical techniques were needed in 338 patients and 144 patients required major techniques. Omental packing was used in 60% of the major injuries and yielded 7% mortality and 8% abscess rates. Gauze packs were used for management of 10% of major injuries and yielded 29% mortality and 30% abscess rates. The patients were randomized to no drain, closed suction, or sump drainage and respective perihepatic abscess rates were 6.7%, 3.5%, and 13% (p less than 0.03; suction compared to closed suction).

Multivariate analysis demonstrated increasing abdominal trauma indices and transfusion requirements as well as sump drainage to be associated independently with perihepatic infection.

1641. Fabian, T. C., et al. (1990). "Carotid artery trauma: management based on mechanism of injury." The Journal of trauma **30**(8): 953-953.

Fifty-six patients with carotid injuries were reviewed (35 penetrating and 21 blunt). Shock correlated with a profound neurologic deficit on admission (p less than 0.03) in those with penetrating wounds. Thirty-one percent had primary repair, 25% had interposition grafting, 17% were ligated, and 17% were anticoagulated. Two graft failures resulted in death. Three blunt common carotid injuries followed direct cervical soft-tissue trauma; 18 internal carotid (ICA) dissections followed apparent extreme neck extension or flexion. Seven had bilateral ICA dissections (39%); none of these died. All dissections were diagnosed by angiography prompted by a change in the neurologic examination or an initial neurologic deficit unexplained by CT scan. Seventy-one percent had major associated injuries; 43% intra-abdominal solid viscus, 24% pelvis/long bone fractures, and 24% cervical spine/facial fractures. Dissections were treated with anticoagulation; 60% improved, 23% were unchanged, and 17% deteriorated. It is concluded that interposition grafting should be avoided if possible following penetrating wounds; liberal angiography is warranted with incompatible CT findings following blunt trauma; and anticoagulation is safe and effective therapy for blunt carotid dissections.

1642. Facione, J., et al. (2016). "[Rehabilitation after a war injury]." Des blesses jeunes et sportifs polytraumatises <>. **66**(7): 799-803.

Rehabilitation after a war injury. Combat wounds can be the cause of serious physical and mental trauma. Injuries caused by the explosion of improvised devices are responsible for multiple penetrating injuries, limb amputations, brain or spinal-cord injuries, and sometimes severe burns. The performance of protective equipment and the effectiveness of the initial medical care allow those injured to survive, often at the cost of severely compromised functional prognoses. Following critical and surgical care, the multidisciplinary teams of Physical Medicine and Rehabilitation (PM et R) intervene with the wounded to initiate rehabilitation and assist with social and occupational reintegration. This support takes place in two steps: the primary phase of "acute rehabilitation" is aimed at preventing and treating complications and starting to relearn activities of daily living; the second phase of "rehabilitation-reintegration" encompasses both the medical and social fields. The implementation of individualized rehabilitation requires the collaboration of PM et R and psychiatric teams, along with various officials within the military institution. New processes specific to the military environment and adapted to the war wounded have been developed: the creation of the War Wounded Rehabilitation and Reintegration Unit (C2RBO: Cellule de Readaptation et Reinsertion des Blesses en Operation); the use of new technologies and funding of bionic prostheses for amputees; the development of sports rehabilitation programs; the creation of tools to promote social and family reintegration; and the improved recognition of and compensation for injuries. In parallel, the care connection has been reorganized to create a "Defense Rehabilitation Pole" underpinned by a territorial network ensuring the implementation of a care course for every injured soldier, from the initial care in the Parisian military hospital complex to the military medical centers closer to the forces.

1643. Fadeev, S. P. and M. I. Shakhina (1998). "[Errors in examining a cadaver at the site of its discovery]." Ob oshibkakh pri osmotre trupa na meste ego obnaruzheniia. **41**(3): 29-30.

Presents data on detection of corporal injuries in subjects without signs of violent death delivered to Bureau of Forensic Medical Expert Evaluation. Recommendations for analysis of such cases are offered.

1644. Fagin, A. P., et al. (2019). "Infection prevalence and patterns in self-inflicted gunshot wounds to the face." Oral surgery, oral medicine, oral pathology and oral radiology **128**(1): 9-13.

OBJECTIVE: Self-inflicted gunshot wounds (SIGSWs) to the craniomaxillofacial region are uncommon injuries but are associated with a high mortality rate. Therefore, treating these patients is a rare occurrence even in the largest trauma centers. As with many rare conditions, data specifically addressing this injury pattern are scarce. Because of the proximity of the blast, even low-velocity injuries can be associated with significant avulsion of tissue, comminution of structures, and tissue die back. Previous case reports have recommended the use of prophylactic antibiotics, but no study has specifically investigated the postinjury infection rate or microbial patterns in this patient population. The

purpose of this study was to answer the following clinical question: "Among patients with SIGW to the maxillofacial region, what is the prevalence of postinjury infection, and are there any microbial patterns that can guide empiric antibiotic selection?", STUDY DESIGN: We designed retrospective cohort study at a level I trauma center in Portland, Oregon. Data on 17 patients who had sustained a SIGSW involving the maxilla or the mandible and survived their initial injury were collected from 2010 to 2017., RESULTS: Patients who had a culture-positive infection within 30 days of their injury were defined to have a postinjury infection. Six of the 17 patients (35%) developed a postinjury infection, with an average time to infection of 11 days from initial injury (range 3-19 days). Of the 17 subjects, 15 (88%) received a course of prophylactic antibiotics, on average, for 14 days (range 3-24 days). Of the 6 cases of postinjury infection, culture grew gram-negative bacteria in 4 cases-anaerobic bacteria in 2 and polymicrobial organisms in 2. There was no clear pattern or prevalence of any specific bacterium, but cultures notably included Staphylococcus aureus, Enterobacter species, Bacteroides species, and Escherichia coli., CONCLUSIONS: SIGSWs are associated with a high rate of postinjury infection (35%) despite prophylactic antibiotic usage in 88% of these cases. Given the antimicrobial patterns observed in this study, prophylactic antibiotics in this patient population should include empiric coverage for gram-negative and anaerobic bacteria.

1645. Fahde, Y., et al. (2017). "Penetrating head trauma: 03 rare cases and literature review." The Pan African medical journal **28**: 305.

Penetrating head trauma (PHT) include all open head injuries with foreign object in the brain. Although less common than closed head trauma, penetrating head trauma carry a worse prognosis. We received three unusual cases of penetrating head injuries whose prognosis was different according to clinical presentation and initial management of the patient. Treatment of penetrating head trauma aims at controlling bleeding, controlling intracranial pressure and preventing infections. Despite the efforts made by national authorities as well as the adequate management in hospitals, penetrating head injuries are still frequent with significant mortality and morbidity.

1646. Faheem, M., et al. (2019). "Mosaic Pattern Foreign Bodies in Computed Tomography of the Head: A Specific Sign to Detect Tempered Glass-Related Head Injury." Indian Journal of Neurosurgery **8**(3): 193-195.

A 40-year-old male patient presented to us with a history of road traffic accident, followed by loss of consciousness and vomiting. Noncontrast computed tomography (NCCT) scan revealed frontal bone defect along with multiple mosaic pattern homogenously hyperdense foreign bodies of nearly similar size in the right frontoparietal region within the extradural space. Debridement craniectomy was done, and multiple pieces of glass were retrieved. The extremely unique radiologic finding and probably first in the English literature prompted us to report this interesting case. Unfortunately, the patient died of myocardial infarction 3â€»days after the injury. Further, this new mosaic pattern radiologic finding on NCCT of the head may help in determining the mechanism of injury due to tempered glass-related head trauma. Window glass may not be always safe as it is thought by commuters.

1647. Fahling, J. M. and L. K. McKenzie (2017). "Oculocardiac Reflex as a Result of Intraorbital Trauma." The Journal of emergency medicine **52**(4): 557-558.

BACKGROUND: The oculocardiac reflex is a decrease in heart rate caused by ocular compression or traction upon the extraocular musculature. Multiple instances of this phenomenon have been described in anesthesia, trauma, craniofacial, and ophthalmology literature, but there is a sparsity of documentation in the emergency medicine literature., CASE REPORT: We describe the observation and management of the oculocardiac reflex in a 26-year-old man with retrobulbar hematoma and intraocular trauma caused by a self-inflicted gunshot wound. WHY SHOULD AN EMERGENCY PHYSICIAN BE AWARE OF THIS?: Prompt recognition of the oculocardiac reflex is important for the emergency physician given the common occurrence of craniofacial trauma and the potentially devastating consequences if not recognized and addressed.

1648. Fakhry, S. and B. Tortella (2007). "Discussion." Journal of Trauma - Injury, Infection and Critical Care **62**(3): 629-630.

1649. Fallon, M. J., et al. (1992). "Wooden transnasal intracranial penetration: an unusual presentation." The Journal of emergency medicine **10**(4): 439-443.

A 2 1/2-year-old child presented to the emergency department with a wooden stick lodged firmly in her right nares. No nasal discharge or neurological abnormalities were noted at presentation. After plain radiographs failed to demonstrate any evidence of a foreign body, computed tomography (CT scan) was obtained that revealed a hypodense region in the right frontal lobe corresponding to the projected tract of the branch. The patient underwent a right frontal craniotomy with debridement of her contused right frontal lobe. She was discharged 8 days postoperatively without evidence of neurologic sequelae. This case illustrates an unusual presentation of intracranial penetration, with only six similar cases found in the literature. It also highlights the need for the emergency physician to be concerned about intracranial penetration when treating intranasal foreign bodies, particularly those of the nonmetallic type. The literature is reviewed regarding transnasal intracranial penetration by wooden foreign bodies.

1650. Famery, N., et al. (2015). "Perforating wounds observed healthy corneas: A one year observatory report." Investigative Ophthalmology and Visual Science **56**(7): 6048.

Purpose: Ophthalmic emergencies are numerous pathologies. Some of them impact visual prognosis immediately and need an emergency surgery. Ocular perforating trauma is a part of those emergencies in witch we can found perforating wounds on healthy corneas. There management and there visual outcomes are not well known. We observed this item on a one year period in the ophthalmologic emergency department of Assitance Publique Hôpitaux de Paris (APHP) in Paris (France). Methods: It was a retrospective chart review with all cases of perforating wounds observed on healthy corneas operated between April 1st 2013 and March 31st 2014 in the ophthalmologic emergency department of APHP in Paris (France). Results: On the observed period, 27562 patients underwent an ophthalmologic examination, 40 eyes had a perforating wound, 29 concerned healthy corneas, 1 Lle was not available for evaluation. Median age was 33 years old (15 to 96). Sex-ratio was 3/1 (21mens/7womens). There was no predominant side of trauma (14 right eyes/14 left eyes). Eight patients had an ophthalmologic preliminary event. Median size of wound was 4.5mm (±3.8mm). Wound was in the central 3mm of the cornea above 8 corneas (29%), linear for 14 corneas (50%), with extraophthamologic involvement for 27 patients (96%). Average initial visual acuity was 0.32 LogMAR, not countable for 16 patients (57%), in witch 3 no light perception (NLP) (19%). Average follow-up was 138 days (±104.8d). Average Lnal visual acuity was 0.24 LogMAR, not countable for 6 patients (21,4%), in witch the half with NLP. Wounds were sutured with an average of 5.4 stiches (1 to 12), needing of 1.6 surgery per patient, average of 5 appointments in the department. Associated trauma were iris trauma (n=17, 17%), traumatic cataract (n=6, 21%), vitreous issue (n=5, 18%), retinal detachment (n=2, 7%), intravitreous hemorrhage (n=2, 7%), retinal or choroidal bleeding (n=2, 7%), scleral wound (n=8, 29%), intraocular foreign body (n=7, 25%), lid or orbit trauma (n=7, 25%). Endophthalmy was not observed. One evisceration was performed during follow-up. Conclusions: When the cornea is healthy before traumatism, a perforating wound allow to obtain an average Lnal acuity better than 0.30 LogMAR but can also be responsible for the loss of visual function in 1 case out of 5. This accident is one emergency examination out of 950.

1651. Fan Gaskin, J. C. and B. J. Gaskin (2015). "An unusual complication of crawford tube insertion." Ophthalmic plastic and reconstructive surgery **31**(1): e11-13.

The authors describe an unusual and challenging complication of bicanalicular (Crawford) stent insertion that has previously never been reported. A 27-year-old man sustained multiple lacerations to the left (L) periocular and facial areas with a glass bottle. He was admitted under the care of the Plastic Surgical team at another institution and underwent repair of the facial, eyelid, and canalicular lacerations in the operating room. During the surgery, a Crawford stylet was guided in the L inferior canaliculus but was not retrieved nasally. Neuroimaging revealed that the metallic stylet of the Crawford tube was within the orbit, extending via the superior orbital fissure into the middle cranial fossa. The patient was then transferred under the care of the neurosurgical team and underwent a combined orbital/neurosurgical procedure to retrieve the stylet.

1652. Fan, L., et al. (2021). "Discriminating mild traumatic brain injury using sparse dictionary learning of functional network dynamics." Brain and behavior **11**(12): e2414.

Mild traumatic brain injury (mTBI) is usually caused by a bump, blow, or jolt to the head or penetrating head injury, and carries the risk of inducing cognitive disorders. However, identifying the biomarkers for the diagnosis of mTBI

is challenging as evident abnormalities in brain anatomy are rarely found in patients with mTBI. In this study, we tested whether the alteration of functional network dynamics could be used as potential biomarkers to better diagnose mTBI. We propose a sparse dictionary learning framework to delineate spontaneous fluctuation of functional connectivity into the subject-specific time-varying evolution of a set of overlapping group-level sparse connectivity components (SCCs) based on the resting-state functional magnetic resonance imaging (fMRI) data from 31 mTBI patients in the early acute phase (<3 days postinjury) and 31 healthy controls (HCs). The identified SCCs were consistently distributed in the cohort of subjects without significant inter-group differences in connectivity patterns. Nevertheless, subject-specific temporal expression of these SCCs could be used to discriminate patients with mTBI from HCs with a classification accuracy of 74.2% (specificity 64.5% and sensitivity 83.9%) using leave-one-out cross-validation. Taken together, our findings indicate neuroimaging biomarkers for mTBI individual diagnosis based on the temporal expression of SCCs underlying time-resolved functional connectivity.

1653. Fanarjyan, R. V., et al. (2013). "Stage management of severe craniocerebral and cervical spine injuries." New Armenian Medical Journal **7**(1): 104-106.

Associated craniocerebral and spinal traumas are devastating pathologies, which mostly affect young males; these injuries result in a high degree of disability and mortality; the treatment outcomes are frequently dissapointing medical doctors. The case presents our experience on stage management of severe craniocerebral and cervical spine injury in a 17-year-old male suffering from a severe traumatic brain injury and C.7 cervical spine fracture with associated spinal cord injury and tetraplegia. Considering the degree of spinal cord damage and the early time of hospitalization (2 hours after trauma) the decision was made to manage the patient immediately with high doses of intravenous steroid Dexamethazone at 55 mg dose level followed by the urgent surgical intervention: decompressive craniotomy with removal of depressed bone fragments, metallic foreign body and epidural hematoma, C.7 corpectomy and decompression of the cervical spinal cord, C.6 -Th.1 spondylodesis with replacement of vertebral body by a bone graft taken from the iliac crest. The graft was stabilized by anterior fixation with a titanium plate and screws. However, due to inadequate behaviour of the patient, after an abrupt head turning the repeated computed tomography displayed anteposition of the metallic construct and bone graft. The patient was again operated and C.6 -Th.1 anterior fixation, as well as posterior lateral mass fixation with metallic rods and screws, was performed. There were no complications in postoperative period. The patient was discharged from the hospital in good condition, with clear consciousness and full recovery of movements and sensory functions. Two-year follow-up examinations revealed the excellent outcome and complete recovery of spinal cord functions.

1654. Fandl, W., et al. (1994). "[Up-to-date reconstruction of gunshot wounds of the face]." Az arc lott serulesenek korszeru helyreallitasa. **87**(6): 173-177.

The extensive damage after gunshot injuries needs excellent primary closure, secondary reconstruction and functional rehabilitation. The huge bone defect can best be reconstructed with vascularized iliac bone graft. An additional advantage of vital bone transplant is the possibility of its support with endosseal implants, which leads to a very good chance for longtime restauration of the masticatory function with a low rate of complications.

1655. Fang, W., et al. (2017). "First identification of Gordonia sputi in a post-traumatic endophthalmitis patient - a case report and literatures review." BMC ophthalmology **17**(1): 190.

BACKGROUND: We present a case of post-traumatic endophthalmitis with relatively good prognosis caused by Gordonia sputi, which, to our knowledge is the first case in the literature., CASE PRESENTATION: A 24 year old man, who underwent an intraocular foreign body extraction half a month before presentation in the left eye, was referred to us complaining of blurred vision and slight pain for 5 days. His first presentation showed moderate intracameral and intravitreous purulent inflammation with a best corrected vision of counting fingers. After gram staining of the intravitreous samples revealed a gram-positive bacilli infection, a combination of amikacin and vancomycin was initially injected intravitreously. The left eye kept stable for three days but deteriorated on the 4th day. On the 5th day after presentation conventional culture characterized the bacterium as an Actinomyces sp. while 16S ribosomal RNA gene sequencing confirmed it as Gordonia sputi. Thereby a complete pars plana vitrectomy combined with lensectomy and silicone oil tamponade was performed. During the surgery an intraocular irrigation with penicillin G was adopted,

followed by administration of intravenous penicillin G twice one day for a week. A relatively normal fundus with slight intracameral inflammation was observed a week after the operation, and the best corrected vision recovered to 0.15. One year later his vision remained 0.1., CONCLUSION: Gordonia sputi should be taken into consideration in patients with post-traumatic endophthalmitis especially due to foreign body penetration. Compared to conventional laboratories, molecular methods are recommended for an accurate diagnosis. A comprehensive strategy of antimicrobial agents and vitrectomy may render a satisfactory result.

1656. Fanning, W. L., et al. (1976). "Puncture wound of the eyelid causing brain abscess." The Journal of trauma **16**(11): 919-920.

A case of brain abscess following an apparently trivial puncture wound to the eyelid is presented to emphasize the importance of meticulous examination of eye wounds in children to look for penetration into the cranial vault. Any suggestion of such penetrating injury either by history, examination, or X-ray should dictate neurosurgical consultation, and immediate local culture and debridement of the wound. If nonoperative management is elected, a careful watch must be kept for signs of infection, which dictate early exploration, and broad-spectrum antibiotic coverage of Gram-positive and Gram-negative organisms common to penetrating skull trauma.

1657. Fanton, L. and B. Karger (2012). "Suicide with two shots to the head inflicted by a captive-bolt gun." Journal of forensic and legal medicine **19**(2): 90-93.

An exceptional case of suicide with two shots to the head inflicted by a captive-bolt gun is reported here. The pathophysiology observed, and related literature, indicate that the capacity of the victim to fire a second shot depended on the depth of skull penetration by the first shot and the extent of damage to nerve structures. In this case, an ante mortem multi-detector computed tomography was possible. From discussion with the radiologist and a 3D reconstruction, the two-shot suicide scenario could be confirmed.

1658. Faraji, M. and F. Ashrafzadeh (2005). "Penetrating head injuries in children." Neurosurgery Quarterly **15**(3): 160-163.

Head trauma is exceedingly common in children but rarely presents as a penetrating injury to the skull. Early recognition and correct management of the possible complications of penetrating head injuries (PHIs) is important and may prevent a poor outcome. The authors' experience with 14 cases of PHIs in children referred to the Department of Neurosurgery during the last 20 years is presented. The characteristic findings on physical examination and imaging studies performed in these cases are described. All cases occurred in children in the first decade of life. There were 10 boys and 4 girls. A damaged globe that had to be exenterated was the earliest complication (1 case), followed by cerebrospinal fluid leakage (3 cases) and diabetes insipidus (1 case). Objects were removed in 11 cases. In addition to plain radiographs, computed tomography scanning and angiography were used as diagnostic procedures. The present series of patients is one of the largest collections of PHIs in children younger than 10 years of age reported in the literature. The need for prompt extrication of these objects and the possible complications of such injuries have been reviewed.

1659. Farhadi, M. R., et al. (2009). "Transorbital penetrating head injury by a toilet brush handle." Acta neurochirurgica **151**(6): 685-687.

BACKGROUND: Transorbital penetrating brain injuries are rare lesions without defined therapy standards., CLINICAL PRESENTATION AND INTERVENTION: A male patient presented at our institution with a toilet brush handle in the right cerebral hemisphere. CT imaging identified the object entering the right orbit and having crossed the right hemisphere in the ventricular plane. After performing a medium-sized craniotomy, the object was removed step-by-step under monitoring with an intraoperative CT scan to ensure no involving major hemorrhage., CONCLUSION: Transorbital penetrating brain injuries are treated best by utilizing all up-to-date technical developments such as intraoperative CT-scanning to increase the safety in the management of such exceptional lesions with increased risk of immediate life-threatening intracranial bleeding.

1660. Farhat, H. I., et al. (2012). "A tangential gunshot wound to the head: case report and review of the literature." The Journal of emergency medicine **43**(2): e111-114.

BACKGROUND: Patients with tangential gunshot wounds (TGSWs) commonly present with a good Glasgow Coma Scale score and without a history of loss of consciousness. Typically, the bullet does not breach the skull, however, there is a considerable force directed into the brain, and these patients are best treated as sustaining a moderate-to-severe blunt head injury. These patients require observation and repeat imaging. Physicians should be aware of this entity as these patients can deteriorate in a delayed fashion., OBJECTIVES: The authors present a case of a TGSW to the head in a neurologically intact patient. The initial post-injury computed tomography (CT) scan showed a very small subdural hematoma (SDH) with no overlying fracture of the skull. A delayed CT scan performed 4 h after arrival to the Emergency Department and 6 h after injury demonstrated an increase in size of the SDH, new traumatic subarachnoid hemorrhage, and bilateral cerebral contusions. Clinically, the patient showed worsening of her neurological examination. She underwent aggressive non-surgical treatment for increased intracranial pressure with almost complete recovery., CONCLUSION: Although patients with TGSWs are typically in good condition upon presentation, these injuries are not always trivial, and these patients should have, at minimum, a non-contrast brain CT scan to evaluate underlying damage to the brain and skull. In addition, a delayed CT scan and close observation on a neurosurgical service are indicated. Copyright Published by Elsevier Inc.

1661. Faridi, S. H., et al. (2012). "Accidental penetrating brain injury through anterior fontanelle: a rare phenomenon." Journal of forensic and legal medicine **19**(2): 109-110.

Penetrating injuries of the anterior fontanelle are exceedingly uncommon and are most often associated with inflictedinjury. This report of a 7-month-old male infant, whose father was working with a knife which accidentally slipped from his hand and penetrated the infants anterior fontanelle and frontal lobe, demonstrates that accidental injuries may also occur rarely.

1662. Farinde, A. (2014). "An examination of co-occurring conditions and management of psychotropic medication use in soldiers with traumatic brain injury." Journal of trauma nursing : the official journal of the Society of Trauma Nurses **21**(4): 153-159.

There are approximately 1.4 million cases of traumatic brain injury (TBI) per year in the United States, with about 23 000 survivors requiring hospitalization. The incidence of TBI has increased in the patient population of the Department of Defense and Veterans Healthcare Administration as a result of injuries suffered during recent military and combat operations. Within the past few years, TBI has emerged as a common form of injury in service members with a subset of patients experiencing postinjury symptoms that greatly affect their quality of life. Traumatic brain injury can occur when sudden trauma (ie, penetration blast or blunt) causes damage to the brain. Traumatic brain injury produces a cascade of potentially injurious processes that include focal contusions and cytotoxic damage. The results of TBI can include impaired physical, cognitive, emotional, and behavioral functioning, which may or may not require the initiation of pharmacological and nonpharmacological interventions when deemed appropriate. Associated outcomes of TBI include alterations in mental state at the time of injury (confusion, disorientation, slowed thinking, and alteration of consciousness). Neurological deficits include loss of balance, praxis, aphasia, change in vision that may or may not be transient. Individuals who sustain a TBI are more likely to have or developed co-occurring conditions (ie, sleep problems, headaches, depression, anxiety, and posttraumatic stress disorder) that may require the administration of multiple medications. It has been identified that veterans being discharged on central nervous system and muscular skeletal drug classes can develop addiction and experience medication misadventures. With the severity of TBI being highly variable but typically categorized as either mild, moderate, or severe, it can assist health care providers in determining which patients are more susceptible to medication misadventures compared with others. The unique development of cognitive and emotional symptoms of TBI can lead to significant impairments, so it is important for all health care providers, including pharmacists, to promote proper use of high-risk psychotropic medications among this patient population by providing effective medication education.

1664. Farley, M. K. and T. H. Pettit (1987). "Traumatic wound dehiscence after penetrating keratoplasty." American journal of ophthalmology **104**(1): 44-49.

Between 1980 and 1986, 14 of our patients had traumatic globe ruptures three days to 13 years after penetrating keratoplasty. There were eight men and six women, ranging in age from 29 to 82 years (average, 62 years). All ruptures occurred at the corneal donor-host interface. Eleven wound separations occurred with corneal sutures in place. Three of five patients who wore protective eyewear at the time of injury had final visual acuity of 20/200 or less. Final visual acuity was better than 20/200 in only seven patients. The force of the blunt trauma was the most significant factor in visual outcome. Ultimate causes of visual failure included posterior segment damage and intractable glaucoma.

1665. Farokhfar, A., et al. (2016). "Common causes of red eye presenting in northern Iran." Romanian journal of ophthalmology **60**(2): 71-78.

AIM: This study aimed to determine the causes of red eye disease among patients of Mazandaran-Northern Iran., METHODS: This cross sectional study included 840 patients who referred to eye clinics with ocular complaints. A detailed history of patients was recorded and their eyes were examined. Then, pre designed checklists were completed by the researcher., RESULTS: The most common cause of red eye was conjunctivitis - 30% (252/ 840), foreign bodies 23.2%, trauma including penetrating or blunt 8.6%, respectively. There was a significant relationship between the red eye trauma, with acute onset and duration of less than a week (P=<0.0001). Diagnoses of red eye were conjunctivitis in 31.3% of the cases separately, viral causes (19.5%), allergic (7%) and bacterial (4%), foreign bodies 22.9%, pterygium 7%, and trauma 6.5%, respectively., CONCLUSION: In the current study, the most common causes of red eyes were conjunctivitis, foreign bodies, and trauma respectively. Red eye was more common in males than in females. An appropriate and proper training of risky factors of red eyes in the future could reduce the risk of serious visual problems.

1666. Farr, A. C., et al. (2010). "Wooden, metallic, hair, bone, and plant foreign bodies in horses: 37 cases (1990-2005)." Journal of the American Veterinary Medical Association **237**(10): 1173-1179.

OBJECTIVE: To characterize features of diagnosis, treatment, and outcome in horses with foreign bodies, exclusive of enteric, inhaled, and foot-penetrating foreign bodies., DESIGN: Retrospective case series., ANIMALS: 37 horses with foreign bodies., PROCEDURES: The incidence of equine foreign bodies from 1990 through 2005 was determined by review of data from veterinary schools participating in the Veterinary Medical Database (VMDB). Medical records of horses with foreign bodies at Purdue University were reviewed, and the following information was retrieved: clinical history; signalment; results of physical, radiographic, and ultrasonographic examinations; results of microbial culture of the draining tract or foreign body material; surgical findings; antimicrobial and anti-inflammatory treatments; and complications of the surgical procedure. Long-term follow-up information was obtained from owners or referring veterinarians., RESULTS: The incidence of foreign bodies in horses with records in the VMDB was 1730/10,000 horse admissions. A preoperative diagnosis of foreign bodies was confirmed via ultrasonography in most horses examined (15/17 horses) and with plain film radiography in a quarter of horses examined (7/24 horses). Wood foreign bodies were the most common (59%; 22/37), followed by metal (24%; 9/37), hair (8%; 3/37), nonsequestrum bone (5%; 2/37), and plant material (3%; 1/37). Postoperative complications associated with the foreign body were more likely to develop with wood foreign bodies (3/22) than with other types of foreign bodies (1/15)., CONCLUSIONS AND CLINICAL RELEVANCE: Wood was the most common penetrating foreign body in the horses in our study and was the type associated with the highest incidence of complications. Ultrasonography was more effective in locating foreign bodies than was radiography (plain and contrast) and should be performed in all horses with suspected foreign bodies.

1667. Farrow, C. S. (1999). "Radiology of pharyngeal balling gun injuries." The Veterinary clinics of North America. Food animal practice **15**(2): 391-vii.

Pharyngeal puncture caused by a balling gun can lead to severe infection and abscessation. Dysphagia and dyspnea soon follow if the injury goes undetected. Radiographically, pharyngeal compression, laryngeal and tracheal

displacement, and extensive gas accumulation throughout the throat and cranial neck regions characterize these injuries. This article describes the typical radiographic appearance of this unique form of trauma.

1668. Farrugia, A., et al. (2009). "Destabilization and intracranial fragmentation of a full metal jacket bullet." Journal of forensic and legal medicine **16**(7): 400-402.

We report a case with an atypical entrance wound as a result of a destabilized full metal jacket bullet penetration. The destabilized bullet by an impact with the dorsal hand experiences a yawing to tumbling motion in flight. The large angle of yaw induces a larger presenting profile upon impact that contributes, associated to a rapid deceleration, to a greater mechanical force on the projectile structure and a fragmentation into core and jacket. Forensic pathologists have to be aware that the metal jacket bullet could tend to break up outside or inside the body particularly after a shooting through a target. This phenomenon induces atypical entrance wounds and atypical X-ray presentation. Copyright 2009 Elsevier Ltd and Faculty of Forensic and Legal Medicine.

1669. Fasina, O. (2013). "BILATERAL ORBITO-OCULAR GUNSHOT INJURY IN A NIGERIAN MALE: CASE REPORT AND REVIEW OF LITERATURE." East African medical journal **90**(1): 33-36.

Orbito-ocular injuries with retained intra-orbital foreign bodies affecting both orbits are uncommon in civilian practice. This case report aims to highlight an unusual presentation of bilateral orbito-ocularinjury with retained intra-orbital foreignbodies following accidental explosion of a locally fabricated dane gun. A 30-year-old male presented with a five day history of bilateral orbito-ocular injury sustained following an explosion of a dane gun he was fabricating. There was immediate loss of vision in both eyes, and initial treatment was sought at a nearby private general medical clinic. Visual acuity at presentation was no perception of light and light perception with inaccurate projection in the right and left eye respectively, and he had an open wound over the left cheek with retained intra-orbital foreign bodies on plain radiographs. He subsequently underwent wound exploration and closure with removal of the foreign bodies. Vision however remained poor and he was lost to follow-up after being referred for vitreo-retinal consultation. The attendant socio-economic impact on the individual and family following severe bilateral orbito-ocular injury could be enormous when it results in bilateral loss of vision in a young adult. Measures should thus be put in place to regulate the handling of firearms so as to possibly reduce the resultant morbidity from such injuries.

1672. Fathalla, H., et al. (2018). "Managing military penetrating brain injuries in the war zone: lessons learned." Neurosurgical focus **45**(6): E6.

OBJECTIVE Managing penetrating military brain injuries in a war zone setting is different than managing common civilian penetrating brain injuries. Triage, i.e., deciding on which patients to treat or not treat, and which to be flown back home, is essential to avoid wasting valuable limited resources. In this study the authors aim to identify reliable predictors of mortality and poor outcome to help develop a protocol for treating their patients in the battlefield. They also demonstrate all the lessons learned from their collective experience regarding some of the controversial management issues. METHODS This study was a retrospective review of 102 patients with penetrating military missile head injuries treated by the authors in various facilities in northern Sinai between 2011 and 2018. Patient demographics, clinical characteristics, imaging characteristics, postoperative complications, and Glasgow Outcome Scale (GOS) scores were recorded for each patient. Several variables associated with mortality and poor outcome that were derived from the literature were analyzed, in addition to variables obtained by direct observation by the authors over time. RESULTS There were 50 patients (49%) with GOS score of 1 (death), 12 patients (11.8%) with GOS score of 2 (survivors in persistent vegetative state), and 40 survivors (39.2%) with varying degrees of disability on the last follow-up evaluation. The authors identified an anatomical danger zone that was found to predict mortality when traversed. Bilateral dilated

fixed pupils and low Glasgow Coma Scale score on admission were also found to be independent predictors of mortality and poor outcome. Based on these findings, a protocol was developed for managing these patients in the war zone. CONCLUSIONS Managing military penetrating head injuries in the war zone is different than civilian gunshot head injuries encountered by most neurosurgeons in urban cities. The authors developed a simple protocol for managing military penetrating injuries in the war zone. They also describe important lessons learned from this experience.

1673. Faulkner, J. A. and E. E. Ferguson (2009). "Innovations in military handling of facial trauma." The Journal of craniofacial surgery **20**(1): 62-67.

As the military medical treatment facilities of Operation Iraqi Freedom have transitioned from make-shift tent facilities to more formal fixed facilities, the capability to deliver more complex care has markedly improved. Using case presentations, the authors illustrate the integration of advances in surgical technology in managing complex and devastating craniofacial trauma at the 332nd Air Force Theater Hospital in Balad Iraq during Operation Iraqi Freedom 2006.

1674. Faulkner, J. R., et al. (2004). "Reactive astrocytes protect tissue and preserve function after spinal cord injury." The Journal of neuroscience : the official journal of the Society for Neuroscience **24**(9): 2143-2155.

Reactive astrocytes are prominent in the cellular response to spinal cord injury (SCI), but their roles are not well understood. We used a transgenic mouse model to study the consequences of selective and conditional ablation of reactive astrocytes after stab or crush SCI. Mice expressing a glial fibrillary acid protein-herpes simplex virus-thymidine kinase transgene were given mild or moderate SCI and treated with the antiviral agent ganciclovir (GCV) to ablate dividing, reactive, transgene-expressing astrocytes in the immediate vicinity of the SCI. Small stab injuries in control mice caused little tissue disruption, little demyelination, no obvious neuronal death, and mild, reversible functional impairments. Equivalent small stab injuries in transgenic mice given GCV to ablate reactive astrocytes caused failure of blood-brain barrier repair, leukocyte infiltration, local tissue disruption, severe demyelination, neuronal and oligodendrocyte death, and pronounced motor deficits. Moderate crush injuries in control mice caused focal tissue disruption and cellular degeneration, with moderate, primarily reversible motor impairments. Equivalent moderate crush injuries combined with ablation of reactive astrocytes caused widespread tissue disruption, pronounced cellular degeneration, and failure of wound contraction, with severe persisting motor deficits. These findings show that reactive astrocytes provide essential activities that protect tissue and preserve function after mild or moderate SCI. In nontransgenic animals, crush or contusion SCIs routinely exhibit regions of degenerated tissue that are devoid of astrocytes. Our findings suggest that identifying ways to preserve reactive astrocytes, to augment their protective functions, or both, may lead to novel approaches to reducing secondary tissue degeneration and improving functional outcome after SCI.

1675. Faverani, L. P., et al. (2011). "Ocular reconstruction after zygomatic complex fracture with retention of a foreign body." The Journal of craniofacial surgery **22**(4): 1394-1397.

Facial injuries with the retention of foreign bodies inside the tissues, both in soft and hard ones, can cause major functional and aesthetic damage. Among the different etiological agents, cutting tools, fragments of a firearm, the splinter of wood, steel, or iron, launched by misuse, or even caused by defects in equipment, are the main cause of these injuries. The aim of this study was to discuss the peculiarity of the multidisciplinary approach in caring of a 33-year-old man, victim of an accident at work, by the rupture of an emery disc and consequent penetration of the fragments in violation of the tissues in the orbital and zygomatic region of the left side, with perforation of the eyeball and orbital-zygomatic fracture. Urgent treatment consisted of debridement of wounds, bleeding control, removal of foreign bodies, fracture reduction with rigid internal fixation, and suture, performed by the oral and maxillofacial surgical team. Reconstruction of orbital tissues by the ophthalmology team consisted of suture of the injuries. About 1 month after the trauma, phthisis bulbi was noted, and the patient underwent a new procedure under general anesthesia for eye evisceration and installation of an alloplastic prosthesis associated with the homogenous sclera. Facial harmony was restored, especially in aesthetics and function of the zygomatic-orbital complex.

1676. Fechner, F. P. and D. G. Deschler (2002). "Microvascular free flap reconstruction after craniofacial trauma." Operative Techniques in Otolaryngology - Head and Neck Surgery **13**(4): 309-315.

Treatment approaches to injuries of the craniofacial skeleton and soft tissues have seen significant advances over the last 20 years. The techniques of open reduction and internal fixation with modern plate and screw fixation systems replaced interosseous wiring of facial fractures. Nevertheless, severe trauma with tissue loss continues to pose a significant challenge to the reconstructive head and neck surgeon. Facial gunshot wounds, for instance, self-inflicted in suicide attempts, cause the most destructive injuries. In the past, conservative treatment of these craniofacial defects included packing and repeated debridement, which commonly resulted in multiple surgical procedures, prolonged hospitalization, and soft tissue contracture. Delayed reconstruction of the resulting tissue voids of the mid- and lower face was difficult and sometimes impossible. The introduction of free, vascularized soft tissue transfer in the reconstructive armamentarium revolutionized the approach to these major injuries. Today, aggressive debridement and early free flap reconstruction can result in improved functional and cosmetic outcome for the trauma patient. A large number of different free flaps are available, ranging from soft tissue (ie fasciocutaneous) or osseous to osteocutaneous and composite flaps. Decisions on the choice of free flap are primarily governed by the specific requirements of the defect, although potential donor site morbidity, the patient's preference, and the personal experience of the surgeon play a role. We review the modern management of severely destructive craniofacial injuries with a special emphasis on the role of free flaps for the reconstructive effort.

1677. Fedorina, T. A. and T. V. Brailovskaia (2009). "[Morbid anatomy of porcine preoral gunshot wound in an experiment]." Stomatologiia **88**(2): 16-19.

In experimental pathological-anatomic study of gunshot wounds of pig upper and lower lips produced by bullet weapon there were received microscopic tissue pictures in 3 wound duct zones according to the disrance from the duct - in the injury zone, tissue zone adjacent to the injury and tissue zone remote from the injury. The zone widths were different depending upon the ditance from the bullet entrance hole; the injury width of reversible and irreversible characters was bigger in the wound duct depth. The data about the morphological changes characrer in the edges of the most heavy degree of gunshot wounds were necessary for receiving objective numeric criterions of the volume of the tissue excision at the moment of primary surgical wounds treatment.

1678. Fehlberg, C. R. and J. K. Lee (2022). "Fibrosis in the central nervous system: from the meninges to the vasculature." Cell and tissue research **387**(3): 351-360.

Formation of a collagenous connective tissue scar after penetrating injuries to the brain or spinal cord has been described and investigated for well over 100 years. However, it was studied almost exclusively in the context of penetrating injuries that resulted in infiltration of meningeal fibroblasts, which raised doubts about translational applicability to most CNS injuries where the meninges remain intact. Recent studies demonstrating the perivascular niche as a source of fibroblasts have debunked the traditional view that a fibrotic scar only forms after penetrating lesions that tear the meninges. These studies have led to a renewed interest in CNS fibrosis not only in the context of axon regeneration after spinal cord injury, but also across a spectrum of CNS disorders. Arising with this renewed interest is some discrepancy about which perivascular cell gives rise to the fibrotic scar, but additional studies are beginning to provide some clarity. Although mechanistic studies on CNS fibrosis are still lacking, the similarities to fibrosis of other organs should provide important insight into how CNS fibrosis can be therapeutically targeted to promote functional recovery.

1679. Fei, J., et al. (2011). "Foreign body embolus to ophthalmic artery following penetrating trauma of the neck." Chinese medical journal **124**(5): 790-792.

Migration of metallic foreign body into the cerebral circulation is rarely seen. Most of the cases reported were due to gunshot wounds and shotgun wounds to the neck and face. When the foreign body is near the great vessel, it must be removed immediately or will cause complications. This study reported a case of delayed metallic foreign body embolus to the ophthalmic artery resulting from an injury to the right neck, which arose from the presence of metallic emboli to the cerebral circulation.

1680. Feichtinger, M., et al. (2007). "Removal of a pellet from the left orbital cavity by image-guided endoscopic navigation." International journal of oral and maxillofacial surgery **36**(4): 358-361.

In the cranio-maxillofacial field, computer-aided surgery based on computed tomography data is becoming increasingly important. Complex surgical procedures can be performed utilizing preoperative imaging to provide real-time localization of surgical instruments in the surgical field. Image-data-based navigation plays an ever-increasing role in cases of minimal invasive surgery. The case is presented here of a 58-year-old male patient referred after a hunting accident with a pellet in the left orbit. After transferring the preoperatively acquired computed tomography data to a commercially available navigation system, the bullet was removed through the original wound canal using an intraoperatively calibrated high-resolution endoscope.

1681. Feinsod, M., et al. (2022). "Baron Larrey at the Dawn of Correlative Neuroanatomy." European neurology: 1-5.

In 1820, a young soldier was accidentally injured by a splinter of a fencing sword that penetrated through the right orbit into the brain. Examination by the French military surgeon Baron D.-J. Larrey revealed nominal aphasia, right hemiplegia, and monocular temporal hemianopia with an altitudinal component in the right eye only. In this paper, we aimed to reconstruct Larrey's contribution to neurology in the eve of correlative neuroanatomy. Larrey predicted that the blade passed from the roof of the right orbit to graze the root of the right optic nerve at the chiasm and from there, into the vicinity of the left Sylvian fissure. This course was verified posthumously 3 months later. Larrey's previous experience with galvanic currents enabled the adoption of Samuel von Sommering's idea of regarding the brain as a telegraphing system made of a multitude of galvanic piles sending and receiving messages from distant points. Larrey's description is a very early diligent study of the tracks of penetrating head injuries. It correlates the symptoms with the injured cerebral tissues together with autopsy verification. Here are the beginnings of the construction of human correlative neuroanatomy, which lingered until flourishing in the first decades of the 20th century.

1682. Fekih, O., et al. (2019). "[Intraocular foreign body and endophthalmitis: risk factors and management]." Corps etranger intraoculaire et endophtalmie: facteurs de risque et prise en charge. **33**: 258.

This study aims to identify the risk factors for post-traumatic endophthalmitis (PTE) due to intraocular foreign body (IFB) in patients with penetrating injuries of the globe and to assess treatment outcomes. We conducted a descriptive, retrospective study of 60 patients hospitalized for penetrating wound due to intraocular foreign body at the Hedi Rais Institute of Ophthalmology, Tunis, over a period of 10 years. Our study involved the patients with penetrating ocular trauma due to intraocular foreign body associated with post-traumatic endophthalmitis. We also determined the clinical risk factors for endophthalmitis in these patients. We collected data from the medical records of 60 patients with penetrating injury due to intraocular foreign body. Clinical symptoms of endophthalmitis were reported in ten of these patients (16.66%). All IFBs were located in the posterior segment. Mean LogMAR visual acuity (VA) at baseline was 2.26. Final Mean LogMAR VA was 2.18. We found a statically significant correlation between the occurrence of endophthalmitis and the following factors: rural origin p=0.021, delays in removing IFB p=0.01, posterior location IFB p=0.012, capsule rupture p=0.022, associated retinal detachment p<0.0001. The identification of risk factors for post-traumatic endophthalmitis allow for better treatment adaptation and preventive measures of this complication to improve prognosis and quality of life.

1684. Felman, A. H. (1971). "Neurogenic pulmonary edema. Observations in 6 patients." The American journal of roentgenology, radium therapy, and nuclear medicine **112**(2): 393-396.

1685. Felsenstein, S., et al. (2013). "Clinical and microbiologic features guiding treatment recommendations for brain abscesses in children." The Pediatric infectious disease journal **32**(2): 129-135.

BACKGROUND: There are no guidelines for the management of brain abscesses in children, and there is a paucity of recent data describing clinical and microbiologic features. We aimed to identify factors affecting outcome to inform antibiotic recommendations., METHODS: From 1999 to 2009, 118 children presented with brain abscesses to 4 neurosurgical centers in the United Kingdom. Clinical, microbiologic and treatment data were collected., RESULTS: The commonest preceding infection was sinusitis, with 59% of all children receiving antibiotics before diagnosis. Nonspecific symptoms were common, with only 13% having the triad of fever, headache and focal neurological deficit. Time between symptom onset and diagnosis varied widely (median, 10 days; range, 0-44). Magnetic resonance imaging was more frequently diagnostic than computed tomography. The most frequent organisms were Streptococcus milleri (38%), except after penetrating head injury or neurosurgery, for which Staphylococcus aureus was most common. The commonest empiric antibiotics were ceftriaxone/cefotaxime and metronidazole, which offered effective antimicrobial therapy in up to 83% of cases. Metronidazole added benefit in a maximum of 7% of cases, with ceftriaxone/cefotaxime alone sufficient in at least 76% and in all cases with cyanotic congenital heart disease or meningitis. A carbapenem would have been effective in 90%. The case fatality rate was 6% (33% in the immunocompromised). Long-term neurological sequelae affected 35%. Age younger than 5 years and a Glasgow Coma Scale score <=8 were associated with poor outcome at 6 months., CONCLUSIONS: We recommend ceftriaxone/cefotaxime and metronidazole as empiric treatment, although metronidazole may be unnecessary in many cases, with antistaphylococcal cover in cases of head trauma. Meropenem potentially would be a better choice in the immunocompromised. A prospective study of intravenous and oral treatment guided by clinical improvement is required beause 1-2 weeks of intravenous antibiotics during a total of 6 weeks may be sufficient in children.

1686. Feng, K., et al. (2015). "Clinical features and prognosis of eyeball rupture: eye injury vitrectomy study." Clinical & experimental ophthalmology **43**(7): 629-636.

BACKGROUND: The objective of the study was to delineate clinical characteristics, surgical interventions, anatomic and visual outcomes of ruptured eye balls after trauma, and establish the prognostic indicators, which can assist clinicians in making correct surgical decisions during globe exploration for ruptured eyes., DESIGN: The study design used was a multicentre prospective cohort study, including six university-affiliated tertiary hospitals., PARTICIPANTS: We selected 242 cases of ruptured globe from the Eye Injury Vitrectomy Study database, until 31 December 2012., METHODS: All selected cases underwent vitreoretinal surgery, enucleation or evisceration, and were followed up for at least 6 months. Age, visual acuity (VA) after injury, ocular trauma zone, time to surgery, corneal laceration, scleral wound, extrusion of iris or lens, ciliary body damage, intraocular haemorrhage, retinal detachment or defect, proliferative vitreoretinopathy (PVR) and choroidal damage were the predisposing factors evaluated by logistic regression models., MAIN OUTCOME MEASURES: We compared the pre-surgical indicators between cases of anatomically restored eyes with VA of 4/200 or better, or eyes with initial no light perception restored light perception or better, and cases of VA worse than 4/200, silicone oil-sustained eyes, phthisis or enucleation., RESULTS: Nearly 40% of cases with ruptured globe were anatomically restored through vitreoretinal surgery. The closed-funnel retinal detachment or extensive retinal loss (odds ratio [OR] = 3.38, P = 0.026), PVR-C (OR = 3.45, P = 0.008), and choroidal damage (OR = 4.20, P = 0.004) were correlated with poor outcomes., CONCLUSION: The closed-funnel retinal detachment or extensive retinal loss, PVR-C, and choroidal damage are the risk factors for unfavourable outcomes in globe ruptures.

1687. Feng, L., et al. (2018). "Complications in transorbital penetrating injury by bamboo branch: A case report." Medicine **97**(19): e0706.

RATIONALE: Wooden transorbital penetrating injury is an uncommon and serious trauma that may cause multiply complications., PATIENT CONCERNS: Here we describe a 62-year-old Chinese woman with a transorbital penetrating injury caused by a long bamboo branch., DIAGNOSIS: Computed tomography scan and magnetic resonance imaging showed the presence of a wooden foreign body., INTERVENTIONS: Cerebrovascular digital subtraction angiography and temporary balloon occlusion were performed with general anesthesia. Anti-inflammatory therapy was subsequently administered., OUTCOMES: Retention of wooden foreign body, orbital cellulitis, and traumatic aneurysm at the right internal carotid artery were diagnosed 1 month later. Coil embolization of the right internal carotid artery aneurysm and endoscopic sinus surgery were then performed, and postoperative condition was monitored and recorded., LESSONS: Penetrating transorbital injury complications may occur because of retained wooden foreign bodies

near the intracranial arteries. Reasonable surgical intervention and special attention should be performed in this kind of trauma.

1688. Feng, Y. P., et al. (2004). "Effect of early apnea period on survival period in canines after craniocerebral gunshot wounds." Chinese Journal of Clinical Rehabilitation **8**(4): 652-653.

Aim: To study the pathophysiological changes in canines after craniocerebral gunshot wounds. Methods: The canines were shot with small-bore musket made in Germany to establish animal models of penetrating craniocerebral injury(PCI) and tangent brain injury(TBI). The following measures were recorded, including respiratory frequency, heart rate(HR), electrocardiogram (ECG), mean arterial pressure(MAP), cerebral blood flow, electroencephalogram (EEG) and so on. Results: After injury, the mean time of apnea was 5.3 min in the PCI group, significantly longer than in the TBI group(1.7 min) (P =0.011 8). Decrease occurred in HR, MAP, artery blood flow as a result of brainstem inhibition, while intracranial pressure had a tendency to increase gradually. A transient flat electroencephalogram was seen immediately after the craniocerebral gunshot wounds. The average survival time of the canines in the TBI group was 568 min longer than that of the PCI group(106 min) (P = 0.0013). Conclusion: 1 Apnea, decreased HR and hypotension are effective in decreasing the mortality of canines caused by gunshot wounds. 2 Intracranial high pressure appeared early and obviously. 3 The animal model, especially TBI model, survived for a long time.

1689. Fenton, T. W., et al. (2005). "Symmetrical fracturing of the skull from midline contact gunshot wounds: reconstruction of individual death histories from skeletonized human remains." Journal of forensic sciences **50**(2): 274-285.

This paper reports a bilaterally symmetrical cranio-facial fracture pattern that is observed in self-inflicted, midline gunshot wounds. Five cases of self-inflicted gunshots wounds are presented as follows: two high-powered rifle cases, two shotgun cases, and one handgun case. In all five cases the remains were either decomposing or skeletonized and submitted to forensic anthropologists. Following identification, the main focus of the anthropological examination was the analysis of perimortem trauma to the skeleton. In each case, the skull was submitted in a highly fragmented state. Nevertheless, by focusing on the pattern of perimortem cranio-facial fractures, the anthropologists contributed key information regarding the circumstances of death. The observed symmetrical cranio-facial fracture patterns in the above cases are described in detail and interpreted. The specific location of the linear fractures is discussed, as well as the theoretical rationale behind the location in terms of skeletal architecture, such as buttresses, struts, and sutures. The interpretive framework provided by this paper may prove helpful to others who are faced with similar cases of cranio-facial fracturing.

1690. Ferguson, L. P., et al. (2020). "Shot in the dark: three patients successfully treated with onabotulinumtoxin A injections for relief of post-traumatic chronic headaches and dystonia induced by gunshot wounds." BMJ case reports **13**(12).

Three patients ranging from 49 to 61 years-old presented to our pain clinic after failing multiple treatment attempts for debilitating, chronic post-traumatic headaches, neck pain and involuntary muscle spasm following gunshot wounds to the head, neck and face. Concurrent cervical dystonia was noted in each patient on presentation. All patients were treated with onabotulinumtoxin A (ONA) injections in the head and neck. Each patient reported between 70% and 100% improvement of their headache pain, neck pain and spasm with a significant reduction in the frequency, duration and intensity of their headaches. This level of improvement has been successfully maintained in all three patients with regular ONA injections at 90-day intervals. Two patients experienced a single relapse in symptoms when scheduling conflicts caused them to miss their regularly scheduled ONA injections by several weeks. These symptoms resolved when their ONA injections resumed, suggesting that ONA is the causative agent alleviating their symptoms.

1691. Fernandes, B. D. R., et al. (2019). "Strategy of Mandibular Central Arch Reconstruction After Firearm Injury." The Journal of craniofacial surgery **30**(7): e629-e630.

Gunshot wounds can cause extensive destruction of soft tissue and bone, and the maxillofacial region is often affected. The reconstructive treatment is complex due to the difficulty to reestablish the central arch mandibular

contour and volume. Moreover, the goal is to avoid postoperative infections and obtain bone graft neovascularization. Therefore, this report shows a clinical case of a patient presenting mandibular deformity with a mandibular central arch discontinuity caused by a firearm injury. The strategy to the reconstructive treatment as performed with a condensed and stabilized particulate autogenous bone graft was essential and effectiveness. After 1 year, it was obtained a satisfactory result to the patient.

1692. Fernandes, R. (2006). "The anterolateral thigh flap in mandibular reconstruction." Atlas of the oral and maxillofacial surgery clinics of North America **14**(2): 185-189.

1693. Fernandes, R. and M. A. Miller (2011). "Patterns of craniofacial injury secondary to gunshots in an urban trauma center." Journal of oral and maxillofacial surgery **69**(9): e-99.

Statement of the Problem: Interpersonal armed violence continues to be one of the greatest problems facing our society. The incidence of gun violence continues to rise and its effects are seen on a daily basis in trauma centers. Injury patterns to the craniofacial region due to GSW have not been reported in the literature for the past 15 years. Given the societal changes as well as the technological advance in firearms, we sought to review recent patterns of craniofacial gunshot injuries in our urban trauma center. Our hypothesis was that there is a change in pattern and extent of injury within this subset of patients. Materials and Methods: This was a retrospective review of the trauma registry database at the University of Florida Jacksonville. Inclusion criteria were patients with a documented gunshot injury to our trauma center during the period of August 2008 to August 2010. We excluded all patients who did not initially present at our trauma center and those whose injuries were not surgically treated. Demographics of gender, age, location of injury, initial management, and outcomes were included in the study. Results of Investigation: We identified 35 patients who met the inclusion criteria for our study. There were 29 (83%) males and 6 (17%) females. The patterns of distribution of the injury were: 11 (31%) to upper face; 13 (37%) midface, and 20 (57%) lower face/neck. 9 (26%) patients had combined injuries to 2 or more regions. The most common combination of involved regions was the lower and midface 4 (11%); the second most common presentation was the midface/upper-face combination accounting for 3 (9%). Two patients had injuries affecting all 3 regions. All of the patients underwent a phased approach to treatment consisting of multiple incisions and drainage, followed by definitive surgery. Eleven of the 35 patients (31%) required tracheostomies at the time of presentation or shortly thereafter. Of the 35 patients, only 3 (9%) patients had significant soft tissue avulsion requiring free tissue transfer during the initial hospitalization. Conclusion: The patterns of facial injuries secondary to gunshot in our case series were roughly equally distributed to each facial third. This pattern has not changed since the last report in the literature over 15 years ago. The majority of the patients in this series did not present with significant soft or hard tissue injuries requiring free tissue transfer. Our experience shows that although the pattern of injury has remained constant, the instance of soft tissue or hard tissue avulsion has decreased significantly.

1694. Fernandez, J. P., et al. (2017). "Applied ultrasonography during the initial assessment of trauma patients." Critical Ultrasound Journal **9**.

Introduction: Ultrasonography is regarded as an indispensable element for physicians who work in trauma care and emergency. The training of professionals working in this field is considered as a determinant for the correct decision making in trauma and emergency. Objective: Demonstrate the importance of the use of ultrasonography for the evaluation of the polytraumatized patient Materials and methods: 824 ultrasound exams were performed in a period between June and November of 2016 in which it was evaluated its use in the care of the polytraumatized patient Results: Airway: 135 US. 89 intubation guides (65%). 14 (10.37%) guides for surgical access. Ventilation: closed thoracic trauma. 183 US. Pleural fluid 117 (63.9%) pneumothorax. 53 (28.9%). Trauma open. 97 US. Penetrating wound without pleural lesion: 25 (25.7%)-confirmed by surgery: 11. Pneumothorax: 67 (69.07%). Pneumothorax and pleural fluid: 5 (5.15%). Abdomen: trauma closed: 239 US FAST-: 127 (53.13%) FAST+: 95 (39.7%). FAST- and Vena CAVA Rating: 17 (7.11%). Penetrating trauma: 67 US. FAST- and peritoneal indemnity: 47. Laparoscopic confirmation: 39 (82.9%). FAST+ and peritoneal indemnity: 20 (29.8%) neurological deficit: 83 US. Altered pupil reflex 13 (15.66%) optic nerve altered: 7 (8.4%) deviation cerebral mediated line: 3 (3.6%). Assessment of vascular axes, compartmental syndrome: 145 US. Decreased pulses: 53 (36.5%). Vascular commitment: 17 (11.7%) Conclusion: The incorporation of anatomical and ultrasonographic knowledge favors the quality of care of physicians who perform in extreme situations. The correct use

of ultrasonography as a diagnostic tool allows to improve the response times and decision making of surgical procedures.

1695. Fernández, L. M. G., et al. (2019). "Management and perioperative outcomes of traumatic brain injury: retrospective study." Colombian Journal of Anesthesiology **47**(2): 100-106.

Introduction: Cranioencephalic traumatism (CET) is a cause of mortality and morbidity in the surgical patient. However, the perioperative management of this entity has not been evaluated in the country's health institutions, despite its high disease burden and potential adverse clinical outcomes.Objective: To evaluate the clinical characteristics of surgical TBI and perioperative outcomes.Methods: Descriptive study of historical review conducted at the Hospital San Vicente Fundación, Medellín, Colombia. Data were collected from the medical records of patients over 13 years of age diagnosed with moderate-severe TBI between 2011 and 2014. Clinical variables, perioperative management, and clinical outcomes up to discharge were analyzed. An exploratory analysis was performed between perioperative management and postoperative mortality or neurological dysfunction.Results: CET was most common in the young male population (89.3%). Severe trauma occurred in 71.1% of patients. Perioperative mortality was 16%, and 54% presented neurological disability at discharge. A strong association was found between mortality or neurological dysfunction and severity of injury and perioperative hypotension.Conclusion: The study found that surgical CET was a high morbidity and perioperative mortality event, highly related to the severity of the injury and the hemodynamic stability of the patient. Despite this, intraoperative hemodynamic and metabolic monitoring remains limited in more than 50% of these patients' surgical procedures.

1696. Fernandez, M., et al. (2022). "Epidemiology and characteristics of firearm injuries in a French level I trauma centre, 2009-2019." Injury prevention : journal of the International Society for Child and Adolescent Injury Prevention **28**(1): 3-8.

BACKGROUND: Firearm injuries (FI) are an increasing problem in Europe but there have been few European epidemiological studies on civilian FI, particularly in France. This study investigated the epidemiology of FI at a French level I trauma centre., METHODS: A retrospective cohort study was conducted of all patients admitted to our centre with an FI between January 2009 and December 2019. We investigated the epidemiological trends of FI during the study period, and characterised the FI., RESULTS: A total of 162 patients were victims of FI. Prevalence was 0.11% and the mean annual incidence was 10.4 per 100 000 habs. A significant increase has been observed over the last 10 years, from 5 cases in 2009 (3.1%) to 30 in 2019 (18.5%). Of the 162 victims, 85 (52.5%) died as a direct result of the FI: 72 suicides (88.9%) and 9 victims of urban violence (11.1%) (armed public environment disorder). 95.3% of the patients died before reaching at the hospital. There were 95 cases (58.7%) of suicide and 33 cases (20.4%) of urban violence. The head was shot in 87 cases (48.9%), the thorax in 32 cases (18.5%) and the lower limbs in 24 cases (13.5%). A total of 106 surgeries were performed on 54 patients (33.3%)., CONCLUSIONS: We identified 162 cases of FI with a mean annual incidence of 10.4 per 100 000 habs. A significant increase in FI was observed over the last 10 years. 52.2% of patients died, and the main context was suicide or attempted suicide.

1697. Fernandez-Melo, R., et al. (2002). "[Penetrating head injury from harpoon. Case report]." Trauma craneoencefalico perforante por arpon. Precentacion de un caso y revision de la literatura. **13**(5): 397-400.

The harpoon presence as aggressor weapon is unusual in the neurosurgical practice. Most cases are associated with diving or sport activities as result of imprudence. A 31 year old patient who sustained a penetrating craniocerebral injury with a fishing harpoon is presented and complementary exams, neurosurgical procedure and postoperative evolution are detailed. We discuss the management of this unusual injury and review the current literature on craniocerebral injuries caused by similar objects.

1698. Fernando, D. M. G., et al. (2015). "Penetrative Injury to the Face Resulting in Delayed Death After Rupture of a Cavernous Sinus Aneurysm on the Contralateral Side." The American journal of forensic medicine and pathology **36**(4): 271-273.

Delayed deaths after assault give rise to medicolegal issues such as whether the assault was directly responsible, did it contribute or was it totally unrelated to the death. We present the case of a patient who sustained penetrative

trauma to the face resulting in the formation of a contralateral, carotid-cavernous fistula, which resulted in aneurysm formation, delayed rupture, and death. A literature search failed to find a similar case.

1699. Fernando, D. M. G. and E. M. K. B. Ekanayake (2021). "Nail Gun Suicide: An Atypical Case Report and Review of the Literature." The American journal of forensic medicine and pathology **42**(3): 267-274.

ABSTRACT: Nail guns are pneumatically driven or powder-actuated tools, which are used to drive nails into wood or concrete. A 42-year-old man, who was a builder by profession and history of antidepressant use, was found dead in his vehicle, holding a "Ramset" nail gun in his right hand. A straight metal nail and a book with a small hole were recovered from the scene.At autopsy, an irregularly circular puncture wound was seen on the forehead and a cruciate laceration was seen on the posterior aspect of the scalp. No burning, blackening, or tattooing was present around either injury. Both internal and external beveling was present with the latter being relatively larger. Toxicological analysis revealed alcohol and methamphetamine in blood. Psychiatric history and substance abuse must also be considered when individuals in construction industry are given access to tools like nail guns. Several unique features not previously reported were observed in this case. The deceased had overcome the built-in safety mechanism of the nail gun, by placing a book in between his forehead and muzzle. Another unique feature is that the nail had exited the cranium. Beveling, a feature commonly found in firearm injuries, was also seen in this case.

1700. Ferrada, P., et al. (2016). "Secondary injury after multiple gunshot wounds." The journal of trauma and acute care surgery **80**(6): 884-885.

1701. Ferrão, A. C. M., et al. (2020). "Reversible Endoscopic Medial Maxillectomy: Endonasal Approach to Diseases of the Maxillary Sinus." International Archives of Otorhinolaryngology **24**(2): 247-252.

Introduction The endoscopic access has reduced the morbidity associated with external approaches in diseases of the maxillary sinus. A reversible endoscopic medial maxillectomy (REMM) is presented as an alternative for treatment of benign maxillary diseases. Objective To describe the REMM technique and report four cases of patients with benign maxillary sinus conditions treated through this approach. Methods The present study was divided into two parts: anatomical and case series. Two cadaveric dissections confirmed the feasibility of the REMM approach. The same technique was performed on four consecutive patients with benign maxillary sinus disease. Results The cadaveric dissections confirmed wide exposure to the maxillary cavity, preserving the anatomy of the maxillary sinus. In the patient series, one patient presented with an antrochoanal polyp, one had a silent sinus syndrome, one had a chronic maxillary sinusitis secondary to a gunshot, and the last one had an inverted papilloma in the maxillary sinus. In all of the cases, the REMM approach provided excellent access and adequate resection, as well as preservation of the inferior turbinate, nasolacrimal duct, and lateral wall of the nose (including its osteomucosal component). Finally, all of the patients had an uneventful postoperative course. Conclusion The REMM technique is an excellent surgical approach to benign conditions of the maxillary sinus. It has few limitations and appears to be associated with less morbidity than conventional techniques.

1702. Ferrara, V. L. (1985). "Acute traumatic mutism." Surgical neurology **23**(6): 573-574.

A patient who had suffered acute trauma to the head is reported. The patient was observed immediately upon admission to the hospital, and he was noted from the outset to have wakeful speechlessness. The evolution and resolution of neurological deficits were also observed. A review of the literature and a discussion of the possible causes of acute traumatic mutism are presented.

1703. Ferri, J., et al. (1993). "[Our experience using free vascularized bone flaps in mandibular reconstruction. The external brachial flap, the fibular flap, the para-scapular flap]." Notre experience des lambeaux libres vascularises osseux dans les reconstructions mandibulaires. Le lambeau brachial externe, le lambeau fibulaire, le lambeau parascapulaire. **94**(2): 74-81.

New techniques developed over the last decade use vascularized bone flaps for maxillofacial reconstructive surgery. Indications for use of three recently described flaps (external brachial, fibular, parascapular) are discussed as a function of the regions to be reconstructed. Three clinical cases are presented, each patient having received one type of flap.

1704. Ferry, D. J., Jr. and L. G. Kempe (1972). "False aneurysm secondary to penetration of the brain through orbitofacial wounds. Report of two cases." Journal of neurosurgery **36**(4): 503-506.

1705. Feugier, P., et al. (2007). "Urgent endovascular covered-stent treatment of internal carotid artery injury caused by a gunshot." European journal of vascular and endovascular surgery : the official journal of the European Society for Vascular Surgery **34**(6): 663-665.

Penetrating non-lethal injuries to the distal extra-cranial internal carotid artery are often a surgical challenge, because of the difficulty of direct exposure and repair of the internal carotid artery at the skull base. We describe a case of a successful emergency treatment, with an endovascular procedure using a PTFE covered-stent, of an internal carotid artery haemorrhagic pseudoaneurysm following penetrating trauma to the neck by single gunshot.

1706. Fezza, J. and R. Wesley (1999). "The importance of CT scans in planning the removal of orbital-frontal lobe foreign bodies." Ophthalmic plastic and reconstructive surgery **15**(5): 366-368.

PURPOSE: To describe the management of foreign bodies in the orbit and frontal lobe., METHODS: Reports of two cases., RESULTS: Both patients underwent successful removal of an orbital-cerebral foreign body by anterior orbitotomy., CONCLUSION: Computed tomography was useful to confirm preoperatively that the foreign body was not adjacent to cerebral blood vessels and to monitor postoperatively for cerebral hemorrhage. A team approach is necessary in the management of orbital-frontal lobe foreign bodies.

1707. Fialkov, J. A., et al. (2001). "Postoperative infections in craniofacial reconstructive procedures." The Journal of craniofacial surgery **12**(4): 362-368.

The rate of, and possible risk factors for, postoperative craniofacial infection is unclear. To investigate this problem, we reviewed 349 cases of craniofacial skeletal procedures performed from 1996 to 1999 at our institution. Infection rate was determined and correlated with the use of implants, operative site, and cause of deformity. The inclusion criteria consisted of all procedures requiring autologous or prosthetic implantation in craniofacial skeletal sites, as well as all procedures involving bone or cartilage resection, osteotomies, debridement, reduction and/or fixation. Procedures that did not involve bone or cartilage surgery were excluded. The criteria for diagnosis of infection included clinical confirmation and one or more of 1) intravenous or oral antibiotic treatment outside of the prophylactic surgical regimen; 2) surgical intervention for drainage, irrigation, and or debridement; and 3) microbiological confirmation. Among the 280 surgical cases that fit the inclusion criteria and had complete records, there were 23 cases of postoperative infection (8.2%). The most common site for postoperative infection was the mandible (infection rate = 16.7%). Multiple logistic regression analysis revealed gunshot wound to be the most significant predictor of postoperative infection. Additionally, porous polyethylene implantation through a transoral route was correlated with a significant risk of postoperative infection.

1708. Fichtner, J., et al. (2015). "The Nelaton Catheter Guard for Safe and Effective Placement of Subdural Drain for Two-Burr-Hole Trephination in Chronic Subdural Hematoma: A Technical Note." Journal of neurological surgery. Part A, Central European neurosurgery **76**(5): 415-417.

BACKGROUND: For chronic subdural hematoma, placement of a Blake drain with a two-burr-hole craniotomy is often preferred. However, the placement of such drains carries the risk of penetrating the brain surface or damaging superficial venous structures., OBJECTIVE: To describe the use of a Nelaton catheter for the placement of a subdural drain in two-burr-hole trephination for chronic subdural hematoma., METHOD: A Nelaton catheter was used to guide placement of a Blake drain into the subdural hematoma cavity and provide irrigation of the hematoma cavity. With the two-burr-hole method, the Nelaton catheter could be removed easily via the frontal burr hole after the Blake drain was

in place., RESULTS: We used the Nelaton catheters in many surgical procedures and found it a safe and easy technique. This method allows the surgeon to safely direct the catheter into the correct position in the subdural space., CONCLUSIONS: This tool has two advantages. First, the use of a small and flexible Nelaton catheter is a safe method for irrigation of a chronic subdural hematoma cavity. Second, in comparison with insertion of subdural drainage alone through a burr hole, the placement of the Nelaton catheter in subdural space is easier and the risk of damaging relevant structures such as cortical tissue or bridging veins is lower. Thus this technique may help to avoid complications when placing a subdural drain. Copyright Georg Thieme Verlag KG Stuttgart . New York.

1709. Figueroa, J., et al. (2017). "Prehospital intubation is associated with favorable outcomes in protect III." Academic emergency medicine **24**: S196.

Background: Traumatic brain injury (TBI) causes more than 2.5 million emergency department visits, hospitalizations, or deaths annually. Prehospital endotracheal intubation has been associated with poor outcomes in patients with TBI in several retrospective observational studies. Objective: To evaluate the relationship between prehospital intubation, functional outcomes, and mortality using high quality data on clinical practice collected prospectively during a randomized clinical trial. Methods: ProTECT III was a multi-center randomized, double-blind, placebo-controlled trial of early administration of progesterone in 882 patients with acute moderate to severe non-penetrating TBI. Prehospital intubation was performed as per local clinical protocol in each participating EMS system. Models for favorable outcome and mortality included prehospital intubation, method of transport, index GCS, age, race, and ethnicity as independent variables. Favorable outcome was defined by a stratified dichotomy of the GOS-E scores in which the definition of favorable outcome depended on the severity of the initial injury. Results: Favorable outcome was more frequent in the 349 subjects with prehospital intubation (57.3%) than in the other 533 (46.0%, p=0.003). Mortality was also lower in the prehospital intubation group (13.8% v. 19.5%, p=0.03). Logistic regression analysis of prehospital intubation and mortality, adjusted for index GCS, showed that odds of dying for those who with prehospital intubation were 47% lower than for those that were not intubated (OR=0.53, 95% CI = 0.36- 0.78). 279 patients with prehospital intubation were transported by air. Modeling transport method and mortality, adjusted for index GCS, showed increased odds of dying in those transported by ground compared to those transported by air (OR=2.10, 95% CI = 1.40-3.15). Decreased odds of dying trended among those with prehospital intubation adjusted for transport method, index GCS score at randomization, age, and race/ethnicity (OR=0.70, 95% CI=0.37-1.31). Conclusions: In this study that excluded moribund patients, prehospital intubation was performed primarily in patients transported by air. Prehospital intubation and air medical transport were associated with favorable outcome and lower mortality, but the effects of each could not be isolated.

1710. Filley, C. M. (2000). "Clinical neurology and executive dysfunction." Seminars in speech and language **21**(2): 95-108.

Executive function is a uniquely human ability that permits an individual to plan, carry out, and monitor a sequence of actions that is intended to accomplish a goal. This crucial neurobehavioral capacity depends on the integrity of the frontal lobes, most importantly the dorsolateral prefrontal cortices and their connections. Executive dysfunction is associated with a wide range of neurologic disorders that affect these regions. In this paper, executive dysfunction is considered from the perspective of behavioral neurology, and the lesion method is employed to illustrate this impairment in a diverse group of disorders. Frontal system damage leading to disturbed executive function is common and clinically significant. Recognition of this syndrome is critical for ensuring the correct diagnosis, accurate prognosis, and appropriate treatment of affected patients. Executive dysfunction also represents an intriguing aspect of brain-behavior relationships and offers important insights into one of the highest cerebral functions.

1711. Filocamo, M. T., et al. (2015). "Urodynamic evaluation before and after continuous intrathecal baclofen infusion (CIBI) in patients on vegetative/minimally conscious state." Neurourology and Urodynamics **34**: S324-S325.

Hypothesis/aims of study Spasticity of either spinal or supraspinal origin may compromise patients severely and is associated with the development of pain, limb contractures and immobility. Baclofen is a structural GABA analogue substance acting on the GABA-B receptor subtype. It is assumed to act at the spinal level attenuating mono and polysynaptic conduction, primarily by inhibiting the release of excitatory transmitters. Baclofen hardly penetrates the blood-brain barrier; therefore, penetration into the cerebrospinal fluid is poor with oral administration. Penn and Kroin

were the first to report good results with continuous intrathecal baclofen infusion (CIBI) in patients with severe spinal spasticity. A dramatic clinical improvement was reported. Spasticity of supraspinal origin is much more common than spinal spasticity, but treatment with CIBI has been evaluated far less frequently in this condition. Reports of successful treatment of patients with supraspinal spasticity are limited. Especially patients with severe traumatic and/or hypoxic brain injury often suffer from severe tetraspasticity that is unresponsive to oral medication, physiotherapy or other antispastic therapies. More limited are the reports on CIBI use in patients in vegetative or minimally conscious state. Moreover CIBI has been demonstrated to be effective to improve bladder capacity or to decrease sphincter dyssynergia in patients affected by spinal cord spasticity. Only a few reports have been published on Traumatic Brain Injury (TBI), especially on the correlation of urodynamic findings, because injured patients commonly have behavioral, cognitive, or communication problems. The injury to the brain itself, impairment of cognitive and behavioral function, may induce voiding problems, such as incontinence. The most commonly expected urodynamic abnormality after TBI is involuntary detrusor contraction, which can be induced by the loss of cortical inhibition caused by suprapontine lesions. Coordinated relaxation of the distal sphincter during detrusor contraction is usually maintained. The incidence of urinary retention after TBI is lower than that after cerebrovascular accident (CVA). Very little is known about changes in urodynamic pattern in patients in Vegetative (VS) or Minimally Conscious State (MCS) after TBI or CVA treated with CIBI. The aim of this study is to urodinamically assess bladder function in patients on VC or MCS before and after CIBI. Study design, materials and methods We enrolled for this study 16 patients (13 males and 3 females), all patients were in VS or MCS for CVA (9 extensive brain hemorrhage) or TBI (7 patients). All patients were urodinamically evaluated before and one month after Baclofen pump implantation. During urodynamic study were evaluated Bladder Compliance (BC), presence and amplitude of Detrusor Overactivity (DO), Maximum Cystometric Capacity (MCC), detrusor pressure at opening bladder neck (detrusor leak point pressure, DLPP) that coincide to detrusor pressure required to void. In all patients were applied the Ashworth scale, separately for upper and lower limbs, and the spasm score, before and after implant, to evaluate changes in spasticity. In all patients were evaluated Post Void Residual (PVR) pre and post CIBI. In 12 patients we performed a second urodynamic evaluation 6 months after implant, evaluating the same urodynamic findings (BC, DO, MCC, DLPP). Statistical analysis were performed using paired t-test and/or paired Wilcoxon test when appropriated to evaluate the difference in Ashworth and spasm scale, and to evaluate the urodynamic results at baseline and 1 and 6 months after CIBI. We used Fisher's exact test to evaluate the number of patients in Clean Intermittent Catheterization (CIC), and the conscious state at baseline and after CIBI. We considered statistical significant when p<0,05. Results Mean age of patients included in the study was 41.3 ± 13.5 years, coma days were 17.4 ± 5.9, elapsed time between cerebral injury and our centre's admission was 149.5 ± 41.5 days. At admission 3 patients were in MCS and 13 in a VS. Time of catheterization was 117,9 ± 98.4 days. At baseline all patients were in spontaneous micturition (reflex urinary incontinence), in 4 out of 16 patients CIC was necessary because high PVR. In all patients we observed an improvement of spasticity, especially of lower limbs after CIBI. The mean Ashworth scale pre-implantation was 2.8 ± 0.4 for upper limbs and 3.5 ± 0.5 for lower limbs, spasm score was 1.8 ± 0.7. After CIBI Ashworth scale was reduced, 2.4 ± 0.5 for upper limbs and 2.2 ± 0.4 for lower limbs with a statistical significant difference (p<0.01). Also spasm score was improved, after CIBI measuring 1.5 ± 0.5 with a significant statistical difference respect baseline (p<0.03). One month After CIBI in 8 out of 16 patients was necessary CIC for high PVR (Fisher's exact test p=0.27). Six months after implantation CIC was necessary in 3 out of 12 patients (Fisher's exact test p=0.3) At urodynamic evaluation mean baseline MCC was 364,6 ± 150.1 ml, one month after CIBI was 391.9 ± 40.8 ml (p<0.03). Mean MCC 6 months after implant (12 patients) was 368.1 ± 146.2 ml (p=0.11) DLPP was 98.3 ± 7.4 cmH2O at baseline and 83.8 ± 11.5 cmH2O 1 month after CIBI, with a significant statistical difference (p=0.04). in the 12 patients evaluated 6 months after CIBI mean DLPP was 85,7 ± 12.8 cmH2O (p=0.05 respect baseline). Mean PVR at baseline was 57.5 ± 21.7 ml, and 100.4 ± 50.9 ml one month after CIBI (p=0.01), although 6 months after CIBI mean PVR was 56.8 ± 24.5 (p=0.58 respect baseline). At baseline in 10 out of 16 patients a DO was identified, after CIBI DO was present in 3 out of 16 patients (p=0.02), and in two patients 6 months after implant. We observed an improvement in conscious state, at hospital admission 13 out of 16 patients were in VS and 3 out of 16 in MCS, at discharge 7 out 16 were in SV and 9 in MCS (Fisher's exact test p=0.14). Interpretation of results The possibility to administer baclofen intrathecally, through a system of programmable infusion pump, has enabled the effective control of spasticity after severe brain injury with fewer side effects compared to oral treatment and with a significant improvement in overall function. At the level of the urinary system, the γ-aminobutyric acid has an inhibitory action on the detrusor contractility, the origin of this mechanism is both in spinal cord and supraspinal. The GABA receptors are involved in the regulation of detrusor contractility through the action carried out on the pelvic ganglia, the sacral parasympathetic nucleus and supraspinal centers. Baclofen has therefore indications for use in the treatment of Lower Urinary Tract Dysfunctions (LUTD) with two main way of action: inhibition of hypertone involving the external urethral sphincter and the increase of detrusor compliance with the consequent increase in the

filling capacity of the bladder. The use of intrathecal baclofen in the patients suffering from disorder of consciousness is spreading more and more, and not only for the treatment of spasticity and neurovegetative crisis but also for the possibility to induce a change in positive of the state of consciousness, many are today reporting in this sense. Another element to be reckoned with in clinical practice is the indication, suggested by some authors, to use early implant in order to prevent the impairment linked with spasticity before it is structured, thus making almost vain the only pharmacological or rehabilitative intervention. This study, even considering the modest numerosity of the sample, allowed to verify that after the implantation of CIBI a significant increase of MCC and a reduction of DLPP. Also the presence of DO is detected with a significantly reduced frequency respect baseline. Accordingly an increase in PVR in the first month was identified. While this data may seem a positive result of the therapy must be related to the type of patient treated, indeed the reduction of a detrusor contraction that it is not supported by supraspinal centers can create an increase of the PVR However, this discrepancy was filled out 6 months after implantation, and the PVR returns comparable to the baseline. Instead, positive results on the reduction of DO were maintained in the long term. The data therefore indicate the need to monitor PVR closely, in the first weeks after implantation, to avoid the risk of bladder supradistension in these patients with disturbance of consciousness. Concluding message This is a preliminary pilot study that needs further validation to determine which is the best management of the dynamics of micturition in patients in vegetative stete/minimally conscios state after continous intrathecal baclofen infusion.

1712. Finck, P. A. and E. F. Donnelly (1970). "Prolonged survival with retention of bullet in orbit, lung, or spleen. Report of three cases. The identification of bullets. The relationship between trauma and malignancy." Journal of forensic sciences **15**(4): 565-580.

1713. Findler, G., et al. (1979). "Cranioplasty with pre-formed methyl methacrylate onlay plates." Neurochirurgia **22**(3): 99-101.

The available manufactured plates for cranioplasty of large skull defects are not always satisfactory. Recently we have used preformed methyl methacrylate plates, in combination with Proplast. This plate prepared adjusted and sterilized before the operation is both cosmetically and mechanically satisfactory.

1714. Fink, S. C., et al. (1997). "Transnasal canthoplasty." The Journal of cranio-maxillofacial trauma **3**(2): 43-48.

The reconstruction of a traumatic telecanthus, particularly the repositioning and securing of the medial canthal tendon, presents a challenge to the reconstructive surgeon. The adequate positioning of the medial canthal tendon for proper intercanthal distance, and apposition of the lid to the globe, is the cornerstone of a successful reconstruction. The authors have developed a technique for transnasal canthoplasty that is fast, relatively easy, and safe. Transnasally, a 16-gauge spinal needle is introduced over a preplaced K-wire using a 4-0 Bunnell stainless wire suture (Ethicon, Somerville, NJ). The medial canthal tendon is lassoed, secured, and then fixed to the contralateral nasal bone. Six patients have undergone this technique to date. The authors believe this procedure offers an improvement to existing methods.

1715. Finkel, M. F. (2006). "The neurological consequences of explosives." Journal of the neurological sciences **249**(1): 63-67.

Neurological injuries produced by explosive blasts are the result of a cascade of events that begin with the initial explosion and evolve from the secondary, tertiary, and quaternary effects that the explosion engenders [Lavonis EJ. Blast Injuries. EMedicine.htm]. Only the results of the primary blast are predictable, and subsequent actions ripple outward in an increasingly random and chance sequence. This article reviews and explains how the ensuing chain of circumstances injures the nervous system, and what examining physicians should anticipate when they treat these patients.

1716. Finkelstein, M., et al. (1997). "Projectile metallic foreign bodies in the orbit: a retrospective study of epidemiologic factors, management, and outcomes." Ophthalmology **104**(1): 96-103.

PURPOSE: Intraorbital projectile metallic foreign bodies are associated with significant ocular and orbital injuries. The authors sought to evaluate epidemiologic factors, the incidence of associated ocular and orbital injury, and

the nature and necessity of surgical intervention in these cases., METHODS: Charts of all patients with projectile intraorbital metallic foreign bodies seen at our institution (27) over the preceding 7 years were evaluated with respect to age, sex, type of injury, associated ocular and orbital injuries, location of the projectile (anterior, epibulbar, or posterior), postinjury visual acuity, and surgical intervention., RESULTS: The majority of patients were male, between the ages of 11 and 30, and had BB pellet injuries. Thirteen projectiles were lodged anteriorly, 4 were in an epibulbar position, and the remaining 10 were posterior to the equator. Twelve of 13 anterior, and 4 of 4 epibulbar foreign bodies were removed surgically, whereas only 2 of 10 posterior foreign bodies required surgery. No case of surgical intervention resulted in a decrease of visual acuity. Associated ocular injuries were both more common and severe in patients with posteriorly located foreign bodies. Final visual acuity was better at presentation and at discharge in patients with anteriorly located foreign bodies., CONCLUSION: Intraorbital projectile metallic foreign bodies can be a source of significant ocular morbidity. Management of these cases is dependent on the location of the projectile. Ancillary radiographic studies can be helpful. Surgery to remove the projectile should be considered in each case, but foreign bodies that are not readily accessible often may be left safely in place. Closer regulation of the pellet gun industry, with an emphasis on education and protective eyewear use, would be helpful in reducing these injuries.

1717. Firat, C., et al. (2012). "Surgical modalities in maxillo-facial fractures: Retrospective analysis of 110 patients." European Journal of General Medicine **9**(4): 258-264.

The objective of this study is to carry out a retrospective analysis of patients in our clinic who underwent surgery for maxillofacial trauma. The retrospective analysis was carried out on data of 110 inpatients with maxillofacial trauma that were treated. The distribution of maxillofacial traumas according to facial bones (maxilla, zygoma, orbita, mandibular, and nasal) was examined. Multi-fragmented fractures of the maxilla anterior wall, orbital base fractures and isolated zygomatic arch fractures were treated with a balloon treatment method by Foley catheter. A total of 161 fracture were treated that 82 (74.54%) were male and 28 (25.45%) were female. Of these patients, 11 (10%) were in the pediatric age group (0-16). The etiology of maxillofacial traumas was examined, as 45 cases were traffic accidents, 32 cases were blows, 30 cases were falling, and 3 were firearm injuries respectively. The anatomic localizations of the maxillofacial fracture were 68 (42.23%) mandibula, 36 (22.36%) maxilla fractures, 21 (13.04%) zygoma fractures, and 26 (16.14%) orbita fractures (naso-orbital or naso-orbito-etmoidal fractures were included). Maxilla fractures were most frequently observed with other facial fractures. Zygoma fractures were also generally observed together with multi-fragmented fractures. The balloon treatment was found very effective to stabilize of multi-fragmented fractures of the maxilla anterior wall, orbita base fractures and zygomatic arch fractures. Since maxillofacial fractures may be seen in many patients who apply to hospitals due to traumas, sufficient experience of doctors working in this field is an important factor in decreasing mortality and morbidity. The most frequent patients are males aged 30 to 40 with maxillofacial trauma caused by a traffic accident, a sports accident, or a blow. Retrospective or epidemiological studies similar to our study are very beneficial for the determination of risk groups, specific precautions, and practical and effective treatment methods.

1718. Firat, C. and Y. Geyik (2013). "Surgical modalities in gunshot wounds of the face." The Journal of craniofacial surgery **24**(4): 1322-1326.

Maxillofacial traumas caused by gunshot wounds may cause quite varied defects. The objective of this study was to evaluate the reconstruction methods in 12 patients with gunshot wound-related mandibular and maxillofacial bony and soft tissue defects. Twelve patients who were operated on for maxillofacial gunshot wounds at our clinic between 2002 and 2012 were included in the study. Seven patients were wounded in a suicide attempt, and 5 were wounded as a result of an accident or in assaults. Two patients underwent reconstruction using free fibula osteocutaneous flap, 4 patients received the free radial forearm osteocutaneous flap, 2 patients received costal bone graft, and 3 patients received iliac bone grafts. Satisfactory functional and aesthetic outcomes were achieved in cases where staged secondary reconstruction, balloon treatment, and consecutive fat and steroid injections into the depressed scar areas were applied. In conclusion, the basic goal in maxillofacial reconstruction is the functional and aesthetic reconstruction of the contours. Because it is not easy to get perfect results with only 1 clinical approach or 1 method, the proper timing and reconstruction method should be selected.

1719. Fischer, H. (1971). "[Trauma and tumor]." Trauma und Tumor. **26**(2): 107-111.

1720. Fischer, H. (1979). "[Gunshot wounds by military weapons]." Schussverletzungen durch Militarwaffen. **97**(7): 284-288.

The review is based on 34 recent publications. Bullet-wounds by military weapons either in drill or war are to be regarded as special kinds of wounds, needing profound knowledge of wound ballistic. However, the therapy of late developing complications may lead to problems.

1721. Fischer, H. (1979). "[Gunshot wounds in peace and their treatment. Review of the literature]." Schussverletzungen im Frieden und ihre Behandlung Literaturubersicht. **97**(2): 49-52.

For therapy of bullet-wounds in peace profound knowledge of their pathogenesis is necessary. This may be especially true for wounds evoked by new developed weapons. It may be assumed that often therapists are not familiar with the effects of these modern weapons. This review of 27 international publications therefore represents particularities of wounds of the body cavities and the extremities. Furthermore the problem of bulletembolies is represented.

1723. Fischer, N. J. (2021). "Mortality following severe liver trauma is declining at Auckland City Hospital: a 14-year experience, 2006-2020." The New Zealand medical journal **134**(1540): 16-24.

INTRODUCTION: Liver injuries sustained in blunt and penetrating abdominal trauma may cause serious patient morbidity and even mortality., AIM: To review the recent experience of liver trauma at Auckland City Hospital, describing the mechanism of injury, patient management, outcomes and complications., METHODS: A retrospective cohort study was performed, including all patients admitted to Auckland City Hospital with liver trauma identified from the trauma registry. Patient clinical records and radiology were systematically examined., RESULTS: Between 2006-2020, 450 patients were admitted with liver trauma, of whom 92 patients (20%) were transferred from other hospitals. Blunt injury mechanisms, most commonly motor-vehicle crashes, predominated (87%). Stabbings were the most common penetrating mechanism. Over half of liver injuries were low risk American Association for the Surgery of Trauma (AAST) grade I and II (56%), whereas 20% were severe grade IV and V. Non-operative management was undertaken in 72% of patients with blunt liver trauma and 92% of patients with penetrating liver trauma underwent surgery. Liver complications occurred in 11% of patients, most commonly bile leaks (7%), followed by delayed haemorrhage (2%). Thirty-two patients died (7%), with co-existing severe traumatic brain injury as the leading cause of death. There was a significant reduction in death from haemorrhage in patients with grade IV and V liver trauma between the first and second half of the study period (p=0.0091)., CONCLUSION: Although the incidence and severity of liver trauma at Auckland City Hospital remained stable, there was a reduction in mortality, particularly death as a result of haemorrhage.

1724. Fischer, S., et al. (2017). "First Lower Two-Thirds Osteomyocutaneous Facial Allograft Perfused by a Unilateral Facial Artery: Outcomes and Vascularization at 1 Year after Transplantation." Plastic and reconstructive surgery **139**(5): 1175e-1183e.

BACKGROUND: Facial allotransplantation provides a unique opportunity to restore facial form and function in severely disfigured patients. Using a single unilateral facial artery for vascularization can significantly reduce surgical duration and thus facilitate the practice of face transplantation., METHODS: A 33-year-old man with a history of high-energy ballistic trauma received a facial allograft comprising the lower two-thirds of the face, including maxilla and mandible. Vascular anastomoses involved one unilateral facial artery and two veins. Vascularization patterns, airway volume, and facial functions were assessed before and 1 year after transplantation. In addition, immunosuppressive therapy and rejection episodes were recorded., RESULTS: One year after transplantation, the facial allograft is well perfused and gradually improving in function. Unilateral facial artery anastomosis remains patent and collateralization with the contralateral side is taking place through collaterals of the submental arteries. Bony perfusion of the maxilla

and mandible is provided periosteally. Bilateral venous outflow is evident. Airway volume is significantly increased compared with before transplantation, and gastrostomy and tracheostomy tubes have been securely removed. The recipient has gained the abilities to smell, speak, feel, and grimace 1 year after transplantation. Steroids were successfully weaned after 9 months, leaving the patient on dual immunosuppressive therapy with tacrolimus and mycophenolate mofetil. Two rejection episodes occurred, of which one was treated by steroid pulse and the other by adjusting the maintenance therapy., CONCLUSIONS: In this patient, a facial allograft comprising the lower two-thirds of the face including the maxilla and mandible is sufficiently perfused by one unilateral facial artery. Bilateral venous outflow, however, seems to be necessary. Facial allotransplantation can significantly and securely improve facial form and function., CLINICAL QUESTION/LEVEL OF EVIDENCE: Therapeutic, V.

1725. Fishbain, D. A., et al. (1987). "Relationship between Russian roulette deaths and risk-taking behavior: a controlled study." The American journal of psychiatry **144**(5): 563-567.

A review of medical examiner records yielded data on 19 men and one woman who died playing Russian roulette. The men differed significantly from 95 male suicide victims who died of gunshot wounds to the head on several variables including age, race, ethnicity, religion, citizenship, marital status, living situation, health, and the likelihood of the death being witnessed. The Russian roulette victims were significantly less likely to die in the bedroom, die in the morning, leave a suicide note, and be depressed but were significantly more likely to have alcohol or drugs in their body fluids and to have a previous history of drug and alcohol abuse.

1726. Fisher, B. and M. Worthen (1999). "Cardiac arrest induced by blunt trauma in children." Pediatric emergency care **15**(4): 274-276.

BACKGROUND: There is incomplete knowledge regarding the outcome of children who suffer a cardiac arrest after blunt trauma. We sought to determine mechanisms of injury, mortality, and rate of organ donation in this population of children., METHODS: Since 1984, all traumatically injured children in San Diego County, California, have been treated at San Diego Children's Hospital. This review encompasses 10,979 pediatric trauma patients evaluated from August 1, 1984 through September 30, 1996. All patients who did not meet the following two criteria were eliminated from the review: 1) a mechanism of blunt trauma, and 2) cardiopulmonary resuscitation performed by a trained medical provider prior to arriving or on arrival to the hospital. A chart review of this set of patients was undertaken to determine mechanism of injury, severity of injury, mortality, and rate of organ donation., RESULTS: In this large metropolitan county, 65 children suffered cardiac arrest following blunt trauma. Accidents involving motor vehicles were the mechanisms responsible for 80% of these injuries. The average Injury Severity Score was 50.3. Mortality was largely related to severe head injury as manifested by a mean Abbreviated Injury Score for head and neck equal to 5.9. All but one of these patients died despite resuscitation. Ninety-four percent of these children died within the first 24 hours of injury. The single survivor was discharged in a vegetative state. Solid organs were obtained from 9% of the patients., CONCLUSION: The outcome from blunt cardiac arrest in children is rapidly and nearly uniformly fatal despite resuscitation. Because severe head injuries resulting in brain death are the leading cause of mortality, a significant percentage of organ donations are obtained from these patients.

1727. Fisher, S. B., et al. (2011). "Pencils and pens: an under-recognized source of penetrating injuries in children." The American surgeon **77**(8): 1076-1080.

Unlike other sharp objects, pens and pencils are readily available to children both at home and school. Although case reports are published, no series of pen or pencil injuries have been reported in the recent literature. We therefore reviewed the incidence and injury profiles of writing instruments as compared with other sources of penetrating trauma. The trauma registry from a large urban pediatric hospital system was queried for nonmissile, nonbite penetrating injuries from 2005 through 2009. Retrospective data was collected on demographics, injuries, operations, admissions, and mortalities. Additionally, data regarding pen and pencil injuries from 2009 to 2010 were collected prospectively, and one case from 2003 was included retrospectively. Fourteen injuries from writing instruments were seen and involved the head and neck (9), chest (1), bladder/perineum (2), and extremities (2). Eleven children were admitted and eight required surgical intervention. One child died from a transhemispheric brain injury after intraorbital penetration by a pencil. Penetrating trauma from writing instruments is not an uncommon source of injury and often requires surgical

intervention to remove the object. Injuries from pens and pencils can be severe or even fatal. Appropriate parent and teacher education regarding the potential risks may help to prevent such injuries.

1728. Fitzgerald, D. B., et al. (2011). "Delayed diagnosis of intracerebral foreign body from the Vietnam War." Military medicine **176**(2): 228-231.

We report on a 22-year-old infantryman who sustained a right frontal wound to his head. He was treated and returned to duty immediately. During a computed tomography scan, 38 years after the incident, a metallic foreign body and disruption of the brain consistent with a projectile track were discovered in his brain. In this report, we review similar cases of delayed discovery of unsuspected foreign bodies and the probable nature of the wound.

1730. Fitzpatrick-Swallow, V. L., et al. (2012). "Lung injury similar to blast lung in a case of shotgun wound of the head." The American journal of forensic medicine and pathology **33**(3): 286-288.

Primary blast lung injury after explosions has been well described in the literature. A case of injury to the lung, after a shotgun wound to the head, similar to primary blast lung, is presented. Histological appearances of the lung revealed alveolar over distension, rupture and intra-alveolar hemorrhage. Primary blast lung injury is considered the reserve of high-order explosives; however, this case reveals similar injuries from a shotgun (low-order explosive), which has not been reported before to the best of our knowledge.

1731. Flament, J. and A. Moraine (2021). "Tree branch through the orbit into the skull: A case report." Radiology Case Reports **16**(4): 795-797.

A 78-year-old woman presented to the Emergency Department with a tree branch through the orbit. Her condition was rated 15/15 on the Glasgow coma scale. Computed tomography showed that the distal extremity of the branch was located between the intracavernous segment of the internal carotid artery and the temporal lobe. The foreign body pushed aside without penetrating the medial rectus, the optic nerve, the internal carotid artery, and the temporal lobe. No intracranial bleeding or pneumencephaly was observed. The chirurgical option was confirmed and the patient transferred for extraction of the foreign body by traction in the axis.

1732. Fleischer, A. S., et al. (1975). "Cerebral aneurysms of traumatic origin." Surgical neurology **4**(2): 233-239.

This report reviews 41 cases of traumatic cerebral aneurysms, including four cases of our own which are presented in detail. They may follow penetrating or closed head injury, and are usually associated with significant additional intracranial damage. Almost half of the patients presented with a delayed subarachnoid hemorrhage within three weeks of the initial head injury, defining an important neurological syndrome. Those patients whose post-traumatic aneurysms have been surgically obliterated have an associated mortality which is half that of patients treated by nonsurgical methods.

1733. Fleming, W. H. and J. C. Bowen (1972). "Early complications of long-term respiratory support." The Journal of thoracic and cardiovascular surgery **64**(5): 729-738.

1734. Flesche, C. W., et al. (2004). "[Telemedicine in the maritime environment--hightech with a fine tradition]." Telemedizin in der Hochseeschifffahrt--Hightech aus Tradition. **99**(3): 163-168.

Access to health care always has been one of the most critical issues for offshore crews. Therefore, telemedicine has a long and outstanding tradition in the maritime environment. Since 1931 Cuxhaven medical center (Medico Cuxhaven) operates as a hospital-based radio medical advice center (RMA) for ships worldwide providing one of the first routine telemedical services worldwide. For a long time this task was performed on a honorary basis by the hospital's

physicians. In 1994 Germany accepted the IMO/ILO (International Maritime Organisation and International Labour Organisation) solution 164. Therefore, in 1998 a formal contract of the German Ministry of Transport officially installed Medico Cuxhaven as the TMAS Center for Germany. According to IMO/ILO solution 164, the RMA provides an expert level of care 24 h/day, 365 days/year. Cuxhaven hospital is a busy general hospital with departments of anesthesia and intensive care, internal medicine, surgery, gynecology and obstetrics, urology, pediatrics, ENT, radiology, and pain medicine. All physicians directly responding to TMAS calls have practical experience in maritime routine and emergency medicine. All incoming emergency calls are primarily handled by board-certified anesthesiologists, experienced in martime emergency medicine (e. g., staffing coastal SAR helicopters, working on rescue boats, carrying out repatriation services for sailors worldwide). If needed, other medical specialists are included. Today, Medico Cuxhaven takes an average workload of one to two emergency calls (response time < 20 s), two to three follow-up calls and approximately one informative call per day. Since 2000 transmission of digital photos has been used for routine RMA. Recently, a system for online and trenddata telemetry of twelve-lead ECG, NIBP (noninvasive blood pressure measurement), CO(2), SaO(2), pulse and respiration rates including the transmission of video images was developed. This system allows worldwide communications as it is capable of all possible means of telecommunication such as GSM, Inmarsat-ISDN or Iridium-Satellite-Transmission. So far, this system has been installed on board several German SAR rescue boats.However, radio telephone and the simple transmission of digital photography remain the basis of maritime radio medical advice service.

1735. Fleuridas, G., et al. (1998). "[Gunshot wounds and injuries of the face in civilian practice]." Plaies et traumatismes balistiques de la face en pratique civile. **99**(2): 75-79.

Firearm wounds are relatively frequent in civilian practice. Due to the variable power of the weapons involved, a wide range of maxillofacial lesions are encountered and classification is a difficult task. In order to predict the gravity of the lesions, we have drawn a classification scheme from our experience with maxillofacial injuries. The scheme was based on the kind of ammunition which gives a better classification than the type of weapon. Three main categories have been identified.

1736. Flint, A. C., et al. (2008). "Post-operative expansion of hemorrhagic contusions after unilateral decompressive hemicraniectomy in severe traumatic brain injury." Journal of neurotrauma **25**(5): 503-512.

Decompressive hemicraniectomy is commonly performed in patients with traumatic brain injury (TBI) with diffuse brain swelling or refractory raised intracranial pressure. Expansion of hemorrhagic contusions in TBI patients is common, but its frequency following decompressive hemicraniectomy has not been well established. The aim of this retrospective study was to determine the rate of hemorrhagic contusion expansion following unilateral hemicraniectomy in severe TBI, to identify factors associated with contusion expansion, and to examine whether contusion expansion is associated with worsened clinical outcomes. Computed tomography (CT) scans of 40 consecutive patients with non-penetrating TBI who underwent decompressive hemicraniectomy were analyzed. Hemorrhagic contusion volumes were measured on initial, last pre-operative, and first post-operative CT scans. Mortality and 6-month Glasgow Outcome Scale (GOS) score were recorded. Hemorrhagic contusions of any size were present on the initial head CT scan in 48% of patients, but hemorrhagic contusions with a total volume of >5 cc were present in only 10%. New or expanded hemorrhagic contusions of >or=5 cc were observed after hemicraniectomy in 58% of patients. The mean volume of increased hemorrhage among these patients was 37.1+/-36.3 cc. The Rotterdam CT score on the initial head CT was strongly associated with the occurrence and the total volume of expanded hemorrhagic contusions following decompressive hemicraniectomy. Expanded hemorrhagic contusion volume greater than 20 cc after hemicraniectomy was strongly associated with mortality and poor 6-month GOS even after controlling for age and initial Glasgow Coma Scale (GCS) score. Expansion of hemorrhagic contusions is common after decompressive hemicraniectomy following severe TBI. The volume of hemorrhagic contusion expansion following hemicraniectomy is strongly associated with mortality and poor outcome. Severity of initial CT findings may predict the risk of contusion expansion following hemicraniectomy, thereby identifying a subgroup of patients who might benefit from therapies aimed at augmenting the coagulation system.

1737. Flint, G. (1999). "Head injuries." The British journal of theatre nursing : NATNews : the official journal of the National Association of Theatre Nurses **9**(1): 15-21.

1738. Flint, L. M., et al. (1984). "Approaches to the management of shotgun injuries." The Journal of trauma **24**(5): 415-419.

Shotgun wounds present specific challenges for the surgeon. Multiple penetrating wounds frequently involve large anatomic areas with potential multi-system injury. Experience with 121 patients sustaining shotgun wounds over the 5-year period ending 31 December 1981 was reviewed to assess results and evaluate treatment protocols. Sixty-six patients had chest wounds with pleural penetration. Twenty-four wounds were minor and were observed. Each had less than five pellets penetrating the pleura. Twenty-two patients had close-range injuries. Fourteen of these required chest tube drainage alone and eight patients required thoracotomy for control of bleeding. Eleven patients died, six as a direct result of the chest injury. In 55 patients with abdominal-retroperitoneal wounds exploratory operations were done if more than four pellets were thought to be lodged intraperitoneally or if signs of peritonitis were present, while lesser wounds without peritoneal findings were observed. In the 15 patients who did not have exploratory operations, there were no deaths or major complications. Thirty-five patients had exploratory operations. Two patients had five intraperitoneal missiles and no clinical evidence of peritonitis but were found to have significant intestinal perforations. Four patients died. Eighty-three patients with extremity wounds were classified according to location of injury. Forty-five had upper extremity wounds, with nine vascular injuries. Two patients died and one limb was amputated because of soft tissue infection. Thirty-eight patients had lower extremity wounds. Five had major vascular injuries. Preoperative arteriography was obtained in 13 patients with extremity injuries; the results of one of these were falsely negative. There were no deaths or amputations.(ABSTRACT TRUNCATED AT 250 WORDS)

1739. Flora, A. S. and R. E. Kose (2018). "Symptoms of posterior glottic stenosis presenting three decades after initial endotracheal trauma." American Journal of Respiratory and Critical Care Medicine **197**(MeetingAbstracts).

Introduction: Five to fourteen percent of patients intubated for more than 10 days are susceptible to stenosis. As the arytenoids fuse in the midline, significant dyspnea typically occurs early in the development of stenosis as a result of forced cord adduction and glottic closure. Interestingly, we present a case of a man who developed dyspnea from posterior glottic stenosis 31 years after a prolonged intubation of 19 days for a self-inflicted gunshot wound to the head. Case Summary: He presented with complaints of persistent cough and increased dyspnea following a severe upper respiratory tract infection a year prior and was subsequently diagnosed as intermittent asthma by his primary care physician. He had no improvement with inhaled corticosteroids and long and short acting beta agonists. Pulmonary function testing demonstrated a moderate degree of fixed central airway obstruction with flattening of both the inspiratory and expiratory phases of the flow volume loop. Airway inspection with bronchoscopy found the vocal cords fixed in a median position with minimal movement of the right cord and questionable complete paralysis of the left vocal cord. A fibrous band was found in the posterior aspect between the arytenoids creating a 4mm opening in the posterior commissure. He underwent microsuspension direct laryngoscopy using a Dedo scope and jet vent with a Lewy suspension apparatus by an otolaryngologist. A sickle knife was used to divide the fibrous scarring between the two arytenoids and the larynx was subsequently dilated without difficulty. The patient returned to his normal baseline on follow up, and spirometry 4 months later found much improvement in his flow volume loop. (Figure presented) Discussion: The most vulnerable area to stenosis of the glottis from prolonged endotracheal intubation is the posterior commissure. Tracheal angulation increases pressure on the fulcrum of the endotracheal tube, causing trauma to the respiratory epithelium overlying the posterior glottis. Prospective studies have shown that this process becomes evident 3-4 weeks after extubation and developing stenosis typically is complete by 16 weeks, even if the patient had a trachestomy. Our case is interesting in that symptoms did not manifest in our patient for three decades, thus highlighting the importance in long-term follow up in patients with prolonged endotracheal intubation, even for years.

1740. Flores, H. A. and R. M. Stewart (2008). "The multiply injured patient." Seminars in thoracic and cardiovascular surgery **20**(1): 64-68.

The multiply injured patient with significant thoracic and extra-thoracic injuries poses a number of challenges. Pericardial tamponade, tension pneumothorax and massive hemothorax can and should be diagnosed clinically. In more stable patients, chest computed tomography (CT) scan is an excellent screening test. The concept of damage control resuscitation and damage control surgery have shown promise in patients with multiple, critical injuries. Beta-blockade of patients with blunt thoracic aortic injuries can be used as a temporizing damage control measure when the risks of

operation or intervention are very high (traumatic brain injury, severe right or bilateral pulmonary contusion, unstable pelvic fractures). Patients with multiple penetrating wounds require the surgical team to be expeditious and flexible, and damage control is a helpful strategy in these patients.

1743. Foley, B. D., et al. (2013). "Mandibular reconstruction using computer-aided design and computer-aided manufacturing: an analysis of surgical results." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **71**(2): e111-119.

PURPOSE: The purpose of this study was to analyze the accuracy of virtual surgical planning in mandibular reconstruction., MATERIALS AND METHODS: This is a retrospective study involving 8 consecutive patients reconstructed with nonvascularized iliac crest bone grafts and free fibula osteomyocutaneous flaps. DICOM data from a maxillofacial skeleton computed tomography (CT) scan were sent to a medical modeling company and used to map the mandibular resection, anatomically place the mandibular reconstruction plate, and create surgical guides. After surgery a postoperative CT compared the virtual plan to the surgical result. Linear measurements [2 transverse and 1 anterior-posterior (A-P)] were performed to determine if the virtual surgical result was achieved. The transverse measurements were made from the condylar head to condylar head and from the gonial angle to gonial angle. The A-P analysis was made by measuring a perpendicular line drawn from the anterior inferior mandibular border to the center point on the condylar head to condylar head measurement., RESULTS: The average surgical error in the A-P dimension for the iliac crest bone grafts and free fibula flap was 0.2 mm (range 0.0 mm to 0.7 mm) and 0.9 mm (range 0.2 mm to 1.9 mm), respectively. In the transverse dimension the average surgical error was 1.6 mm (range 0.7 mm to 2.4 mm) and 2.7 mm (range 1.9 mm to 4.5 mm) from condyle to condyle, and 1.7 mm (range 0.7 mm to 2.7 mm) and 2.5 mm (range 0.4 to 4.8 mm) from gonial angle to gonial angle., CONCLUSION: The use of CAD-CAM (Medical Modeling, Golden, Colorado) technology for the fabrication of surgical resection guides and mandibular reconstruction plates resulted in an accurate surgical result.

1744. Folio, L., et al. (2013). "Semi-automated trajectory analysis of deep ballistic penetrating brain injury." Military medicine **178**(3): 338-345.

BACKGROUND: Penetrating head injuries (PHIs) are common in combat operations and most have visible wound paths on computed tomography (CT)., OBJECTIVE: We assess agreement between an automated trajectory analysis-based assessment of brain injury and manual tracings of encephalomalacia on CT., METHODS: We analyzed 80 head CTs with ballistic PHI from the Institutional Review Board approved Vietnam head injury registry. Anatomic reports were generated from spatial coordinates of projectile entrance and terminal fragment location. These were compared to manual tracings of the regions of encephalomalacia. Dice's similarity coefficients, kappa, sensitivities, and specificities were calculated to assess agreement. Times required for case analysis were also compared., RESULTS: Results show high specificity of anatomic regions identified on CT with semiautomated anatomical estimates and manual tracings of tissue damage. Radiologist's and medical students' anatomic region reports were similar (Kappa 0.8, t-test $p < 0.001$). Region of probable injury modeling of involved brain structures was sensitive (0.7) and specific (0.9) compared with manually traced structures. Semiautomated analysis was 9-fold faster than manual tracings., CONCLUSION: Our region of probable injury spatial model approximates anatomical regions of encephalomalacia from ballistic PHI with time-saving over manual methods. Results show potential for automated anatomical reporting as an adjunct to current practice of radiologist/neurosurgical review of brain injury by penetrating projectiles.

1745. Folkerson, L. E., et al. (2018). "Coagulopathy as a predictor of mortality after penetrating traumatic brain injury." The American journal of emergency medicine **36**(1): 38-42.

STUDY HYPOTHESIS: Traumatic brain injury (TBI) is a leading cause of mortality with penetrating TBI (p-TBI) patients having worse outcomes. These patients are more likely to be coagulopathic than blunt TBI (b-TBI) patients, thus we hypothesize that coagulopathy would be an early predictor of mortality., METHODS: We identified highest-level trauma activation patients who underwent an admission head CT and had ICU admission orders from August 2009-May 2013, excluding those with polytrauma and anticoagulant use. Rapid thrombelastography (rTEG) was obtained after emergency department (ED) arrival and coagulopathy was defined as follows: ACT>=128s, KT>=2.5s, angle<=56degree, MA<=55mm, LY-30>=3.0% or platelet count<=150,000/muL. Regression modeling was used to assess the association of coagulopathy on mortality., RESULTS: 1086 patients with head CT scans performed and ICU admission orders were reviewed. After exclusion criteria were met, 347 patients with isolated TBI were analyzed-99 (29%) with p-TBI and 248 (71%) with b-TBI. Patients with p-TBI had a higher mortality (41% vs. 10%, p<0.0001) and a greater incidence of coagulopathy (64% vs. 51%, p<0.003). After dichotomizing p-TBI patients by mortality, patients who died were younger and were more coagulopathic. When adjusting for factors available on ED arrival, coagulopathy was found to be an early predictor of mortality (OR 3.99, 95% CI 1.37, 11.72, p-value=0.012)., CONCLUSIONS: This study demonstrates that p-TBI patients with significant coagulopathy have a poor prognosis. Coagulopathy, in conjunction with other factors, can be used to earlier identify p-TBI patients with worse outcomes and represents a possible area for intervention.

1746. Forcht Dagi, T. (1983). "Penetrating missile injuries of the brain." Critical Care Quarterly **6**(1): 67-81.

It is apparent that penetrating injuries of the head, though invariably serious, need not be invariably fatal. Of the patients who are alert, slightly drowsy, or have only a focal deficit, almost all who have been carefully resuscitated, examined, and searched for operable lesions, and who have undergone careful surgical debridement of bone and meticulous closure, and intensive antibiotic therapy will survive. The practice of careful nursing care, the support of respiration and vital functions, and the prevention of systemic infection will ensure a satisfying functional recovery in most patients who survive the initial injury.

1747. Ford, E. G., et al. (1990). "It may be more significant than you think: BB air rifle injury to a child's head." Pediatric emergency care **6**(4): 278-279.

BB guns of 20 years ago were constructed of coils and springs which generated relatively little force, so that a projectile posed little threat of serious injury. Today, the coil and spring construction has been replaced by pump action pneumatic chambers which allow generation of muzzle velocities near 350 ft/sec. Speeds of 150 ft/sec and 200 ft/sec are required for skin penetration and bone penetration, respectively. We present a seven-year-old boy who suffered intracranial parenchymal injury from an air-powered BB gun projectile while playing with friends. We discuss literature which suggests these once-innocent toys are now harbingers of severe, if not fatal, injury.

1749. Foreman, B., et al. (2016). "Bedside detection of spreading depolarizations using cortical depth electrodes in severe non-surgical traumatic brain injury: Preliminary experience." Neurocritical care **25**(1): S64.

Introduction: Spreading depolarizations (SDs) are pathological waves of neuronal depolarization that occur in 56% of patients with traumatic brain injury (TBI) who require surgical treatment of focal lesions. The incidence of SDs in non-surgical TBI is unknown, but in theory SDs can be detected using cortical depth electrodes (dEEG) placed at bedside via burrhole. We hypothesized that the incidence of SDs recorded using dEEG in non-surgical patients would be similar to that documented in surgical TBI. Methods: For the study period starting 4/2015, we included severe, non-penetrating TBI who did not require urgent neurosurgery on admission. All patients underwent bedside burrhole placement of intracranial pressure, tissue oxygen, regional blood flow and dEEG monitors via a single quad-lumen bolt per institutional protocol. Data were recorded on Moberg CNS with DC-coupled amplifiers. Results: Over a 12-month period, 15 patients (age 44+/-19; 80% male; GCS range 3-7) underwent monitoring for a mean duration of 97.7+/-43.5 hours,

beginning 11.0 hours (median, quartiles: 8.1-18.9) after injury. 12/15 (80%) monitoring devices were placed in non-dominantfrontal lobe, targeting cerebral cortex. 5/15 patients had focal pathology in the monitored lobe, while 4/15 had contralateral frontal lesions and 6/15 had diffuse injury or involvement of other lobes. Overall, 2/15 (13%) exhibited SDs. 7/15 (47%) patients died, including those with SDs. There were no significant hematomas or infections related to invasive neuromonitoring. Conclusions: The incidence of SDs detected with dEEG placed in non-dominant frontal lobe was lower than previously reported with injury-targeted placement of subdural strips in surgical TBI patients. This may be due to more restricted spatial sampling of dEEG, lack of targeting to injured peri-lesional tissue, and/or lower innate incidence of SD in patients with non-surgical or more diffuse injuries. Targeted placement of subdural electrodes through burr holes may be warranted in non-surgical TBI patients.

1750. Forget, A. P., et al. (2002). "[Evaluation of verification of brain death and coordination with hospital organ procurement at the University Hospital at Lille]." Evaluation du recensement des morts encephaliques par la coordination hospitaliere de prelevement au CHU de Lille. **21**(7): 550-557.

OBJECTIVES: To determine the incidence of brain death (BD) and to evaluate the registration of potential organ donors (PD) by the organ procurement team (OPT)., STUDY DESIGN: Two-year prospective audit in the French university hospital of Lille., PATIENTS AND METHODS: All deaths occurring in the intensive care units or the emergency department were studied. If death was consecutive to brain damage, on-site review of medical records and charts was performed. Death cause, presence of criteria for brain death and reference to the OPT were recorded for each death. A medical expert staff evaluated the incidence of and reasons for unsuitability for organ donation. After 12 months of observation, a protocol for "systematic alert of the OPT when brain death is suspected" was broadcast and evaluated during the next 12 months., RESULTS: During the first period, 277 BD occurred and 119 PD were suitable for organ donation. The OPT recorded 80 PD (67.2% of all PD) and 45 multi-organ procurements (MOP) were performed. Physicians opposed two major reasons for not calling OPT: anticipation of a non-validated medical contraindication in 18 cases and approach of the family without the OPT team in 21 cases. After broadcast of the protocol, 110 PD were identified and the OPT was called in 93 cases (84.5% of all PD, $p < 0.004$ versus first period). Fifty-three MOP were performed., CONCLUSION: The OPT was not called to manage one-third of the PD. The protocol for "systematic alert of the OPT when brain death is suspected" improves the call of the OPT and increases MOP.

1751. Forsyth, R. J., et al. (2005). "Non-linear mixed effects modelling of recovery trajectories after paediatric traumatic brain injury." Developmental Neurorehabilitation **10**(4): 288-289.

Purpose: Improved understanding of the recovery trajectories seen after TBI would improve service planning and delivery for individual children. It is also a potentially powerful research tool since it may be easier to detect treatment effects in smaller studies when expected recovery in the control group is better defined. We used non-linear mixed effects modelling of recovery trajectories to improve understanding of outcome. Methods: Longitudinal recovery profiles comprising sequential total WeeFIM® scores (as often as every 14 days) were collated for 107 children with closed TBI sequentially admitted to a rehabilitation service. Inflicted, open or penetrating injuries were excluded, as were children with prior neurological morbidity or TBI. Data were available for age at injury (AgeInj) and proxies of injury severity including GCS, duration of PTA (defined by the COAT) and time to follow commands (TFC, defined as time in days until command-following observed twice within a 24 hour period). Modelling was performed using the nlme library in the R statistical environment. Results: Inspection of recovery trajectories suggested a logistic function of the form $y(t) = MaxWeeFIM/[1 +exp(\{T50 - t\}/scale)]$, defined by three parameters: MaxWeeFIM (the asymptotic final WeeFIM), T50 (time to 50% MaxWeeFIM) and scale (rate of recovery). There were strong relationships between TFC and both scale and T50. No covariates for MaxWeeFIM were identified. A simple expression for the expected recovery trajectory uses values for MaxWeeFIM of 112; for T50 of 4.4+(TFC x 2.1) and for scale of 7.7 + (TFC x 0.5). Other predictor functions improve accuracy at a slight cost in terms of complexity. Conclusions: Knowledge of an individual child's TFC enables prediction of the form of the remainder of their recovery trajectory. The range of individual children's T50 and scale scores from these predicted values was ~20 days (scale) and 30 days (T50) with interquartile ranges for both of ~7 days. This information can inform individual service planning and inform clinical trial design.

1752. Fournier, D., et al. (1981). "[Intra-orbital phlegmon due to trauma from a dental prosthesis (author's transl)]." Dent pour oeil. Ou a propos d'un cas de phlegmon intra-orbitaire par traumatisme du a une prothese dentaire. **82**(3): 196-200.

1753. Fox, C. J., et al. (2006). "Delayed evaluation of combat-related penetrating neck trauma." Journal of vascular surgery **44**(1): 86-93.

OBJECTIVE: The approach to penetrating trauma of the head and neck has undergone significant evolution and offers unique challenges during wartime. Military munitions produce complex injury patterns that challenge conventional diagnosis and management. Mass casualties may not allow for routine exploration of all stable cervical blast injuries. The objective of this study was to review the delayed evaluation of combat-related penetrating neck trauma in patients after evacuation to the United States., METHOD: From February 2003 through April 2005, a series of patients with military-associated penetrating cervical trauma were evacuated to a single institution, prospectively entered into a database, and retrospectively reviewed., RESULTS: Suspected vascular injury from penetrating neck trauma occurred in 63 patients. Injuries were to zone II in 33%, zone III in 33%, and zone I in 11%. The remaining injuries involved multiple zones, including the lower face or posterior neck. Explosive devices wounded 50 patients (79%), 13 (21%) had high-velocity gunshot wounds, and 19 (30%) had associated intracranial or cervical spine injury. Of the 39 patients (62%) who underwent emergent neck exploration in Iraq or Afghanistan, 21 had 24 injuries requiring ligation (18), vein interposition or primary repair (4), polytetrafluoroethylene (PTFE) graft interposition (1), or patch angioplasty (1). Injuries occurred to the carotid, vertebral, or innominate arteries, or the jugular vein. After evacuation to the United States, all patients underwent radiologic evaluation of the head and neck vasculature. Computed tomography angiography was performed in 45 patients (71%), including six zone II injuries without prior exploration. Forty (63%) underwent diagnostic arteriography that detected pseudoaneurysms (5) or occlusions (8) of the carotid and vertebral arteries. No occult venous injuries were noted. Delayed evaluation resulted in the detection of 12 additional occult injuries and one graft thrombosis in 11 patients. Management included observation (5), vein or PTFE graft repair (3), coil embolization (2), or ligation (1)., CONCLUSIONS: Penetrating multiple fragment injury to the head and neck is common during wartime. Computed tomography angiography is useful in the delayed evaluation of stable patients, but retained fragments produce suboptimal imaging in the zone of injury. Arteriography remains the imaging study of choice to evaluate for cervical vascular trauma, and its use should be liberalized for combat injuries. Stable injuries may not require immediate neck exploration; however, the high prevalence of occult injuries discovered in this review underscores the need for a complete re-evaluation upon return to the United States.

1754. Fraga-Manteiga, E., et al. (2014). "An optimized computed tomography protocol for metallic gunshot head trauma in a seal model." Veterinary radiology & ultrasound : the official journal of the American College of Veterinary Radiology and the International Veterinary Radiology Association **55**(4): 393-398.

Computed tomography (CT) is commonly used to assess animals with head trauma. However, strongly attenuating objects such as metallic gunshot cause artifacts that may make accurate localization of shrapnel pieces difficult. The purpose of this study was to develop an optimized CT protocol for minimizing metal artifacts in an animal model of gunshot head trauma. A cadaver head of a stranded Gray seal (Halichoerus grypus) was shot post-mortem with a 0.223-inch caliber rifle. The head was frozen, thawed, and scanned using a multislice CT scanner and protocols with varying acquisition and reconstruction parameters. Scans were acquired with and without use of the scanner's proprietary Extended CT Scale (ECTS) mode and beam hardening reduction (Posterior Fossa Optimization [PFO]) filter. Window/level display settings were also varied. For each protocol and each of five selected metallic shrapnel pieces, a single observer measured combined metal halo artifact and shrapnel area using a hand-traced region of interest. The number of hypo- and hyper-attenuating streak artifacts was also recorded. Measurements were repeated for three different reading sessions. Metal CT artifacts were minimized with a high-frequency image reconstruction algorithm and a wide window setting. Further artifact reduction was achieved with a proprietary ECTS raw data reconstruction technique and a very wide window. This enabled a more confident evaluation of surrounding bone. On the other hand, these techniques are unfortunately not effective under conditions of soft tissue evaluation. Increasing tube voltage and use of a proprietary PFO filter did not yield a significant reduction in metal artifacts.

1755. Franchebois, P., et al. (1964). "[ORBITO-SINUSAL INJURIES BY A RIFLE BOLT]." TRAUMATISMES ORBITO-SINUSIENS PAR CULASSE DE CARABINE. **72**: 2023-2024.

1756. Franco, A., et al. (2018). "Forensic thanatology and the pink tooth phenomenon: From the lack of relation with the cause of death to a potential evidence of cadaveric decomposition in dental autopsies - Case series." Forensic science international **291**: e8-e12.

Forensic thanatology comprises the investigation of every phenomenon related to death performed through cadaveric exams. The pink tooth phenomenon (PTP) emerges as a thanatological finding registered during medical or dental autopsy. The PTP consists of a reddish or pink coloration caused in the teeth by the penetration of pulpal hemoglobin in the dentinal tubules. Initially, the PTP was associated with specific violent deaths, such as drowning, hanging and poisoning. However, scientific reports have pointed towards the occurrence of PTP as an expression of cadaveric decomposition regardless of the cause of death. The present study aims to report eight dental autopsies of victims of violent death that presented the PTP. The autopsies were conducted by forensic pathologists and dentists between 2013 and 2018. Seven victims were males and one was female. The age ranged above 6years old. Cranio-encephalic trauma, firearm shooting and asphyxia figured as the causes of death. All the victims were in advanced decomposition. The PTP was detected in deciduous and permanent, anterior and posterior and maxillary and mandibular teeth. Forensic experts, especially dentists, must be aware of the PTP for more detailed registration of postmortem findings and more accurate cadaveric exams.

1757. Franco Rodriguez, N. E., et al. (2013). "Tamoxifen favoured the rat sensorial cortex regeneration after a penetrating brain injury." Brain research bulletin **98**: 64-75.

A penetrating brain injury produces a glial scar formed by astrocytes, oligodendrocytes, microglia and NG2 cells. Glial scar is a barrier preventing the extent of damage but it has deleterious effects in the regeneration of the axons. Estradiol and tamoxifen reduce gliosis and have neuroprotective effects in the hippocampus and the spinal cord. We evaluated the proliferation of glia and the electrocorticogram in the sensorial cortex in a brain injury model. At seven days post-injury, estradiol, tamoxifen and estradiol plus tamoxifen reduced the number of resident and proliferative NG2 and reactive astrocyte vimentin+ cells. Estradiol and tamoxifen effects on NG2 cells could be produced by the classical oestrogen receptors found in these cells. The glial scar was also reduced by tamoxifen. At thirty days post-injury, the amount of resident and proliferative astrocytes increased significantly, except in the estradiol plus tamoxifen group, whilst the oligodendrocytes proliferation in the glial scar was reduced in treated animals. Tamoxifen promotes the survival of FOX-3+ neurons in the injured area and a recovery in the amplitude of electrocorticogram waves. At thirty days, estradiol did not favour the survival of neurons but produced a greater number of reactive astrocytes. In contrast, the number of oligodendrocytes was reduced. Tamoxifen could favour brain repair promoting neuron survival and adjusting glial cell number. It seems to recover adequate neural communication.

1758. Frank, M., et al. (2013). "Nail projectiles propelled by a mason's lacing cord: an experimental approach." International journal of legal medicine **127**(1): 153-158.

The recent clinical observation of two unintentional penetrating ocular and cerebral injuries due to 90-mm construction nails gave occasion to an experimental study to check the alleged trauma mechanism for plausibility. Both casualties reported that they had attached a mason's lacing cord to the masonry using a nail as anchoring when suddenly the nail was yanked from its moorings and propelled like a missile by the overstretched lacing cord. As to the best of the authors' knowledge, this mechanism of injury has not yet been reported in any of the literature; it was the aim to find an experimental approach to review the plausibility of the alleged sequence of events leading to the accidents. The tensile strength at break and strain at break of different mason's lacing cords (diameter of 1 and 2 mm) were measured according to DIN EN ISO 2062 by using a tensile testing machine. Based on the maximum spring energy of the lacing cords, which was determined 174.9 J for the 1-mm cord (length 10 m) and 747.4 J for the 2-mm cord (length 10 m), the maximum possible velocity of the nails as projectiles was calculated to be 243.5 m/s for the 1-mm cord and 503.4 m/s for the 2-mm cord. The critical elongation a cord of a certain length has to be stretched to deliver enough kinetic energy to a 90-mm nail to surpass the threshold velocity for skin penetration, which was investigated by Sellier (1977) to be approximately 18 m/s, was also calculated. To conclude, the energy delivered by the cords is high

enough to surpass the rather low threshold velocity of nails. The details of how these accidents occurred, which seemed questionable at first, can be reasonably explained by trauma biomechanics.

1760. Franklin, G. A. and J. K. Lukan (2002). "Self-inflicted crossbow injury to the head." The Journal of trauma **52**(5): 1009.

1761. Frasca, D., et al. (2011). "Microdialysis study of metronidazole cerebral distribution in patients with acute brain injury." Clinical Microbiology and Infection **17**: S195.

Objectives: Metronidazole is part of the standard therapy of bacterial brain abscess and considered to penetrate well blood-brain barrier (BBB) [1]. However dosing regimens are based on plasma and few cerebral spinal fluid (CSF) pharmacokinetic (PK) studies [2,3]. As infections mainly occur in tissue extracellular fluid (ECF), corresponding unbound ECF antibiotic concentrations are responsible for the antimicrobial effect. This study aims to explore metronidazole distribution in patients with acute brain injury, by comparing their unbound concentrations in brain and plasma. Methods: After local ethic approval and written informed consent, four brain injured patients, sedated, mechanically ventilated, monitored by cerebral microdialysis (CMA 71, membrane lenght 10 mm, membrane diameter 0.6 mm, molecular cut-off 100 kDa; CMA, Stockholm, Sweden) and receiving metronidazole for an infection or prophylaxis, were enrolled. PK study succeeded to 500 mg of metronidazole over 30 minutes and brain dialysates and blood samples were collected over 400 minutes. In vivo probes recoveries were evaluated individually by retrodialysis. Metronidazole was assayed by HPLC. Results: Mean metronidazole brain to plasma AUC ratio was 0.86±0.14 (range from 0.74 to 1.06). All patients had metronidazole concentrations versus time curves in brain delayed (mean time-to-peak = 69±30 min) and peaks were smoother than corresponding curves in plasma with mean Cmax in brain and plasma of 14.5±1.2 and 19.1±2.4 mg/µL, respectively. Mean half-lives was 379±131 min in plasma; Cmin were 7.2±4.0 mg/µL in plasma and 5.5±1.3 mg/µL in brain. Mean probe recovery was 78.8±1.3%. Conclusion: Our findings confirm previous studies in CSF, metronidazole penetrates well BBB. Indeed, in acute brain injury patients, unbound metronidazole AUCs in brain and plasma are close. Therefore unbound metronidazole concentration in plasma could be a good surrogate of metronidazole active concentration in brain for PK monitoring in routine.

1762. Fraser, L. and S. Thomas (2016). "Temporal bone trauma - A review." Otorhinolaryngologist **9**(2): 45-51.

The total number of temporal bone fractures is decreasing, however more casualties are surviving their injuries and require otolaryngological input. Due to often multi-system injury, patients should be initially managed according to Advanced Trauma Life Support principles. Common sequelae include conductive or sensorineural hearing loss, facial nerve injury, cerebrospinal fluid leak, vertigo and tinnitus. High resolution CT is the investigation of choice, using 1-1.5 mm slices in the coronal and axial planes. Immediate, delayed and late complications of temporal bone trauma are discussed, including the controversy surrounding management of facial nerve weakness. 7-10 % of temporal bone fractures are complicated by facial nerve weakness. A framework for patient evaluation is suggested.

1763. Frautschi, R. S., et al. (2019). "Reconstruction of Secondary Calvarial Defects with Ex Situ Split Calvarial Bone Grafts: Long-Term Evaluation of Outcomes." Plastic and reconstructive surgery **143**(1): 223-233.

BACKGROUND: Autologous bone continues to represent the first choice for reconstruction of calvarial defects. However, unanswered questions remain on the natural history of the graft and the influence of patient-related risk factors. This study investigated the outcomes of skull reconstruction with split calvarial bone graft, examining the natural history and stratifying the risk of unfavorable results., METHODS: Patients who underwent cranioplasty with split calvarial bone graft between 1982 and 2016 at the Cleveland Clinic were analyzed, recording demographics, comorbidities, indications, size and location of defect, and outcomes including complications and reoperations. Changes in graft thickness were analyzed using computed tomographic and magnetic resonance imaging scans., RESULTS: Forty-one patients with an average age of 33.2 years, cranial defect size of 68 cm, and mean follow-up of 28 months were

included. The majority of patients (85 percent) had significant risk factors, with 43 percent suffering prior infection. Seventy-three percent of patients experienced successful restoration. A major complication was recorded in 26.8 percent; resorption occurred in 19.5 percent of patients (in 75 percent only at the recipient site), with 9.8 percent requiring reoperation. Patients with one or more risk factors or a smoking history were more likely to experience a complication. The mean ratio of the graft to the bicortical donor bone thickness was 0.48 +/- 0.17 for the recipient site and 0.57 +/- 0.10 for the donor site at an average radiographic follow-up of 11.9 +/- 10.9 years., CONCLUSIONS: This study demonstrated a 73.2 percent first-attempt success rate in a high-risk population. The grafts maintain thickness over time, with no evidence of bone hypertrophy. Defect characteristics and patient systemic factors appear to be important variables influencing success., CLINICAL QUESTION/LEVEL OF EVIDENCE: Therapeutic, IV.

1764. Fredericks, C., et al. (2017). "Delayed cerebrospinal fluid leak after penetrating cervical trauma." Trauma (United Kingdom) **19**(1): 63-65.

Stab wound injury to the cervical spinal cord is a rare occurrence and usually presents with immediate, disastrous, and permanent neurological consequences. Rarer, and potentially as severe, is the complication of a delayed cerebrospinal fluid leak following a stab wound to the cervical spine. In this case, magnetic resonance imaging demonstrates a cerebrospinal fluid leak that extends to the skin with injury to the posterior dura at the C1/C2 level. Epidemiology and management of penetrating cervical spinal cord injury and delayed cerebrospinal fluid leaks are discussed.

1765. Freeman, K., et al. (2019). "Traumatic brain injury impairs cerebral blood flow regulation through disruption of inside-out signaling between capillaries and upstream arterioles." Shock **51**(6): 104.

Introduction: Traumatic brain injury (TBI) impairs neurovascular coupling, the process of cerebral blood flow regulation that delivers blood when demanded by metabolically active neurons (functional hyperemia). The pathophysiologic mechanisms of this impairment are not fully understood. It was recently discovered that functional hyperemia depends upon capillary endothelial cells responding to neuronal activity through inward-rectifier potassium channels. These vascular ion channels generate a regenerative, hyperpolarizing electrical signal that propagates from the capillaries along the vascular wall to dilate the upstream arteriole. We hypothesized that signaling from capillaries to penetrating arterioles (inside-out signaling) is disrupted in TBI. Methods: Mice were randomized to either fluid percussive brain injury or control treatment. TBI mice were recovered for 3-5 days prior to imaging. Cerebral blood flow was visualized through a cranial window under anesthesia, utilizing fluorescence of intravascular FITCdextran measured by multiphoton microscopy. Penetrating arterioles were identified by observing direction of RBCs flowing into the brain, and downstream capillaries were selected for study. The vascular response to capillary stimulation was measured by picospritzing 10 mM potassium directly on the capillary bed. Diameter and blood flow through the penetrating arterioles was measured at baseline, in the absence of calcium, and in response to elevated potassium. Results: We obtained in vivo images of cerebral capillaries and their penetrating arterioles in in TBI and control animals. Myogenic tone, measured as the difference in arteriolar diameter between baseline and calcium free conditions, was increased after TBI. In controls, capillary stimulation with high potassium caused vasodilation of the upstream arteriole and an increase in local blood flow. After TBI, the response to potassium was abrogated, with the same stimulus resulting in a transient constriction and decrease in local blood flow. Conclusions: In vivo cerebral hemodynamics are altered after TBI. We observed increased myogenic tone in the penetrating arterioles, and a paradoxical arteriolar response to stimulation of the downstream capillary bed. These results provide a novel mechanism that explains altered neurovascular coupling after brain injury.

1766. Freitas, M. B., et al. (2022). "LUNG CANCER METASTASES IN THE BRAIN: MAJOR RESPONSE WITH AFATINIB." Chest **161**(6): A570.

TYPE: Late Breaking Abstract TOPIC: Lung Cancer INTRODUCTION: Lung cancer (LC) is the leading cause of cancer-related death worldwide and it is responsible for nearly 50% of brain metastasis (BM) cases. Afatinib is a second-generation irreversible EGFR tyrosine kinase inhibitor, indicated in the treatment of metastatic LC with activating EGFR mutations. CASE PRESENTATION: A 71-year-old woman, ECOG PS 1, was diagnosed with stage IVb LC (T3N0M1b), EGFR mutated (exon 18: Glu790Lys, Lys744Asn, Gly719Ser). Staging brain MRI showed 2 left brain lesions, suggestive of BM, not surgically approachable: one in the parietal region (20x16mm) and another (3mm) in the temporo-occipital

transition. In the Multidisciplinary Tumor Board was decided treatment with afatinib and stereotactic brain surgery (SBS). To plan SBS another brain MRI was performed showing a significant reduction of the left parietal lesion (10x8mm; figure 1) and complete disappearance of the other lesion, after 8 days of treatment, and SBS was canceled. Reevaluation after 3 months revealed partial imaging response on the lung and brain (BM with 9mm, major axis). Due to grade 2-3 skin rash and paronychia, the treatment dose was reduced until 20mg/day, with good tolerance. DISCUSSION: Despite having incomplete blood-brain barrier penetration, afatinib has the potential to treat LC BM, with a reported intracranial response rate ranging from 35%-72.9%. This efficacy was demonstrated in this case report, allowing brain radiation sparing strategy. CONCLUSIONS: This case report shows the effectiveness of afatinib in BM from EGFR mutated lung adenocarcinoma. DISCLOSURE: No significant relationships. KEYWORD: Brain metastases

1767. Fremont, R., et al. (2022). "P457. Damage to Elements of the Cortico-Striatal-Thalamo-Cortical Circuit are Associated With Repetitive Behaviors in Patients With Penetrating Brain Injury." Biological Psychiatry **91**(9): S272-S273.

Background: Damage to cortico-striato-thalamo-cortical (CSTC) circuits is associated with the development of repetitive behaviors in animals and humans. However, the types of repetitive behaviors that are developed after injury to these structures are poorly defined. Methods: We compared the effects of damage to separate elements of CSTC circuits sustained by veterans of the Vietnam War on the later point prevalence of repetitive thoughts and behaviors. We performed partial correlations (correcting for cognition, age, education, and global brain damage) between volume loss from TBI in specific elements of CSTC circuits (lateral and medial orbitofrontal and dorsolateral prefrontal cortices, anterior cingulate cortex, thalamus, and basal ganglia) and current scores on the Yale-Brown Obsessive Compulsive Scale (Y-BOCS) Symptom Checklist, the Yale Global Tic Severity Scale (YGTSS), and the Hamilton Anxiety Rating Scale (HAM-A) in 126 Vietnam war veterans with penetrating brain injuries and 36 matched control subjects. Results: We found that volume loss in the left dorsolateral prefrontal cortex was associated with the development of compulsive behaviors, whereas volume loss in the basal ganglia was associated with the development of tics. No regions of interest were associated with anxiety or obsessions. Conclusions: Our findings suggest that traumatic brain injury resulting in damage to specific CSTC elements can be associated with the development of repetitive behaviors and tics that are not necessarily accompanied by obsessions or anxiety. Supported By: NIH Keywords: Dorsolateral Prefrontal Cortex, Basal Ganglia, Compulsive Behaviors, Lateral Orbitofrontal Gyrus, Obsessive Compulsive Disorder (OCD)

1768. Frenette, A. J., et al. (2019). "A Pilot Randomized Controlled Trial Comparing Levothyroxine to Placebo in Neurologically Deceased Donors." Progress in transplantation (Aliso Viejo, Calif.) **29**(3): 261-268.

BACKGROUND: Although commonly prescribed, the efficacy of levothyroxine to improve heart function in neurologically deceased donors is unclear. We evaluated the feasibility of a randomized controlled trial to compare levothyroxine to placebo on the variation of left ventricular ejection fraction, in hemodynamically unstable donors., METHODS: We conducted a pilot, double-blinded, randomized controlled trial. Deceased donors with reduced left ventricular ejection fraction or needing vasopressors were included. We randomized participants to a 20 mug bolus followed by a 20 mug/h infusion of levothyroxine or an identically appearing placebo. We report the proportion of recruited participants, the time to the administration of the study drug, and protocol violations., RESULTS: Twenty-four participants (N = 24/104; 23.1%) were eligible. Five of them (N = 5/24; 20.8%) were excluded by the attending physician. Four others were not included, due to family refusal for research (n = 2/24;8.3%) and unavailability of research staff (n = 2/24; 8.3%). Fifteen participants were randomized (N = 15/104; 14.4%). Mean time between the echocardiography and the initiation of the drug was 1.73 hours, and14 (93.3%) of 15 of the participants received the drug within 2 hours after the echocardiography. We report no study violation. The study was stopped prematurely because of low recruitment., CONCLUSION: This pilot trial suggests that the success of a definitive randomized control trial to assess the efficacy of levothyroxine in deceased donors could benefit from a multicenter recruitment and education on the evidence surrounding the pharmacological management of organ donors. The need for consent to research interventions in deceased donors should also be clarified.

1769. Friedman, I. B., et al. (2010). "Using principles of motor learning to treat apraxia of speech after traumatic brain injury." Journal of Medical Speech-Language Pathology **18**(1): 13-31.

Background: This study examined the effectiveness of a modified version of the Motor Learning Guided (MLG) approach, a treatment protocol to establish functional speech that incorporates principles of motor learning: blocked

and random practice schedules, delayed and summary knowledge of response (KR) feedback, and specificity of training. Methods: A 29-year-old male survivor of traumatic brain injury diagnosed with moderate-severe apraxia of speech (AOS) participated in this protocol. A time-series ABA design measured the participant's production of two sets of five target items, and his ability to maintain accurate productions several months after treatment. Results: Improvements were seen in the participant's ability to produce both sets of trained items; however, the second set of target items were practiced with more frequency, which may have lead to a greater accuracy of production in less time compared to the first set of five target items. Conclusions: Application of motor learning principles through the modified MLG approach can lead to increased accuracy and automaticity of trained target items, and the ability to maintain accurate phrase production following cessation of treatment. Adherence to a frequent practice schedule and other motor learning principles is influential to success of this treatment for AOS.

1770. Friedman, J., et al. (2022). "Laryngeal keel for management of anterior glottic web in patient with ballistic injury to the glottis." Otolaryngology Case Reports **23**.

Penetrating neck trauma can result in life-threatening injuries to the airway and major vascular structures. Surgeons must also be cognizant that laryngeal injuries also require timely evaluation and management. Traumatic glottic injuries and laryngeal surgery are two possible causes of glottic stenosis which remains a serious clinical concern. Multiple different approaches and surgical techniques exist but there is no clear guidance in determining the optimal procedure. The use of a keel in the treatment of glottic webs was first described in the 1950s, but to our knowledge, this is the first report detailing endoscopic keel placement following penetrating glottic trauma involving the anterior commissure. The endoscopic approach is a useful modality for preventing glottic stenosis and avoids the need for open laryngofissure.

1771. Friedrich, R. E. and F. Schulz (2005). "[Mandibular fracture following stab injury with a knife]." Unterkieferfraktur durch Messerstich. **215**(1-2): 27-33.

Stab injuries of the face accompanied by fractures of the jaws are rare. The report deals with the case of a young man, who suffered a penetrating stab injury to the cheek and fracture of the mandible in an assault. The forensic questions to be answered were if the findings were compatible with a stab and subsequent fracture, if one of the confiscated instruments could have been the causative weapon and if the injury had to be assessed as life-threatening. Both the soft and the hard tissue injury confirmed the assumption that they were caused by a stab. It was not possible, however, to assign the injury to a specific knife from the submitted exhibits on the basis of the clinical findings. In the discussion the serious nature of stab injuries in the facial region is emphasized.

1772. Fries, D., et al. (1984). "[Brain-death unit and renal transplantation. Evaluation of 5 years' experience]." Centre d'accueil de morts cerebrales et transplantation renale. Bilan de cinq annees de fonctionnement. **3**(2): 94-98.

From 1977 to 1982, 170 potential organ donors were referred to "a brain-death unit". A vast majority of these patients were provided by intensive care units of district general hospitals from Ile-de-France. This fact confirms the dispersion of potential organ donors and the usefulness of an organ-procurement structure based in an University Hospital. Its effectiveness is demonstrated by an harvesting rate of 58%, largely over the already published reports in case of absence of such a center. It is concluded that the adoption of this system by other hospitals would significantly increase the number of cadaver kidney grafts available for transplantation whereas actually the number of kidney grafts remains dramatically low in France.

1773. Frimpong, P., et al. (2021). "Incidence and management of mandibular fractures in a low-resource health facility in Ghana." Journal of the Korean Association of Oral and Maxillofacial Surgeons **47**(6): 432-437.

Objectives: The mandible and other parts of the maxillofacial region suffer significant morbid injuries following road traffic accidents. Our study gives epidemiological description of mandibular fractures in Ghana and also evaluates the relevance of closed reduction and indirect fixation for managing mandibular fractures in low-resource health facilities in low-income countries like Ghana. Patients and Methods: This is a retrospective study involving 268 patients who reported to the Department of Oral and Maxillofacial Surgery of the Sunyani Regional Hospital with mandibular fractures from January 2010 to December 2019. Patient medical records were assessed for information on age, sex,

fracture etiology, anatomic location of fracture, time of day of road traffic accident, and other associated injuries. Results: A total of 268 patients were included in this study (males, 216 [80.6%]; females, 52 [19.4%]). Motor vehicular accident (MVA) was the leading cause of mandibular fractures (202 injuries, 75.4%). Other etiologies included assault (39, 14.6%), gunshot (13, 4.9%), falls (12, 4.5%), and industrial accidents (2, 0.7%). Of the 161 male cases caused by MVA, 121 (75.2%) occurred at night and in the evening while the remaining 40 (24.8%) occurred in the morning and afternoon. Among all managed 222 patients, 212 (79.1%) were treated with closed reduction and indirect fixation technique while 10 (3.7%) were treated with open reduction and direct fixation. Conclusion: Closed reduction with indirect fixation could successfully be used to manage mandibular fractures in low resourced health facilities, especially in low-income countries. The poor lightening system on roads in Ghana is a major contributory factor to motor vehicular accidents.

1774. Frisardi, F., et al. (2014). "Decompressive craniectomy may cause diagnostic challenges to assess brain death by computed tomography angiography." Minerva anestesiologica **80**(1): 113-118.

According to Italian legislation to diagnose brain death (BD) after the initial documentation of the clinical signs, repetition of clinical testing and confirmation of the loss of bioelectrical activity of the brain (EEG) is required. However, when EEG is unreliable it is necessary to demonstrate cerebral circulatory arrest (CCA). Accepted imaging techniques to demonstrate CCA include: cerebral angiography, cerebral scintigraphy, transcranial Doppler (TCD) and computed tomography angiography (CTA). This latter technique, due to its large availability, low invasivity and easy and fast acquisition is widely used over the country. Nevertheless its diagnostic reliability is affected by some limitations in patients with decompressive craniectomy. Here we report two cases of brain injury with clinical signs of BD and at the same time, opacification of intracranial arteries on CTA and a pattern consistent with flow arrest on the corresponding insonable arteries on TCD. The discrepancy between CTA and TCD results points out a methodology limitation that could be overcome by updating Italian legislation according to other European Countries legislation.

1775. Fritz, M. A. and T. M. Haffey (2013). "Application of autologous free tissue transfer in the management of massive traumatic tissue loss." Otolaryngologic clinics of North America **46**(5): 903-913.

This review describes a general approach and philosophy in the management of massive facial trauma with extensive tissue loss, with particular highlight on the role of free tissue transfer.

1776. Froind, S., et al. (2013). "Delayed diagnosis of intracranial injury due to a dog bite--a case report and review of the literature." International journal of pediatric otorhinolaryngology **77**(9): 1400-1402.

OBJECTIVES: Dog bite injury of the head and neck is not rare in children although intracranial injury is reported anecdotally. Among the case reports there is a significant number of patients in whom the diagnosis of penetrating cranial injury was delayed. The aim of the study was to describe a patient with a trans mastoid head injury due to a dog bite that was not diagnosed at presentation and review similar cases in the literature., METHODS: A 13-year-old girl was admitted to the emergency room with severe head, neck and breast lacerations. She was transferred to the operating room for debridement and only then was a trans mastoid fracture diagnosed. We searched for case reports in the literature describing children suffering from dog bites in whom the diagnosis of intracranial injury was delayed., RESULTS: We found descriptions of five children, 4 after dog bite and one after tiger bite. Four of them were under two years of age and all had scalp lacerations that were treated at presentation. The time period to diagnosing the brain injury was one day to three weeks. The symptoms that led to the diagnosis were fever in 3 patients, meningitis in two, brain abscess in one child and four of them developed neurological signs. All of the children had surgical intervention after diagnosis., CONCLUSIONS: Intracranial injury after dog bite should be suspected in any child with scalp lacerations. Adequate investigations should be performed at presentation with careful attention to this specific type of trauma.

1777. Frosen, J., et al. (2019). "Outcome and rational management of civilian gunshot injuries to the brain-retrospective analysis of patients treated at the Helsinki University Hospital from 2000 to 2012." Acta neurochirurgica **161**(7): 1285-1295.

BACKGROUND: Treatment of gunshot wounds of the brain (GSWB) remains controversial and there is high variation in reported survival rates (from < 10 to > 90%) depending on the etiology and country. We retrospectively analyzed the outcome of a series of consecutive GSWB patients admitted alive to a level 1 trauma center in a safe high-income welfare country with a low rate of homicidal gun violence., METHODS: Patients admitted due to a GSWB to the HUS Helsinki University Hospital during 2000-2012 were identified from hospital discharge registry and log books of the emergency room and ICU. CT scans and medical records of these patients were reviewed. Univariate analysis and backward logistic regression were performed, and their results compared with that of a systematic literature review of factors related to the outcome of GSWB patients., RESULTS: Sixty-four patients admitted alive after GSWB were identified. Eighty percent had self-inflicted GSWB, 81% were contact shots, and 70% were caused by handguns. In-hospital mortality was 72%. Factors associated with mortality in our series were low GCS (<= 8) at admission, transventricular bullet trajectory, and associated damage to deep brain structures, as reported before in the literature. Of the 64 patients admitted alive, 42% (27/64) were admitted to ICU, 34% (22/64) underwent surgery, and in 25% (16/64), craniotomy and hematoma evacuation was performed. Mortality in the surgically treated group was 32% but near 100% without surgery and ICU treatment. Median GOS in the surgically treated patients was 3 (range 1-5)., CONCLUSIONS: GSWB caused by contact shot from handguns has a high mortality rate, but can be survived with reasonable outcome if limited to lobar injury without significant damage to deep brain structures or brain stem. In such GSWB patients, initial aggressive resuscitation, ICU admission, and surgery seem indicated.

1779. Fry, R. E. and W. J. Fry (1980). "Extracranial carotid artery injuries." Surgery **88**(4): 581-587.

From December, 1975, to December, 1979, 54 carotid artery injuries have been treated by the Southwestern Medical School Department of Surgery. Seventy-eight percent were due to gunshot wounds, 20% were due to stab wounds, and 2% were secondary to blunt trauma. Thirty-three percent involved the internal carotid artery, and the external carotid artery was involved in 20%. Eighteen percent of the patients presented with a major associated venous injury and 8% with an arteriovenous fistula. Partial or complete disruption accounted for the majority of injuries. There was a 10% mortality rate. Four percent of the deaths were due directly to carotid vascular trauma. Because of our experience we believe, whenever possible, all patients should have the benefit of preoperative arteriography. This allows for a well planned operation and avoids major unnecessary neck dissection. High lesions involving the internal carotid artery may be exposed easily by anterior dislocation of the jaw, thus allowing ready access to the base of the skull. Injuries involving extensive areas of the internal carotid artery (lesions extending intracranially) are best managed by extracranial-intracranial (EC-IC) bypass with internal carotid artery ligation. Severe neurologic deficit is best treated by ligation of the carotid artery. Seven patients have undergone EC-IC bypass and 86% of these returned to or maintained normal neurologic status, while the other 14% remained neurologically stable. It is our impression that the risk of neurologic deficit is lessened by this maneuver without added mortality or morbidity.

1781. Fujii, T., et al. (1979). "[A case of penetrating cerebellar injury (author's transl)]." No shinkei geka. Neurological surgery **7**(9): 881-887.

1782. Fujimoto, S., et al. (1987). "[Three cases of an intracranial wooden foreign body]." No shinkei geka. Neurological surgery **15**(7): 751-756.

Three cases of intracranial wooden foreign body are reported discussing the diagnostic and therapeutic problems. First case is a 50-year-old man. After drinking, he drove a bike and fell to the ground. On admission the wooden foreign body could not been detected in appearance. CT scan showed low density area similar to air in bilateral anterior horn of lateral ventricle. The patient was treated for traumatic pneumocephalus at first. Later, it proved that he was stabbed with a foreign body penetrating into the contralateral frontal lobe through the left nasal cavity. It was

extracted by endonasal approach by otolaryngologist, fortunately without trouble. The foreign body was a branch of tree. The second case is an 18-year-old man. He was driving a car, and suffered injury. He was stabbed with a wooden stake penetrating into his left eye. Immediately, bifrontal craniotomy was performed and the stake was withdrawn carefully. Moreover bone fragments were removed. The third case is a 61-year-old man. When he cut the timber by chain saw, a piece of wood hit and stabbed his right eye directly. Immediately right front temporal craniotomy was performed. The piece of wood was withdrawn from the right eye, and pieces of glass, wood and bone fragments were evacuated. It is difficult to confirm intracranial foreign body accurately by means of only plain skull film and usual CT scans. It is necessary to utilize various function of CT scanner. For example, it is useful to know CT values or select measure mode with window width and level or make reconstruction image to sagittal or coronal section, and so on.(ABSTRACT TRUNCATED AT 250 WORDS)

1783. Fujimoto, Y., et al. (2001). "Spontaneous migration of a bullet in the cerebellum--case report." Neurologia medico-chirurgica **41**(10): 499-501.

A 15-year-old boy presented with a gunshot wound in the left cerebellar hemisphere. He was confused and left cerebellar signs were noted. The patient underwent the first surgery for debridement of the entry wound in the left parietal region and second surgery to remove the bullet. However, the bullet could not be located via a left unilateral suboccipital craniectomy in the park bench position, because it had migrated to the opposite side due to the effects of gravity in just a few hours. Skull radiography obtained just before the third surgery showed that the bullet had returned to the left side, and it was removed easily via the previous craniectomy in the sitting position. The clinical course suggests that in removing a bullet, skull radiography or computed tomography should be obtained just before surgery, or even intraoperatively, and that those findings should be the basis for the surgical procedure and operative position.

1784. Fujiwara, K., et al. (2017). "[Transoral Penetrating Cranial Injury by a Chopstick:A Case Report]." No shinkei geka. Neurological surgery **45**(8): 685-690.

Intracranial injury resultant from a chopstick penetrating the oral cavity is often fatal in children, and only 5 clinical cases have been reported. If the depth of penetration is indeterminable, due to the chopstick being removed or the remaining piece not being located, then injury management is challenging; here, we report such a case. A 26-month-old girl fell over with a plastic chopstick in her mouth. The chopstick was removed immediately and without breakage by her father. He noted that around 3 cm of the pointed end had pierced the palate. CT revealed air bubbles in the retropharyngeal space but no abnormality in the cranium. Subsequent complications included bacterial meningitis and right hemiparesis but neither MRI nor any alternative imaging modality could aid in locating the intracranial lesion that induced the weakness. Neurological findings suggested injury of the right lateral corticospinal tract at the lower end of the medulla oblongata. An axial T2-weighted MRI showed a 30-mm high signal path of penetration from the posterior nasopharyngeal wall to the dura at the craniocervical junction. When the route is extended 36 mm intracranially from the wound orifice, the path makes superficial contact with the right lateral portion of the medulla oblongata, which corresponds with the lateral corticospinal tract. We therefore hypothesize that this was the lesion location but that it was too small to be detected using MRI.

1785. Fukuda, S., et al. (2015). "A search for protective drugs against diabetic blood-brain barrier dysfunction model in vitro." Journal of pharmacological sciences **128**(3): S235.

The prevalence of diabetes mellitus (DM) is increasing rapidly worldwide. The dysfunction of vascular endothelial cells is considered to be a key initial step in diabetic angiopathy, and to affect the progression and severity of DM. In the brain, DM-associated vascular inflammation may contribute to early breakdown of the functional integrity of the blood-brain barrier. The BBB dysfunction allow blood components penetration into the brain parenchyma, and these insults may link with acceleration of neurological damages. Thus BBB protection against hyperglycemia has a strong influence to prevent cerebral damages. In the present study, we clarified the effects of several compounds on BBB dysfunction model induced by hyperglycemia. We investigated the effect of pitavastatin, candesartan, cilostazol, GLP-1 and GLP-2 on barrier function in rat capillary endothelial cells (RBEC). Barrier functions were estimated by measuring the transendothelial electrical resistance (TEER) and permeability of sodium fluorescein. Pitavastatin, candesartan and GLPs prevented the decrease of barrier function induced by hyperglycemia. Our results suggest that those compounds have a potential to be the BBB-protective drug.

1786. Fukutake, T. and T. Hattori (2004). "Missile injury of the head disclosed by computed tomographic scan 60 years later." The Journal of trauma **56**(2): 453.

1787. Fulcher, T. P., et al. (2002). "Clinical features and management of intraorbital foreign bodies." Ophthalmology **109**(3): 494-500.

PURPOSE: To review the clinical features and management of patients with intraorbital foreign bodies., DESIGN: Noncomparative interventional case series., PATIENTS AND METHOD: Forty patients seen at two regional orbital surgery departments with intraorbital foreign bodies were reviewed., MAIN OUTCOME MEASURES: Visual acuity, surgical interventions, and complications., RESULTS: Seventy-three percent of patients were younger than 30 years old. There were 22 metallic, inorganic; 5 nonmetallic, inorganic; and 13 organic intraorbital foreign bodies (IOrbFb) in this series. Thirty patients were seen at the time of injury, and 10 patients were seen in a delayed setting with orbital complications. Thirty-four patients had surgical removal of their IOrbFb either because of complications or easy surgical access. Six patients had no surgery because of posteriorly located inorganic foreign bodies. Thirteen patients had resultant blind eyes; 12 of these were blind from the initial trauma., CONCLUSIONS: Loss of vision in conjunction with IOrbFbs is usually a result of the initial trauma. All patients should have antibiotic therapy because of the high incidence of secondary orbital infections. Computed tomography is the best initial mode of imaging. Surgical removal is indicated for all organic IOrbFbs. Inorganic IOrbFbs should be removed if causing complications or if located anteriorly after discussion of potential surgical complications with the patient. Posteriorly located inorganic IOrbFbs should be left alone, unless they are causing significant orbital complications.

1788. Fulcher, T. P. and T. J. Sullivan (2003). "Orbital roof fractures: management of ophthalmic complications." Ophthalmic plastic and reconstructive surgery **19**(5): 359-363.

PURPOSE: To review the clinical features and management of patients with orbital roof fractures., METHODS: Non-comparative, retrospective case review of 21 patients presenting with orbital roof fractures., RESULTS: The orbital roof fractures in our series resulted from motor vehicle accidents, blunt trauma, head injuries, and penetrating orbital injuries. Associated orbital and ocular injuries included other ipsilateral orbital fractures (16 cases), traumatic optic neuropathy (3 cases), ptosis (2 cases), perforating eye injuries (2 cases), intraorbital foreign bodies (2 cases), and oculomotor nerve palsy (1 case). Six patients required surgical intervention for ophthalmic sequelae, which included motility problems (4 cases), lagophthalmos (1 case), and a retained intraorbital foreign body with a cerebrospinal fluid leak (one case). The outcome of surgery was favorable in all cases, with complete resolution of symptoms in five of six patients., CONCLUSIONS: Orbital and ocular injuries are common in association with orbital roof fractures. A multidisciplinary approach to management is required because facial and cerebral injuries are also common. Most patients can be managed conservatively. The specific ophthalmic indications for surgical intervention are limited, but the outcome in these cases is gratifying.

1789. Fullarton, G. M., et al. (1987). "An evaluation of open scalp wounds." Archives of emergency medicine **4**(1): 11-16.

A retrospective study of 661 adult patients with open scalp wounds attending the Accident and Emergency Department of Glasgow Royal Infirmary, Glasgow, Scotland, was performed. Detailed information was recorded about history, nature of open wounds ('contused' or 'incised'), wound exploration and radiological findings. The commonest cause of injury was assault (40%), followed by falls (34%). Half of the patients had been drinking alcohol. The majority of scalp wounds were 'contused' (84%) resulting equally from assaults and falls; 'incised' wounds (16%) were more commonly due to assault. Although division of the occipitofrontalis aponeurosis was infrequent (18%), most (78%) of the skull fractures occurred in this group. Wound exploration detected nine fractures not evident on skull X-rays. To maximise fracture detection rate, careful wound exploration should be an important adjunct to skull radiography and, in particular, division of the occipitofrontalis aponeurosis should alert the casualty officer to the likelihood of a skull fracture.

1790. Fullington, R. J. and C. M. Otto (1997). "Characteristics and management of gunshot wounds in dogs and cats: 84 cases (1986-1995)." Journal of the American Veterinary Medical Association **210**(5): 658-662.

OBJECTIVE: To determine history, signalment, physical examination findings, treatment, complications, outcome, and prognostic indicators of dogs and cats treated for gunshot wounds at an urban veterinary referral hospital., DESIGN: Retrospective study., ANIMALS: 82 dogs and 2 cats., RESULTS: Young (< 3 years old) sexually intact males were overrepresented. Of the 122 injuries, 52 were to limbs (23/52 were associated with fractures), 32 involved the thorax, 14 involved the abdomen, 14 involved the head, 6 involved the neck, and 4 involved the vertebral column. Seven animals were euthanatized because of financial concerns. Of the remaining 77, 11 died and 66 were discharged from the hospital. Conservative treatment was adequate for animals with limb injuries not associated with a fracture. However, animals with evidence of peritoneal penetration required an exploratory laparotomy. Animals with thoracic injuries usually could be managed with conservative treatment or thoracocentesis. Only 1 animal underwent thoracotomy. Wound infection developed in 4 animals. Initial treatment of animals with gunshot wounds should include administration of antibiotics effective against gram-positive and -negative bacteria., CLINICAL IMPLICATIONS: Most dogs with gunshot wounds that receive adequate treatment can be expected to survive. However, dogs with vertebral column or abdominal wounds may have a worse prognosis than dogs with thoracic or limb injuries.

1791. Fung, H. S., et al. (2008). "Gunshot injury in Hong Kong: Report of 2 cases." Journal of the Hong Kong College of Radiologists **11**(2): 85-88.

Gunshot injury is a serious but uncommon type of trauma in Hong Kong. This report describes 2 cases of gunshot injury, 1 by a handgun and 1 by a shotgun. The literature is reviewed, with emphasis on important imaging features and associated forensic implications.

1792. Funk, G. F., et al. (1995). "Free-tissue transfer reconstruction of midfacial and cranio-orbito-facial defects." Archives of otolaryngology--head & neck surgery **121**(3): 293-303.

OBJECTIVE: To review our results using free-tissue transfer to reconstruct midfacial and cranio-orbito-facial defects., DESIGN: Case series., SETTING: The University of Iowa Hospitals and Clinics, Iowa City., PATIENTS: Fourteen of 21 patients had defects that resulted from ablative oncologic surgery; six had severe mid-facial trauma; and one had Romberg's disease., INTERVENTIONS: Four latissimus dorsi, 11 rectus abdominis, three scapula, and four forearm free-tissue transfer flaps were used., MAIN OUTCOME MEASURES: Adequate flap separation of vital structures (intracranial contents and carotid artery) from the sinonasal or oropharyngeal cavities; restoration of palatal competence, oral diet, and speech intelligibility; maxillary dental rehabilitation; aesthetic results; complications; and the patient's return to social activities outside the home after surgery., RESULTS: The intracranial contents (six cases) or carotid artery (four cases) were protected from sinonasal or oropharyngeal contamination by the reconstructive flap in all cases in which this was required. Functional closure of the palate with the flap or a prosthesis was possible in 12 of the 13 patients with a palatal defect; seven of these 13 patients have had full maxillary dental rehabilitation. Twenty patients take an oral diet. Sixteen patients have normal or easily understood speech. Fourteen patients engage in social activities outside the home, and eight have returned to full-time employment. No vascular flap failures occurred in this series., CONCLUSIONS: The use of free-tissue transfer flaps is a safe and effective technique for repairing large midfacial and cranio-orbito-facial defects resulting from ablative oncologic surgery or trauma.

1793. Furlow, B. (2006). "Diagnostic imaging of traumatic brain injury." Radiologic technology **78**(2): 145-149.

In this Directed Reading, the history and epidemiology of traumatic brain injury (TBI) will be briefly introduced, the physical and physiological nature of TBI reviewed and the role of imaging in the assessment of TBI patients described. New imaging techniques and recent findings about the neurological correlates of TBI symptoms and outcomes from studies using different imaging modalities and techniques will also be discussed. This directed reading will focus on closed-head TBI; penetrating missile brain injuries, such as those caused by bullet wounds, will not be reviewed.

1794. Fuse, A., et al. (2011). "Current status of preparedness for blast injuries in Japan." Japan Medical Association Journal **54**(5): 310-317.

In recent years, blast injuries worldwide have primarily been caused by explosions of improvised explosive devices detonated in terrorist attacks. The most common mechanism of injury among U.S. soldiers in Iraq and Afghanistan war is explosions. Blast injuries are complicated, being compounded by injuries caused by blast waves in addition to penetrating and blunt trauma. Moreover, maintaining safety and security is a major concern in providing medical care and requires an understanding of blast physics and blast injury pathophysiology, especially in cases of blast lung injury (BLI) and blast-induced traumatic brain injury (bTBI). In this paper, we present our review of the current status of preparedness for blast injuries, which was conducted with the cooperation of the Cabinet Office of the Government of Japan and the Japan Self Defense Force. Based on this review, we created two action card systems and a medical record system in Japanese for blast injuries: "Survival Cards for Explosive Events for the First-on-scene Responder," "Survival Cards for Explosive Events for Medical Staff Providing Prehospital and Hospital Medical Care," and the "Medical Records System for Blast Injuries." These were developed with reference to preparedness guidelines issued by the United States and European countries and are available on the Cabinet Office website. As the next step, guidelines for the treatment of blast injuries should be established and full-scale drills should be conducted as preparedness activities.

1795. Gaal, A., et al. (2016). "Limited antibiotic dosing during the operative management of mandible fractures is not associated with an increased risk for surgical site infections." Journal of oral and maxillofacial surgery **74**(9): e27-e28.

Purpose: The purpose of this study is to answer the research question: Among patients undergoing transoral operative treatment of isolated, open mandible fractures, do those who receive only intraoperative antibiotics when compared to those receiving intraoperative antibiotics and other antibiotics dosing combinations, e.g. preoperative or postoperative antibiotics, have an increased risk of surgical site infections (SSIs). We hypothesize that there is no difference in the frequency of SSIs between patients receiving intraoperative antibiotics and those receiving intraoperative plus additional preoperative or postoperative antibiotics. The aims of this study are to estimate and compare: 1) the frequencies of SSIs and 2) adverse antibiotic effects (AAEs) between patients who receive only intraoperative antibiotics and those who receive intraoperative antibiotics plus additional preoperative or postoperative antibiotics while undergoing operative treatment of open mandible fractures. Methods: STUDY DESIGN/SAMPLE To answer the research question, the investigators designed and implemented a retrospective cohort study that enrolled a sample derived from the patients who presented to Harborview Medical Center (HMC) between June 30th, 2009 and July 31st, 2014 with open mandibular fractures. Inclusion criteria were subjects age 18 years or older with isolated open mandibular fractures treated operatively via transoral approaches. Subjects were excluded if they presented with any other fractures, complex mandibular fractures (e.g. requiring transcervical approach), gunshot wounds, pre-existing concomitant mandibular fractures, fracture site infections present, closed mandibular fractures, immunocompromised (e.g. HIV+, any immunosuppressive medication), or if they received antibiotics for any other indication. The primary predictor variable was antibiotic exposure. The experimental (intraoperative) group received antibiotics administered within 1 hour before surgical incision, with possible intraoperative re-dosing consistent with the Joint Commission's Surgical Care Improvement Project (SCIP) criterion for prophylactic surgical antibiotics1. The control group subjects received antibiotics per the experimental group plus additional preoperative and/or postoperative antibiotics. The primary outcome variable was the presence or absence of SSIs (e.g. the presence of pus, osteomyelitis, or wound dehiscence requiring more intervention than local wound care). The secondary outcome variable was the presence or absence of an AAE. Uni-, bivariate, and multiple logistic regression statistics were used and statistical significance was set at $p<0.05$. Results: The sample was composed of 510 subjects with a mean age of 29 ± 11.4 years. 86% were males. The experimental group had 58 (11%) subjects. The control group had 452 (89%) subjects. The SSI frequencies in the experimental and control groups were 9% and 17% respectively. OR 0.45 (95% CI 0.17-1.15) P=0.13. In the multivariable logistic regression model, only tobacco use was associated with an increased risk for SSI; OR = 2.7 (95% CI 1.5-5.2), p=0.0015∗ ∗ ∗. There were 5 (1%) AAEs reported. All AAEs were isolated to the control group. Conclusion: Limiting antibiotic exposure to only intraoperative antibiotics among patients undergoing transoral operative treatment of isolated open mandible fractures is not associated with an increased risk of SSIs. These results support the assertion that intraoperative antibiotics alone suffice in the management of open mandible fractures.

1796. Gabikian, P., et al. (2012). "Isolated superior orbital fissure syndrome resulting from gunshot wound to the head." Current problems in diagnostic radiology **41**(4): 112-113.

1797. Gaboriau, H. P. and K. L. Kreutziger (1998). "Penetrating injuries of the face." The Journal of the Louisiana State Medical Society : official organ of the Louisiana State Medical Society **150**(1): 6-9.

In dealing with gunshot wounds to the face, the emergency department physician should have a basic knowledge of ballistics. Securing an airway (either intubation or surgical airway) should be the top priority. The location of the wound dictates which patient should be intubated. Plain x-ray films of the face and skull, as well as CT scan in certain situations, allow determination of the extent of damages to the skeleton as well as intracranial injuries. Clinical symptoms suggesting an underlying vascular injury require an angiogram. After thorough debridement of the wounds, fractures are treated either with open-reduction and internal fixation or closed-reduction and intermaxillary fixation.

1798. Gadicherla, S., et al. (2016). "Mandibular fractures and associated factors at a tertiary care hospital." Archives of Trauma Research **5**(4).

Objectives: The aim of this study was to evaluate the distribution, etiology and type of mandibular fractures in subjects referred to our institution. Methods: A retrospective study of 689 subjects, during the period from May 2010 to September 2013 with mandibular fractures was conducted. Information on age, gender, mechanism of injury and sites of trauma was obtained from the trauma registry. Data were tabulated and analyzed statistically. Results: A total of 653 subjects had mandibular fractures, out of which 574 were males. The mean age of the participants was 31.54 ±13.07. The majority of the subjects were between 21-40 years of age, in both males (61.7%) and females (54.4%). The major cause of fractures was road traffic accidents (87.4%) followed by fall (6.9%) and assault (4%), with the least frequent being gunshot injuries (0.3%). Almost half of the patients had parasymphysis fractures (50.2%), followed by angle (24.3%), condyle (20.4%), ramus (2.3%) and coronoid (2%). A total of 115 patients had bilateral fractures out of which 29 had parasymphysis, 12 had body fractures and 74 had bilateral condylar fractures. Double mandibular fractures were reported in 193 subjects; out of which 151 subjects had double contralateral and 42 had double unilateral fractures. Triple unilateral fracture was reported in only one subject. A total of 338 subjects had multiple fractures among the study population. Conclusions: Mandibular fractures can be complicated and demanding, and have a compelling impact on patients' quality of life. Our study reported that parasymphysis was the most common region involved in mandible fractures.

1799. Gadkari, S. S. (2007). "Evaluation of 19 cases of inadvertent globe perforation due to periocular injections." Indian journal of ophthalmology **55**(2): 103-107.

BACKGROUND: Inadvertent globe perforation due to periocular injection is a serious iatrogenic complication., AIM: To study risk factors, management and visual outcome of inadvertent globe perforation during periocular injection, in cases referred to a tertiary eye care center., DESIGN AND SETTING: Retrospective study at a tertiary referral center with a single investigator., MATERIALS AND METHODS: Nineteen consecutive cases with a clinical diagnosis of globe perforation were studied (1998-2004). Clinical setting, risk factors, clinical presentation, management and visual outcome were analyzed., RESULTS: Retrobulbar injections 6 (32%), peribulbar injections 10 (53%) and subconjunctival injections 3 (16%) were responsible for inadvertent globe perforation. Anesthetists accounted for 6 (32%) injections and 13 (69%) were referred from high volume community settings. Anesthetists identified the mishap on the table in 17% (1 out of 6) of cases and the ophthalmologists in 69% (9 out of 13) myopia was present in 10 (53%). Breaks were located inferotemporally in nine eyes. Four underwent laser and cryopexy, 14 (74%) underwent vitreous surgery. Visual acuity greater than 20/200 was achieved in 12 patients., CONCLUSION: Myopia was found to be a significant risk factor. Inferotemporal breaks were common. Anesthetists were more likely to miss this complication when it occurred. In this series, intervention salvaged vision in a significant number of eyes.

1800. Gaidash, A. A., et al. (2014). "[Membranes structure and physical and mechanical erythrocytes properties in the early period of traumatic brain injury caused by less-lethal firearms]." Voenno-meditsinskii zhurnal **335**(4): 14-21.

The dynamics of erythrocytes properties in the acute phase of traumatic brain injury caused by less-lethal firearms has been studied by the methods of atomic force and morphometry. The experiments have been performed on sheep by a Makarych pistol single shot at the parietooccipital area. It has been established that under the influence of the shock waves the erythrocyte disks and transmembrane liquid oscillatory fluctuations (flicker) are increased. The fluctuations are rapidly attenuated and the shock waves energy is accepted by cytoplasmic membranes lipoproteids. As

a result the interface tlipid-protein, phase transitions are hastened. The membranes undergo heterogeneous structural, physical and mechanical transformations the character of which is determined by the phase transitions direction. In the spots of phospolipid liquid clusters accumulation the fluidity is increased and marks caused by membranes lamination and spreading appear. In the spots of phospholipids solid phase the surfaces become hydrophobic and marks caused by membranes local embrittlement and fragility appear. The transmembrane fluid hydrodynamic flows heterogeneity is increased due to deformation processes irregular spreading. The flows acceleration causes the hydrodynamic ruptures-like defects. The flows deceleration results in depressions evolving through the mechanism of creeping erosions.

1801. Gaier, E. D., et al. (2020). "Poor prognoses of open globe injuries with concomitant orbital fractures." Orbit (Amsterdam, Netherlands) **39**(4): 241-250.

PURPOSE: Orbital trauma, particularly with open globe injury, can have a wide range of visual outcomes, which can be difficult to predict at presentation. Clinical features on presentation may provide insight into visual prognosis. We hypothesized that patients with open globe injuries and concomitant orbital fractures have poorer visual outcomes than patients without orbital fractures., METHODS: We reviewed the charts of 77 patients with isolated open globe injuries (OG) and 76 patients with open globe injuries and concomitant orbital fractures (OGOF). Multivariate regression analysis was performed to assess the relative influence of individual presenting historical and clinical features on visual outcome., RESULTS: OGOF patients were more likely to have sustained blunt trauma than a sharp, penetrating injury compared to OG patients. Ocular wound locations were more posterior and likely to involve multiple zones in OGOF compared to OG patients. Among OGOF patients, orbital floor fractures were the most common and roof fractures were the least common, but the latter was associated with presenting NLP vision and multiple zone involvement. The presence of an orbital fracture independently increased the odds of subsequent evisceration/enucleation (OR: 4.6, 95% CI 1.3-20.1, p = .0246) and NLP vision (OR: 6.81, 95% CI 2.42-21.85, p = .0005) when controlling for zone, mechanism of injury, uveal prolapse and demographic variables., CONCLUSIONS: The presence of an orbital fracture independently confers a worse visual and ocular prognosis in patients with open globe injuries. Patients with open globe injuries in this category should be appropriately counseled.

1802. Gajavelli, S., et al. (2015). "Glucose and oxygen metabolism after penetrating ballistic-like brain injury." Journal of cerebral blood flow and metabolism : official journal of the International Society of Cerebral Blood Flow and Metabolism **35**(5): 773-780.

Traumatic brain injury (TBI) is a major cause of death and disability in all age groups. Among TBI, penetrating traumatic brain injuries (PTBI) have the worst prognosis and represent the leading cause of TBI-related morbidity and death. However, there are no specific drugs/interventions due to unclear pathophysiology. To gain insights we looked at cerebral metabolism in a PTBI rat model: penetrating ballistic-like brain injury (PBBI). Early after injury, regional cerebral oxygen tension and consumption significantly decreased in the ipsilateral cortex in the PBBI group compared with the control group. At the same time point, glucose uptake was significantly reduced globally in the PBBI group compared with the control group. Examination of Fluorojade B-stained brain sections at 24 hours after PBBI revealed an incomplete overlap of metabolic impairment and neurodegeneration. As expected, the injury core had the most severe metabolic impairment and highest neurodegeneration. However, in the peri-lesional area, despite similar metabolic impairment, there was lesser neurodegeneration. Given our findings, the data suggest the presence of two distinct zones of primary injury, of which only one recovers. We anticipate the peri-lesional area encompassing the PBBI ischemic penumbra, could be salvaged by acute therapies.

1803. Gajavelli, S., et al. (2019). "Long-term preclinical safety evaluation of clinical-grade human neural stem cells in rodent model of traumatic brain injury." Journal of neurotrauma **36**(13): A77-A78.

Traumatic brain injury (TBI) is a progressive disease, characterized with disability amongst its survivors due to loss of neural tissue. Transplantation of neural stem cells (NSCs) is an option to replace lost cells and restore function. Following robust durable engraftment of clinical trial grade human fetal neural stem cells (hNSC; Neuralstem Inc.), we initiated a safety/tumorigenicity study needed in order to obtain FDA approval for a TBI clinical indication. To evaluate the potential tumorigenicity of hNSCs, cells were transplanted in immune-compromised rats with penetrating ballistic-like brain injury (PBBI). Adult male athymic rats were subjected to unilateral PTBI via rapid inflation of a balloon attached to a perforated probe that was stereotactically inserted through the right frontal cortex. Animals were randomized to

two groups (n = 20 per group). At one-week postinjury, animals received perilesional microinjection of vehicle (Group A) or 3 million green fluorescent protein (GFP) expressing hNSCs (Group B). Animals were euthanized at 6 months post-transplantation. Tumorigenecity potential was assessed by examining brain and peripheral organ sections for oncogenic features such as abnormal mitoses, nuclear atypia, and necrosis in hematoxylin eosin stained section as well as quantitation of Ki67 positive mitotic figures in brains and spinal cords. The transplanted cells within brain sections showed pleomorphic density with seamless boundaries and no signs of tumorigenicity. Neither morphological nor immunohistochemical indicators indicative of preneoplastic or neoplastic growth were evident in transplanted cells. No abnormal masses were detected in peripheral tissues. While some peripheral tissue masses were detected, these were found to be benign neoplasms common to this species of rodents. Collectively, data supports the notion that hNSC can be considered a safe cell therapy option for TBI patients.

1804. Gajavelli, S., et al. (2017). "Human stem cell transplantation in TBI." British journal of neurosurgery **31**(4): 499.

Objectives: Traumatic Brain Injury (TBI) is associated with the worst outcomes with both high mortality and severe disability. While no treatment strategies are available, stem cell transplantations have emerged as putative therapeutic approaches. In this rodent study, we evaluated the survival, differentiation and functional outcome of FDA approved human fetal neural stem cells (hNSC; Neuralstem Inc.) in a rat model. Methods: Adult Sprague-Dawley rats underwent a unilateral penetrating ballistic brain injury (PBBI). Stereotactic injection of control or hNSCs into the PBBI penumbra was performed one week later. Animals were sacrificed and brains histologically assessed for transplant survival, cell maturation and synapse formation. Function was evaluated using the rotatrod and Morris Water Maze. Results: Robust survival and transplant engraftment could be seen by 8 weeks. Processes were extensive and could be observed as far as the hindbrain. The processes emanating from the transplant follow intact white matter tracts. Transplanted cells displayed a neuronal phenotype. Functional recovery, both motor performance and spatial memory, were better compared to injured controls. Conclusion: PBBI is conducive to human fetal neural stem cells engraftment and survival. The transplanted cells are capable of extending processes and differentiate to neurone. Cell transplantation results in improved functional performance. We conclude that hNSC transplants may offer a potential treatment for PTBI.

1805. Gajdos, M. and J. Vyrostko (1997). "[Brain injuries with abattoir guns]." Poranenie mozgu jatocnou pistol'ou. **76**(10): 518-521.

The authors present a report on the treatment of 16 patients with brain injuries caused by a slaughterhouse gun. Nine patients had to be re-operated because of the presence of a foreign body; the primary operations of six patients were made in another surgical department. Two patients were re-operated twice. The reason for the first revision were bone fragments. The reason for the second revision was nasal liquorrhoea and posttraumatic hydrocephalus. Three patients (18.75%) of the investigated group died. The immediate cause of death was cerebral oedema. Eleven patients (68.75%) were referred for after-treatment to other health facilities, their condition had already improved. Two patients (12.5%) were referred in a poor, unaltered condition (coma). The rare incidence of gunshot injuries leads to a certain embarrassment how to treat patients with this type of injury. It was found that in gunshot wounds of the head and brain it is necessary to revise the gunshot canal from a craniotoic approach, remove foreign bodies, bone fragments, brain debris and then close perfectly the aperture in the dura mater, remove the margins of the bone contaminated with the injuring object and suture the skin. The authors draw attention to difficulties associated with localisation of the foreign body in the gunshot canal and possibilities of peroperative application of two-dimensional ultrasonography.

1806. Galanis, D. J., et al. (2018). "Rural Level III centers in an inclusive trauma system reduce the need for interfacility transfer." The journal of trauma and acute care surgery **85**(4): 747-751.

BACKGROUND: Development of Level III trauma centers in a regionalized system facilitates early stabilization and prompt transfer to a higher level center. The resources to care for patients at Level III centers could also reduce the burden of interfacility transfers. We hypothesized that the development and designation of Level III centers in an inclusive trauma system resulted in lower rates of transfer, with no increase in morbidity or mortality among the non-transferred patients., METHODS: State trauma registry data from January 2009 through September 2015 were examined from five rural hospitals that transfer patients to our highest (Level II) trauma center and resource hospital. These five

rural hospitals began receiving state support in 2010 to develop their trauma programs and were subsequently verified and designated Level III centers (three in 2011, two in 2013). Multivariate logistic regression was used to examine the adjusted odds of patient transfers and adverse outcomes, while controlling for age, gender, penetrating mechanism, presence of a traumatic brain injury, arrival by ambulance, and category of Injury Severity Score. The study period was divided into "Before" Level III center designation (2009-2010) and "After" (2011-2015)., RESULTS: 7,481 patient records were reviewed. There was a decrease in the proportion of patients who were transferred After (1,281/5,737) compared to Before (516/1,744) periods (22% vs. 30%, respectively). After controlling for the various covariates, the odds of patient transfer were reduced by 32% ($p < 0.0001$) during the After period. Among non-transferred patients, there were no significant increases in adjusted odds of mortality, or hospitalizations of seven days or more, Before versus After., CONCLUSIONS: Development of rural Level III trauma centers in a regionalized system can significantly reduce the need for transfer to a remote, higher level trauma center. This may benefit the patient, family, and trauma system, with no adverse effect upon patient outcome., LEVEL OF EVIDENCE: Epidemiological, level III.

1807. Galante, J. and J. A. London (2010). "Left ventricular bullet embolus: a case report and review of the literature." The Journal of emergency medicine **39**(1): 25-31.

Missile embolization to the heart occurs infrequently in penetrating trauma. The lack of a concentrated experience at any single institution contributes to the controversies pertaining to diagnostic and therapeutic approaches to management. The objective of this study was to describe a case of a left ventricular bullet embolus and provide a detailed diagnostic and therapeutic framework for management of intracardiac projectiles. Initial management of a patient with suspected intracardiac projectiles is dictated by his or her hemodynamic status. Unstable patients generally require operative intervention. In the stable patient, associated injuries must be sought. Localization of the projectile can be aided by echocardiogram, fluoroscopy, or angiography. Definitive management is individualized, and can range from observation to percutaneous or operative extraction. The decision depends on the cardiac chamber involved, the patients' symptoms, and the projectile's size, shape, and location within the chamber. Missile embolus to the heart is an infrequent occurrence, but when found presents a diagnostic and therapeutic challenge. Management strategies should be individualized. A detailed management algorithm is provided.

1808. Galea, J., et al. (2009). "Intravenous interleukin-1 receptor antagonist achieves experimentally neuroprotective cerebrospinal fluid concentrations within a therapeutic time window." British journal of neurosurgery **23**(5): 478.

Objective: Interleukin-1 (IL-1) is implicated in experimental ischaemic brain injury. Its naturally occurring antagonist (IL-1RA) is highly neuroprotective and can be administered therapeutically, showing few adverse effects and inhibiting the systemic acute phase response. A single dose regime pilot study showed that it penetrates cerebrospinal fluid (CSF) at experimentally-therapeutic concentrations, but this was achieved rather slowly. Determining the optimal protocol for rapid IL-1RA delivery in subarachnoid haemorrhage (SAH) is essential before testing biological efficacy. Design: An open-labelled dose-ranging pharmacokinetic study. Subjects: 25 patients with SAH and external ventricular drains inserted for clinical reasons. Methods: Patients received intravenous (IV) IL-1RA as a bolus followed by a 4 hour infusion. Pharmacometric analysis of pilot data enabled identification of the administration regime that could achieve experimentally-therapeutic CSF IL-1RA levels within 30 min. Patients were allocated to five regimes, using IV boluses of 100 to 500 mg and IV infusions ranging from 1 to 10 mg kg-1 h-1. Plasma and CSF sampling was performed as informed by a D-optimal design. Analysis was done using nonlinear mixed effects modelling. Results: IL-1RA plasma and CSF concentrations fell within predicted intervals. The regime leading to experimentally-therapeutic CSF concentrations of IL-1RA within 40 minutes was 500mg bolus followed by IV infusion at 10 mg kg-1 h-1. Conclusion: Experimentally neuroprotective CSF concentrations in SAH patients was achieved within a reasonable therapeutic time window. Pharmacokinetic analysis suggests IL-1RA transport across the blood-CSF barrier is passive. Identification of this delivery regime allows further efficacy studies of IL-1RA in SAH.

1809. Galea, J. P., et al. (2009). "Intravenous interleukin-1 receptor antagonist achieves experimentally neuroprotective cerebrospinal fluid concentrations within a therapeutic time window." Cerebrovascular Diseases **27**: 187.

Background: The cytokine interleukin-1 (IL-1) has been heavily implicated in experimental ischaemic brain injury. Its naturally occurring antagonist (IL-1RA) is highly neuroprotective. In humans, it shows few adverse effects and inhibits aspects of the systemic acute phase response to stroke. A pilot study showed penetration into cerebrospinal fluid (CSF)

at experimentally-therapeutic concentrations, but this was achieved rather slowly. The optimal protocol for rapid delivery of IL-1RA in acute cerebrovascular disease remains unknown and is essential prior to testing biological efficacy in patients. Methods: 25 patients with subarachnoid haemorrhage (SAH) and external ventricular drains inserted for clinical reasons received intravenous (IV) IL-1RA as a bolus followed by a 4 hour infusion. Pharmacometric analysis (simulation) of pilot study data identified the administration regime that could potentially achieve experimentally-therapeutic CSF IL-1RA levels within 30 min (fig 1). For safety reasons, patients were sequentially allocated to five administration regimes. Each regime reflected a stepwise increase in peak plasma concentration of IL-1RA. Plasma and CSF sampling was performed at specified intervals as informed by a D-optimal design. Results: Plasma and CSF concentrations of IL-1RA in all five regimes fell within predicted intervals (fig 2). The regime leading to experimentally-therapeutic CSF concentrations of IL-1RA within 30 minutes in SAH patients was confirmed as a 500mg bolus followed by an IV infusion at 10 mg/kg/h. No significant adverse events were noted. Conclusion: It is possible to achieve experimentally neuroprotective CSF concentrations in patients with SAH within a reasonable therapeutic time window (30 minutes). Pharmacokinetic analysis suggests that IL-1RA transport across the blood-CSF barrier in SAH is passive. Identification of this delivery regime allows further studies of efficacy of IL-1RA in acute cerebrovascular disease.

1810. Gallina, E., et al. (1990). "[Intracranial post-traumatic aneurysm of the internal carotid artery as cause of epistaxis: considerations on 2 cases]." Aneurisma post-traumatico intracranico della carotide interna come causa di epistassi: considerazioni su due casi. **10**(6): 607-613.

Aneurysm of the internal carotid artery is rarely mentioned as a cause of epistaxis. This condition is quite rare but it is important to consider aneurysms in the etiology of epistaxis because of their high mortality rate and since they require management quite different from that of epistaxis of other origins. After arteriosclerosis the most frequent cause of an aneurysm of the internal carotid artery is a closed or penetrating craniofacial trauma injuring the artery. This leads to subsequent aneurysmal dilation of the cavernous and petrous portions of the artery itself. Aneurysms of the cavernous portion of the artery are more frequent. In this location the aneurysm has a close anatomical relationship with the sphenoid sinus as well as the nasal fossae. In the present paper two cases of traumatic intracavernous carotid aneurysms presenting epistaxis are described. In the first case, reported 25 years ago, the diagnosis was made on an autoptic table in young man who died after two severe episodes of massive nasal hemorrhage. The second case involved a 17-year-old man with a severe epistaxis reported one month after a close craniofacial trauma. An intracranial carotid pathology was suspected because of the recurrence of nose-bleeding and the history of reduced visual activity. Therefore angiography was performed which revealed a small aneurysm of the intracavernous segment of the left internal carotid artery. Subsequently, an endovascular balloon embolization of the aneurysm was successful, preserving the parent artery. The importance of considering aneurysms in the differential diagnosis of massive epistaxis is emphasized.

1811. Gallo, P., et al. (2010). "Intrauterine head stab wound injury resulting in a growing skull fracture: a case report and literature review." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **26**(3): 377-384.

INTRODUCTION: Penetrating injuries of the gravid uterus are rare complications of pregnancy with gunshot wounds most common than stab wounds. Fetal head injury is an unusual sequela of these penetrating traumas., MATERIALS AND METHODS: We describe the case of a 20-year-old pregnant woman stabbed at the lower abdomen at 30th weeks of gestation. She was nonsurgically managed by serial examination and continuous fetal monitoring., RESULTS: Spontaneous vaginal delivery occurred at term with good maternal and fetal outcome. The newborn examination revealed a right temporal swelling interpreted as a subcutaneous hemangioma. At 2 years and 6 months of life, the child was led to our attention with a pulsating bulge in the right temporal region. Clinical examination and imaging were indicative of a typical growing skull fracture. The child underwent neurosurgical procedure for repairing of the dural tear and bone defect according to the senior author's personal technique, described in details, with a good neurological and esthetic outcome., CONCLUSION: Thirty-two cases of stab wounds to the pregnant uterus have been reported to date in medical literature with two cases of fetal head injury.Growing skull fractures are rare complications of head injury and only one case has been described in the perinatal period following blunt trauma to the mother's abdomen 2-3 weeks before birth.

1812. Galvagno Jr, S. M., et al. "Helicopter emergency medical services for adults with major trauma." (12).

Background, Although helicopters are presently an integral part of trauma systems in most developed nations, previous reviews and studies to date have raised questions about which groups of traumatically injured people derive the greatest benefit., Objectives, To determine if helicopter emergency medical services (HEMS) transport, compared with ground emergency medical services (GEMS) transport, is associated with improved morbidity and mortality for adults with major trauma., Search methods, We ran the most recent search on 29 April 2015. We searched the Cochrane Injuries Group's Specialised Register, The Cochrane Library (Cochrane Central Register of Controlled Trials; CENTRAL), MEDLINE (OvidSP), EMBASE Classic + EMBASE (OvidSP), CINAHL Plus (EBSCOhost), four other sources, and clinical trials registers. We screened reference lists., Selection criteria, Eligible trials included randomized controlled trials (RCTs) and nonrandomized intervention studies. We also evaluated nonrandomized studies (NRS), including controlled trials and cohort studies. Each study was required to have a GEMS comparison group. An Injury Severity Score (ISS) of at least 15 or an equivalent marker for injury severity was required. We included adults age 16 years or older., Data collection and analysis, Three review authors independently extracted data and assessed the risk of bias of included studies. We applied the Downs and Black quality assessment tool for NRS. We analyzed the results in a narrative review, and with studies grouped by methodology and injury type. We constructed 'Summary of findings' tables in accordance with the GRADE Working Group criteria., Main results, This review includes 38 studies, of which 34 studies examined survival following transportation by HEMS compared with GEMS for adults with major trauma. Four studies were of inter-facility transfer to a higher level trauma center by HEMS compared with GEMS. All studies were NRS; we found no RCTs. The primary outcome was survival at hospital discharge. We calculated unadjusted mortality using data from 282,258 people from 28 of the 38 studies included in the primary analysis. Overall, there was considerable heterogeneity and we could not determine an accurate estimate of overall effect., Based on the unadjusted mortality data from six trials that focused on traumatic brain injury, there was no decreased risk of death with HEMS. Twenty-one studies used multivariate regression to adjust for confounding. Results varied, some studies found a benefit of HEMS while others did not. Trauma-Related Injury Severity Score (TRISS)-based analysis methods were used in 14 studies; studies showed survival benefits in both the HEMS and GEMS groups as compared with MTOS. We found no studies evaluating the secondary outcome, morbidity, as assessed by quality-adjusted life years (QALYs) and disability-adjusted life years (DALYs). Four studies suggested a small to moderate benefit when HEMS was used to transfer people to higher level trauma centers. Road traffic and helicopter crashes are adverse effects which can occur with either method of transport. Data regarding safety were not available in any of the included studies. Overall, the quality of the included studies was very low as assessed by the GRADE Working Group criteria., Authors' conclusions, Due to the methodological weakness of the available literature, and the considerable heterogeneity of effects and study methodologies, we could not determine an accurate composite estimate of the benefit of HEMS. Although some of the 19 multivariate regression studies indicated improved survival associated with HEMS, others did not. This was also the case for the TRISS-based studies. All were subject to a low quality of evidence as assessed by the GRADE Working Group criteria due to their nonrandomized design. The question of which elements of HEMS may be beneficial has not been fully answered. The results from this review provide motivation for future work in this area. This includes an ongoing need for diligent reporting of research methods, which is imperative for transparency and to maximize the potential utility of results. Large, multicenter studies are warranted as these will help produce more robust estimates of treatment effects. Future work in this area should also examine the costs and safety of HEMS, since multiple contextual determinants must be considered when evaluating the effects of HEMS for adults with major trauma.

1813. Galvin, I. M., et al. "Cooling for cerebral protection during brain surgery." (1).

Background, Patients undergoing neurosurgery are at risk of cerebral ischaemia with resultant cerebral hypoxia and neuronal cell death. This can increase both the risk of mortality and long term neurological disability. Induced hypothermia has been shown to reduce the risk of cerebral ischaemic damage in both animal studies and in humans who have been resuscitated following cardiac arrest. This had lead to an increasing interest in its neuroprotective potential in neurosurgical patients. This review was originally published in 2011 and did not find any evidence of either effectiveness or harm in these patients. This updated review was designed to capture current evidence to readdress these issues., Objectives, To evaluate the effectiveness and safety profile of induced hypothermia versus normothermia for neuroprotection in patients undergoing brain surgery. Effectiveness was to be measured in terms of short and long term mortality and functional neurological outcomes. Safety was to be assessed in terms of the rate of the adverse events infection, myocardial infarction, ischaemic stroke, congestive cardiac failure and any other adverse events reported by the authors of the included studies., Search methods, For the original review, the authors searched the

databases Cochrane Central Register of Controlled Trials (CENTRAL), MEDLINE (OvidSP), EMBASE (OvidSP) and LILACS to November 2010. For the updated review all these databases were re-searched from November 2010 to May 2014., Selection criteria, As in the original review, we included randomized controlled trials (RCTs) of induced hypothermia versus normothermia for neuroprotection in patients of any age and gender undergoing brain surgery, which addressed mortality, neurological morbidity or adverse event outcomes., Data collection and analysis, Three review authors independently extracted data and two independently assessed the risk of bias of the included studies. Any discrepancies were resolved by discussion between authors., Main results, In this updated review, one new ongoing study was found but no new eligible completed studies were identified. This update was therefore conducted using the same four studies included in the original review. These studies included a total of 1219 participants, mean age 40 to 54 years. All included studies were reported as RCTs. Two were multicentred, together including a total of 1114 patients who underwent cerebral aneurysm clipping, and were judged to have an overall low risk of bias. The other two studies were single centred. One included 80 patients who had a craniotomy following severe traumatic brain injury and was judged to have an unclear or low risk of bias. The other study included 25 patients who underwent hemicranicectomy to relieve oedema following cerebral infarction and was judged to have an unclear or high risk of bias. All studies assessed hypothermia versus normothermia. Overall 608 participants received hypothermia with target temperatures ranging from 32.5 [degrees]C to 35 [degrees]C, and 611 were assigned to normothermia with the actual temperatures recorded in this group ranging form 36.5 [degrees]C to 38 [degrees]C. For those who were cooled, 556 had cooling commenced immediately after induction of anaesthesia that was continued until the surgical objective of aneurysm clipping was achieved, and 52 had cooling commenced immediately after surgery and continued for 48 to 96 hours., Authors' conclusions, We found no evidence that the use of induced hypothermia was associated with a significant reduction in mortality or severe neurological disability, or an increase in harm in patients undergoing neurosurgery.

1814. Gandhi, C. D., et al. (2012). "The novel use of Onyx for the rapid treatment of a traumatic carotid injury." Journal of neurointerventional surgery **4**(4): e18.

Penetrating neck injury causing internal carotid artery (ICA) transection is nearly always fatal. The novel use of Onyx Liquid Embolic System (Onyx LES) for rapid hemostasis of a traumatic cervical ICA transection is reported. A patient with a gunshot wound to the face and neck underwent emergent catheter angiography which revealed contrast extravasation from the right cervical ICA consistent with traumatic transection. The ipsilateral cerebral hemisphere showed collateral blood supply from the posterior communicating artery, and ipsilateral external carotid artery anastomoses of the facial, ethmoidal and ophthalmic arteries. Rapid endovascular repair of the transected cervical ICA was performed using Onyx LES. Onyx34 was injected at a rapid rate of 1 ml/min into the right ICA. Injection was continued until cast formation completely occluded the proximal cervical ICA but preserved the external carotid artery. This method very rapidly controlled bleeding and should be considered in these cases.

1815. Ganga, A., et al. (2022). "ANTIBIOTIC PROPHYLAXIS IN PENETRATING TRAUMATIC BRAIN INJURY: OUTCOMES FORM A SINGLEINSTITUTIONAL SERIES AND META-ANALYSIS OF THE LITERATURE." Journal of neurotrauma **39**(11-12): A115-A116.

Penetrating traumatic brain injury (pTBI) is a medical emergency with high mortality. Surviving patients face infection risk stemming from foreign body transgression into the CNS. Research regarding the use of antibiotic prophylaxis to pTBI patients is outdated and contradictory. We performed a MEDLINE literature review and analyzed a local series to learn whether prophylactic antibiosis can reduce infection risks among pTBI patients. Our local series contained 21 patients from 2015-2019 (20 male, 1 female; mean age 32 ± 13 years). The most common mechanisms of injury were cranial gunshot wounds. 17 patients received prophylactic antibiotics (regimen range: 1 to >30 days) and 4 did not. Among those receiving antibiotics, 7 received cefazolin alone while 10 received broad spectrum antibiotics. 4 patients (19%) developed CNS infections (3 intraparenchymal brain abscesses, 1 meningitis), with 2 requiring surgical intervention. 2/4 patients (50%) who did not receive prophylactic an-tibiotics developed CNS infections, compared to 2/17 (12%) who received prophylactic antibiotics. Of the 4 patients who developed intracranial infections, all speciated at least one gram-positive organism and 1/3 speciated a gram-negative organism. In the literature, we identified 330 cases. 216/330 (65%) cases received prophylactic antibiotics and 114 did not. Among patients who received antibiotics, 38 (17%) developed an infection. Among patients who did not, 23 (20%) developed an infection (Fisher's exact test, p = .55). While the literature suggests no benefit concerning prophylactic antibiosis, our institutional series indicates that pTBI carries a risk of infection and prophylactic antibiotics may decrease risk of this outcome.

1816. Gannushkina, I. V., et al. (1982). "Increased blood-brain barrier dysfunction around cerebral stab wounds in rats immunized to brain antigens. A quantitative study on endogenous albumin and globulin." Acta neurologica Scandinavica **66**(4): 482-487.

The extravasation of serum albumin and immunoglobulin G (IgG) was assayed by electroimmunoassay in cerebral cortex homogenates of rats subjected to stab wound injury either 2 weeks after immunisation to brain antigens or without prior immunisation. The amount of IgG in the brain was significantly higher in immunised than in non-immunised rats 3 and 24 h after injury. A significantly enhanced extravasation of albumin in immunised rats was found only after 24 h. It is concluded that immunisation to brain antigens enhances the vulnerability of the blood-brain barrier in rats subjected to stab wound injury.

1817. Gant, T. D. and L. I. Epstein (1979). "Low-velocity gunshot wounds to the maxillofacial complex." The Journal of trauma **19**(9): 674-677.

A review of the past literature of gunshot wounds indicates that the clinical material deals mainly with high-velocity missile injuries from military experience. A series of 66 cases of low-velocity gunshot wounds to the maxillofacial complex at San Francisco General Hospital between 1971 and 1978 indicates a clinical difference between injuries caused by low-velocity as compared to previously reported high-velocity missiles. Damage to vital structures resulting from missile injury to the maxillofacial complex are classified in three anatomic areas: 1) supra-orbital (28 cases of which 20 involved neurological damage); 2) mid-face (24 cases of which 8 involved the orbits and/or globe); 3) lower face (14 cases, of which 3 involved laceration of the carotid and 2 involved airway obstruction necessitating tracheostomy). The management of gunshot wounds to the maxillofacial area is outlined, emphasizing: 1) Debridement and prompt closure of intraoral wounds with antibiotic coverage: 2) Early stabilization of mandible fractures: 3) Indications for tracheostomy; 4) Arteriographic studies. In our series there were only four infections, which were treated easily with incision and drainage and appropriate antibiotic selection.

1818. Ganti, L., et al. (2014). "How much does a TBI cost?" Brain injury **28**(5-6): 827-828.

Objective: To determine the predictors of hospital costs associated with traumatic brain injury. Methods: These data are derived from the Florida Brain and Spinal Cord injury prospective registry from the institution, a level I trauma centre. In order to be eligible for the BSCIP, the patient must be a legal resident of the state of Florida, have suffered a moderate-tosevere brain injury, be medically stable and there should be a reasonable expectation that, with the provision of appropriate services and supports, the person can return to a community-based setting, rather than reside in a skilled nursing facility. Data are limited to TBIs from 1 January 2012 to 30 June 2013. Costs information was obtained from total hospital charges vs actual collections. Statistical analyses were performed in JMP 10 for the Macintosh. Results: A total of 170 TBIs were identified during the study period. The median age of the cohort was 42, with an IQR of 24-60 years and a range of 9 months to 93 years. Seventy-eight per cent were male. The mechanism was 31% MVC, 18% fall, 23% recreational vehicles, 11% assault, 14% pedestrian struck, 2% gun shot wound and 1% selfinflicted. The median length of hospitalization was 16 days, with an IQR of 8-25 and a range of 1-60 days. The median hospitalization cost per TBI patient including emergency services was $162 523. Individual factors associated with increased hospitalization cost of TBI included: reduced probability of survival ($p<0.0001$), increased hospital length of days ($p<0.0001$), mechanism of injuries (pedestrian struck by vehicle [$p=0.0001$], recreational vehicle injury [$p=0.005$], motor vehicle accident [$p=0.006$], assault [$p=0.05$]; all compared to fall) and non-transferred patients ($p=0.0003$). On multivariate analysis, the factors that remained predictive for increased cost were a lower probability of survival ($p=0.0006$), a longer hospital length of stay ($p<0.0001$) and patients whose mechanism of injury was not a fall ($p=0.039$), when controlling for GCS score ($p=0.0014$). Conclusion: The cost of hospitalization for TBI is significantly increased by longer hospital stay, lower survival chance and higher GCS score, while cost is significantly lower for patients who sustain a TBI due to fall vs motor vehicle collision.

1820. Gao, G., et al. (2019). "Donor Characteristics, Recipient Outcomes, and Histologic Findings of Kidney Allografts With Diffuse Donor-derived Glomerular Fibrin Thrombi." Transplantation **103**(9): 1921-1927.

BACKGROUND: Limited data are available on whether donor kidneys with diffuse glomerular fibrin thrombi (GFT) are safe to use. In this study, the clinicopathologic characteristics of allografts with diffuse donor-derived GFT were examined., METHODS: All deceased donor kidney transplant implantation biopsies from our institution between July 2011 and February 2018 with diffuse GFT were included. A control group for comparison consisted of all cases with implantation biopsies obtained during the study period without diffuse GFT. Clinical data were extracted from electronic medical records for all study patients, including donor information., RESULTS: Twenty-four recipients received kidneys with diffuse GFT from 16 deceased donors. All donors died from severe head trauma. On average, 79% of glomeruli contained fibrin thrombi. Nineteen cases had subsequent biopsy; all revealed resolution of GFT. Compared with the control group, kidneys with diffuse GFT had longer cold ischemia time (34 versus 27 h), were more frequently pumped using machine perfusion (100% versus 81%), and recipients experienced a higher frequency of delayed graft function (58% versus 27%). Only 2 grafts with diffuse GFT failed within the first year. Overall graft survival was similar between the diffuse GFT group and control group., CONCLUSIONS: Deceased donor kidneys with diffuse GFT appear to be safe to use given that nearly 92% of recipients in this cohort who received such allografts experienced good clinical outcomes. Histologically, GFT demonstrated rapid resolution following transplantation. Interestingly, diffuse GFT only occurred in donors who suffered severe head trauma in this cohort, which may be a predisposing factor.

1821. Gao, J., et al. (2000). "[Penetrating wounds of the heart: analysis of 56 patients]." Zhonghua wai ke za zhi [Chinese journal of surgery] **38**(5): 358-359.

OBJECTIVE: To assess the management of penetrating cardiac injuries., METHODS: 56 patients with penetrating wounds of the heart were studied retrospectively. The study lasted for 11 years., RESULTS: Stab wounds accounted for 89.3% of the 56 patients. 56 patients underwent thoracotomy. Preoperative infusion was less than 1,000 ml in 68% of the patients. Preoperative pericardiocentesis was done only in 2 patients, of whom one was false negative. Four patients with cardiac arrest soon after arrival were subjected to emergency thoracotomy; three survived. After the operation, 2 patients died of associated abdominal injuries and failure of cerebral resuscitation. The overall survival rate was 96.4%., CONCLUSIONS: Early diagnosis and prompt thoracotomy are essential to the treatment of penetrating cardiac injuries. Preoperative massive transfusion and pericardiocentesis are not advocated.

1822. Gao, J., et al. (2006). "Transplantation of primed human fetal neural stem cells improves cognitive function in rats after traumatic brain injury." Experimental neurology **201**(2): 281-292.

Traumatic brain injury (TBI) often produces cognitive impairments by primary or secondary neuronal loss. Stem cells are a potential tool to treat TBI. However, most previous studies using rodent stem or progenitor cells failed to correlate cell grafting and cognitive improvement. Furthermore, the efficacy of fetal human neural stem cells (hNSCs) for ameliorating TBI cognitive dysfunction is undetermined. This study therefore characterized phenotypic differentiation, neurotrophic factor expression and release and functional outcome of grafting hNSCs into TBI rat brains. Adult Sprague-Dawley rats underwent a moderate parasagittal fluid percussion TBI followed by ipsilateral hippocampal transplantation of hNSCs or vehicle 1 day post-injury. Prior to grafting, hNSCs were treated in vitro for 7 days with our previously developed priming procedure. Significant spatial learning and memory improvements were detected by the Morris water maze (MWM) test in rats 10 days after receiving hNSC grafts. Morphological analyses revealed that hNSCs survived and differentiated mainly into neurons in the injured hippocampus at 2 weeks after grafting. Furthermore, hNSCs expressed and released glial-cell-line-derived neurotrophic factor (GDNF) in vitro and when grafted in vivo, as detected by RT-PCR, immunostaining, microdialysis and ELISA. This is the first direct demonstration of the release of a neurotrophic factor in conjunction with stem cell grafting. In conclusion, human fetal neural stem cell grafts improved cognitive function of rats with acute TBI. Grafted cells survived and differentiated into neurons and expressed and released GNDF in vivo, which may help protect host cells from secondary damage and aid host regeneration.

1823. Gao, M., et al. (2017). "Syringe needle skull penetration reduces brain injuries and secondary inflammation following intracerebral neural stem cell transplantation." Experimental and Therapeutic Medicine **13**(3): 885-890.

Intracerebral neural stem cell (NSC) transplantation is beneficial for delivering stem cell grafts effectively, however, this approach may subsequently result in brain injury and secondary inflammation. To reduce the risk of

promoting brain injury and secondary inflammation, two methods were compared in the present study. Murine skulls were penetrated using a drill on the left side and a syringe needle on the right. Mice were randomly divided into three groups (n=84/group): Group A, receiving NSCs in the left hemisphere and PBS in the right; group B, receiving NSCs in the right hemisphere and PBS in the left; and group C, receiving equal NSCs in both hemispheres. Murine brains were stained for morphological analysis and subsequent evaluation of infiltrated immune cells. ELISA was performed to detect neurotrophic and immuno-modulatory factors in the brain. The findings indicated that brain injury and secondary inflammation in the left hemisphere were more severe than those in the right hemisphere, following NSC transplantation. In contrast to the left hemisphere, more neurotrophic factors but less pro-inflammatory cytokines were detected in the right hemisphere. In addition, increased levels of neurotrophic factors and interleukin (IL)-10 were observed in the NSC transplantation side when compared with the PBS-treated hemispheres, although lower levels of IL-6 and tumor necrosis factor-α were detected. In conclusion, the present study indicated that syringe needle skull penetration vs. drill penetration is an improved method that reduces the risk of brain injury and secondary inflammation following intracerebral NSC transplantation. Furthermore, NSCs have the potential to modulate inflammation secondary to brain injuries.

1824. Gao, W., et al. (2018). "A possible candidate for triply degenerate point fermions in trigonal layered PtBi2." Nature Communications **9**(1).

Triply degenerate point (TP) fermions in tungsten–carbide-type materials (e.g., MoP), which represent new topological states of quantum matter, have generated immense interest recently. However, the TPs in these materials are found to be far below the Fermi level, leading to the TP fermions having less contribution to low-energy quasiparticle excitations. Here, we theoretically predict the existence of TP fermions with TP points close to the Fermi level in trigonal layered PtBi2 by ab initio calculations, and experimentally verify the predicted band topology by magnetotransport measurements under high magnetic fields up to 40 T. Analyses of both the pronounced Shubnikov–de Haas and de Haas–van Alphen oscillations reveal the existence of six principal Fermi pockets. Our experimental results, together with those from ab initio calculations, reveal the interplay between transport behaviors and unique electronic structures, and support the existence of TP fermions in trigonal layered PtBi2.

1825. Garcia, A., et al. (2014). "Cost-utility analysis of prehospital spine immobilization recommendations for penetrating trauma." The journal of trauma and acute care surgery **76**(2): 534-541.

BACKGROUND: The American College of Surgeons' Committee on Trauma's recent prehospital trauma life support recommendations against prehospital spine immobilization (PHSI) after penetrating trauma are based on a low incidence of unstable spine injuries after penetrating injuries. However, given the chronic and costly nature of devastating spine injuries, the cost-utility of PHSI is unclear. Our hypothesis was that the cost-utility of PHSI in penetrating trauma precludes routine use of this prevention strategy., METHODS: A Markov model based cost-utility analysis was performed from a society perspective of a hypothetical cohort of 20-year-old males presenting with penetrating trauma and transported to a US hospital. The analysis compared PHSI with observation alone. The probabilities of spine injuries, costs (US 2010 dollars), and utility of the two groups were derived from published studies and public data. Incremental effectiveness was measured in quality-adjusted life-years. Subset analyses of isolated head and neck injuries as well as sensitivity analyses were performed to assess the strength of the recommendations., RESULTS: Only 0.2% of penetrating trauma produced unstable spine injury, and only 7.4% of the patients with unstable spine injury who underwent spine stabilization had neurologic improvement. The total lifetime per-patient cost was $930,446 for the PHSI group versus $929,883 for the nonimmobilization group, with no difference in overall quality-adjusted life-years. Subset analysis demonstrated that PHSI for patients with isolated head or neck injuries provided equivocal benefit over nonimmobilization., CONCLUSION: PHSI was not cost-effective for patients with torso or extremity penetrating trauma. Despite increased incidence of unstable spine injures produced by penetrating head or neck injuries, the cost-benefit of PHSI in these patients is equivocal, and further studies may be needed before omitting PHSI in patients with penetrating head and neck injuries., LEVEL OF EVIDENCE: Economic and value-based evaluation, level II.

1826. Garcia, R. M., et al. (2015). "Early Postoperative Complications following Gracilis Free Muscle Transfer for Facial Reanimation: A Systematic Review and Pooled Data Analysis." Journal of reconstructive microsurgery **31**(8): 558-564.

BACKGROUND: Multiple studies have detailed promising smile restoration following gracilis free muscle transfer for facial reanimation but information detailing the potential complications is lacking. The aim of this study is to systematically review the literature to evaluate the reported complication rate associated with this procedure. We also aim to determine the most common occurring complications., METHODS: The PubMed, Embase, and Web of Science databases were queried with multiple search strategies for published articles between January 1950 and February 2013 that detailed gracilis free muscle transfer for facial reanimation. Title, abstract, and full text review was performed. Complications were defined as any reported, identifiable adverse outcome that required an alteration in treatment for correction., RESULTS: The literature search yielded 62 studies of gracilis free muscle transfer for facial reanimation. Overall, 36 articles (58%) reported whether or not a complication had occurred. The overall complication rate based on pooled proportions was 9.6% and the most commonly occurring complications were postoperative hematoma (3.6%) and infection (3.5%)., CONCLUSIONS: Our data suggests that complications after gracilis free muscle transfer for facial reanimation may be underreported and this complex procedure may in fact be associated with significant adverse outcomes as high as 9.6%. 1827. Garcia-Manzanares, M. D., et al. (2000). "Brown-Sequard syndrome associated with Horner's syndrome after a penetrating trauma at the cervicomedullary junction." Spinal cord **38**(11): 705-707.

STUDY DESIGN: Case report of a 21-year-old man that had concurrence of Brown-Sequard syndrome and Horner's syndrome after a penetrating trauma in the neck., OBJECTIVES: This report analyzes the location of lesions that cause a combination of Horner's and Brown-Sequard syndrome. It is important to know the anatomic structure of spinal cord and the sympathetic nerve chain., SETTING: Spinal Cord Unit, Department of Physical Medicine and Rehabilitation, Hospital La Fe, Valencia, Instituto Oftalmologico de Alicante, Alicante, Spain., METHODS: Description of a single patient case report., RESULTS: The clinical findings and MRI showed a good correlation. The Horner's syndrome was confirmed with a 4% cocaine test. The patient received a conservative treatment with high-dose steroid therapy (NASCIS-3)., CONCLUSION: The patient presented with Brown-Sequard syndrome and Horner's syndrome. Clinical examination and MRI made a quick and correct diagnosis. The patient recovered completely after the conservative treatment.

1828. Garcia-Molina, A. (2012). "[Phineas Gage and the enigma of the prefrontal cortex]." Phineas Gage y el enigma del cortex prefrontal. **27**(6): 370-375.

Perhaps the most famous brain injury in history was a penetrating wound suffered by a rail road worker named Phineas Gage on September 13, 1848. Twelve years after his injury, on the 21st of May, 1860 Phineas Gage died of an epileptic seizure. In 1868 Dr. Harlow gave an outline of Gage's case history and first disclosed his remarkable personality change. One might think this report would assure Gage a permanent place in the annals of neurology, but this was not the case. There was a good reason for this neglect: hardly anyone knew about Harlow's 1868 report. Dr. David Ferrier, an early proponent of the localisation of cerebral function, rescued Gage from obscurity and used the case as the highlight of his famous 1878 Goulstonian lectures. Gage had, through a tragic natural experiment, provided proof of what Ferrier's studies showed: the pre-frontal cortex was not a "non-functional" brain area. A rod going through the prefrontal cortex of Phineas Gage signalled the beginning of the quest to understand the enigmas of this fascinating region of the brain.

1829. Garcia-Pertierra, S., et al. (2022). "Surgical management of intrathoracic wooden skewers migrating from the stomach and duodenum in dogs: 11 cases (2014-2020)." The Journal of small animal practice **63**(5): 403-411.

OBJECTIVES: To describe the clinical presentation, management and outcome of cases presenting with intrathoracic wooden skewers originating from the abdominal gastrointestinal tract., MATERIALS AND METHODS: Clinical records of dogs presented and treated for an intrathoracic wooden skewer were reviewed from June to August 2020. Data included signalment, clinical presentation, duration of clinical signs, haematological and biochemical abnormalities, diagnostic imaging findings, surgical procedure, postoperative complications and outcome., RESULTS: Eleven dogs were included in the study. In all cases, the foreign body was identified as a wooden skewer. The most common clinical signs were anorexia/hyporexia (n=7), vomiting/regurgitation (n=7), lethargy (n=6), pyrexia (n=4) and gait abnormalities/lameness (n=3). CT correctly identified a wooden skewer in all cases when performed (n=7). A coeliotomy combined with transdiaphragmatic thoracotomy was performed in six of 11 cases (55%), a coeliotomy

combined with median sternotomy in four of 11 cases (36%) and a median sternotomy alone was performed in one case. Foreign bodies penetrated from the stomach (n=10) or the duodenum (n=1). Intrathoracic trauma was most commonly identified to the lungs (n=3) and pericardium (n=3). Complications occurred in three of 11 cases (27%), two minor and one resulting in death. Ten of the 11 cases (91%) survived to discharge. Long-term outcome was available for seven of 11 cases (66%), all of them excellent., CLINICAL SIGNIFICANCE: Despite the challenges of managing wooden skewers penetrating the thoracic cavity from the abdominal gastrointestinal tract, the majority of the patients are stable to undergo diagnostic procedures, surgical exploration and management with low morbidity and excellent short- and long-term prognosis.

1830. Garcia-Segura, L. M., et al. (1999). "Aromatase expression by astrocytes after brain injury: implications for local estrogen formation in brain repair." Neuroscience **89**(2): 567-578.

Recent evidence indicates that 17beta-estradiol may have neuroprotective and neuroregenerative properties. Estradiol is formed locally in neural tissue from precursor androgens. The expression of aromatase, the enzyme that catalyses the conversion of androgens to estrogens, is restricted, under normal circumstances, to specific neuronal populations. These neurons are located in brain areas in which local estrogen formation may be involved in neuroendocrine control and in the modulation of reproductive or sex dimorphic behaviours. In this study the distribution of aromatase immunoreactivity has been assessed in the brain of mice and rats after a neurotoxic lesion induced by the systemic administration of kainic acid. This treatment resulted in the induction of aromatase expression by reactive glia in the hippocampus and in other brain areas that are affected by kainic acid. The reactive glia were identified as astrocytes by co-localization of aromatase with glial fibrillary acidic protein and by ultrastructural analysis. No immunoreactive astrocytes were detected in control animals. The same result, the de novo induction of aromatase expression in reactive astrocytes on the hippocampus, was observed after a penetrating brain injury. Furthermore, using a 3H2O assay, aromatase activity was found to increase significantly in the injured hippocampus. These findings indicate that although astrocytes do not normally express aromatase, the enzyme expression is induced in these glial cells by different forms of brain injury. The results suggest a role for local astroglial estrogen formation in brain repair.

1831. Gardner, W. J. and E. W. Shannon (1970). "Pneumocranium from gunshot wound of brain." JAMA **214**(13): 2333-2334.

1832. Garg, R. K., et al. (2015). "A novel classification of frontal bone fractures: The prognostic significance of vertical fracture trajectory and skull base extension." Journal of plastic, reconstructive & aesthetic surgery : JPRAS **68**(5): 645-653.

PURPOSE: The broad spectrum of frontal bone fractures, including those with orbital and skull base extension, is poorly understood. We propose a novel classification scheme for frontal bone fractures., METHODS: Maxillofacial CT scans of trauma patients were reviewed over a five year period, and frontal bone fractures were classified: Type 1: Frontal sinus fracture without vertical extension. Type 2: Vertical fracture through the orbit without frontal sinus involvement. Type 3: Vertical fracture through the frontal sinus without orbit involvement. Type 4: Vertical fracture through the frontal sinus and ipsilateral orbit. Type 5: Vertical fracture through the frontal sinus and contralateral or bilateral orbits. We also identified the depth of skull base extension, and performed a chart review to identify associated complications., RESULTS: 149 frontal bone fractures, including 51 non-vertical frontal sinus (Type 1, 34.2%) and 98 vertical (Types 2-5, 65.8%) fractures were identified. Vertical fractures penetrated the middle or posterior cranial fossa significantly more often than non-vertical fractures (62.2 v. 15.7%, $p = 0.0001$) and had a significantly higher mortality rate (18.4 v. 0%, $p < 0.05$). Vertical fractures with frontal sinus and orbital extension, and fractures that penetrated the middle or posterior cranial fossa had the strongest association with intracranial injuries, optic neuropathy, disability, and death ($p < 0.05$)., CONCLUSIONS: Vertical frontal bone fractures carry a worse prognosis than frontal bone fractures without a vertical pattern. In addition, vertical fractures with extension into the frontal sinus and orbit, or with extension into the middle or posterior cranial fossa have the highest complication rate and mortality.

1833. Garg, S. J., et al. (2005). "Bone from an orbital floor fracture causing an intraocular foreign body." American journal of ophthalmology **139**(3): 543-545.

PURPOSE: To describe the ophthalmoscopic and radiologic findings of a patient who sustained blunt orbital trauma. A piece of bone from the fractured orbital wall caused an intraocular foreign body., DESIGN: Case report., METHODS: An 18-year-old man underwent full ophthalmoscopic examination 1 week after sustaining blunt ocular trauma to the right eye while playing basketball. B-scan ultrasonography and computed tomography of the orbits were also performed., RESULTS: Visual acuity, intraocular pressure, and anterior segment examination were normal. Funduscopic examination revealed a fragment of bone that had penetrated the sclera, choroid, and retina. A hole in the sclera was visible. No treatment was performed. Three months later, the patient had no ocular complaints or complications as a result of this injury., CONCLUSION: Bone from a patient's orbit may cause an intraocular foreign body that may be followed conservatively in certain circumstances.

1834. Garner, J. (2005). "The early hospital management of gunshot wounds. Part 1: Head, neck and thorax." Trauma **7**(3): 143-154.

The management of gunshot wounds is an increasing problem for UK emergency doctors, but not to an extent where it has become routine or allowed individuals to gain significant experience in their treatment. This article reviews the pathophysiology of gunshot injury in general before examining the evidence available concerning the management of gunshot wounds to the head neck and thorax. © 2005 Edward Arnold (Publishers) Ltd.

1835. Garrido-Hermosilla, A. M., et al. (2018). "Penetrating orbital trauma without ocular compromise in gender-based violence." Traumatismo orbitario penetrante sin afectacion ocular en contexto de violencia de genero. **93**(8): e58.

1836. Gas, C., et al. (1999). "[Isolated fractures of the orbital floor. Conclusions of a retrospective study of 85 cases]." Fractures isolees du plancher orbitaire. Conclusions d'une etude retrospective portant sur 85 cas. **100**(1): 27-33.

UNLABELLED: We present a retrospective study of 85 patients presenting an isolated orbital floor fracture between 1993 and 1997; 79 of them (93%) were operated via a subciliary or transconjunctival approach. Surgical procedure included autologous graft or biomaterial (coral, polydioxanone) depending on the cases. The study was focused on clinical data (concerning diplopia, enophthalmia and sensorial disturbances) which were recorded pre- and post-operatively., RESULTS: 58 patients (68%) had a pre-operative diplopia, and 9 (11%) had a persistent post-operative diplopia: all of these patients were operated more than 8 days after trauma; no post-operative diplopia occurred without pre-operative diplopia; 8 patients (9%) presented a pre-op enophthalmia: all of them came more than 10 days after the trauma; a perfect symmetry was obtained post-operatively in only one of these 8 patients; no enophthalmia occurred in patients without pre-op enophthalmia; sensorial disturbances were seen pre-operatively in 27 patients (32%) and post-operatively in 17 (20%); no correlation was found with the timing or the procedure of the surgery., COMMENTS: The interest of an early diagnosis and treatment is confirmed, in order to avoid late functional (diplopia) or esthetic (enophthalmos) disturbances. Thus it seems necessary to obtain a computed tomography for any orbital trauma as conventional radiography can be less sensitive. Concerning the surgical procedure, resorbable biomaterials seem to be very well tolerated and easy to use. Autologous bone grafts always lead to a certain degree of morbidity without real advantage. The best way seems to be the trans-conjonctival approach, but subciliary incisions can also be used in these cases. The most important remaining problem to solve is probably focused on sensorial disturbances: their incidence is high and there is a high rate of sequels: further studies are obviously necessary to improve the knowledge of etiopathogenic factors and determine the best therapeutic attitude.

1837. Gascho, D., et al. (2020). "Noninvasive 7 tesla MRI of fatal craniocerebral gunshots - a glance into the future of radiologic wound ballistics." Forensic science, medicine, and pathology **16**(4): 595-604.

Compared to computed tomography (CT), magnetic resonance imaging (MRI) provides superior visualization of the soft tissue. Recently, the first 7 Tesla (7 T) MRI scanner was approved for clinical use, which will facilitate access to these ultra-high-field MRI scanners for noninvasive examinations and scientific studies on decedents. 7 T MRI has the potential to provide a higher signal-to-noise ratio (SNR), a characteristic that can be directly exploited to improve image quality and invest in attempts to increase resolution. Therefore, evaluating the diagnostic potential of 7 T MRI for

forensic purposes, such as assessments of fatal gunshot wounds, was deemed essential. In this article, we present radiologic findings obtained for craniocerebral gunshot wounds in three decedents. The decedents were submitted to MRI examinations using a 7 T MRI scanner that has been approved for clinical use and a clinical 3 T MRI scanner for comparison. We focused on detecting tiny injuries beyond the wound tract caused by temporary cavitation, such as microbleeds. Additionally, 7 T T2-weighted MRI highlighted a dark (hypo intense) zone beyond the permanent wound tract, which was attributed to increased amounts of paramagnetic blood components in damaged tissue. Microbleeds were also detected adjacent to the wound tract in the white matter on 7 T MRI. Based on the findings of radiologic assessments, the advantages and disadvantages of postmortem 7 T MRI compared to 3 T MRI are discussed with regard to investigations of craniocerebral gunshot wounds as well as the potential role of 7 T MRI in the future of forensic science.

1838. Gascho, D., et al. (2020). "Postmortem Computed Tomography and Magnetic Resonance Imaging of Gunshot Wounds to the Neck." Journal of forensic sciences **65**(4): 1360-1364.

Postmortem magnetic resonance imaging (MRI) is rarely used for the radiologic assessment of gunshot injuries, although it has clear advantages over postmortem computed tomography (CT) with regard to the imaging of soft tissue injuries. Another benefit in using MRI is that lodged projectiles composed of nonferromagnetic material such as lead present only marginal metal artifacts compared with severe artifacts on CT. This case report presents CT and MRI findings in a case with two gunshot wounds to the neck: a perforating wound and a nonperforating wound with a lead bullet lodged in the cervical spine. The decedent underwent CT and MRI before the scheduled autopsy. A ring of radiopaque material under the dermis in the fatty tissue was identified at both entrance wounds on CT, which was indicative of contact shots. The perforating gunshot was clearly indicated on CT by bullet fragments along the wound channel through the perforated 6th cervical vertebra and the fractured cricoid cartilage at the exit wound. The second trajectory, however, was only assumed based on the presence of gunshot residues at the entrance wound and the position of the lodged bullet. The radiologic assessment was severely impeded by the metal artifacts on CT. Barely noticeable metal artifacts on MRI allowed for clear visualization of the soft tissue injuries and the ruptured medulla oblongata. Only MRI clarified the soft tissue injuries of the brainstem noninvasively, which could provide specific and graphic information on the rapidity of death and the incapacitation of the victim.

1839. Gascho, D., et al. (2020). "Synergy of CT and MRI in detecting trajectories of lodged bullets in decedents and potential hazards concerning the heating and movement of bullets during MRI." Forensic science, medicine, and pathology **16**(1): 20-31.

The purpose of this study was to assess the value of magnetic resonance imaging (MRI) in addition to computed tomography (CT) in gunshot wound cases with bullets or pellets lodged inside the head. In this context, the potential heating and movement of the lodged bullets were additionally investigated using animal models. Eleven forensic cases of penetrating gunshot wounds underwent CT and MRI. The data of each imaging modality were reviewed according to the following relevant characteristics: bony lesion at the entrance, intracranial bone fragments, intracranial metal fragments, gunshot residues, the wound channel and the severity of metal artifacts. Four-point Likert scales were used for the assessment. The heating of projectiles and their magnetic field interactions with the static magnetic field were assessed using animal models. MRI presented major advantages in cases with transversal trajectories and non-ferromagnetic bullets compared to CT. In general, MRI enabled a clear visualization of the wound channel and gunshot-related soft tissue injuries. An image fusion of CT and MRI datasets demonstrated the individual strengths of both modalities. Radio frequency (RF)-induced heating due to bullets lodged inside the brain tissue was invalidated. The likelihood of ferromagnetic projectile migration inside brain tissue is low. MRI of decedents with a bullet lodged inside their heads is viable and provides a valuable supplement to CT. The in situ, noninvasive depiction of the wound channel and gunshot-related soft tissue injuries on MRI can contribute to the knowledge of wound ballistics.

1840. Gascho, D., et al. (2021). "Cinematic rendering of a burst sagittal suture caused by an occipito-frontal gunshot wound." Forensic science, medicine, and pathology **17**(4): 726-729.

The computed tomography (CT) scan of a 19-year-old man who died from an occipito-frontal gunshot wound presented an impressive radiating fracture line where the entire sagittal suture burst due to the high intracranial

pressure that arose from a near-contact shot from a 9 mm bullet fired from a Glock 17 pistol. Photorealistic depictions of the radiating fracture lines along the cranial bones were created using three-dimensional reconstruction methods, such as the novel cinematic rendering technique that simulates the propagation and interaction of light when it passes through volumetric data. Since the brain had collapsed, depiction of soft tissue was insufficient on CT images. An additional magnetic resonance imaging (MRI) examination was performed, which enabled the diagnostic assessment of cerebral injuries. Copyright © 2021. The Author(s).

1842. Gasiorek, J. (1989). "[A case of elongated styloid process syndrome]." Przypadek zespolu przedluzonego wyrostka rylcowatego. **43**(3): 244-246.

The elongated styloid process was discovered during tonsillectomy in the tonsilar loge. However, the patient complaints were typically for chronic tonsillitis.

1843. Gasparini, G., et al. (2002). "Maxillofacial traumas." The Journal of craniofacial surgery **13**(5): 645-649.

Craniofacial traumas often involve the orbital region. This report describes an unusual case of penetration of an object into the left upper oral vestibule up to the left medial-upper orbital wall. The object was an indicator switch. A multidisciplinary approach was necessary to make a correct diagnosis and to apply the best surgical treatment. The object was surgically removed, and rigid internal fixation was used to reconstruct the inferior and medial orbital walls. The aesthetic and functional results were good. One year later, the patient showed a slight enophthalmos with normal ocular motility.

1844. Gassend, J.-L., et al. (2021). "Classic but unexpected: a case of Jefferson fracture." Forensic science, medicine, and pathology **17**(2): 346-349.

A man was found lying dead next to a ladder, with only a laceration surrounded by an abrasion visible upon external examination. No skull fractures were palpable. A CT scan and MRI showed a Jefferson fracture of the atlas, associated to a posterior displacement of the skull, a fracture of the dens of the axis, and fractures of the bodies of C5 and C6. Jefferson fractures typically result from a blow to the apex of the skull. In such cases, forensic pathologists should suspect the existence of a Jefferson fracture, particularly when no severe injuries are visible externally.

1846. Gataa, I. S. and Q. H. Muassa (2011). "Patterns of maxillofacial injuries caused by terrorist attacks in Iraq: retrospective study." International journal of oral and maxillofacial surgery **40**(1): 65-70.

Over the past 5 years, Iraq has witnessed daily terrorist attacks mainly using improvised explosive devices. The aim of this study was to analyze the patterns of maxillofacial injuries caused by terrorist attacks in a sample of Iraqi casualties. Records from two hospitals, including 551 patients who sustained maxillofacial injuries due to terrorists attacks, were analyzed according to the patients' age, sex, site of injury, type of injury and cause of injury. Concomitant injuries and mortality were also considered. The most common age group affected was those aged 15-29 years. Most of these injuries were caused by improvised explosive devices (71%). More than one facial zone was injured in 212 patients (38%). Isolated soft tissues injuries were detected in (54%) of victims. Pure maxillofacial injuries comprised 33%. The most common injuries associated with this type of trauma were eye injuries (29%). The mortality rate was 2% from pure maxillofacial injuries. Terrorist attacks cause unique maxillofacial injuries, which should be considered a new entity in the trauma field.

1847. Gates, M. A., et al. (1996). "Chondroitin sulfate proteoglycan and tenascin in the wounded adult mouse neostriatum in vitro: dopamine neuron attachment and process outgrowth." The Journal of neuroscience : the official journal of the Society for Neuroscience **16**(24): 8005-8018.

Extracellular matrix (ECM) molecules, including chondroitin-4 or chondroitin-6 sulfate proteoglycans (CSPGs) and tenascin, are upregulated in and around wounds and transplants to the adult CNS. In the present study, striatal wounds from adult mice were used in a novel in vitro paradigm to assess the effects of these wound-associated molecules on embryonic dopamine cell attachment and neurite outgrowth. Light and electron microscopic immunocytochemistry studies have shown that astroglial scar constituents persist in cultured explants for at least 1 week in vitro, and despite the loss of neurons from adult striatal explants, there is a retention of certain structural features suggesting that the wound explant-neuron coplant is a viable model for analysis of graft-scar interactions. Explants from the wounded striatum taken at different times after a penetrating injury in vivo were used as substrates for embryonic ventral mesencephalon neurons that were plated on their surfaces. Dopamine cell attachment is increased significantly in relation to the expression of both CSPG and tenascin. The increase in neuronal attachment in this paradigm, however, is accompanied by a postlesion survival time-dependent significant decrease in neuritic growth from these cells. In vitro ECM antibody treatment suggests that CSPG may be responsible for heightened dopamine cell attachment and that tenascin simultaneously may support cell attachment while inhibiting neurite growth. The present study offers a new approach for the in vitro analysis of cell and molecular interactions after brain injury and brain grafting, in essence acting as a nigrostriatal transplant-in-a-dish.

1848. Gates, T. and J. L. Frodel (1998). "Frontobasilar blast injuries: access and treatment." The Journal of cranio-maxillofacial trauma **4**(2): 32-31.

Blast injuries involving the frontobasilar region and orbit can present difficult evaluation and treatment challenges. This article presents the surgical treatment of four patients presenting with blast-type injuries involving the central periorbital region and anterior skull base. Three of these were the result of close-range gunshot wounds, and one was caused by an avulsive penetrating tree branch injury during a motor vehicle accident. All four patients underwent frontal craniotomy for exposure to repair significant intracranial injuries. Following intracranial repair of dural and brain injuries, anterior cranial fossa reconstruction was performed. In two of these patients, elective supraorbital osteotomies were performed to allow improved access to the posterior aspect of the anterior skull base. The healing period of all four patients has been without complications relative to the anterior fossa injuries.

1849. Gates, T. R. and M. Hardjasudarma (1992). "Neuroimaging of fractureless transforamen magnum penetrating injury of the cerebellum." The American journal of emergency medicine **10**(1): 69-72.

An unusual case of penetrating injury to the cerebellum by a foreign body is described. The authors recommend plain radiographs and computed tomography to rule out fractures of the skull vault and base and the upper cervical spine, as well as to ascertain the presence and location of foreign bodies. Magnetic resonance imaging is ideal for the follow-up assessment of brain damage.

1851. Gaujac, C., et al. (2007). "Comparative analysis of 2 techniques of double-gloving protection during arch bar placement for intermaxillary fixation." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **65**(10): 1922-1925.

PURPOSE: This study was conducted to comparatively evaluate, in a prospective and randomized manner, 2 techniques for providing double-gloving protection during arch bar placement for intermaxillary fixation., MATERIALS AND METHODS: A total of 42 consecutive patients in whom application of an Erich bar was indicated for intermaxillary fixation were equally divided into 2 groups. In group 1, 2 sterile surgical gloves were used; in group 2, a nonsterile disposable inner glove was used under a sterile surgical glove. Wilcoxon, Mann-Whitney, Kruskal-Wallis, and binomial statistical tests were used to analyze the findings., RESULTS: A total of 103 perforations were found in the outer gloves

(47 in group 1 and 56 in group 2), along with 5 perforations in inner gloves in both groups (alpha = .01). No significant statistical difference was found between groups in terms of inner glove perforations (alpha = .05). The nondominant hand presented with 70.9% of the perforations, statistically significant to 1%., CONCLUSIONS: Both double-gloving techniques were found to provide effective clinician protection. The use of a nonsterile disposable glove under the surgical glove is possible for less-invasive procedures, offering the same safety as using 2 sterile surgical gloves while decreasing operational costs. This method does not eliminate the need to change gloves when a perforation is suspected or noted during the surgery, however.

1853. Gaur, N., et al. (2016). "Bilateral complete blindness following globe-sparing single-bullet orbital injury." Indian journal of ophthalmology **64**(10): 770-771.

1854. Gawdat, T. I. and R. A. Ahmed (2010). "Orbital foreign bodies: expect the unexpected." Journal of pediatric ophthalmology and strabismus **47 Online**: e1-4.

Data of three pediatric patients with orbitofacial trauma were reviewed. Two patients presented with recurrent orbital inflammation with partial remission with antibiotics. One patient presented with diplopia. All patients underwent full opthalmic examination and computed tomography (CT) of the brain and orbit, followed by surgical intervention. The indication for surgery was either abscess evacuation, repair of blowout fracture, or mass excision. All of the patients had intraorbital wood foreign bodies that were not evident on CT and were not suspected from the history given by the parents. All were surgically removed. One patient had multiple wood foreign bodies (more than 10). Chronic or recurrent orbital inflammation, unexplained proptosis, or orbital masses following orbitofacial trauma in children should raise the suspicion of intraorbital foreign bodies even if not detected by CT studies. Presence of other sequelae of trauma such as blowout fracture does not exclude the possibility of associated foreign bodies. Copyright 2010, SLACK Incorporated.

1855. Geary, U. M., et al. (1997). "Occult gunshot injury of the temporal bone." Journal of accident & emergency medicine **14**(3): 185-186.

Increasing firearms violence has produced much public disquiet in recent months and Liverpool has seen a particularly well publicized spate of shootings. This is a case report of an initially occult intracranial injury which illustrates the unpredictable nature of missile trauma and the importance of computerised tomography in all cases of gunshot injury to the head.

1856. Gebhart, F. T. F., et al. (2012). "Gas at postmortem computed tomography--an evaluation of 73 non-putrefied trauma and non-trauma cases." Forensic science international **222**(1-3): 162-169.

Postmortem computed tomography (PMCT) has become an important complement in investigating forensic cases allowing an accurate detection of gas accumulations. The present study investigated the presence and distribution of gas in a large number of non-putrefied cases of traumatic and non-traumatic deaths. Furthermore the possibility of pneumobilia secondary to blunt abdominal trauma was studied. Retrospectively, 73 cases, underwent a whole-body PMCT prior to autopsy. These were divided into four groups: penetrating trauma (20 gunshot cases, 13 stabbing cases), blunt abdominal trauma (20 cases) and a control group of 20 non-trauma cases. Exclusion criteria were visible signs of decomposition. Each group was screened for gas accumulations in the vascular system, internal organs, soft tissues and body cavities. Gas accumulations were present in 98% of the trauma cases, compared to 80% of the control group. The most affected structures and/or organs in the trauma group were soft tissues, vessels and the liver. In most cases of the trauma group gas was associated with open injuries and lacerations of vessels. Furthermore, in the gunshot group gas was frequently seen in the intracranial cavity. Pneumobilia occurred in one case of the blunt trauma group; in that control group gas was also seen, but less frequently. Gas accumulation showed a strong association with traumatic events, but even the majority of non-trauma cases showed gas accumulations. Despite the exclusion of cases with visible

decomposition signs, a putrefactive origin of gas was assumed in some cases. Gas accumulations are a frequent finding in PMCT with a higher incidence in (open) trauma cases. Even though a differentiation between putrefactive and traumatic gas accumulations is still difficult, knowledge of the circumstance surrounding the case may help identify the origin of gas.

1857. Geggel, H. S., et al. (1984). "Histology of human conjunctival transplantation." Cornea **3**(1): 11-15.

The technique of conjunctival transplantation has proven very successful in reestablishing an intact ocular surface in patients with severe ocular surface disease in whom conventional treatment has failed. We present follow-up on the histology of the transplanted conjunctival tissue in four alkali-burned patients who underwent penetrating keratoplasty 3-28 months following conjunctival transplantation. The corneal button was re-epithelialized in all patients. The fate of the transplanted tissue agreed with experimental observations made in the rabbit model, i.e., under areas of vascularization and inflammation, the transplanted tissue resembled conjunctiva with numerous goblet cells and 3-4 cell layers of nonkeratinized, stratified epithelium. In one patient, a definite "transition zone" from conjunctival to corneal appearing epithelium was seen in an area with minimal inflammation and vascularization, again confirming the animal results showing that transdifferentiation of conjunctival to corneal epithelium can occur.

1858. Geisenberger, D., et al. (2020). "The punched-out tissue complex (skin-bone "imprimatum") in shots from captive-bolt guns: does it act as a secondary projectile?" International journal of legal medicine **134**(3): 1095-1102.

From the first half of the twentieth century to the present day, injuries and fatalities from captive-bolt livestock stunners are a major topic in forensic medicine. The vast majority of cases account for suicides with the frontal, temporal, parietal, and occipital regions being the most common sites of entrance (in descending order of frequency). Due to the limited length of the bolt, the corresponding wound channel within the braincase is only several centimeters long. It has been a controversial subject for a long time, whether the skin-bone complex punched out by the conically grooved end of the steel rod may act as a "secondary projectile" being propelled beyond the actual path of the bolt. To answer this question, experimental shots from various types of captive bolt-guns were fired to simulants. Video-documentation employing a high-speed motion camera showed that the punched-out pieces of skin and bone did not move further than the bolt. Thus, a secondary extension of the total wound channel could not be observed. However, the suction effect caused by the bolt's rearward movement may induce a slight retrograde displacement of the skin-bone complex.

1860. Gekeler, F., et al. (2005). "Intraconal grease-gun injury: a therapeutic dilemma." Ophthalmic plastic and reconstructive surgery **21**(5): 393-395.

The case of a 31-year-old man with an accidental grease-gun injury to his left orbital region is presented. CT and MRI showed a well-delineated intraconal cyst in the superior aspect of the left orbit surrounded by a significant inflammatory response. The patient was followed for 11 months. Diplopia was not reported at any time, and visual acuity, visual fields, and all other examinations remained normal. Uneventful surgical removal was performed at the patient's request. Histopathologic examination demonstrated a typical picture of lipogranulomatous inflammation. In a review of the accessible literature, only four cases of intraorbital grease-gun injuries were detected; all of them submitted to early surgical removal. We conclude, however, that an intraconal oil/grease cyst can be carefully monitored and--in the absence of symptoms--must not necessarily be removed.

1861. Gelazius, R., et al. (2018). "Self-inflicted face gunshot injuries: two case reports." Stomatologija **20**(1): 32-36.

Self-inflicted gunshot injuries to the head and neck area are challenging cases. Immediate and complex approach is required due to complexity of head and neck anatomy. The extent of injury largely depends on velocity of a rifle and penetrated tissues. Management of these type of patients consist of vital resuscitation, primary wound management, soft and hard tissue reconstruction and rehabilitation. Here we present two cases of self-inflicted gunshot injuries with low and high velocity rifles.

1862. Gelender, H., et al. (1988). "Temporary keratoprosthesis for combined penetrating keratoplasty, pars plana vitrectomy, and repair of retinal detachment." Ophthalmology **95**(7): 897-901.

The Landers-Foulks temporary keratoprosthesis was used to combine penetrating keratoplasty, pars plana vitrectomy, and scleral buckling in the management of 13 eyes with opaque cornea and posterior segment abnormalities. In seven cases, trauma precipitated the ocular disease. Complications of cataract surgery resulted in anterior and posterior segment pathology in six cases. The corneal graft was initially clear in all cases. However, corneal edema complicated phthisis bulbi in four cases and followed homograft reaction in two cases. Eight eyes with retinal detachment (RD) preoperatively were successfully reattached. In five eyes, the retina redetached as these eyes became phthisical. Visual function improved in six cases. In general, eyes with a history of trauma had a much poorer outcome than did eyes with anterior and posterior segment problems related to previous cataract surgery.

1863. Gelesko, S., et al. (2011). "Subcranial navigation-assisted repair of frontobasal skull fractures." Journal of oral and maxillofacial surgery **69**(9): e37-e38.

Statement of the Problem: The management of frontobasar fractures with orbital roof involvement has historically been transcranial, with multiple potential complications including brain injury, significant bleeding, and poor esthetic outcomes. The primary objective of this retrospective cohort study was to determine whether displaced frontobasal skull fractures involving the orbital roof may be safely and successfully repaired via a navigation-assisted transorbital approach. The secondary objective was to review the prevalence, management, and clinical outcomes of patients treated over the past 10 years at Legacy Emanuel Hospital (LEH) in Portland, OR for frontobasal skull fractures. Materials and Methods: A retrospective chart review of all patients with frontobasal skull fractures presenting to a level 1 trauma center from 2001-2011 were reviewed. Patients were identified using the Legacy Emanuel Trauma Registry. Patients with displaced frontobasal fractures, both pure and impure, involving the orbital roof, with dural embarrassment, who were treated via a subcranial, intraorbital, navigation-assisted approach were included in the study cohort. Patients who died within 24 hours of admission and who had significant brain injury were excluded from the study. Fractures were classified utilizing the Manson frontobasal fracture anatomic classification system. All patients in the study cohort underwent transorbital dural repair, fracture reduction, and plate stabilization of fractures. Normalization of orbital volumes was confirmed using intraoperative CT navigation software. Patients in the comparison group: those treated without navigation, those who had concomitant displaced frontal sinus fractures, disruption of the nasofrontal recess, and/or frontal sinus outflow obstruction underwent transcranial orbital roof repair and cranialization of the frontal sinus. The study cohort was compared to the comparison group, patients treated with traditional methods, on the basis of mean hospital days of stay, minor complications, and major complications. Data Analysis: Data were analyzed using descriptive statistics; major and minor complications were defined and analyzed. Results: Data were obtained from 800 subjects treated at LEH from 2001-2011 for frontobasal skull fractures, identified using the LEH Trauma Registry. Seven patients with displaced frontobasal fractures involving the orbital roof who were treated via a navigation-assisted transorbital approach were included in the study cohort. Patients were mostly male (57%), and ages ranged from 16 to 47 years. The minor complication rate was similar between the study cohort and the comparison group. Only one major complication was identified in the study group, pneumocephalus, requiring an additional operation via a transcranial approach. Conclusions: Subcranial, navigation-assisted approaches to frontobasal skull fractures, with and without dural embarrassment, has efficacy for carefully selected patients and may obviate the need for conventional open procedures in patients without frontal sinus outflow obstruction.

1864. Gelesko, S., et al. (2013). "A protocol for computer planning and intraoperative imaging as an aid to reconstruction of gunshot wounds to the face." Journal of oral and maxillofacial surgery **71**(9): e7-e8.

Problem: Facial gunshot wounds result in extensive soft and hard tissue loss. Computer-aided surgical simulation has been described as an aid in the reconstruction of complex cranio-maxillofacial deformities, incorporating the creation of guide stents, cutting guides, and models, as well as use of intraoperative imaging to facilitate transfer of the virtual plan to the patient.1,2 There are currently no guidelines for utilizing computer planning and intraoperative imaging in comprehensive reconstruction for patients with severe post-traumatic hard and soft tissue loss. The purpose of this investigation is to review our experience with computer-aided surgery in the setting of gunshot wounds to the face and propose a treatment protocol. Materials and Methods: Between January 2009 and March 2013, nine patients

with complex, avulsive, facial gunshot wounds were managed according to a protocol utilizing computer-aided design/computer-aided manufacturing (CAD/CAM) software. The virtual plan was transferred to the patient via a combination of cutting guides, guide stents, and intraoperative navigation. Accurate placement of implants, bone grafts, and composite tissue free flaps was confirmed with intraoperative computerized tomography (CT). The protocol involves a staged approach to surgical reconstruction, beginning with: 1) damage/hemorrhage control, airway stabilization, and maxillo-mandibular stabilization, as indicated; 2) debridement of non-viable bone and soft tissue; 3) virtual reconstruction using commercially available craniomaxillofacial surgical simulation software, and “back-conversion” of virtual plan into navigation system; 4) navigation-assisted reconstruction of midfacial skeletal anatomy; 5) computer-aided oro-mandibular reconstruction with or without microvascular free tissue transfer using custom guide stents and cutting guides; 6) navigation- assisted, computer-aided palatomaxillary reconstruction with microvascular free tissue transfer using cutting guides and guide stents as indicated; 7) navigation-assisted reconstruction of the internal orbit; and 8) confirmation of accurate reconstruction using intraoperative CT imaging. Data Analysis: Data analysis for this retrospective case series is limited to descriptive statistics obtained via chart review. Subjective comparison of the computer- assisted presurgical plan to the postoperative CT scan was completed intraoperatively. Jaw position, facial projection, separation of the nose and mouth, and oral competence was evaluated postoperatively at least one month after surgery. Results: All nine patients had severe disruption of the orbits, midface and mandible, with massive hard and soft tissue avulsion and oral-nasal communication. The computer- assisted surgery was successfully implemented in all patients and proved to be a useful adjunct for: the restoration of orbital volume, facial projection and symmetry; the inset of composite tissue free flaps, and the facilitation of dental implant supported prosthetic rehabilitation. Fibular free flaps were utilized to immediately reconstruct the maxilla and mandible in six patients, facilitating orthognathic jaw position, favorable facial projection, separation of the nose and mouth, and oral competence. The remaining patients were treated without microvascular free tissue transfer, but the virtual planning, pre-bent reconstruction plates, and intraoperative imaging significantly aided accurate reconstruction. Intraoperative CT scans facilitated recognition of minor inaccuracies in orbital plate placement in two patients, the position of which was corrected prior to leaving the operating room. Conclusion: Computer-aided presurgical planning, custom cutting guides and guide stents, and intraoperative imaging have the potential to favorably affect the functional and aesthetic outcomes of patients with severe facial injuries resulting from gunshot wounds.

1865. Geller, E., et al. (1997). "Head injuries in children from plastic hairbeads." Pediatric radiology **27**(10): 790-793.

BACKGROUND: Plastic hairbeads are often worn as decorative hair fasteners by children. Serious, penetrating head injuries may result from their use and have been observed in some children following a fall., OBJECTIVE: The objective of this report is to describe the imaging findings in children who have sustained head injury while wearing plastic hairbeads., MATERIALS AND METHODS: Three children with significant head injuries resulting from embedded hairbeads are described. Three additional cases of minor head injury reported to the Consumer Product Safety Commission are summarized., RESULTS: One child sustained a minimally depressed skull fracture without brain injury. The second child required surgical repair of a depressed skull fracture complicated by a parenchymal hemorrhage and dural tear. A third child required surgical evacuation of an organized, liquefied epidural hematoma 2 weeks after an initial evaluation at an outside emergency room., CONCLUSION: Children wearing plastic hairbeads are at risk for severe head injury following a fall. Caution must accompany their use.

1866. Gellis, M. B. (1983). "Massive craniofacial injury: initial treatment and methods of reconstruction." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **41**(9): 605-608.

A patient with a massive craniofacial injury is presented to illustrate useful flaps that may be used in the reconstruction of this type of injury. Initial management, consisting of basic life support, is indicated, because many patients who appear to be unsalvageable may be successfully restored to an active, productive life. Reconstruction of soft-tissue deficits was accomplished using the forehead and deltopectoral flaps. Although other methods of reconstruction may be used, the forehead and deltopectoral flaps remain among the more reliable flaps to restore thin lining to mucosal and external skin surfaces where bulky tissues are not desired.

1867. Gelston, C. D., et al. (2005). "Orbital foreign body masquerading as conjunctival melanoma 60 years after injury." Clinical & experimental ophthalmology **33**(6): 661-663.

A 74-year-old man presented with a 6-month history of a pigmented conjunctival lesion on his left eye. The lesion was initially suspicious for conjunctival melanoma. The patient admitted to a remote history of trauma from a airgun pellet over 60 years ago. Anterior examination revealed a 6 x 6 mm pigmented left conjunctival lesion and B-scan of the lesion was suggestive of a retained orbital foreign body. The lesion was removed through a transcaruncular medial orbitomy and pathology showed a retained orbital foreign body. A newly pigmented conjunctival lesion although initially concerning for melanoma represented a retained orbital body that surfaced many years after the initial orbital trauma.

1868. Gembitskii, E. V., et al. (1996). "[Pulmonary complications in severe combined craniocerebral trauma (their pathogenesis, clinical picture, diagnosis and treatment)]." Legochnye oslozhneniia pri tiazheloi sochetannoi cherepno-mozgovoi travme (patogenez, klinika, diagnostika, lechenie). **74**(2): 12-16.

Within 1979-1989 the authors treated 26 wounded soldiers and officers with brain injury inflicted by mine explosion. 5 patients were in severe condition, 18 in extremely grave and 3 in critical condition. The patients had concomitant blast injuries and contusions. Pulmonary complications observed in such patients compused to DIC and respiratory distress syndromes running in the presence of marked metabolic disorders, hypoxia and intoxication. It is thought important that conservative therapy of respiratory disorders in patients with brain traumas were not constricted with correction of bronchial obstruction. The additional intensive treatment of the above syndromes is needed including extracorporeal detoxication (plasmapheresis) and hyperbaric oxygenation.

1869. Gennari, T. D. and M. S. Koizumi (1995). "[Determination of the trauma severity level]." Determinacao do nivel de gravidade do trauma. **29**(5): 333-341.

The severity of traumas in hospitalized patients was characterized by means of the Injury Severity Score (ISS) was studied prospectively. One hundred trauma patients hospitalized in a trauma referral health facility located in S. Paulo, Brazil, were analyzed. Of the total number of patients, 68 had blunt trauma and 32 penetrating trauma. As to ISS, it was discovered that 53.0% of the blunt trauma patients had mild trauma (ISS 1-15), 29.4% moderate trauma (ISS 16-24), and 17.6% showed severe trauma (ISS 25); 34.4% of the penetrating trauma patients had mild trauma, 18.7% moderate trauma and 46.9% severe trauma. The mean and standard deviations relating to the ISS of blut and penetrating trauma patients were, respectively, 14.9 +/- 8.1 and 20.8 +/- 11.0; the respective mortality rates were of 11.8% and 12.5%.

1870. Gentile, R. C., et al. (1996). "Diagnosis of traumatic cyclodialysis by ultrasound biomicroscopy." Ophthalmic surgery and lasers **27**(2): 97-105.

BACKGROUND AND OBJECTIVE: To evaluate the ability of high-frequency ultrasound biomicroscopy to diagnose traumatic cyclodialyses not evident on clinical examination., PATIENTS AND METHODS: Six eyes to six patients with posttraumatic hypotony and/or shallow anterior chamber and suspected cyclodialysis clefts were examined with slit-lamp biomicroscopy, gonioscopy, B-scan ultrasonography, and ultrasound biomicroscopy. Ultrasound biomicroscopy provided high resolution of cross-sectional images of the anterior chamber angle, posterior chamber, and anterior uveal tissue., RESULTS: Ultrasound biomicroscopy confirmed the disinsertion of the ciliary body from the scleral spur and associated ciliary body detachment in all eyes. Gonioscopy failed to demonstrate a cyclodialysis cleft in five eyes because of hyphema (two eyes) and abnormal iris architecture (related to trauma) precluding visualization of the angle recess (three eyes). Using information from ultrasound biomicroscopy imagining, one patient underwent a ciliary body reattachment procedure and repair of the cyclodialysis cleft., CONCLUSION: Ultrasound biomicroscopy is a noninvasive method that can accurately diagnose the presence of traumatic cyclodialyses and can aid in surgical management. It is particularly useful in the presence of hazy media, hypotony, and/or abnormal anterior segment anatomy.

1871. George, D. D., et al. (2022). "Meningitis due to intra-abdominal cerebrospinal fluid fistula following gunshot wound successfully treated with antibiotics and blood patch: A case report and literature review." Surgical neurology international **13**.

Background: Penetrating spinal cord injury (PSCI) represents an average of 5.5% of all SCIs among civilians in the United States. The formation of a cerebrospinal fluid (CSF) fistula following PSCI occurs in approximately 9% of cases.

Intra-abdominal CSF fistulae are rarely reported. Case Description: We present the case of a 28-year-old Caucasian female who suffered a single gunshot wound to the abdomen with a missile fragment lodged within the left L2 pedicle and transverse process without obvious canal compromise. The patient developed bacterial meningitis 13 days after the initial injury, treated with IV antibiotics. CT myelogram demonstrated intra-abdominal ventral CSF fistula from the left L2–L3 neuroforamen. The patient was successfully treated with fluoroscopy-guided dorsal autologous blood patch graft. Conclusion: This case highlights a rare complication of PSCI successfully managed with the use of a blood patch graft.

1872. George, E. D. and T. F. Dagi (1995). "Military penetrating craniocerebral injuries. Applications to civilian triage and management." Neurosurgery clinics of North America **6**(4): 753-759.

Although facilities at many civilian centers far exceed those historically available to military neurosurgeons in the field, the principles derived from combat injuries continue to apply. It is hoped that there may be differences in salvageability at the margin owing to the availability of more sophisticated imaging and critical care monitoring techniques, neuroanesthesia, and the advent of possible pharmacologic neural salvage agents.

1873. George, M. and J. Round (2006). "An Eiffel penetrating head injury." Archives of disease in childhood **91**(5): 416.

1874. George, R., et al. (2019). "Coil Embolization of the Internal Carotid Artery in Patient with Retained Transcranial Knife." World neurosurgery **127**: 237-240.

BACKGROUND: We describe endovascular coil embolization of the internal carotid artery before removing a retained knife blade partially occluding the lacerum segment of the internal carotid artery., CASE DESCRIPTION: A 21-year-old male presented to the emergency department with a retained transcranial knife after sustaining a stab to the left temporal scalp. He was hemodynamically stable and neurologically intact on presentation. Computed tomography angiography followed by digital subtraction angiography revealed narrowing of the lacerum segment of the left internal carotid artery by the tip of the knife blade with adequate blood flow from the contralateral internal carotid artery. Embolization and occlusion of the internal carotid artery proximal and distal to the knife tip were performed. The patient was transferred to the neurosurgical operating room for extraction of the knife. A repeat left carotid artery angiogram post knife extraction showed no displacement of the coils and no extravasation of contrast. Follow-up imaging confirmed a good outcome., CONCLUSIONS: A staged approach of digital subtraction angiography and endovascular therapy followed by surgical treatment is a safe and effective management strategy for patients presenting with a retained transcranial knife and suspected vascular injury.

1875. Gepp, R. and M. Quiroga (2012). "Spinal cord trauma in children: Clinical features." Child's Nervous System **28**(5): 774.

Introduction: Spinal Cord Injury (SCI) is a common cause of morbidity and mortality in children. This study analyzed the clinical characteristics of SCI in children 10 years of age and younger, forms of prevention, and ways to improve treatment. Methods: Ninety-three children were reviewed between 1996 and 2009. The variables studied were: type, age, cause, neurological level, association between SCI and TBI, arthrodesis surgery, time lapsed between trauma and diagnosis, and causes of death. The statistical evaluations were done using the Chi Square andANOVAscales, in the SPSS program version 11.0. Results: The most common cause of the spinal cord injury was automobile accidents. Getting run over by a car was second (29.1%), followed by firearm injuries (11.8%). The thoracic spine was the most commonly impacted area. Evaluation showed that 83.9% had complete neurological injury. Associated TBI was present in 35.5% of the cases. Only 21.5% of the patients required arthrodesis of the spine. In 31.2% of the cases, myelopathy was not diagnosed at the time of the accident. There was no statistical correlation between TBI and a delayed diagnosis of SCI ($p \geq 0.231$). Five children (5.4%) died during the followup period. Discussion: The study showed that the cause of the trauma is associated with motricity in children and that prevention is important. Trauma from automobile accidents was a main cause, and, in older children, firearm injuries are an important risk. Spinal cord injury was not always diagnosed in children at the time of accident. Educating family members and training emergency teams to adequately treat children with multiple traumas are measures that can help reduce the incidence of SCIs and neurological damage.

1876. Gerard, M., et al. (1999). "[Surgical technique of limbal autotransplantation in severe and recent eye burns]." Technique chirurgicale de l'autotransplantation limbique dans les brulures oculaires graves et recentes. **22**(4): 502-506.

We report our surgical technique of limbal autograft for recent severe ocular burns. Our procedure is a modified Kenyon and Tseng technique. We discuss our main observations when using this procedure for serious ocular burns which demonstrate the physical signs best indicating surgery, the limbal region to be used, and optimal postoperative follow-up.

1877. Gerdin, W., et al. (2022). "A pilot multicentre cluster randomised trial to compare the effect of trauma life support training programmes on patient and provider outcomes." BMJ open **12**(4): e057504.

Introduction Trauma accounts for nearly 10% of the global burden of disease. Several trauma life support programmes aim to improve trauma outcomes. There is no evidence from controlled trials to show the effect of these programmes on patient outcomes. We describe the protocol of a pilot study that aims to assess the feasibility of conducting a cluster randomised controlled trial comparing advanced trauma life support (ATLS) and primary trauma care (PTC) with standard care. Methods and analysis We will pilot a pragmatic three-armed parallel, cluster randomised controlled trial in India, where neither of these programmes are routinely taught. We will recruit tertiary hospitals and include trauma patients and residents managing these patients. Two hospitals will be randomised to ATLS, two to PTC and two to standard care. The primary outcome will be all-cause mortality at 30 days from the time of arrival to the emergency department. Our secondary outcomes will include patient, provider and process measures. All outcomes except time-to-event outcomes will be measured both as final values as well as change from baseline. We will compare outcomes in three combinations of trial arms: ATLS versus PTC, ATLS versus standard care and PTC versus standard care using absolute and relative differences along with associated CIs. We will conduct subgroup analyses across the clinical subgroups men, women, blunt multisystem trauma, penetrating trauma, shock, severe traumatic brain injury and elderly. In parallel to the pilot study, we will conduct community consultations to inform the planning of the full-scale trial. Ethics and dissemination We will apply for ethics approvals to the local institutional review board in each hospital. The protocol will be published to Clinical Trials Registry - India and ClinicalTrials.gov. The results will be published and the anonymised data and code for analysis will be released publicly.

1878. Gerlach, K. (2008). "[Physical and sexual child abuse]." Kindliche Opfer sexueller und korperlicher Gewalt. **65**(7): 381-388.

Child abuse may result in dramatic short and longtime damage of children's physical and emotional well being. This underscores the clinician's special responsibility to contribute a sound professional and scientific approach to the multiprofessional diagnosis and intervention in suspected child abuse cases. The approach is to correlate the probability of a given finding with the history and comparing it to biomechanical principles. Of concern are especially all serious injuries with an alleged trivial or inadequate for age mechanism, missing, vague or changing patterns of explanation, injuries of different age, delay of medical care and allegations by independent observers or even the child. Exact documentation of all medical examinations is the basis of any forensic expertise if child abuse is to be considered. This paper ist dealing with morhological findings following various kinds of violence which can often be observed in connection with child abuse, as well as the interpretation of characteristic patterns of findings. Furthermore, practicable procedures after diagnosing child abuse ar being discussed on the basis of legal terms.

1879. Gerold, K. B. (1991). "Cranial gunshot wounds best managed in specialized trauma centers." The Journal of the American Osteopathic Association **91**(5): 425-430.

1880. Gervaise, A., et al. (2010). "[Imaging of cranial gunshot traumas]." Imagerie des traumatismes craniens par arme a feu. **91**(11 Pt 1): 1113-1120.

Cranial traumas from gunshot wounds are characterised by the impact of a high velocity projectile. There are therefore serious, life threatening traumas. CT Scan is essential in the emergency setting for initial evaluation of traumatic bone and parenchymatous injuries to determine the indication for neurosurgery and appropriate medical

management. In case of survival, CT Scan and MRI can be used to monitor progress and any possible complications, in particular vascular or infectious complications which are specific to this type of injury.

1881. Gervasio, K. A., et al. (2015). "Prognostic Value of Ocular Trauma Scores in Patients With Combined Open Globe Injuries and Facial Fractures." American journal of ophthalmology **160**(5): 882-888.e882.

PURPOSE: To assess the prognostic value of the Ocular Trauma Score in patients with combined open globe injuries and facial fractures., DESIGN: Retrospective cohort study., METHODS: A comprehensive chart review was conducted on 25 patients (28 eyes) identified from the Elmhurst City Hospital Trauma Registry between January 1, 2000 and June 30, 2012. Elmhurst City Hospital is a level 1 trauma center located in Elmhurst, New York, USA., RESULTS: Average age was 52 (range 18-88) and patients were predominantly male (84%). The majority of patients had an Ocular Trauma Score of 1 (87.5%), and of these patients, 76% and 14% had final visual acuities of no light perception (NLP) and light perception/hand motion (LP/HM), respectively. These corresponded to 74% and 15% predicted by the original Ocular Trauma Score guidelines (100% sensitive and 100% specific). Ocular Trauma Score of 1 was associated with zone 3 eye wound location (P = .02). Independent of Ocular Trauma Score, initial visual acuity and frontal bone fractures were predictive of NLP (P = .006 and P = .047). Nonblindness was associated with nasal bone fractures (P = .047)., CONCLUSION: This study validates the use of the Ocular Trauma Score in patients with combined facial fracture and open globe injury. The presence of facial fractures does not appear to influence visual prognosis for open globe injuries with an Ocular Trauma Score of 1. In the absence of data to calculate a full Ocular Trauma Score, initial visual acuity was the strongest predictor of final visual outcome.

1882. Gewertz, B. L., et al. (1980). "Management of penetrating injuries of the internal carotid artery at the base of the skull utilizing extracranial-intracranial bypass." The Journal of trauma **20**(5): 365-369.

Penetrating injuries of the internal carotid artery at the base of the skull often require permanent or transient occlusion of the injured vessel during repair. Extracranial-intracranial bypass (EC-IC) was employed in five patients to insure adequate cerebral perfusion during cervical exploration. Preoperative neurologic deficits were noted in three patients; two demonstrated complete reversal following EC-IC. This experience suggests that EC-IC can maintain adequate cerebral perfusion during repair of internal carotid injuries and allow selective revascularization of patients with neurologic deficit and carotid occlusion.

1883. Ghadersohi, S., et al. (2017). "Presentation, workup, and management of penetrating transorbital and transnasal injuries: A case report and systematic review." American journal of rhinology & allergy **31**(2): 29-34.

BACKGROUND: A foreign body (FB) penetrating intracranially after passing transorbitally or transnasally is a rare occurrence. However, otolaryngologists are increasingly being asked to participate in the care of these patients for both endoscopic removal of the object and repair of any skull base defects., OBJECTIVE: To assess the presentation, workup, and management of transnasal or transorbital penetrating FB injury., METHODS: Systematic review of the presentation, workup, and management of transnasal or transorbital penetrating FB injury; plus, a case report of a 53-year-old woman with a transorbital penetrating rose bush branch. We searched medical literature data bases, which resulted in 215 total titles, which were then narrowed based on inclusion and exclusion criteria., RESULTS: Thirty-five cases of transorbital or transnasal low-velocity trauma that involved the paranasal sinuses were reviewed from 33 articles. The average age was 30 years, 40% of the objects were made of wood. Fifty-seven percent of the cases were transorbital, whereas 43% were transnasal. Forty-six percent of the surgical interventions were completed endoscopically or with endoscopic assistance. Complications of injury were common, with 66% of patients experiencing cerebrospinal fluid leaks; 23%, permanent blindness; 17%, meningitis; 14%, ophthalmoplegia; 9%, decreased visual acuity; and 3%, brain abscess. Our patient presented with a traumatic cerebrospinal fluid leak, and recovered well after transorbital and endoscopic removal of the branch, skull base repair, and a prolonged course of antibiotics and antifungal medications., CONCLUSIONS: Transnasal and transorbital penetrating FB injuries are a relatively uncommon occurrence but when they do occur require rapid workup and interdisciplinary management to prevent acute and delayed complications.

1884. Ghoraba, H. H., et al. (2021). "Long-Term Outcome of Pars Plana Vitrectomy for Retained Posterior Segment Intraocular Foreign Body Secondary to Gunshot Injury." Clinical ophthalmology (Auckland, N.Z.) **15**: 1897-1904.

PURPOSE: To report the long-term outcome of pars plana vitrectomy (PPV) for management of retained posterior segment intraocular foreign body (IOFB) secondary to gunshot injury., METHODS: This is a retrospective interventional case series including consecutive patients who had PPV for retained posterior segment IOFB secondary to gunshot injury. Main outcome measures were final best-corrected visual acuity (BCVA), long-term globe survival and detection of complications. Spearman correlation analyzed relationships between numerical data. Kruskal-Wallis test compared differences in initial BCVA and final BCVA across variables. Categorical variables were tested using Chi square or Fisher's exact test. P value is significant at 0.05., RESULTS: The study included 103 eyes of 103 patients. Mean baseline BCVA was 0.01 decimal unit (2 logMAR). Mean duration from primary repair to PPV was 3 weeks. Mean duration of post-operative follow-up was 60 months. Mean final BCVA was 0.04 decimal unit (1.3 logMAR), p 0.001. Post-operatively, BCVA improved in 58.2% of patients. Nineteen patients (18%) gained >=2 lines of vision, and 15 patients (14.5%) achieved final BCVA of 0.4 decimal unit (logMAR 0.4). All complications were related to the original injury. These included macular scar (19%), macular pucker (6%), recurrent retinal detachment (4%), subretinal fibrosis (3%), consecutive optic atrophy (3%), and PVR (3%). Phthisis bulbi or sympathetic ophthalmia did not develop in any case., CONCLUSION: PPV for removal of IOFB caused by gunshot injury yielded long-term favorable functional outcome with excellent globe survival. Poor initial BCVA, location of IOFB in the posterior pole, associated lens injury and retinal detachment are significant adverse prognostic factors for final BCVA but not for globe survival.

1885. Ghorbani, M., et al. (2020). "Successful endoluminal reconstruction of a pseudoaneurysm of the internal carotid artery following a transorbital stab injury." Clinical neurology and neurosurgery **194**: 105838.

Traumatic penetrating injuries to the internal carotid artery (ICA) resulting in the formation of a traumatic pseudoaneurysm are potentially devastating injuries. Previously treatment included, open surgical occlusion of the affected vessel or endovascular embolization. However, with the advent of flow diverter stents, endoluminal reconstruction has become a viable treatment option. In this case report we describe the successful managment of an ICA pseudoaneurysm due to a transorbital stab injury. Endoluminal reconstruction in a traumatic aneurysm is a feasible option. Considering the risk of hemorrhagic complications due to dual antiplatelet therapy required after flow diverter placement, this treatment should only be chosen if insufficient collateral supply is found and occlusion of the affected vessel is not a viable option.

1886. Giacino, J., et al. (2016). "Behavioral and functional recovery in patients with prolonged traumatic disorders of consciousness." Archives of physical medicine and rehabilitation **97**(10): e3.

Research Objectives: To determine the incidence of recovery of pre-selected behavioral "benchmarks" during a 6-week period of inpatient rehabilitation. To establish the relationship between behavioral recovery and functional outcome ratings on the Disability Rating Scale (DRS). To compare behavioral and functional recovery between patients in MCS+, MCS- and VS. Design: Post-hoc analysis of subjects enrolled in the placebo arm of a previously-completed, prospective multicenter randomized-controlled trial of amantadine hydrochloride. We tracked the recovery of six behavioral benchmarks drawn from the Coma Recovery Scale e Revised (CRS-R) over a 6-week period during inpatient rehabilitation, investigated the relationship between the number of benchmarks recovered and the level of function attained on the Disability Rating Scale (DRS) by week 6 and compared differences in outcome between participants in VS, MCS- and MCS+ at the 6-week follow-up. Setting: Eleven rehabilitation hospitals in the United States and Europe with high admission rates for patients with post-traumatic disorders of consciousness. Participants: Subjects were 97 consecutively-enrolled patients between the ages of 16 e 65 who suffered a non-penetrating TBI 4 to 16 weeks prior to enrollment, and were receiving usual and customary inpatient physical, occupational and speech therapy services. All psychoactive medications were withdrawn prior to enrollment and subsequent use discouraged. At enrollment, 33 participants were in a vegetative state (VS) and 64 were in a minimally conscious state (MCS) as defined by a DRS score > 11 and absence of consistent command-following and reliable communication on the CRS-R. The MCS group was stratified further into MCS+ and MCS- subgroups, based on the presence or absence of behavioral signs of language comprehension or expression as defined by the CRS-R. Patients with pre-injury CNS-related disability, medical instability, pregnancy, significant renal disease, > 1 seizure in the prior month, prior amantadine treatment or allergy to amantadine were excluded. The protocol was approved by the institutional review boards of all participating sites and written informed consent obtained from each patient's legally authorized representative. The trial from which these data were extracted was registered with the ClinicalTrials.gov Protocol Registration System (ID# NCT00970944) and

independent oversight provided by an external Data Safety Monitoring Board. Interventions: Not applicable. Main Outcome Measure(s): Primary- Coma Recovery Scale e Revised. Secondary- Disability Rating Scale. All DRS and CRS-R assessments were conducted blindly. Results: The incidence of recovery of each of the six behavioral benchmarks was significantly higher for participants in MCS (range: 40% for reliable yes-no communication to 57% for object recognition and intelligible speech) relative to those in VS (range: 11% for reliable communication to 20% for consistent command-following). By the end of week 6, 20% of the entire sample had recovered all six behavioral benchmarks. Among the remainder, 8.42% recovered five benchmarks, 5.26% recovered four, 4.21% recovered three, 7.37% recovered two, 12.63% recovered one and 42.11% recovered none. In the MCS subgroup, 25% of participants recovered all 6 benchmarks and 37% recovered at least 5. In comparison, 11% of the VS subgroup recovered all 6 benchmarks and 14% recovered at least 5 (Mantel-Haenszel Chi-Square: 13.9374, P = 0.0002). Approximately 74% of participants who achieved all 6 benchmarks progressed to the moderately severe to severe disability range on the DRS. Conversely, nearly 68% of participants who failed to recover any benchmarks remained in the vegetative to extreme vegetative range. The median DRS score at week 6 was 11 (moderately-severe) for participants who achieved all six benchmarks, 18 for those with three (severe to extremely severe) and 23 (vegetative to extreme vegetative state) for those with none. Regression analysis demonstrated a linear relationship between the number of enchmarks recovered by week 6 and degree of residual disability on the DRS (Adjusted R-square = 0.6381; P < 0.0001). For each benchmark detected, the DRS score decreased (i.e., improved) by 1.7 points on average. while nearly half of the MCS+ subgroup (46.2%) recovered all 6 benchmarks, approximately 1 in 10 subjects in the MCS- (8.82%) and VS (11.4%) subgroups did so (see table 5). Degree of disability at week 6 indexed by the mean DRS differed significantly in favor of the MCS+ subgroup (MCS+ = 12; MCS- = 17; VS = 23; Kruskal-Wallis Test = P<0.001), as did the percentage of participants who emerged from MCS (MCS+ = 73.1%; MCS- = 38.2%; VS = 14.3%; chi2MH = 21.20, 1 d.f., P < 0.0001). Conclusions: Significant functional recovery is common in patients with prolonged traumatic DoC following discharge from the intensive care setting. Patients in MCS with evidence of language function are most likely to recover other high-level behaviors linked to improvement in functional status. These findings should be considered in the context of early decision-making in the ICU concerning intensity of care and indications for rehabilitative treatment.

1887. Gianelli Castiglione, A., et al. (1998). "Intracranial insertion of a nasogastric tube in a case of homicidal head trauma." The American journal of forensic medicine and pathology **19**(4): 329-334.

A case of accidental intracranial penetration of a 29-cm-long portion of nasogastric tube (NGT) in a 27-year-old female victim of a severe homicidal skull and brain trauma is reported. Accidental penetration of the NGT occurred through a large fracture of the ethmoid lamina cribrosa. In addition to a systematic review of previously reported cases, circumstantial data, clinical aspects, and autopsy data have been analyzed to draw medicolegal considerations concerning the connection between death and insertion of an NGT, which may also contribute to the ascertaining of any possible professional responsibility of medical staff, in a case fraught with numerous legal complications.

1888. Giannakopoulou, M., et al. (2000). "NMDA receptor mediated changes in IGF-II gene expression in the rat brain after injury and the possible role of nitric oxide." Neuropathology and applied neurobiology **26**(6): 513-521.

This study was undertaken in order to investigate the role of insulin-like growth factor (IGF)-II, c-fos, N-methyl-D-aspartate (NMDA) receptors, and nNOS in the cellular processes following a penetrating brain injury. IGF-II mRNA levels, as determined by Northern analysis, were decreased at 4, 8, and 24 h after brain injury, in the lesioned, compared to the contralateral intact hemisphere. Forty-eight and 72 h after the injury, there was no difference between the lesioned and the contralateral intact hemisphere in IGF-II mRNA levels. c-fos mRNA levels followed a parallel, but opposite course: They were increased at 4, 8 and 24 h after the injury, while at 48 and 72 h c-fos mRNA levels in the lesioned hemisphere did not differ from those in the intact. Administration of MK-801 reversed the injury-induced decrease in IGF-II mRNA levels. Administration of MK-801 resulted in an increase in IGF-II mRNA in both the intact and the lesioned hemispheres. Brain injury resulted in an increase in nNOS immunopositive cells in the hippocampal formation, which was detectable at 4 and 12, but not 48 h after the injury. These results suggest that IGF-II, c-fos, NMDA receptors and nNOS are involved in the cellular responses to brain injury.

1889. Giatsidis, G., et al. (2017). "Reflections on a Decade of Face Transplantation." Annals of surgery **265**(4): 841-846.

On November 27, 2005, Isabelle Dinoire underwent the world's first partial face transplant in Amiens (France) after a dog attack had left her face severely disfigured. The abrupt surgical leap found the medical community and society unprepared to deal with the scientific, ethical, and societal implications of a surgical procedure that was striving to transition from sci-fi novels to science. Today, 10 years and over 35 transplants later, public opinion has become accustomed to the concept of "face restoration" through transplantation. However, face transplantation is far from being a safe "routine" surgery and the science behind it is still mostly unknown. Patients and multidisciplinary teams of physicians confront daily medical challenges, life-threatening risks, and personal struggle that only in part come to light. Could (or should) this be the laborious, uncertain, and high-risk trajectory of disruptive medical innovation? Over the last decade, some medical discoveries and surgical advancements in the field have been closely accompanied by partial regulatory frameworks, intense ethical discussions, and meaningful changes in social beliefs across cultures and continents. Yet, a very long way is to come and the questions we still have today greatly outweigh the answers we can offer. Here, we take the chance of the 10-year anniversary of face transplantation to reflect on the path traveled and to look forward to the challenges lying ahead.

1890. Gibikote, S., et al. (2006). "Pneumorrhachis secondary to traumatic pneumomediastinum in a child." Pediatric radiology **36**(7): 711-713.

Pneumorrhachis (air within the spinal canal) is rare, and even more so in the paediatric population. We report a case in a 4-year-old boy that resolved spontaneously on treating the underlying traumatic pneumomediastinum, and discuss the causes, mechanism and implications of this condition.

1891. Giese, A., et al. (2002). "Pattern of injury and clinical prognosis of penetrating craniocerebral trauma from gunshot wounds." Rechtsmedizin **12**(1): 13-23.

Gunshot injuries to the neuro-cranium are relatively rare in western European metropolitan areas. These injuries carry a high mortality and only a fraction of the victims survives till intensive care can be provided at a trauma center. We have analyzed the injury pattern, early complications and the clinical course of 31 patients, which on arrival at the emergency room of the University Hospital Eppendorf, Hamburg, Germany, could be stabilized for further diagnostic imaging procedures and neurosurgical assessment and therapy. The initial neurological performance status and injury pattern diagnosed on initial CT scans, such as bihemispheric injury, intraventricular hematoma, burst fractures of the vault, and severe brain edema were strong negative predictors for a poor clinical outcome. The epidemiology and reasons for these injuries and the spectrum of weapons used are presented.

1892. Giese, A., et al. (2002). "Head injury by gunshots from blank cartridges." Surgical neurology **57**(4): 268-277.

BACKGROUND: Blank cartridge handguns are generally underestimated in their capacity to inflict serious and potentially life threatening injuries. The predominant reasons for these injuries are suicide or suicide attempts, followed by accidental injuries., METHODS: A series of 26 gas gunshots to the neurocranium is presented. The injury pattern relevant to neurosurgical practice is illustrated in a case summary of 7 selected cases and the clinical courses as well as outcomes are presented., RESULTS: The injury pattern demonstrates that the energy density of the gas jet and the high temperatures of the exploding gas volume cause extensive soft tissue injuries. In close-range shots the gas jet takes on physical properties of a projectile. In these injuries impression fractures and dislocation of bone fragments are common., CONCLUSIONS: Gas handguns, contrary to public opinion, are dangerous weapons and may inflict potentially fatal injuries to the neurocranium when fired at close range. These weapons are frequently used in criminal or careless activities predominantly by young males. Extensive CNS injuries including hematomas, subarachnoid hemorrhage, foreign body contamination, and increased intracranial pressure are frequently observed.

1893. Giffen, M. A., Jr., et al. (2018). "Forensic Radiology Pitfalls: CT Imaging in Gunshot Wounds of the Head." Journal of forensic sciences **63**(2): 631-634.

Computed tomography (CT) imaging is increasingly used in emergency departments and trauma services and is being offered as a supplemental tool with autopsy in coroner's and medical examiner's offices throughout the United States. The availability of CT images in lieu of traditional X-rays for medicolegal autopsies may lead to misinterpretation of images for forensic pathologists who are not familiar with these types of images. Forensic pathologists must become

familiar with CT imaging, the basis of CT image formation and how to interpret CT images appropriately. We highlight potential pitfalls of CT image interpretation through two cases of fatal gunshot wounds of the head. Antemortem CT imaging available at the time of autopsy led to discrepancy between the initial image findings and the autopsy due to inexperienced manipulation of the images. With appropriate understanding of CT image interpretation and manipulation, forensic personnel should be able to avoid most sources of misinterpretation. 1897. Gill, Z. A., et al. (2020). "Problems related to prosthetic components seen in amputees of pakistan law enforcement agencies during prosthetic episodes." Rawal Medical Journal **45**(3): 656-660.

Objectives: To identify the common issues r el at ed t o pr ost het i c component s among amputees of law enforcement agencies reporting for fol l ow-up i n Armed Forces Insti tute of Rehabilitation Medicine (AFIRM), Rawalpindi and calculate the life for the frequently changed components. Methodology: It was a cross-sectional descriptive study carried out in AFIRM Rawalpindi from October 2013 to December 2014. Through non-probability consecutive sampling, we included individuals with amputations of any etiology. Information was recorded about the type, side, and etiology of amputation, place of injury, time passed in months since previous consultation, the reasons for follow-up (damaged prosthetic foot, damaged liner, socket problems, accessories problems, and problems with cosmetic gloves and sleeves), and the average life of the frequently changed components. Results: Of 98 individuals (mean age 27±6 years, range: 18-43 years), majority suffered from IED bl ast i nj ur y (n=44, 44. 9%) i n Feder al l y Administered Tribal Areas (FATA) region (n=58, 59.2%). Transtibial amputation (n=78, 79.6%) was the most common level of amputation, with equal percentage for the side of body involved (46 each). The average fol l ow-up t i me f rom t he l ast consultation was 17±15 months (range 2-32 months). The primary prosthetic concerns for the follow-up were regarding prosthetic foot and liner (34 each). The average ti mes after whi ch prosthetic foot and liner were replaced since initial provi si on were 22±10 months (range12-32 months) and 5±3 months (range 2-8 months), respectively. Conclusion: Maximum patients reported with issues related to prosthetic foot and liner. The average life reported for these components was shorter than previous studies.

1898. Gilmour, D. F., et al. (2003). "Trans-orbital intra-cranial air gun injury." European journal of ophthalmology **13**(3): 320-323.

PURPOSE: To describe a case of trans-orbital intra-cranial air gun injury with a discussion on air gun related morbidity and mortality., METHODS: Case report and literature review., RESULTS: The air gun pellet travelled through the orbit without penetrating the globe. It passed into the middle cranial fossa through the superior orbital fissure and lodged in the temporal lobe. The patient was managed conservatively with antibiotics and antiepilectis., CONCLUSIONS: Air gun design has changed in recent years resulting in an increased morbidity and mortality. Stricter legislation on the sale and use of these weapons needs to be implemented.

1899. Gimenez, L. G., et al. (2022). "A review of the genetic epidemiology of preterm birth in a Latin American population." Placenta **122**: 6.

Objetives: Preterm birth (PTB) is considered a complex and heterogeneous trait resulting from the interplay of several genetic and environmental factors. The greatest single risk factor for delivering a preterm neonate is a history of a prior PTB. The role of other proposed predictors such as maternal and/or genetic factors, environment, or synergy or

interaction between these remains unknown. PTB can be categorized by its clinical presentation: idiopathic (PTB-I), premature rupture of membranes (PTB-PPROM), and medically induced (PTB-M). The clinical subtypes PTB-I and PTB-PPROM are together designated spontaneous preterm birth (PTB-S). Given the heterogeneity within clinical subtypes of preterm birth, it is helpful to examine the subtypes separately in terms of etiology and management. In addition, identifying specific characteristics of each clinical subtype is essential to employing effective prevention methods of preterm birth. Results: We found significant differences in epidemiological characteristics of mothers of premature newborns among the different clinical subtypes in a Latin American population. PTB-PPROM represented 37.9% of the sample, PTB-I 36.6%, and PTB-M 25.5%. This distribution was different from that described in the literature. The PTB-I subtype was characterized by younger mothers of lower socioeconomic status, PTB-PPROM was characterized by environmental factors resulting from inflammatory processes, and PTB-M was characterized by increased maternal or fetal risk pregnancies. The main risk factor for PTB-I and PTB-M was to have a prior preterm delivery; however previous spontaneous abortion was not a risk factor, suggesting a reproductive selection mechanism. The characterization of preterm subtypes is important not only to elucidate the heterogeneity in the etio-pathogenesis, but also to implement measures that are more efficient in the treatment of preterm birth. Moreover, we evaluated the associations between specific candidate genes and clinical subtypes of PTB. Twenty-four single-nucleotide polymorphisms (SNPs) were genotyped in 18 candidate genes in 709 infant triads. Of them, 243 were PTB-I, 256 were PTB-PPROM, and 210 were PTB-M. These data were analyzed with a Family-Based Association. It's noteworthy that PTB was nominally associated with rs2272365 in PON1, rs883319 in KCNN3, rs4458044 in CRHR1, and rs610277 in F3. Regarding clinical subtypes analysis, three SNPs were associated with PTB-I (rs2272365 in PON1, rs10178458 in COL4A3, and rs4458044 in CRHR1), rs610277 in F3 was associated with PTB-PPROM, and rs883319 in KCNN3 and rs610277 in F3 were associated with PTB-M. Conclusion: Based on these results, it was possible to identify polymorphisms potentially associated with specific clinical subtypes of PTB in this Latin American population. These results could suggest a specific role of such genes in the mechanisms involved in each clinical subtype.

1900. Ginsberg, L. E., et al. (1993). "CT in penetrating craniocervical injury by wooden foreign bodies: reminder of a pitfall." AJNR. American journal of neuroradiology **14**(4): 892-895.

The authors report three cases of penetrating craniocervical injury by wooden foreign bodies, which were initially hypodense on CT and thought to be air. When these structures were scrutinized with higher window settings, they had a higher attenuation and a unique striated internal architecture which the authors propose may be specific to wood.

1901. Gioia, S., et al. (2014). "Instantaneous death due to transorbital reverse penetration of a screw in an accidental fall: unusual autopsy case report and review of the literature." The American journal of forensic medicine and pathology **35**(1): 15-19.

We present a peculiar autopsy case of a transorbital penetrating head injury, in a male worker, after an accidental fall onto a screw not completely stuck into a wooden board. A 13-cm screw entered the cranium 9.5 cm deep, penetrating with the flat end, a condition defined in literature as "reverse penetration." The death was instantaneous and caused by a neurogenic shock due to injuries to the brain stem and the right cerebellar hemisphere. These injuries, enabled by the length of the screw, are generally described in literature as due to nontransorbital penetrations, frequently associated with posterior entry and a large intracranial injury. The ocular globe has been, furthermore, perfectly preserved thanks to its mobility in the orbit. Even the dynamic of the incident is peculiar because of the stationary nature of the penetrating object, which the victim actively fell on by accident. To the best of our knowledge, the matter is therefore a very peculiar mortal case of transorbital intracranial penetration, whose verified injuries and dynamics are absolutely atypical. The case is now under discussion, and a review of pertinent literature is performed.

1902. Gipe, B. T., et al. (1981). "Delayed cerebral embolization of a shotgun pellet with fatal consequences." The Journal of trauma **21**(4): 326-329.

A case of shotgun pellet embolization to the middle cerebral artery is presented. Embolization occurred approximately 36 hours following successful resuscitation of blood pressure, respirations, and neurologic function in a 21-year-old man who had sustained a massive chest wound. The diagnosis of pellet embolization was made within 8 hours of the onset of neurologic deficits; however, fatal cerebral infarction had occurred before surgery could be

undertaken. Seven similar cases are briefly reviewed and it is concluded that low velocity and low kinetic energy missiles are more likely to embolize, and that left lower extremity injuries are more frequently involved in embolization. In all cases of shotgun trauma to the chest cerebral embolization of pellets should be considered at any sign of neurologic change and skull films obtained. Surgical intervention is necessary before cerebral infarction.

1908. Giri, P. (2018). "Penetrating injury of skull bone : Its a knife!" Journal of neurotrauma **35**(16): A226.

Presenting the experience of two difficult skull base injuries with sharp object ; knife. Both the time young patients and most commonly had been hit from front. First one suffered on the temporal squamous part and got penetration upto sellar region, the second one had on frontal region reaching upto tuberculum sellae. The sharp ragged edges were the main crucial weapon risk factor and the depth and path were the patient related factors while delivering out of the knives. In both the cases, adequate craniotomies were done and releasing of the knieves blades was the most difficult part. Penetration of the dura matter and injury to the cortical substance decide the neurological prognosis of the patients. In both the cases, the dura was pierced sharply and the tracjectory of the knieves were so much luckily safe that both the patients were neurologically intact preop and postop. We didn't come across the deadly complication of meningitis in any case and no postop csf leakage was noted. Both the patients were discharged on 8th day and had nice follow up of one year. There were no delayed complications like wound infection seizures and meningitis. We learned from our cases that penetration tracjectory decides the initial neurological damage and emergency of the situation. The adequacy of the craniotomy helps a lot in delivering the weapon and the complications like meningitis can be taken care with proper antibiotics. We are presenting these cases to share the expierence of operating on knife injury supposedly rare on skull. Literature review showed isolated case reports with knife injury and none of them has operated two cases in a single institute.

1909. Girod, D. A. (2008). "Free tissue reconstruction of traumatic facial bony defects." Operative Techniques in Otolaryngology - Head and Neck Surgery **19**(2): 80-85.

Traumatic facial bony defects present one of the most challenging problems for the facial plastic reconstructive surgeon. The most common mechanisms of trauma resulting in a bony defect of the facial skeleton include gunshot injuries, motor vehicle accidents, and burns. These bony defects of the facial skeleton resulting from trauma rarely occur in isolation. Rather, there is uniformly varying degrees of soft-tissue trauma and/or loss, potential visual, neurological and spinal injuries, and other associated life-altering implications. The application of free tissue transfer techniques to

the management of these complex defects has allowed a significant change in paradigm, permitting early intervention and improved long-term outcomes. © 2008.

1910. Girotto, J. A. and J. Gruss (2004). "Primary post-traumatic mandibular reconstruction in infancy: a 10-year follow-up." The Journal of craniofacial surgery **15**(2): 255-260.

Ballistic trauma to the craniofacial skeleton combines the challenges of complex bone injury and loss with severe soft tissue injury and violation of the naso-orbital or oropharyngeal cavities. The authors report a patient who experienced a unique ballistic injury at 28 months of age that resulted in loss of the mandibular ramus and condyle. A segmental injury to the facial nerve was also identified. Primary costochondral grafting and delayed interpositional nerve grafting was undertaken. After 10 years, the patient has nearly 40 mm of opening, with only slight deviation to the injured side. Her facial nerve regeneration provides complete orbicularis oculi function, oral competence, and only slight facial asymmetry. This traumatic reconstruction differs from that of patients with hemifacial microsomia or post-traumatic/arthritic ankylosis in that the joint space itself was spared. Thus, the costochondral graft benefits from the remaining articular disk and upper disk space and is able to rotate and translate. Function and growth are adequately re-established, even in this young pediatric patient.

1912. Giulian, D. (1987). "Ameboid microglia as effectors of inflammation in the central nervous system." Journal of neuroscience research **18**(1): 155-153.

Techniques for selective isolation, labeling, stimulation, and destruction of ameboid microglia allow study of some fundamental questions in neuroimmunology. Examination of surface morphology, proliferative capacity, and cytochemistry suggests that microglia are a class of brain mononuclear phagocytes distinct from blood monocytes, spleen macrophages, or resident peritoneal macrophages. Moreover, cultured ameboid microglia isolated from newborn brain can be induced to grow thin cytoplasmic projections several hundred microns in length; these process-bearing cells resemble a differentiated form of microglia found in adult brain. Ameboid microglia may contribute to brain inflammation by engulfing debris, by releasing cytotoxins, by killing neighboring cells, and by secreting astroglial growth factors. Importantly, ameboid microglia are closely tied to a network of immunomodulators that include colony-stimulating factors and Interleukin-1. The presence of activated microglia during normal embryogenesis and at sites of penetrating brain injury suggests that these cells serve as important effectors linking the immune system with growth and repair of the CNS.

1913. Giulian, D., et al. (1989). "The role of mononuclear phagocytes in wound healing after traumatic injury to adult mammalian brain." The Journal of neuroscience : the official journal of the Society for Neuroscience **9**(12): 4416-4429.

We monitor cellular responses to a penetrating wound in the cerebral cortex of adult rat during the first weeks after injury. Two classes of activated mononuclear phagocytes containing acetylated low-density lipoprotein (ac-LDL) receptors appear within hours at the wound site. One type of cell surrounding the lesion edge had thin, delicate processes and is identical in appearance to ramified microglia found in developing brain. Within the lesion, round cells are recognized as blood-borne macrophages when labeled by intravenous injection of carbon particles. Thus, both process-bearing reactive microglia and invading macrophages respond to brain trauma. The greatest number of ac-LDL(+) or nonspecific esterase(+) mononuclear phagocytes appears 2 days after injury within the wound site and are associated with a peak production of the cytokine interleukin-1 (IL-1). Because intracerebral infusion of IL-1 is known to stimulate astrogliosis and neovascularization (Giulian et al., 1988), we examine the time course of injury-induced reactive astrogliosis and angiogenesis. A 5-fold increase in the number of reactive astroglia is found at 3 d and a marked neovascularization at 5 d after injury. During the first week, mononuclear phagocytes engulf particles and clear them from the wound site either by migrating to the brain surface or by entering newly formed brain vasculature. To investigate further the role of reactive brain mononuclear phagocytes in CNS injury, we use drugs to inhibit trauma-induced inflammation. When applied in vivo, chloroquine or colchicine reduce the number of mononuclear phagocytes in damaged brain, help to block reactive astrogliosis and neovascularization, and slow the rate of debris clearance from

sites of traumatic injury. In contrast, the glucocorticoid dexamethasone neither reduces the number of brain inflammatory cells nor hampers such responses as phagocytosis, astrogliosis, neovascularization, or debris clearance in vivo. Our observations show that mononuclear phagocytes play a major role in wound healing after CNS trauma with some events controlled by secretion of cytokines. Moreover, certain classes of immunosuppressive drugs may be useful in the treatment of acute brain injury.

1914. Givner, A., et al. (2002). "Reimaging in pediatric neurotrauma: factors associated with progression of intracranial injury." Journal of pediatric surgery **37**(3): 381-385.

PURPOSE: The purpose of this study was to characterize the radiologic changes that are seen in the first 24 to 48 hours after head injury and to correlate those changes with clinical findings, to determine which children are at greatest risk for progression of their neurologic injury., METHODS: The authors identified 104 children (less-than-or-equal17 years of age) who had a second computed tomography (CT) scan of the head within 24 to 48 hours of admission. CT scans were evaluated systematically in a blinded fashion. Mechanism of injury, findings on physical examination, therapeutic measures, and changes in management were recorded from hospital medical records. The 50 children whose second CT scan showed progression of injury were compared with the 54 patients whose intracranial injuries were unchanged or improved on their second CT., RESULTS: Twenty-six percent of patients (13 of 50) with radiographic progression of injury had an admission Glasgow coma score of 15. Progression of injury was more common, however, in patients with lower Glasgow coma scores, averaging 9 on admission and 10 at the time of the second CT. Progression of injury also was more common if the initial head CT showed 3 or more intracranial injuries, mass effect, intraventricular hemorrhage, or an epidural hematoma., CONCLUSIONS: Children with an intracranial injury identified on their initial head CT scan should undergo a second scan 24 hours after injury, especially if the initial CT shows 3 or more intracranial injuries, mass effect, intraventricular hemorrhage, or an epidural hematoma. . 1915. Glapa, M., et al. (2009). "Gunshot wounds to the head in civilian practice." The American surgeon **75**(3): 223-226.

Gunshot wounds to the head are associated with poor outcome. We reviewed data to identify prognostic factors. We performed a retrospective study of all patients admitted to a Level 1 trauma center with isolated gunshot injury to the head during 6 1/2 years. Data collected included demographics, mechanism of injury, prehospital and resuscitation room data, and initial CT scan characteristics. The primary outcome measure was the Glasgow Outcome Scale. Seventy-two patients with isolated gunshot wounds to the head were admitted. Overall mortality was 58 per cent. The mortality for patients with an initial Glasgow Coma Scale score of 8 ($P < or = 0.0001$). Fifty per cent had pupillary abnormalities on arrival at the Emergency Department. Mortality in this group was 78 per cent versus 53 per cent in those with normal pupillary reflexes ($P = 0.06$). Elevated plasma lactate was associated with nonsurvival. Thirteen per cent of survivors were assessed as able to live independently after their injury. Civilian gunshot injury to the head is related to high mortality. Indicators of outcome are the admission Glasgow Coma Scale score, pupillary abnormality, metabolic acidosis, and CT pattern of severe injury. The majority of deaths occur at an early stage. Among survivors the functional outcome can be acceptable.

1916. Glass, L., et al. (2013). "Mental paper folding performance following penetrating traumatic brain injury in combat veterans: a lesion mapping study." Cerebral cortex (New York, N.Y. : 1991) **23**(7): 1663-1672.

Mental paper folding is a complex measure of visuospatial ability involving a coordinated sequence of mental transformations and is often considered a measure of mental ability. The literature is inconclusive regarding the precise neural architecture that underlies performance. We combined the administration of the Armed Forces Qualification Test boxes subtest measuring mental paper folding ability, with a voxel-based lesion symptom mapping approach to identify brain regions associated with impaired mental paper folding ability. Using a large sample of subjects with penetrating traumatic brain injury and defined lesions studied over 2 time points, roughly 15 and 35 years post-injury, enabled us to answer the causal questions regarding mental paper folding impairment. Our results revealed that brain injury significantly exacerbates the decline of performance on mental paper folding tasks over time. Our study adds novel neuropsychological and neuroimaging support for parietal lobe involvement; specifically the right inferior parietal lobule (Broadmann's Area [BA] 40) and the left parahippocampal region (BAs 19, 36). Both areas were consistently associated

with mental paper folding performance and demonstrate that the right parietal lobe and the left parahippocampal gyrus play an integral role in mental paper folding tasks.

1917. Glass, L., et al. (2016). "Neural signatures of third-party punishment: evidence from penetrating traumatic brain injury." Social cognitive and affective neuroscience **11**(2): 253-262.

The ability to survive within a cooperative society depends on impartial third-party punishment (TPP) of social norm violations. Two cognitive mechanisms have been postulated as necessary for the successful completion of TPP: evaluation of legal responsibility and selection of a suitable punishment given the magnitude of the crime. Converging neuroimaging research suggests two supporting domain-general networks; a mentalizing network for evaluation of legal responsibility and a central-executive network for determination of punishment. A whole-brain voxel-based lesion-symptom mapping approach was used in conjunction with a rank-order TPP task to identify brain regions necessary for TPP in a large sample of patients with penetrating traumatic brain injury. Patients who demonstrated atypical TPP had specific lesions in core regions of the mentalizing (dorsomedial prefrontal cortex [PFC], ventromedial PFC) and central-executive (bilateral dorsolateral PFC, right intraparietal sulcus) networks. Altruism and executive functioning (concept formation skills) were significant predictors of TPP: altruism was uniquely associated with TPP in patients with lesions in right dorsolateral PFC and executive functioning was uniquely associated with TPP in individuals with lesions in left PFC. Our findings contribute to the extant literature to support underlying neural networks associated with TPP, with specific brain-behavior causal relationships confirming recent functional neuroimaging research.

1918. Glasscock, M. E., 3rd, et al. (1979). "Rehabilitation of the face following traumatic injury to the facial nerve." The Laryngoscope **89**(9 Pt 1): 1389-1404.

Etiology, diagnosis, and surgical management of facial paralysis due to traumatic injury of the VIIth cranial nerve are discussed. Sixty patients are reviewed who underwent some type of surgical procedure for the repair of the facial nerve. These cases are categorized according to etiology, which includes temporal bone fractures, iatrogenic injuries, and penetrating wounds of the head and neck. The results of a poll of eight leading otologists on their approaches to several aspects of the surgical management of these injuries are presented in the Discussion section. The diagnostic and prognostic studies associated with facial paralysis, as well as the more common surgical procedures available for repair of the facial nerve, are briefly reviewed.

1919. Glick, Y., et al. (2019). "The Israeli Defense Forces Point of Injury Antimicrobial Treatment Protocol - A New Protocol and Review of the Literature." Military medicine **184**(Suppl 1): 78-82.

INTRODUCTION: Combat wound infection is a common and serious complication, leading to significant morbidity and mortality. In 2005, a point of injury antimicrobial protocol was published by the Israel Defense Forces, in which Moxifloxacin was chosen. During 2016-2017, a revision of this protocol was performed and concluded with the publication of an updated protocol. The purpose of this report is to present this process and the revised protocol, together with a review of the literature., METHODS: We searched "Medline" and "Google Scholar" for studies dealing with antimicrobial prophylaxis in trauma, for militaries' point of injury antimicrobial protocol protocols and for established surgical antimicrobial prophylaxis protocols., RESULTS: Point of injury antimicrobial protocol is aimed at preventing early infection and its complications. The choice of Moxifloxacin for this purpose may not be optimal since Moxifloxacin spectrum might be overly broad, there is scant evidence supporting it for this indication, and the available preparation does not meet distinctive technical requirements. Contrarily, Ceftriaxone seemed to have suitable microbiological, pharmacological and technical features., CONCLUSION: Point of injury antimicrobial protocol should be used especially when evacuation and definitive surgical treatment are delayed. According to present scientific data and operational needs, Ceftriaxone was chosen for most penetrating injuries, with Metronidazole addition for penetrating abdominal and cranial trauma.

1920. Gloulou, F., et al. (2009). "Unusual suicides with band saws: two case reports and a literature review." Forensic science international **183**(1-3): e7-10.

Suicides or suicide attempts with power saws (band, circular or chain saws) are rather rare events and only a few case reports exist in the forensic literature. The use of a band saw, in particular, has been extremely rare in cases of suicide. We report two cases of suicide that occurred in the same suburban area, three years apart. In each case, the victim was a carpenter and had a history of psychiatric disorder and/or of prior suicide attempts. We summarize the findings of the death scene investigations, the pertinent autopsy findings, and also summarize the world literature pertaining to suicide committed with power saws.

1921. Gluncic, I., et al. (2001). "Unusual stab wound of the temporal region." Croatian medical journal **42**(5): 579-582.

We report the case of an unusual penetrating injury of the temporal region of the head caused by knife. A long kitchen knife was protruding from the upper auricular area of the left temporal region of victims head. It cut through the posterosuperior part of the left auricula and remained fixed to the postauricular region. Brain computorized tomography (CT) scan revealed that the knife had reached deep into the petrous part of the temporal bone, and was directed toward the sulcus of the sigmoid sinus. There were no signs of intracranial bleeding. An otorhinolaryngologist and a neurosurgeon removed the knife in operating room, with the patient in general anesthesia. The audiogram obtained after 7 days of hospitalization showed left conductive hearing loss of 40 dB at frequencies up to 2 kHz, and of 90 dB above 2 kHz, probably due to hemotympanum caused by the operation. Control examinations performed 14 days and one month after discharge confirmed the patients complete recovery and no significant defects in his hearing or balance. We suggest multidisciplinary teamwork as a proper approach in the treatment of such injuries.

1922. Gluncic, V., et al. (2019). "Anesthetic Management of Jael Syndrome With Impacted Blade in Close Proximity to the Internal Carotid Artery: A Case Report." A&A practice **12**(10): 369-371.

A patient presented with a stab injury caused by a knife penetrating the orbital floor and maxillary sinus along the skull base with the tip situated adjacent to the left internal carotid artery. A flexible fiberoptic bronchoscope loaded with an endotracheal tube was initially positioned superior to the vocal cords and advanced into the trachea immediately following induction. The blade was removed after occluding endovascular balloons were positioned distal and proximal to the potential internal carotid artery injury site. Therefore, contralateral nasal fiberoptic intubation might be safely performed in patients with unilateral maxillofacial trauma, no intracranial penetration, and minimal bleeding.

1923. Gnjidic, Z., et al. (2002). "Epidemiological, forensic, clinical, and imaging characteristics of head injuries acquired in the suicide attempt with captive bolt gun." Acta neurochirurgica **144**(12): 1271-1277.

The captive bolt gun (slaughterer's gun) is a tool used in the meat industry for "humane killing" of animals. Used with the intent of suicide, the captive bolt gun causes very serious injuries. We analysed 19 self-inflicted head injuries with captive bolt gun during the past 20 years. Autopsy of 20 pigs killed by this method was also performed. All 19 cases were middle-aged men from rural areas, with low level of education, and without a previous psychiatric history. Five of them used the captive bolt gun daily in their professional activities, while the remaining 14 handled it only sometimes. In seven cases suicide was primarily successful, while in five patients, despite intensive medical care, serious craniocerebral injuries eventually resulted in death. Total mortality was 63.2%. The clinical appearance of the entrance wound and the imaging characteristics of the cranial trauma are very specific, and can be easily differentiated from firearm or other penetrating injuries. These wounds were always primarily infected with mixed bacterial flora from the skin. Therefore, besides radical primary wound care, especially of the wound canal with removal of foreign bodies, it is important to administer high doses of wide spectrum antibiotics.

1924. Go, J. L., et al. (2019). "Traumatic Neck and Skull Base Injuries." Radiographics : a review publication of the Radiological Society of North America, Inc **39**(6): 1796-1807.

Patients with blunt and penetrating traumatic injuries to the skull base and soft tissues of the neck present to the emergency department every day. Fortunately, truly life-threatening injuries to these regions are relatively uncommon. However, when encountered and not correctly diagnosed, these entities may result in severe morbidity or mortality. The radiologist plays a critical role recognizing these injuries, in which findings may often be subtle and the anatomy potentially challenging to identify. Multisection CT and CT angiography are commonly performed to assess these injuries in the emergency department. Vascular injury to the neck may result in dissection, occlusion,

pseudoaneurysm formation, or frank extravasation resulting in stroke or death. Airway compromise may result from laryngotracheal injury. Injuries to the pharynx and esophagus may result in perforation. Injuries to the temporal bone may result in vascular injury to the internal carotid artery or facial nerve injury, which would require immediate surgery or intervention to prevent paralysis.©RSNA, 2019.

1925. Godard, E., et al. (2019). "Transorbital penetrating trauma caused by a fall on the antenna of a radio receiver: Case report and review." Revue de Medecine Legale **10**(3): 113-117.

We report the case of a patient who died after falling on the antenna of a radio receiver that was stood on the floor. External examination showed an orificial contuse wound, less than a centimetre in diameter, on the right upper eyelid. There was no ocular lesion. Full-body CT (computed tomography) scan imagery revealed a fracture of the roof of the right orbit and diffuse intra and pericerebral haemorrhages. Those haemorrhages had caused the death of the patient. Penetrating transorbital traumas represent a very small part of cranial traumas and orbital pathologies. They are usually linked to the high-velocity traumas associated with traffic accidents or penetration by firearm projectiles. Low-energy penetrating transorbital traumas are even less frequent; associated prognoses are rarely lethal and generally functional. These traumas cause minimal palpebral or periocular wounds that can seem insignificant upon external forensic examination, especially when the foreign body involved is fully intracranial or absent. Performing a cerebral scan, or even post-mortem angiography, thus appears to be a key-procedure, very useful to the medical examiner.

1926. Godil, S. S., et al. (2011). "Cranial reconstruction after decompressive craniectomy: prediction of complications using fuzzy logic." The Journal of craniofacial surgery **22**(4): 1307-1311.

INTRODUCTION: Cranial reconstruction after decompressive craniectomy (DC) has been shown to be associated with a relatively high complication rate (16.4%-34%) compared with standard neurosurgical procedures (2%-5%). Most studies that have previously attempted to formulate a multivariate model for identifying factors predictive of postoperative complications of cranioplasty either were unsuccessful or yielded conflicting results. Therefore, fuzzy logic-based fuzzy inference system (FIS), which has proven to be a useful tool for risk prediction in medical and surgical conditions, was used in this study to identify predictors of complications of cranioplasty., METHODS: A retrospective chart review of all the patients who underwent DC followed by elective cranioplasty at Aga Khan University Hospital, during a 10-year period (2000-2010), was carried out to collect data on 24 carefully selected preoperative variables or inputs. The proposed FIS had 24 inputs, 3 outputs, and a set of 7 fuzzy-based rules. All inputs were assigned degrees of membership, and complications were further divided into "severe," "minor," and "least" output classes with each of them representing 2 membership functions: "less" and "more." For each set of inputs, a specific portion of the hypersurface was masked out. The centroid of this subsurface represented the defuzzified output corresponding to 1 percentage value for each output. The maximum of these outputs for each of the 3 output classes was selected to be the final output class. Each output class was compared to the actual outcome of patients, and positive predictive value, negative predictive value, sensitivity, and specificity of FIS for predicting complications were calculated., RESULTS: A total of 89 patients (mean [SD] age, 33.1 [15.0] y; male-to-female ratio, 3:1) were included in the study. The common postoperative complications included seizures (14.6%), cerebrospinal fluid leak (4.5%), neurologic deficits (3.4%), hydrocephalus (3.4%), superficial wound infection (3.4%), and osteomyelitis (2.2%). The FIS correctly identified all 7 patients who developed severe complications after cranioplasty (true positives) and all 82 patients who did not develop severe complications (true negatives). Thus, the FIS has a sensitivity and specificity of 100% in predicting severe complications., CONCLUSIONS: Our study shows that the procedure of cranioplasty is associated with a high complication rate and that FIS has a 100% sensitivity and specificity in predicting severe complications after cranioplasty. It will prove to be an invaluable tool for clinicians once the results are validated by a similar prospective study with a larger sample size.

1927. Godino, M., et al. (2010). "Ventricular dysfunction associated with brain trauma is cause for exclusion of young heart donors." Transplantation proceedings **42**(5): 1507-1509.

OBJECTIVE: Ventricular dysfunction (VD) in the context of brain death (BD) is one medical cause that may be reversed to extend the range of donors for cardiac transplant programs. The aim of this study was to identify and quantify the causes for exclusion of potential heart donors and to define risk factors for VD among the BD population., MATERIALS AND METHODS: This study of 100 heart-beating potential donors defined subjects as those younger than 50

years. We defined hemodynamic dysfunction (HD) as failure to achieve hemodynamic objectives despite the use of inotropic agents by protocol or upon diagnosing VD., RESULTS: Among 246 BD subjects were 100 potential heart donors. Of these, 75 were transformed into real donors (RD) including 13 heart RD and 62 noncardiac RD. The conversion rate of BD subjects younger than 50 years to heart RD was 17%. When we analyzed the medical reasons for exclusion of the 62 donors who were not converted to heart RD, we observed that HD was the major cause (34%). When we analyzed the causes for exclusion related to cause of death, cranial trauma predominated (52%; P = .01; relative risk 3.5; 95% confidence interval 1.4-8.5)., CONCLUSION: Hemodynamic dysfunction represented the major cause for loss of heart donors; it was associated with younger patients with cranial trauma.

1928. Goel, N., et al. (1994). "Grease gun injuries to the orbit and adnexa." Ophthalmic plastic and reconstructive surgery **10**(3): 211-215.

The grease gun injury is an uncommon injury to the orbit. However, high-pressure injection of grease, oil, or paint is frequently reported in injuries of the hand and usually affects the fingers or palm, which require complicated surgical and medical care. Two cases of grease gun injury to the orbit are reported: one, a catastrophic injury, and the other resulting in satisfactory recovery after surgical debridement and adjuvant medical treatment. Presentation, investigation, and therapy are discussed.

1929. Goffin, J. and C. Plets (1985). "Tension pneumocephalus in association with ventriculoperitoneal shunt." Acta neurochirurgica **76**(3-4): 121-124.

The authors report a case of tension pneumocephalus in association with a ventriculoperitoneal shunt for obstructive hydrocephalus, due to the presence of a pineal tumour. In this unique form of tension pneumocephalus, air from the middle ear must have penetrated into the brain parenchyma and later on into the ventricular system through pre-existing congenital defects in the bony tegmen tympani and the covering dura mater. The possible pathogenetic mechanisms of this kind of tension pneumocephalus are discussed.

1930. Goffstein, R. and T. C. Burton (1982). "Differentiating traumatic from nontraumatic retinal detachment." Ophthalmology **89**(4): 361-368.

Five hundred and eighty-six phakic retinal detachments were studied to characterize the features of 111 cases with a history of trauma and to establish improved guidelines for medico-legal determinations. Twenty-eight percent of contusion detachments were myopic, nine times higher than expected. Myopes typically developed giant tears and nasal dialyses (p less than 0.001); emmetropes developed inferotemporal dialyses (p less than 0.005). Lattice degeneration did not increase post-traumatic detachments risk. Dialyses and giant tears caused 69% of traumatic detachments and 6% of nontraumatic detachments (p less than 0.001). Forty-seven percent of contusion detachments had no late objective evidence of trauma. Five percent of detachments with a history of trauma were not caused by trauma (false positives).

1931. Gofman, V. R. and A. S. Kiselev (1998). "[The surgical procedure in blind gunshot wounds of the skull base]." Khirurgicheskaia taktika pri slepykh orgnestrel'nykh raneniiakh osnovaniia cherepa. **157**(5): 74-78.

Personal clinical observations during the recent years allow the authors to confirm the indisputable value of surgical experience got during the Great Patriotic War (1941-1945) and in particular, the "fourfold" scheme proposed by V. I. Voiachek for the diagnosis and treatment of blind gunshot wounds to the skull base. Computed tomography considerably increases the probability of detection of the exact localization of foreign bodies in complex anatomical structures of the skull and thus facilitates choosing the most rational surgical management. The use of the electro-optical transducer for the extraction of foreign bodies from almost inaccessible areas of the skull base decreases the risk of operation.

1932. Goga, D., et al. (1998). "[Microvascular mandibular reconstruction and implantology. A study of the stability of long-term results, apropos of 2 cases followed for 8 years]." Reconstruction mandibulaire microvascularisee et implantologie. Etude de la stabilite des resultats a long terme, a propos de deux cas suivis a 8 ans. **99**(5-6): 231-234.

The objective of this study was to determine the long term stability of implants on mandibles reconstructed by microvascular bone transfer. We present two cases of mandible reconstruction, the first one was performed after tumor resection and the second one after gunshot injury. The reconstructions were performed by iliac crest osseous and osteocutaneous free flaps and the mean follow-up period was 8 years. The implant was an IMZ Titanium and a classic prosthetic system was used. No complication was observed (mucous ulceration, infiltration around the implant), and the feared friction phenomenon between the neo mucosa and the reconstructed bone has not been a problem for long term follow-up.

1933. Goh, A. Y. T. and Q. Mok (2004). "Clinical course and determination of brainstem death in a children's hospital." Acta paediatrica (Oslo, Norway : 1992) **93**(1): 47-52.

AIM: To study the aetiology and clinical course of children with brainstem death in a paediatric intensive care unit (ICU) and to determine whether current the practices that are used to declare brainstem death conform to accepted criteria., METHODS: A retrospective review chart of all patients with brainstem death (n = 31) admitted to the paediatric ICU between January 1995 and December 1998 was drawn up., RESULTS: Mean age of the patients was 51.9 +/- 54.5 mo with the main diagnoses being head trauma in 11 children, anoxic encephalopathy in 7, brain tumour in 5, drowning in 4, CNS haemorrhage in 3 and CNS infection in 1 child; 32.3% of the children were given pre-ICU admission cardiopulmonary resuscitation. The average time from insult to suspected brainstem death was 27 h and suspected brainstem death to confirmation was 25 h, with an average of 1.6 examinations performed. EEG was done in 14 patients, with electrocerebral silence in 8 after the first examination and in a further 5 after repeat testing. Cerebral blood-flow scans were done in 3 children and evoked potentials in 1 child., CONCLUSIONS: Trauma remains the most common primary diagnosis leading to brainstem death. Intensivists in this large hospital for children mainly conform to accepted guidelines for determination of brainstem death although there is a wider use of ancillary tests to aid diagnosis. The study also showed a low rate of < 10% of organ procurement for transplantation.

1934. Gokcek, C., et al. (2007). "Intracranial foreign body." Turkish neurosurgery **17**(2): 121-124.

Intracranial foreign bodies due to nonmissile intracranial penetrations occur rarely. Most of these penetrating injuries result from industrial accidents or criminal assaults. The complications which cause mortality in early stage are intracerebral hemorrhage, contusion, major vascular injury and meningitis. In case of such injuries, foreign bodies near the major vascular structures should not be attempted to taken out. Total excision of the foreign body via craniotomy should be planned and possible dural and vascular injuries should be repaired during surgery. Urgent surgery should be performed as there is 53% morbidity in case of late surgery and 62% morbidity in nonoperated cases. We herein report a 20-year old man who attempted suicide by introducing a nail into his brain and review the related literature.

1935. Gökdemir, M. T., et al. (2012). "Analysis of patients injured during the local elections in sanliurfa province." Turkiye Acil Tip Dergisi **12**(1): 29-33.

ObjectivesCriminal cases constitute a significant part of the patients referred to the emergency department. In this study, we aimed to analysis the cases who admitted to our emergency department resulted in judicial incidents due to the local elections in the surrounding of Sanliurfa. Methods Cases referred to the Emergency Department due to injuries obtained during the local elections held on March 29, 2009 were included in the study. Computer records, hospital treatment order books, judicial records, and autopsy reports were examined. Results In total, 126 people injured during the local elections between March 29, 2009 and March 30, 2009 were referred to the Emergency Department of the Education and Research Hospital, Sanliurfa. The Hospital Disaster Plan was activated, and triage was performed. Of the 126 patients, 119 (94.4%) were male, and 7 (5.6%) were female; the average age was 37 years. The most frequent cause of injury was beating, and deaths were mostly due to cranial trauma caused by firearm injuries. After first evaluation and treatment in the emergency department, of the 98 (77.7%) were discharged, 28 (22.3%) were hospitalized, and 6 died. Conclusions In the present study, our objective was to draw attention to the criminal incidents resulted from mass casualities in the districts of Sanliurfa and its villages and management of those cases in our emergency department.

1936. Gold, M. (2016). "Partially Thrombosed Internal Maxillary Pseudoaneurysm after Gunshot Wound." Craniomaxillofacial Trauma and Reconstruction **9**(4): 335-337.

A 29-year-old man arrived in our emergency department after being shot on the face. Computed tomography (CT) revealed multiple facial bone fractures along the bullet trajectory. On day 10 of admission, CT angiogram of the neck revealed a partially thrombosed pseudoaneurysm in the parapharyngeal fat pad. The pseudoaneurysm was successfully treated with coil embolization. This report discusses diagnosis and treatment of a partially thrombosed internal maxillary artery pseudoaneurysm. Although digital subtraction angiography is the gold standard for pseudoaneurysm diagnosis, CT angiography may provide complimentary information, as seen in this case.

1937. Goldberg, R. A., et al. (1993). "Oculoplastic uses of cranial bone grafts." Ophthalmic surgery **24**(3): 190-196.

Cranial bone grafting for craniofacial reconstruction has gained wide acceptance in recent years and is being used with increasing frequency by ophthalmic plastic surgeons. Alloplastic materials (particularly newer materials such as porous polyethylene, hydroxyapatite, and rigidly fixated metal alloys) have a clear role in orbital reconstruction, and in many oculoplastic applications are the material of choice. However, in certain applications cranial bone grafts may be superior, eg, in managing large posttraumatic or postsurgical orbital defects or orbito-sinus defects in the milieu of chronic sinusitis. We describe our current techniques for harvesting full-thickness outer-table grafts and split-thickness periosteally-bound "fish-scale" grafts. Harvesting cranial bone grafts is not without risk and donor site morbidity, and we do not advocate the use of cranial bone grafts in those cases that might be managed as well (or better) with alloplastic material. At the same time, ophthalmic surgeons involved in orbital reconstruction should be familiar with the indications for bone grafts and comfortable with harvesting techniques so that they are not limited when circumstances warrant the use of autogenous material.

1938. Goldman, J. L., et al. (1996). "Priorities in the management of penetrating maxillofacial trauma in the pediatric patient." The Journal of cranio-maxillofacial trauma **2**(1): 52-55.

Penetrating facial trauma is uncommon in children; a large series published by Cooper et al revealed that only 1% to 2% of the total population of infants and children admitted for trauma during their study period had a diagnosis of penetrating trauma to the head or neck. Little has been published specifically addressing these injuries in the pediatric population. The records of 20 patients treated for penetrating facial injuries at Kosair-Children's Hospital in Louisville, Kentucky from January 1991 through December 1994 were reviewed. The location, mechanism and extent of injury, as well as the diagnostic and management practices used in patient treatment, were collected. Categorizing the injuries relative to the involvement of one or more facial zones helped guide diagnostic studies and therapeutic intervention and predict associated injuries. This article evaluates the authors' method of management and any differences in management between pediatric and similarly injured adult patients.

_____

1939. Goldman, R. L. and R. F. Carmody (1984). "Foreign body pulmonary embolism originating from a gunshot wound to the head." The Journal of trauma **24**(3): 277-279.

Foreign body pulmonary emboli from a cranial venous sinus are unusual. Two patients are presented with gunshot wounds to the head who subsequently developed foreign body pulmonary emboli. Neither had any pulmonary complaints at presentation or during followup. Radiologists and primary care physicians should be aware of the possibility of distal missile pulmonary emboli when a foreign body enters the peripheral venous system or an intracranial venous sinus.

_____

1940. Gomez, D., et al. (2012). "Controversies in the management of splenic trauma." Injury **43**(1): 55-61.

BACKGROUND: The technologic innovations of the last three decades, coupled with a deeper understanding of the immunologic role of the spleen, have significantly shifted the management of splenic injuries towards non-operative approaches. However, there continuous to be a wide range of practice patterns related to the non-operative management of splenic injuries, from which the authors infer a gap between the best available evidence and its translation into practice. We sought to explore ongoing areas of controversy in the non-operative management of splenic trauma with the aim of further elucidating why these controversies continue to exist., METHODS: We explored areas of ongoing controversy in the management of splenic injury though a series of iterative surveys. We invited 70

experts in trauma care from ten countries around the world to participate. Areas of controversy explored included: indications and frequency for in-hospital and follow-up imaging, definitions of failure of non-operative management, indications for angioembolisation and non-operative management in special populations (i.e. elderly, concomitant traumatic brain injury, penetrating trauma)., RESULTS: A 49% response rate was obtained. Even though a wide range of practice patterns were identified, no controversies were identified in areas that do not involve the adoption of new technologies. In areas where practice pattern variation was observed, the strong influence of the local environment was constantly identified as an impediment to changes in practice., CONCLUSIONS: We have identified that barriers present within local practice environments are the major driving forces behind controversies in the non-operative management of splenic injuries.

1941. Gomez, D. E., et al. (2019). "Pharyngeal trauma in dairy cattle: 27 cases." Journal of veterinary internal medicine **33**(4): 1833-1839.

BACKGROUND: Characterization of the clinical signs, response to treatment and prognosis can be useful information for decision-making when evaluating cattle with pharyngeal trauma., OBJECTIVE: To describe the signalment, history, clinicopathologic, endoscopic, ultrasonographic, radiographic, and postmortem findings as well as treatments and outcomes of cattle diagnosed with pharyngeal perforation/trauma., ANIMALS: Review of medical records of cattle >1 month of age admitted to a Veterinary Teaching Hospital from 1995 to 2017., METHODS: Retrospective study. Review of medical records of cattle with pharyngeal perforation/trauma identified by oral or endoscopic examination in hospital setting., RESULTS: Twenty-seven out of 7550 (0.36%) cases met the inclusion criteria. Pharyngeal perforation/trauma was associated with the administration of a bolus in 24 (89%) cows and a magnet in 3 (11%) cases. The boluses contained monensin (n = 12), calcium salts (n = 5), iodine (n = 1), aspirin (n = 1), vitamins (n = 1), and an unknown product (n = 4). The primary clinical signs were dysphagia, swelling of the throatlatch, subcutaneous emphysema, swelling, and pain on palpation of the throatlatch. Seventeen (63%) cows were discharged whereas 10 (37%) were euthanized. Median time between the suspected traumatic event and hospital admission was 1 day (range: 0.5-3 days) and 2 days (range: 0.5-15) for surviving and nonsurviving cattle, respectively. All 5 cows that suffered pharyngeal trauma associated with administration of calcium salt bolus were euthanized., CONCLUSIONS AND CLINICAL IMPORTANCE: Pharyngeal trauma is a rare condition in cattle. Case fatality rate increases if not diagnosed and treated promptly. The nature of the penetrating foreign body influences the outcome.

1942. Gomez, J., et al. (2008). "[Brain abscess. The experience of 30 years]." Abscesos cerebrales. Experiencia de 30 anos. **130**(19): 736-739.

BACKGROUND AND OBJECTIVE: The aim of this study was to evaluate epidemiological and clinical aspects of brain abscess (BA) and changes in clinical patterns during the last 30 years., PATIENTS AND METHOD: Observational study of a cohort of non-pediatric patients with BA admitted at a 944-bed hospital. Data collection from clinical records was done according to a standard protocol. We analysed epidemiological, clinical and microbiological data and localization as well as changes during a 30 year period divided in 2 equal length phases: 1976-1989 (P1), and 1990-2005 (P2)., RESULTS: 108 patients with BA were included (mean age: 45 years; range: 12-86; > 40 years in 42.4% P1, and 71.4% in P2, $p < 0.05$); 66 patients were treated in P1 and 42 in P2 (annual incidence: 4-5 cases and 2-3 cases per 10(6) population in P1 and P2, respectively). A predisposing condition was identified in 86% cases with statistically significant differences ($p < 0.05$) in: otitis media (18.2% vs 2.4%); dental infection (3% vs 16.7%); penetrating cranial trauma (16.7% vs 0%); post-neurosurgery (15.1% vs 21.4%), in P1 and P2, respectively; microbiologic diagnosis was made in 76% (no statistical differences P1/P2). Clinical aspects statistically different in P1/P2: severely altered mental status (10.6% vs 0%); vomiting (37.9% vs 21.4%); focal neurological deficits (37.9% vs 71.4%). No statistically significant differences were found in other epidemiological, clinical, radiological, microbiological or outcome characteristics in P1/P2., CONCLUSIONS: In spite of a lower incidence in P2 and certain epidemiological and clinical differences in P1/P2, mortality and relapses rates have not significantly changed in a 30 year period.

1943. Gomez, J., et al. (2019). "Early continuous transcranial doppler in the ICU in patients with traumatic brain injury." Journal of Neuroimaging **29**(2): 277-278.

Background and Purpose: Cerebral hemodynamic changes after sustaining traumatic brain injury (TBI) are a major factor responsible for morbidity and mortality in this disease population. A plethora of research is available on continuous monitoring of the brain's hemodynamic response following such injury using invasive modalities like brain tissue oxygenation, regional blood flow, microdialysis, and electroencephalography. There is emerging interest in noninvasive monitoring of cerebral hemodynamics in guiding clinical paradigms in TBI. Transcranial Doppler ultrasound (TCD) is a noninvasive, portable modality to study the large intracranial vessels, and measure cerebral blood flow velocities. Numerous hemodynamic indices can be derived from TCD waveforms, which can serve as indicators of cerebral events, including vasospasm, hypoperfusion, hyperperfusion, vasoreactivity, and autoregulation. TCD can also be used to elucidate phenomenon such as the triphasic hemodynamic response with continuous monitoring after TBI. This ongoing study focuses on the feasibility and utility of TCD to evaluate changes in cerebral hemodynamic patterns following TBI. Methods: This institutional review board-approved study involves enrolling patients -18 years old admitted to the Neuro-Sciences Intensive Care Unit (ICU) or Trauma ICU at a tertiary-level academic medical center with a diagnosis of TBI. Diagnosis is confirmed with historical and radiographic evidence of head injury including, but not limited to traumatic subarachnoid hemorrhage, intraparenchymal contusion, intraventricular hemorrhage, diffuse axonal injury, or epidural hematoma. Eligible patients need to have a leveled trauma code (1-3), defined by emergency department admission and trauma team evaluation. Patients are excluded for pregnancy, incarceration, or penetrating skull trauma. Continuous TCD recordings are obtained from the bilateral middle cerebral arteries (MCAs) using a monitoring headband from the bilateral MCAs for 15 minutes-1-hour duration with a maximum of 4 hours of monitoring. Informed consent is obtained from the patient or surrogates prior to use of any of the collected data for research. Physiological parameters, including blood pressure intracranial pressure, end-tidal carbon dioxide, and arterial oxygen saturation, are recorded during TCD monitoring. Results: In this ongoing study, between 06/01/2018 and 09/15/2018, 400 patients were screened for study enrollment. Thirty-eight patients screened positive for TBI, with 13 found eligible for inclusion. Of these eligible patients, 9 expired prior to TCD scanning or declined consent. Data were able to be analyzed from 3 of the remaining 4 patients. Descriptive parameters of this sample (n = 3) included mean age of 62 years and mean Glasgow Coma Scale score of 13.6 on admission. All patients had neuroradiographically confirmed subarachnoid hemorrhage, with 1 patient having diffuse axonal injury. All met criteria for mild TBI. Mean values for physiological parameters included mean arterial pressure (98 mmHg), systolic blood pressure (BP) (148.33 mmHg), diastolic BP (74.67 mmHg), hemoglobin (7.77 g/dL), and pulse (90 bpm) during TCD. An average of 30 minutes of TCD recording was obtained on each patient. The TCD monitoring was well tolerated with no adverse effects. Mean duration of time between admission and TCD study was 5.33 days. Mean length of ICU stay was 13 days. MCA peak flow was aggregated for all patients with a mean flow of 82.4 and 51.55 for right and left recordings, respectively. Conclusion: At this time, no abnormal results have been observed. Our ongoing study is limited by the small sample size. While no anomalous flow patterns have been recorded, we have shown that monitoring cerebral hemodynamics with continuous TCD is feasible in ICU patients. This ongoing study provided a practical assessment of the feasibility of continuous TCD and allowed for the creation of a workflow to continue to pursue recording the triphasic response in moderate-to-severe TBI patients.

1944. Gomez-Caro, A., et al. (2006). "Role of conservative medical management of tracheobronchial injuries." The Journal of trauma **61**(6): 1426-1425.

BACKGROUND: The purpose of this study is to describe and assess the effectiveness of conservative treatment as the chosen treatment for tracheobronchial injury (TBI) management. This is a retrospective and descriptive study, which took place at a single center., METHODS: From January 1993 to July 2004, 33 TBIs were treated in our hospital. Eighteen (54.5%) were iatrogenic injuries and 15 (45.5%) were traumatic noniatrogenic injuries. Eighteen (55%) of the TBI patients were women and 15 (45.5%) were men, with a mean age of 46.7 +/- 23.4 years (range, 14-88 years). Eighteen (54.5%) of the injuries were caused by orotracheal intubation or tracheostomy, 13 (39.4%) by blunt trauma, and 2 (6.1%) by penetrating tracheal injuries. The average diagnostic delay was 18.29 +/- 19.8 hours. The mean injury size was 2.6 +/- 1.3 cm (range, 1-7 cm). Fourteen (42.4%) injuries were located in the cervical trachea, 8 (24.2%) in the thoracic trachea, 10 (30.3%) in the bronchi, and 1 (3%) involved both trachea and the main bronchi. Conservative treatment was applied in 20 (60.6%) of the 33 cases. Surgery should be performed in cases of esophageal-associated injuries, progressive subcutaneous or mediastinal emphysema, severe dyspnea requiring intubation, difficulty with mechanical ventilation, pneumothorax with an air leak through the chest drains, or mediastinitis., RESULTS: Conservative medical or surgical treatments achieved good outcomes in 28 (84.8%) cases. Five patients (15.2%) died while in the hospital; 4 of these were medically treated and 1 was surgically treated. Mortality was related to older

patients and patients that had been diagnosed during mechanical ventilation. Major symptoms (progressive subcutaneous emphysema, dyspnea, sepsis) were detected more often in cartilaginous injuries ($p < 0.05$). Conservative treatment was considered more effective in membranous injuries ($p < 0.05$), and these sorts of injuries were not related to a high mortality rate ($p > 0.05$). Mortality was not related to conservative treatment, sex, diagnostic delay, injury mechanism, location, or length of the TBI ($p < 0.05$)., CONCLUSIONS: Conservative treatment for TBI is effective regardless of the mechanism of production, length, or site of the injury. Conservative treatment should be carefully assessed in patients who meet strict selection criteria. Membranous injuries can be treated more often with a conservative approach, however, cartilaginous injuries should be treated surgically if major symptoms are detected.

Comentarios al articulo "Neumoencefalo como complicacion de puncion dural inadvertida en analgesia epidural". **57**(9): 603-604.

1946. Goncalves, B., et al. (2016). "Characteristics of patients with gunshot wounds to the head-an observational Brazilian study." Critical Care **20**.

Introduction Penetrating gunshot wounds to the head (PGWH) are associated with high mortality and morbidity. Getulio Vargas Hospital is a public trauma center in Rio de Janeiro with a high volume of neurocritical patients and an unusual number of civil patients admitted with PGWH. The aim of this study was to describe patients with PGWH admitted in Intensive Care Unit (ICU), investigating clinical characteristics, complications and management that could be related to a better outcome in this setting. Methods We retrospectively assessed the hospital records of every patient with PGWH admitted to the ICU from October 1st, 2014 to September 30th, 2015. Exploratory analysis of clinical data, image results, treatment, complication and outcomes was made. The primary end point was the modified Rankin scale at hospital discharge. Results In the period of the study, 1789 patients were admitted to the ICU and 13 PGWH patients were included. There were 10 male patients (77 %) and 3 female (23 %), with a mean age of 30 years (range 14- 64). There were no self-inflicted lesions (all PGWH were results of aggression). Glasgow Coma Scale at admission was 8 or less in 10 patients. On admission, 7 patients were anisocoric, 8 presenting shock, 5 had associated body lesions from another gunshot wound (such as limbs or in the thorax). Mean SAPS 3 was 67 (range 35-94) and mean Apache II, 26 (range 8-37). The CT scan findings were: midline shift in 8 patients, 7 single lobe haemorrhages (such as frontal or parietal lobe), and 6 patients with bleeding in more than one lobe. Six patients had subarachnoid and 3 had intraventricular hemorrhage. Early surgical procedure was made to 10 patients (mainly decompressive craniectomy). The mean hospital length of stay was 21 days (range 2 to 136 days). Six patients had wound infection, and three, infection in other sites. The mortality rate for the entire group was 54 % (7 out 13). 4 patients progressed to brain death. Of the six patients discharged from the hospital, four had good outcome (defined as modified Rankin scores of 0-3), and two, bad outcome (modified Rankin of 4). Conclusions In agreement with previous reports, our results showed that the surviving group was mostly of hemodynamically stable patients, included all with GCS above 8, and had lower SAPS3 and APACHE 2 scores. Patients with multiple gunshot wounds, even on non-vital organs, had worse outcome.

1947. Gonnering, R. S. (1987). "Ocular adnexal injury and complications in orbital dog bites." Ophthalmic plastic and reconstructive surgery **3**(4): 231-235.

Orbital dog bites, though statistically uncommon, occur most frequently in children and are associated with severe ocular adnexal injury. Of 16 victims, two-thirds were under 10 and over half under 5 years of age. The wounds consisted of numerous periorbital punctures, and in most cases, full-thickness lid lacerations involving the tear system. There were no serious injuries to the globe. Reversible amblyopia occurred in two children under 3 years of age with damage to the levator muscle. One child suffered a naso-orbital fracture. Because of the obvious nature of the injury, most patients present early and can be managed well with meticulous wound care and primary surgical repair. The use of prophylactic antibiotics, though controversial, appears prudent in such cases. Ophthalmologists treating these injuries must be aware of serious potential complications including occult facial fracture or intracranial penetration in young children, septicemia caused by bacillus DF-2 in patients with prior splenectomy, tetanus, and rabies.

1948. Gonul, E., et al. (1999). "Orbital foreign bodies after penetrating gunshot wounds: retrospective analysis of 22 cases and clinical review." Minimally invasive neurosurgery : MIN **42**(4): 207-211.

We conducted a retrospective analysis of 22 patients having orbital penetrating gunshot wounds treated over a 4-years period. The neurological status and the site of injury for each patient are evaluated in this study. We propose a practical protocol in the management of these orbital foreign bodies. Surgical treatment was performed in 4 patients (had functional deficit) with medial orbitotomy in 2, lateral orbitotomy in 1, and superior orbitotomy in 1. 3 of them are improved, in one case the blindness has been continued. 18 patients were treated conservatively and all of them are improved. All patients were followed-up for 2 years with cranial X-rays and CT scans. Neurological sequelae were regressed which existed before the surgery. In conservatively treated cases, infection, migration and functional deficit were not seen. In conclusion, orbital penetrating gunshot wounds must be evaluated precisely by the surgeon and this evaluation sets the guidelines for management. The operation should be reserved for the patients in whom the necrotic soft tissues or orbital damages restrict ocular movements.

1950. Gonul, E., et al. (1997). "Causes of infections and management results in penetrating craniocerebral injuries." Neurosurgical review **20**(3): 177-181.

From February 1992 to December 1994, 148 patients with penetrating craniocerebral injuries were treated surgically with primary and secondary debridement including repair of dural defects and removal of retained intracranial bone and metal fragments. Dural defects were closed primarily or with temporalis fascia, pericranium, and cadaver graft. Cerebrospinal fluid fistulas were observed in 11 (7.3%) patients; 7 of these were infected. Central nervous system (CNS) infection was seen in 2 patients without CSF fistula. Excluding those 11 patients with CSF fistula CNS infection was shown in 2 of the 137 cases (1.5%). All patients underwent CT scans periodically. In 51 (34%) of 148 patients, bone and metal fragments were determined on control CT scans. During this time, 12 patients died (8%). Most of deaths were caused by the direct effect of brain injury and occurred within the first month after injury. Fragments retained after first debridement were followed periodically by CT scan. Surgery was not performed until infection developed. Retained fragments did not increase the infection risk, but high rates of infection did occur in cases with CSF fistula.

1951. Gonul, E., et al. (1999). "Craniocerebral gunshot wounds: Analysis of 288 cases, a clinical review." Turkish neurosurgery **9**(1-2): 1-7.

This paper is a retrospective analysis of 288 craniocerebral gunshot wounds treated over a 5-year period. Twenty-one in-hospital deaths occurred, most as a direct result of brain injury. The level of central nervous system (CNS) damage was the most valuable prognostic factor in these cases. The presence of diffuse brain damage, brainstem injury, CNS infection, or ventricular injury was associated with poor outcome.

1952. Gonul, E., et al. (2005). "Penetrating orbitocranial gunshot injuries." Surgical neurology **63**(1): 24-31.

BACKGROUND: The aim of this study was to analyze the effect of a surgical management protocol and other important clinical features on the prognosis of patients who had penetrating orbitocranial gunshot injuries., METHODS: Thirty-five patients (30 unilateral, 5 bilateral) who had penetrating orbitocranial gunshot injuries were analyzed. The wounds were mainly caused by shrapnel fragments or bullets. Craniotomy was the standard treatment in all patients. Investigated clinical features included Glasgow Coma Scale (GCS) score on admission, the mode and the extent of brain injury, and the presence of an intracranial retained foreign body. The prognostic importance of complications such as infection, intracranial hemorrhage, cerebrospinal fluid leak, and epileptic seizures was also investigated. The mechanism and the injury characteristics of the patients were evaluated by predicting the visual outcome of the victims according to a newer classification system as well as other variables pertinent to this specific clinical setting of severe eye trauma. Final visual acuities of the patients were also measured., RESULTS: The outcome of 35 penetrating orbitocranial gunshot injured patients was as follows: death in 3 patients, vegetative state in 1, severe disability in 2, moderate disability in 2, and good recovery in 27 cases. Localization and extent of the injury and GCS score on admission were the most important indicator for good neurological outcome. The predictors for good visual outcome were type B, grade 1, zone I,

and relative afferent pupillary defect-negative injuries. The predictors for poor outcome were type A, grade 5, zone III, and relative afferent pupillary defect-positive injuries., CONCLUSION: The prognosis of the injury depends on the course of the bullet or shrapnel fragment and the interdisciplinary care. An extensive preoperative evaluation of penetrating orbital trauma and a combined ophthalmic and neurosurgical approach are recommended to minimize the morbidity of the patients. However, complete removal of the foreign material in a deep or ventricular localization is not mandatory because careful debridement and tight closure of dura provides desired outcome. Evaluation of trauma mechanism and injury characteristics according to the Ocular Trauma Classification System seems to predict accurately the visual outcomes in this series.

1953. Gonullu, M. E., et al. (2016). "The Surgical Strategy for the Intraorbital Foreign Bodies." The Journal of craniofacial surgery **27**(7): 1785-1788.

PURPOSE: Four patients with intraorbital foreign bodies admitting to our clinic between 2001 and 2011 are presented. Their clinical and radiologic findings and surgical strategies are discussed., OBJECTIVE: The success of surgery for the intraorbital foreign bodies largely depends on the determination of the exact localization of them. Radiologic examination should follow clinical diagnosis. Computed tomographic views are especially required to demonstrate the foreign body., MATERIALS AND METHODS: Four patients with different etiologies of trauma are presented. Each had computed tomography views for foreign body localization. All but 1 had surgery for removal of the object under general anesthesia., RESULTS: No complications were observed postoperatively. Only 1 patient is followed up without an operation due to the risk of damaging delicate structures that the foreign body is close to. He has no loss of function., CONCLUSION: Early removal of foreign bodies in orbital region is usually preferred due to the risk of neurologic damage and other complications. Surgical removal is quite challenging for foreign bodies like wood. Magnets can be used for metallic bodies.

1954. Gonzalez, C., et al. (2011). "Impact of therapeutic temperature modulation in severe traumatic brain injury." Neurocritical care **15**(1): S213.

Introduction It is estimated that 1.7 million people suffer from Traumatic Brian Injury (TBI) every year in the United States. This constitutes a major public health problem. Secondary brain injury is a consequence of multiple factors including excess glutamate, oxidative damage and ischemia. Therapeutic temperature modulation may have a neuro protective role in these patients. However temperature modulation may cause increased ICU length of stay, increase ventilator days, thromboembolic events, pneumonia and other infections complications. Methods We retrospectively analyzed 28 charts of patients admitted to NSICU or TICU in our institution, between 2007-2009. Inclusion criteria: GCS < 9, admission to the ICU 24 hrs and non-penetrating TBI. The patients were divided into a temperature modulation group, both induced normothermia and hypothermia, and controls. The decision to use temperature modulation was at the discretion of the attending physician. Results There were thirteen patients in the temperature modulation (TM) group (10 males, 3 females) and fifteen in the control group (C) (12 males and 3 females). Mean aGCS was 4.15±1.72 for TM group and 4.71±1.90 for C group; p=0.43. The ICU los was, TM group 19.64±8.25, C group 14.5±7.90; p=0.16). Ventilator days were 17.5±9.65, 14.21±10.18 in TM group and controls p=0.41. Maximal ICP in TM group 36.7±22.08 and controls 30.5±21.97; p=0.47. Mortality was 15.4 % in TM group and 20% in controls p=0.7 Conclusions In this cohort of subjects with severe TBI there was a weak trend towards increased length of ICU stay in the TM group without a difference in mortality or ventilator days. The difference in maximal ICP may indicate significant selection bias as this was a retrospective study patients may have been treated with therapeutic hypothermia because of increasing ICP. We will need to continue to study this in a larger cohort to determine if these observations are statistically significant.

1955. Gonzalez-Cruz, J., et al. (2007). "Penetrating orbitocranial injury to the sella: case report and review of the literature." The Journal of the Louisiana State Medical Society : official organ of the Louisiana State Medical Society **159**(6): 310-314.

UNLABELLED: A 39-year-old woman sustained a self-inflicted transorbital penetrating injury that resulted in direct pituitary injury with hypopituitarism and decreased vision in the opposite eye. Several hormone deficiencies were detected. Even though this patient did not develop any other complications from her injury (abscess, cerebrospinal fluid fistula or pseudoaneurysm), after two years of follow-up no recovery of pituitary or visual function has occurred.,

CONCLUSION: From our experience in this case, we propose a conservative multidisciplinary approach when dealing with this type of lesion. Broad spectrum antibiotic coverage and early detection and replacement of any hormone deficiency should be instituted.

1957. Goodman, C., et al. (2012). "Penetrating brain injury from nail guns: Epidemiological, clinical and forensic characteristics." Journal of neurotrauma **29**(10): A85-A86.

Introduction Nail guns, essential tools in modern construction, propel nails using compressed air, electromagnets, explosive gases or gunpowder. 37,000 nail gun injuries, including cranial injuries, occur annually. There are similarities and differences between penetrating head injury from nail guns versus firearms. Methods We ascertained and reviewed cases of cranial nail gun injuries at the Ben Taub General Hospital (one of two Level I Trauma Centers in Houston, Texas) and the Harris County Institute of Forensic Sciences. The site of injury, patient demographics, clinical outcome and nature of the projectiles were recorded. Nails ejected from nail guns are classified by size ranging from finishing nails (25.4mm long · 1.47 mm weighing 336 mg) to framing nails (152.4mm long · 6.68mm weighing 45.36 gm). Results We identified six cases of cranial nail gun injury. All were in men below age 45 years. Two cases were fatal and four were non-lethal with four accidents, one assault and one suicide attempt. The penetration was supratentorial in five and infratentorial in one. Large framing nails were the solitary projectiles in 5 cases and in the one suicide attempt, multiple (4) finishing nails penetrated the skull. In the lethal cases, one involved the nail traveling through the thin bones of the orbit into the brain, and the other caused hemorrhage following removal of the nail at the construction site where the injury occurred. It appears that venous sinuses were penetrated and tamponaded by the nail, and upon removal of the projectile, hemorrhage and clinical deterioration ensued. In the survivable cases, nails were removed under controlled conditions. The most serious morbidity was ataxia and cranial nerve dysfunction from pontine and cerebellar damage in the case of infratentorial penetration. The severity of tissue damage inflicted by a penetrating missile depends on the amount of kinetic energy that the projectile brings to the transaction. Nail gun injuries differ from firearm injuries because they possess less kinetic energy. Nails emerge from nail guns at a velocity of between 100-150 meters/second; therefore, even the heaviest framing nail will possess modest kinetic energy compared to firearm bullets. Additionally, framing nails possess a flat head that affixes the nail to the skull, preventing the projectile from completely entering the cranial vault. Lethality occurs when vascular structures such as venous sinuses are lacerated or when the projectile travels relatively unimpeded through thin bone. Conclusions Nail gun brain injuries are increasing in frequency with more widespread use of these tools largely among young men. Mechanistically the tissue injury reflects parenchymal laceration without large kinetic energy transfer with cavitation and shock waves. Survival is likely unless vascular structures are lacerated or the projectile penetrates vital parenchymal structures. These injuries may be preventable and public health campaigns are underway to educate end users about the correct and safe use of nail guns. If injury with cranial penetration occurs, it is critical that the nail not be removed at the construction site, during transport or in the emergency center, but under controlled conditions in the operating room. The ballistics of nail gun injuries differ fundamentally from firearm injuries; therefore, they are not an appropriate model of high energy penetrating brain injury.

1958. Goodman, J., et al. (2016). "Penetrating brain injury from nail guns: Epidemiological, clinical and forensic features." Neurology **86**(16).

Objective: To report clinical aspects of cranial nail gun injuries. Background: Nail guns are essential tools in construction but nail gun injuries result in 37,000 Emergency Department visits annually including cranial injuries. Methods: We reviewed cranial nail gun injuries at the Ben Taub General Hospital and the Harris County Institute of Forensic Sciences. Injury site, demographics, outcome and nature of the projectiles were recorded. Results: We identified six cases of cranial nail gun injury. All were in men below age 45 years. Two were fatal and four were non-lethal with four being accidental, one assault and one suicide attempt. The penetration was supratentorial in five and infratentorial in one. Large framing nails were solitary projectiles in 5 cases and in the suicide attempt, multiple finishing nails penetrated the skull. Lethal cases involved the nail traveling through thin orbital bones into the brain or hemorrhage following ill-advised nail removal at the construction site. In the non-lethal injuries, the nails were removed

under controlled conditions. The most serious morbidity was ataxia and cranial nerve dysfunction from pontine and cerebellar damage following infratentorial penetration. Nails emerge from nail guns at a velocity of 100-150 meters/second; therefore, even the heaviest framing nail possess modest kinetic energy compared to firearm bullets. In addition, framing nails possess a flat head that affixes the nail to the skull, preventing the projectile from completely entering the cranial vault. Conclusions: Nail gun brain injuries are increasing reflecting widespread use of these tools particularly among young men. The tissue injury reflects parenchymal laceration without large kinetic energy transfer. These injuries are preventable and public health campaigns are underway to educate users about the safe use of nail guns. If injury with cranial penetration occurs, it is critical that the nail be removed under controlled conditions in the operating room.

1962. Goodrich, J. T., et al. (1992). "Split-thickness bone grafts in complex craniofacial reconstructions." Pediatric neurosurgery **18**(4): 195-201.

We have operated on 20 patients with various forms of complex skull defects due either to trauma, tumor, or craniofacial problems. These cases have required complex reconstruction of defects involving the calvarium and anterior skull base. We review here our techniques of using locally harvested split-thickness calvarium bone grafts in the reconstruction of complex face and anterior fossa defects, secondary to tumor, trauma and craniofacial problems. With these harvesting techniques sufficient bone becomes available for large reconstructions, with minimum morbidity to the patient. The aesthetic results are excellent allowing for good facial and forehead contouring with minimal risk to the patient. In the case of traumatic injuries the surgery can also be performed early with the risk of infection being markedly reduced. Long-term results with split-thickness calvarial grafts have shown less bone resorption when compared with rib grafts.

1964. Gopal, L., et al. (1995). "Retinal detachment secondary to ocular perforation during retrobulbar anaesthesia." Indian journal of ophthalmology **43**(1): 13-15.

The clinical characteristics and the retinal breaks associated with rhegmatogenous retinal detachments secondary to accidental globe perforation during local infiltration anaesthesia in five highly myopic eyes are presented. Retinal detachment was total with variable proliferative vitreoretinopathy. The pattern of retinal breaks was rather typical and predictable. Management involved vitreous surgery with internal tamponade by silicone oil in four eyes and perfluoropropane gas in one eye. At the last follow-up, all eyes had attached retina. One eye did not recover useful vision due to possible concurrent optic nerve damage.

1965. Gopal, L., et al. (1995). "Vitrectomy for accidental intraocular steroid injection." Retina (Philadelphia, Pa.) **15**(4): 295-299.

BACKGROUND: Accidental perforation of the globe and intraocular injection of steroid is a potential complication of periocular injections. Final outcomes in eyes in which this complication has occurred have been reported

to be unsatisfactory in the past. However, the advent of vitrectomy has altered their prognosis significantly., METHODS: A retrospective analysis was done of five cases of accidental intraocular steroid injection, treated by vitrectomy. Additional procedures involved treatment of retinal breaks (where required) with endolaser or transscleral cryopexy. Scleral buckling was done in one case., RESULTS: Barring one case in which retinal detachment developed, there were no postoperative complications. At last follow up all patients had satisfactory recovery of visual acuity; had attached retina; and quiet anterior chamber and vitreous cavities., CONCLUSION: Vitrectomy is associated with satisfactory results in cases of accidental intraocular steroid injection. Delay up to a few days does not seem to materially influence the outcome.

1966. Gor, D. M., et al. (2001). "Radiologic differentiation of intraocular glass: evaluation of imaging techniques, glass types, size, and effect of intraocular hemorrhage." AJR. American journal of roentgenology **177**(5): 1199-1203.

OBJECTIVE: The accurate detection of intraocular foreign bodies is critically important in treating ocular trauma. The purpose of this study was to evaluate the efficacy of CT, MR imaging, and sonography in detecting seven types of glass varying in size and placed in three locations in the globe, and to examine the effect of intraocular hemorrhage., MATERIALS AND METHODS: Glass pieces were cut into 1.5-, 1.0-, and 0.5-mm pieces and implanted on the corneal surface and the anterior and posterior chambers of 42 fresh porcine eyes. Twenty-one eyes were scanned comparing axial CT, helical CT, and MR imaging. The remaining 21 eyes were scanned using helical CT and sonography after implantation in a simulated human skull before and after placement of blood in the anterior chamber (hyphema)., RESULTS: Detection rates were 57.1% for helical CT, 41.3% for axial CT, and 11.1% for T1-weighted MR imaging (n = 63 fragments). Results were significant ($p < 0.0001$). Sonography detected 43% of glass fragments in the posterior chamber and 24% in the anterior chamber. Detectability was greatest for green beer bottle glass (90.3%) and least for spectacle glass (43.1%) ($p < 0.0001$). Detection rates for size ranged from 96.2% at 1.5 mm to 48.3% at 0.5 mm, which was also significant ($p < 0.0001$). On helical CT, anterior chamber glass was easiest to detect (91.7%) and corneal surface glass the most difficult (64.9%). Hyphema made no statistical difference ($p < 0.0001$)., CONCLUSION: Helical CT was the most sensitive imaging modality for the detection of intraocular glass. The sensitivity of detection was unaffected by hyphema but was determined by the type of glass, size, and location.

1967. Gorbulenko, V. B., et al. (2002). "[Treatment of the wounded and patients with acquired facial defects and deformations]." Lechenie ranenykh i bol'nykh s priobretennymi defektami i deformatsiiami litsa. **323**(8): 19-96.

The authors describe the peculiarities of surgical treatment of 293 casualties with gunshot injuries and burns of maxillofacial area and 637 oncologic patients. The working classification of facial defects and deformations based on topographic-and-anatomic, morphological, functional and expert signs was developed 4 degrees of tissue lesions that are very important in the choice of rational treatment method were selected. Individual dental splints and method of formation combined round petiole consisted of arterialized musculocutaneous and dermatofatty parts were proposed. Long experience obtained in surgical treatment of patients with acquired facial defects and deformations permitted to reduce the treatment periods and to obtain good and satisfactory functional and cosmetic results in 95.3% of the cases.

1968. Gordon, D. (1976). "Depressed fractures and missile wounds of the skull." Nursing mirror and midwives journal **142**(8): 45-46.

1969. Gordon, D. S. (1974). "Depressed fractures and missile wounds of the skull." British journal of hospital medicine **12**(2): 177-192.

It is customary to consider head injuries in two chief categories; generalized and localized, while recognizing that some patients have features of both types of injury. In this article the features of generalized brain damage are considered only briefly and in relation to very severe penetrating head injuries. There is no room for complacency about the surgical management of depressed fractures of the skull. Delayed diagnosis or inadequate surgery still gives rise to serious complications. Advances in supportive treatment evolved in the past decade have improved the outlook for patients with severe depressed fractures and penetrating wounds resulting from explosions or firearms. The mortality from penetrating missile injuries, however, remains high.

1970. Gordon, D. S. (1975). "Surgery of violence. V. Missile wounds of the head and spine." British medical journal **1**(5958): 614-616.

The patient with a cerebral gunshot wound has a very unstable condition. In Belfast emphasis has been laid on rapid evacuation and on starting resuscitation within a few minutes of injury. Early and adequate transfusion combats shock; controlled ventilation helps limit the rise in intracranial pressure. Intracranial haematomata should be sought by early operation. Operation seldom improves neurological function in missile wounds of the spine.

1971. Gordon, D. S. and G. A. Blair (1974). "Titanium cranioplasty." British medical journal **2**(5917): 478-481.

The technique of repairing defects of the skull with titanium is described. The skull contour can be accurately reproduced. The technique is simpler than wiring or suturing methods. The material is inert, radiolucent, and rigid.

1973. Gordon, M. N., et al. (1997). "Exaggerated astrocyte reactivity after nigrostriatal deafferentation in the aged rat." The Journal of comparative neurology **388**(1): 106-119.

Although clinical experience suggests that brain injury in the aged is associated with a poor prognosis, little research has examined this phenomenon at a cellular or molecular level. Unilateral 6-hydroxydopamine lesions of the nigrostriatal system were produced in 6-, 15- or 24-month-old rats. In the deafferented neostriatum, the time-dependent induction of glial fibrillary acidic protein (GFAP) was larger and persisted longer in the aged rats. The response of middle-aged rats was intermediate. In contrast, no induction of S-100 or glutamine synthetase was observed in any age group. In a second series of rats with stab wounds in the neostriatum, there were substantially larger GFAP inductions than after deafferentation, but fewer effects of age. However, in both lesion paradigms, GFAP staining increased in the contralateral striatum of old rats, but not in young rats. These data support and extend our earlier work describing larger GFAP RNA inductions after fornix transections in aged mouse hippocampus. The consistency of this exaggerated glial reactivity in the aged brain after modest injury suggests the following: 1) aged astrocytes are more sensitive to gliotrophic factors released by terminal degeneration, 2) larger quantities of such factors are produced after injury, 3) clearance of these factors is delayed in old rodents, and/or 4) aged astrocytes are less able to terminate GFAP inductions after activation. Given the potential role of inflammatory reactions as pathogenic mechanisms in Alzheimer's dementia, these data suggest that age-related glial hypersensitivity may independently increase the risk for some degenerative diseases.

1976. Gorissen, Z., et al. (2019). "Pneumocephalus: a rare and life-threatening, but reversible, complication after penetrating lumbar injury." Acta neurochirurgica **161**(2): 361-365.

Pneumocephalus, the presence of intracranial air, is a complication especially seen after neurotrauma or brain surgery. When it leads to a pressure gradient, a so-called tension pneumocephalus, it may require emergency surgery. Clinical symptomatology, especially in young children, does not differentiate between a pneumocephalus and a tension pneumocephalus. An additional CT scan is therefore warranted. Here, we report on a rare case of pneumocephalus after penetrating lumbar injury. Additionally, the pathophysiology of pneumocephalus, as well as its recommendations for diagnosis and treatment, will be elucidated.

1977. Goswami, S. (2013). "A bullet in the maxillary antrum and infratemporal fossa." Indian journal of dental research : official publication of Indian Society for Dental Research **24**(1): 149.

A young male patient was shot from a revolver on his left temple from a close range, but surprisingly he survived. On imaging, a complete bullet was found occupying his left maxillary sinus and infratemporal fossa. The bullet, after hitting and breaking the neck of the mandible on the left side, ricocheted and entered the left maxillary sinus through its posterior wall. It was removed safely by a combination of sublabial antrotomy and endoscopic approach.

1980. Govorun, M. I., et al. (2009). "[Damages of ENT-organs inflicted by the weapon of not-lethal (traumatic) action]." Voenno-meditsinskii zhurnal **330**(9): 32-37.

There was effectuated a research of killability of traumatic weapon in laboratory as well as during analyzing of clinical observations. There were considered the results of treatment of 8 persons, suffered from traumatic weapon. It was occurred a clinical recovery by 7 wounded persons from 8. There was 1 case of lethal outcome for first hours, caused by trauma of temporal bone and cerebrum (suicide). Thus, influence of traumatic weapon on ENT-organs can be a reason of serious penetrating wounds, facial bones fracture, hematomas and contusion, formation of foreign bodies and middle ear barotraumas.

1981. Gowing, G., et al. (2006). "Mouse model for ablation of proliferating microglia in acute CNS injuries." Glia **53**(3): 331-337.

Activation of microglia, the primary immune effectors of the CNS and proinflammatory signaling, is a hallmark of brain damage. However, it remains controversial whether microglial cells have beneficial or detrimental functions in various neuropathological conditions. We report the generation of transgenic mice that express a mutant form of herpes simplex virus type 1 thymidine kinase (HSV-1 TK(mt-30)) driven by the myeloid-specific CD11b promoter. Using two paradigms of nervous system damage, hypoglossal nerve axotomy, and cortical stab injury, we show that specific ablation of proliferating microglia in CD11b-TK(mt-30) mice can be achieved by administration of ganciclovir. For example, after hypoglossal nerve injury, a 75% reduction in proliferating microglial cells was observed at the site of injury. The CD11b-TK(mt-30) transgenic mouse should provide a valuable tool for studying the role of microglia in CNS damage and repair. Copyright (c) 2005 Wiley-Liss, Inc.

1982. Goyal, K., et al. (2021). "Ocular spectrum of kite injury: A six-year trend at a tertiary eye care center." Indian journal of ophthalmology **69**(2): 286-289.

Purpose: To assess ocular morbidity attributable to kites (patang) with emphasis on the cause, type and severity of the injury, complications, and final visual outcome., Methods: All the patients with a history of kite injury during months of Makar Sankranti for consecutive 6 years (2014-2019) were included in this study. A B-scan, orbital X-ray, and CT scan were performed for extensive ocular evaluation., Results: : Out of 68 patients with kite-related injury, 58 were male and 10 were female. Globe rupture (20), lid laceration (18), penetrating injury (9), wooden foreign body in the anterior or posterior chamber (7), superficial foreign body (4), hyphema (7), and vitreous hemorrhage (3) due to falling from height were noted. Factors associated with a poor final visual outcome in our study were poor initial visual acuity, globe rupture, intraocular foreign body, and development of endophthalmitis., Conclusion: Kites can cause serious preventable injuries mostly among pediatric males. The use of protective eyewear and public awareness can decrease ocular injury significantly.

1984. Goycoolea, A. N., et al. (2014). "Transorbital penetrating brain injury, caused by metallic cloth hanger in a 3 year old child; removal strategy and review of literature." Child's Nervous System **30**(11): 1991-1992.

Penetrating brain injury is a very rare condition during times of peace. In the child population, low-velocity, non-missile objects are the most frequent.We report the case of a 3 years old child, who fell into a metallic cloth hanger resulting in a severe type of Traumatic Brain Injury. To avoid unwanted movement of the hanger, the patient was deeply sedated and connected to mechanical ventilation, that allow us to complete the study with computed tomography, 3D reconstructions, and brain angiography. We concluded that there was no vascular damage or brain hemorrhage. With the tip of the hanger just 1 millimeter from the right internal Carotid artery, and 3 millimeters from the brain stern, a dangerous and ambitious removing strategy was proposed. With direct angiography vision, and the operating room prepared for open skull vascular reparation, the team removed the hanger slowly pulling it backwards with no immediate complications. After the sedation was suspended, the child had a complete right side third nerve palsy, with normal visual function and no other neurologic damage. One week after the removal of the hanger, the patient had positive clinical evolution, a post procedure MRI showing minimal hemorrhagic contusion and no infectious complication, free from antibiotic treatment. He was discharged wile partially recovering the right third nerve palsy. Penetrating transorbital brain injury are uncommon and potentially severe lesions. The damage mechanism is mainly direct laceration of vascular structures or parenchymal contusion. Damage could occur during the accident or removal, as the object may be tamponading an injured vessel. Strategies to remove foreign objects without causing secondary damage could vary case to case. Diverse objects are described in the literature, but no cases of cloth hangers were found in the review. Authors (primarily Japanese) agree that no attempt should be made to remove the foreign body without the backup of an operating room, or a complete study of vascular structures involved. As explained through this case, a careful and multidisciplinary approach to these infrequent cases will increase the chances of a positive outcome.

1985. Gozzi, M., et al. (2009). "Dissociable effects of prefrontal and anterior temporal cortical lesions on stereotypical gender attitudes." Neuropsychologia **47**(10): 2125-2132.

Clinical observations of patients with ventral frontal and anterior temporal cortical lesions reveal marked abnormalities in social attitudes. A previous study in seven patients with ventral prefrontal lesions provided the first direct experimental evidence for abnormalities in social attitudes using a well-established measure of gender stereotypes, the Implicit Association Test (IAT). Here, we were able to test whether these first findings could be reproduced in a larger sample of 154 patients with penetrating head injuries, and to determine the differential effects of ventromedial prefrontal (vmPFC) and ventrolateral prefrontal (vlPFC) cortical lesions on IAT performance. In addition, we investigated the role of the superior anterior temporal lobe (aTL), recently shown to represent conceptual social knowledge. First, we used a linear regression model to identify the role of each of the three regions, while controlling for the extent of damage to other regions. We found that larger lesions in either the vmPFC or the superior aTL were associated with increased stereotypical attitudes, whereas larger lesions in the vlPFC were associated with decreased stereotypical attitudes. Second, in a confirmatory analysis, we grouped patients by lesion location and compared their performance on the IAT with that of healthy volunteers. Compared to controls, patients with lesions in either the vmPFC or the superior aTL showed increased stereotypical attitudes, whereas patients with lesions in the vlPFC showed decreased stereotypical attitudes. The functional contributions of these regions in social attitudes are discussed.

1986. Grabb, P. A., et al. (1997). "Continuous intraoperative electromyographic monitoring of cranial nerves during resection of fourth ventricular tumors in children." Journal of neurosurgery **86**(1): 1-4.

The authors reviewed the results of continuous intraoperative electromyographic (EMG) monitoring of muscles innervated by cranial nerves in 17 children whose preoperative imaging studies showed compression or infiltration of the fourth ventricular floor by tumor to determine how intraoperative EMG activity correlated with postoperative cranial nerve morbidity. Bilateral lateral rectus (sixth) and facial (seventh) nerve musculatures were monitored in all children. Cranial nerve function was documented immediately postoperatively and at 1 year. Of the 68 nerves monitored, nine new neuropathies occurred in six children (sixth nerve in four children and seventh nerve in five). In five

new neuropathies, intraoperative EMG activity could be correlated in one of four sixth nerve injuries and four of five seventh nerve injuries. Electromyographic activity could not be correlated in four children with new neuropathies. Of 59 cranial nerves monitored that remained unchanged, 47 had no EMG activity. Twelve cranial nerves (three sixth nerves and nine seventh nerves) had EMG activity but no deficit. Of four children with lateral rectus EMG activity, three had new seventh nerve injuries. Lateral rectus EMG activity did not predict postoperative abducens injury. The absence of lateral rectus EMG activity did not assure preserved abducens function postoperatively. Likely because of the close apposition of the intrapontine facial nerve to the abducens nucleus, lateral rectus EMG activity was highly predictive of seventh nerve injury. Although facial muscle EMG activity was not an absolute predictor of postoperative facial nerve dysfunction, the presence of facial muscle EMG activity was associated statistically with postoperative facial paresis. The absence of facial muscle EMG activity was rarely associated with facial nerve injury. The authors speculate that EMG activity in the facial muscles may have provided important intraoperative information to the surgeon so as to avoid facial nerve injury.

In 184 rabbits experiments it was demonstrated that debridement with suction of the damaged portion of the brain within the macroscopically intact brain tissue and a leak-proof suture undertaken on the 1st and 3rd day following a penetrating skull-brain trauma in irradiated with 400 r and non-irradiated animals prevents heamorrhagic and purulent complications, permits primary healing of the wound, and a nearly 100% survival of the animals. The irradiated animals without debridement died in 67% of cases, non-irradiated--in 43%. Debridement limited to wound debris washing-out failed to free the irradiated animals from purulent complications, but prevented the development of cerebral haematomas, the mortality being reduced to 40%. In the non-irradiated animals such debridement did not alter the mortality figures.

1989. Gracias, V. H., et al. (2001). "Computed tomography in the evaluation of penetrating neck trauma: a preliminary study." Archives of surgery (Chicago, Ill. : 1960) **136**(11): 1231-1235.

HYPOTHESIS: Penetrating neck trauma has traditionally been evaluated by surgical exploration and/or invasive diagnostic studies. We hypothesized that computed tomography (CT), used as an early diagnostic tool to accurately determine trajectory, would direct or eliminate further studies or procedures in stable patients with penetrating neck trauma., DESIGN: Retrospective case series., SETTING: Academic, urban, level I trauma center., PATIENTS: Hemodynamically stable patients without hard signs of vascular injury or aerodigestive violation who had sustained penetrating trauma to the neck., INTERVENTIONS: Patients underwent a spiral CT as an initial diagnostic study after initial evaluation in the trauma bay. Further invasive studies were directed by CT findings., MAIN OUTCOME MEASURES: Number of invasive studies performed., RESULTS: Twenty-three patients were identified during the 30-month period. Nineteen patients sustained gunshot wounds; 3, shotgun wounds; and 1, a stab wound. One patient died of a cranial gunshot wound. Three isolated zone I, 1 isolated zone II, 9 isolated zone III, and 10 multiple neck zone trajectories were evaluated. Thirteen patients were identified by CT to have trajectories remote from vital structures and required no further evaluation. Ten patients underwent angiography. Only 2 underwent bronchoscopy and esophagoscopy. Four

patients were discharged from the emergency department; 7 other patients were discharged within 24 hours. No adverse patient events occurred before, during, or after CT scan., CONCLUSIONS: Computed tomography in stable selected patients with penetrating neck trauma appears safe. Invasive studies can often be eliminated from the diagnostic algorithm when CT demonstrates trajectories remote from vital structures. As a result, efficient evaluation and early discharge from the trauma bay or emergency department can be realized. Further prospective study of CT scan after penetrating neck trauma is needed.

1990. Graf, C. J., et al. (1981). "Complications of spinal drainage in the management of cerebrospinal fluid fistula." Journal of neurosurgery **54**(3): 392-395.

Continuous cerebrospinal fluid (CSF) drainage may be used in the treatment CSF fistula. The procedure, however, is not without risk. Marked gradients between the intracranial and intraspinal CSF pressures and intravasation of air through an unsealed fistula may produce serious neurological problems. The use of continuous CSF drainage requires an alert, informed nursing staff to avert catastrophe.

1992. Grafman, J., et al. (1990). "Wisconsin Card Sorting Test performance based on location and size of neuroanatomical lesion in Vietnam veterans with penetrating head injury." Perceptual and motor skills **71**(3 Pt 2): 1120-1122.

We examined Wisconsin Card Sorting Test performance in a large group of brain-damaged patients and controls. No differences were found between patients with frontal lesions only and those with nonfrontal lesions. Patients with left dorsofrontal and anterior temporal lobe lesions committed the most perseverative errors. More analyses regarding requirements for information processing on the Wisconsin Card Sorting Test are needed.

1993. Grafman, J., et al. (1988). "Intellectual function following penetrating head injury in Vietnam veterans." Brain : a journal of neurology **111 (Pt 1)**: 169-184.

The extent to which intellectual processes are preserved as a function of preinjury 'intelligence' and of size and location of the brain lesions was evaluated in Vietnam war veterans who survived penetrating missile wounds. With regard to an overall postinjury intelligence test score, preinjury intelligence was most predictive, size of lesion was next most predictive and lesion location was least important. For subtest scores from the same intelligence test, lesion location assumed much greater predictive value. Specifically, left temporal and occipital lesions impaired performance on subtests assessing vocabulary and object-function matching ability.

1994. Grafman, J., et al. (1986). "The relationship of brain-tissue loss volume and lesion location to cognitive deficit." The Journal of neuroscience : the official journal of the Society for Neuroscience **6**(2): 301-307.

We examined the relationship of preinjury intelligence, a lesion-severity variable (brain-tissue loss volume), and lesion location to the persistence of cognitive deficits in Vietnam veterans with penetrating brain wounds. Using stepwise multiple linear regression procedures, we found that preinjury intelligence predicted a significant amount of the variance on postinjury cognitive testing, being a better predictor for tests requiring a number of complementary cognitive processes (e.g., intelligence tests) than for tests measuring a specific cognitive process (e.g., face recognition). Brain-tissue volume loss was found to play a larger role when a global cognitive measure was used, but a smaller role when a specific cognitive process was measured. Finally, lesion location was shown to be a significant predictor of performance only for specific cognitive processes. Nevertheless, preinjury intelligence/education appears to play an even larger role in postinjury performance than either brain-tissue loss volume or a particular structural loss.

1995. Grafman, J., et al. (1986). "Face memory and discrimination: an analysis of the persistent effects of penetrating brain wounds." The International journal of neuroscience **29**(1-2): 125-139.

This study was designed to examine the effects of penetrating head injury upon face discrimination and memory in 213 brain-injured Vietnam veterans and 49 normal controls. Impairment on tests of face memory was most associated with bilateral lesions and with unilateral lesions of the temporal lobe. Impairment on a test of face discrimination was most associated with right hemisphere, and with bilateral lesions which included either frontal or parietal lobe involvement. Performance on these tasks appeared independent of other visuospatial or verbal tasks. Cluster analysis revealed a dissociation between performance on facial memory and facial discrimination tasks.

1996. Grafman, J., et al. (1985). "Isolated impairment of memory following a penetrating lesion of the fornix cerebri." Archives of neurology **42**(12): 1162-1168.

Persistent memory problems were reported by a 39-year-old man who suffered a penetrating brain wound while serving in Vietnam 15 years earlier. Neuropsychological testing indicated an unusually isolated memory impairment. Computed tomography revealed transection of the columns of the fornix cerebri with no temporal-lobe involvement and minimal thalamic damage. We suggest that the fornix cerebri has a role in the maintenance of information accessibility to both encoding and recall during post-working memory processing and in the organization of verbal information during encoding and/or retrieval for declarative (recall) purposes. These processes are not essential for verbal recognition but can result in decrements on specific laboratory tasks and in social adjustment.

1997. Graham, E. W., et al. (2014). "Decreased subject contrast and summation artifact: an explanation for a nearly imperceptible bullet by X-ray examination." The American journal of forensic medicine and pathology **35**(4): 249-252.

X-ray examination is used to detect foreign bodies during forensic autopsy of a suspected gunshot wound case. There are several previously described situations in which a projectile is not immediately localized by radiography. In this report, we present a case of a metal bullet lodged near the atlanto-occipital junction, where it was present but not readily apparent on radiograph. Although computed tomography is ideal for detecting such objects, many forensic pathologists must still rely on x-ray only. To our knowledge, the forensics literature does not contain a case where a lead bullet was rendered nearly imperceptible by x-ray examination. We describe 2 concepts of radiation physics-poor x-ray penetration and summation artifact-which can cause a radiopaque object such as a bullet to seem much less so. The difference between best practices in hospital and forensic radiology may explain how this occurred. This case serves to caution the pathologist that forensic radiographs may not completely depict the type or quantity of projectiles present in a gunshot wound case.

1998. Grahm, T. W., et al. (1990). "Civilian gunshot wounds to the head: a prospective study." Neurosurgery **27**(5): 696-700.

Previous retrospective studies of cranial gunshot wounds have failed to determine whether aggressive field resuscitation, triage to a neurosurgical center, and early surgical intervention can improve the assumed poor outcome of these severely injured patients. Therefore, we studied 100 consecutive patients prospectively to establish a systematic approach to treatment. If the patient retained two or more neurological signs after aggressive field resuscitation/intubation, a computed tomographic scan was performed. Rapid surgical debridement was done unless the patient deteriorated to clinical brain death. The Glasgow Coma Scale (GCS) score after resuscitation was 3 to 5 in 58 patients, 6 to 8 in 8 patients, 9 to 12 in 12 patients, and 13 to 15 in 22 patients. Seventy-six computed tomographic scans and 43 craniotomies were performed. The Glasgow Outcome Scale scores showed that 60 patients died, 2 were vegetative, 6 were severely disabled, 20 were moderately disabled, and 13 had good outcomes. There were 10 postoperative deaths. No patient with a GCS score of 3 to 5 had a satisfactory outcome; however, outcome progressively improved as the GCS score increased. We conclude that all cranial gunshot patients should initially receive aggressive resuscitation. Patients with stable vital signs should be examined by computed tomographic scan. If the patient's GCS score after resuscitation is 3 to 5 and no operable hematomas are present, then no further therapy should be offered. All patients with a GCS score greater than 5 should receive aggressive surgical therapy.

2000. Granier, P. and H. Namaki (2012). "[Coverage of post-traumatic brain exposure by a total temporal flap: a case report]." Couverture d'une exposition cerebrale post-traumatique par un lambeau temporal total : a propos d'un cas. **58**(5): 301-308.

Major defect of the scalp associated with penetrating brain injury is one of the most challenging issues in acute craniofacial trauma. Depressed skull fractures associated with injuries of the skin and periosteal tissue can be easily covered using various locoregional scalp flap techniques. However, if the skin is damaged around the wound, the surgical possibilities are reduced, allowing only local transposition flap or free flap coverage with many disadvantages for the latter such as vascular micro-anastomosis issues, unsuitable underlying vascular status, and a "patch" effect which is often unsightly. The authors describe, using a clinical case, the steps to provide a total temporal flap to cover a defect of both skin and bone. This can be performed in three separated stages: the first is the empowerment of both middle temporal pedicles; the second stage, 15 days later, is the section, transposition and coverage of the wound; the third stage, 30 days later, is the flap separation. 2002. Grant, S., et al. (2015). "Direct optic neuropathy in a simple temporal laceration: A case report." International journal of oral and maxillofacial surgery **44**: e216.

Background: Facial lacerations are a common presentation in emergency departments. It is important to appreciate the mechanism of injury and the anatomy of structures involved in penetrating lacerations in the maxillofacial region. These penetrating injuries can easily be over looked, especially if the patients appear well on presentation. Case report: We report an unusual injury with a serious complication. A65-year-old gentleman lost his footing whilst buttering toast with a sharp kitchen knife. He fell to the floor with the knife penetrating the right temporal region. He immediately removed the knife, there was no loss of consciousness. There was a single laceration to the right temporal region. The right eye had no perception to light, a total afferent and efferent pupillary defect and partial ophthalmoplegia. CT scan revealed signs of penetration through the skin, temporalis, postero-lateral orbital wall and orbital apex. There was no injury to the globe or either retrobulbar or intracranial haemorrhage. Discussion: Direct Traumatic Optic Neuropathy (TON) results from disruption of the optic nerve by a penetrating object. Direct TON causes severe and immediate loss of vision with little prospect of recovery. The initial visual acuity is the strongest predictor of visual recovery. Only two similar cases of penetrating trauma in the temporal region resulting in directTONhave been identified in the literature. This case presentation, with clinical photographs and CT scan images, highlights the structures that are at risk of damage from penetrating trauma in the maxillofacial region.

2003. Grant, W. F., Jr. and K. G. Swan (1980). "Gunshot wounds of the orbit." The Journal of trauma **20**(9): 809-811.

Isolated gunshot wounds of the orbital contents are relatively rare, and therefore their management deserves updating in terms of current practices. Two cases of isolated gunshot wounds to the orbital contents are presented, and the diagnosis, management, and prognosis are reviewed. In general, in the absence of light perception, enucleation within a planned timetable is the treatment of choice to prevent sympathetic ophthalmia from destroying sight in the uninjured eye. If light perception is present, every attempt should be made to preserve the injured eye. Enucleation of a blind injured eye is the treatment of choice because it is a more complete eradication of the potential for sympathetic ophthalmia. In selected cases, evisceration can be successfully substituted.

2004. Grassetto, A., et al. (2012). "Rotational thromboelastometry analysis and management of life-threatening haemorrhage in isolated craniofacial injury." Blood coagulation & fibrinolysis : an international journal in haemostasis and thrombosis **23**(6): 551-555.

Massive haemorrhage from facial fractures is rare but the associated mortality rate is high. Here, we describe a case in which thromboelastometry [rotational thromboelastometry (ROTEM)]-guided administration of prothrombin complex concentrate and fibrinogen concentrate was effective in correcting coagulopathy in a 68-year-old man with serious craniofacial trauma and massive haemorrhage. The patient, a cyclist who collided with a car, was transferred to

the emergency department of our hospital with signs of shock and significant bleeding from multiple fractures and soft tissue injuries to the face. Blood gas analysis and standard laboratory tests revealed the presence of anaemia and acidosis, and our massive haemorrhage protocol was initiated. E-FAST and total-body computed tomography scans excluded the possibility of bleeding from other sites. All efforts were directed towards stopping bleeding from craniofacial lesions, but the surgeon experienced difficulty in maintaining haemostasis. ROTEM analysis revealed severe coagulopathy and was indispensable in guiding transfusion: 2 g tranexamic acid, followed by 1000 IU prothrombin complex concentrate, 5 g fibrinogen and 2 U platelet concentrate. Two hours later, ROTEM analysis showed that coagulopathy had been corrected, and haemostasis was confirmed by cessation of bleeding. This report highlights the potential for using ROTEM to guide treatment with fibrinogen and prothrombin complex concentrates in the presence of profuse multifocal bleeding and severe coagulopathy.

2005. Graves, W. C., et al. (2021). "Pre- and in-hospital mortality for moderate-to-severe traumatic brain injuries: an analysis of the National Trauma Data Bank (2008-2014)." Brain injury **35**(3): 265-274.

Objectives: This study aimed to: (1) evaluate pre- and in-hospital mortality for moderate-to-severe TBI in the U.S. by injury type (blunt vs. penetrating) and (2) estimate annual regression-adjusted mortality from 2008-2014. Methods: Data were analyzed from the National Trauma Data Bank (N=247,648). Multivariable logistic regression analyses were performed by injury type to assess changes in mortality between study periods (early period: 2008-2010; late period: 2011-2014) and to estimate annual regression-adjusted mortality. Mortality odds ratios and 95% confidence intervals were calculated. Results: Total observed mortality was 18.8%. After covariate adjustment, patients in the late period had an increased odds of prehospital mortality compared to patients in the early period for blunt (OR: 4.69; 95%CI: 4.41-4.98) and penetrating trauma (OR: 4.71; 95%CI: 4.39-5.06). In contrast, patients in the late period had a decreased odds of in-hospital mortality compared to patients in the early period for blunt (OR: 0.95; 95%CI: 0.91-0.98) and penetrating trauma (OR: 0.92; 95%CI: 0.85-0.98). Conclusions: The decreasing in-hospital mortality trend is consistent with previous literature. Additional research is warranted to validate the observed increase in prehospital mortality and to identify best practices that can improve prehospital outcomes for patients with moderate-to-severe TBI.

2006. Gray, E., et al. (2002). "Survey of trauma patients requiring maxillofacial intervention, ages 56 to 91 years, with length of stay analysis." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **60**(10): 1114-1125.

PURPOSE: The purpose of this study was to analyze trauma patients, ages 55 and older, sustaining multiple injuries including maxillofacial trauma. Factors influencing length of intensive care unit stay (ICUS) and length of total hospital stay were delineated and examined to determine if specific causes of increased length of stay could be elucidated, and, once known, if these causes could translate into recommendations tailored to the oral and maxillofacial surgery trauma practice., PATIENTS AND METHODS: One hundred ninety-six patients, 55 years of age or older, who received either consultation alone, or consultation with surgical treatment, by oral and maxillofacial surgeons, from January 1991 to August 1998 were included in this study. Variables of interest included location of traumatic event, mechanism of injury, patient age and gender, comorbidities on presentation, Injury Severity Score (ISS), specific injuries incurred, ICUS, length of hospital stay (LOS), surgical interventions, and disposition., RESULTS: Complications were the statistically significant factor determining length of ICU stay. ICUS, complications incurred, and ISS were the important predictors of total LOS. The significant complications affecting LOS were infectious, respiratory, and hematologic complications., CONCLUSION: The number of complications the patient incurs after an injury can predict length of ICUS. Length of ICUS, ISS, and number of complications incurred were the strongest predictors for total length of hospital stay. Other variables, including age, gender, living or dead, blunt versus penetrating injury, ISS, fracture site (skull, midface, or lower face), and comorbidities on presentation were not statistically significant in this patient population. Infectious, respiratory, and hematologic complications were the complications most closely correlated with increasing length of ICUS and total hospital stay. 2009. Greaves, I., et al. (2002). "Fluid resuscitation in pre-hospital trauma care: a consensus view." Journal of the Royal College of Surgeons of Edinburgh **47**(2): 451-457.

Fluid administration for trauma in the pre-hospital environment is a challenging and controversial area. The available evidence does not clearly support any single approach. Nevertheless, some provisional conclusions may be drawn. It was with this intention that the Faculty of Pre-Hospital Care (RCSEd) arranged to meet in August 2000 in an attempt to reach a working consensus. The following guidelines are the result of those discussions. It is intended that they will be modified as future research brings clarity to the area. When treating trauma victims in the pre-hospital arena cannulation should take place en route, where possible. Only two attempts at cannulation should be made. Transfer should not be delayed by attempts to obtain intravenous access. Entrapped patients require cannulation at the scene. Normal saline may be titrated in boluses of 250 ml against the presence or absence of a radial pulse (caveats; penetrating torso injury, head injury, infants).

2010. Green, A. J., et al. (2005). "Post-traumatic epidermoid cyst presenting with headache." Neurology **64**(9): 1657.

2011. Greenberg, J. K., et al. (2014). "Management of children with mild traumatic brain injury and intracranial hemorrhage." The journal of trauma and acute care surgery **76**(4): 1089-1095.

BACKGROUND: Traumatic brain injury (TBI) is a significant public health problem affecting tens of thousands of children each year, and an important subset of these patients sustains intracranial hemorrhage (ICH). The purpose of this study was to test the hypothesis that we could identify a subset of children with traumatic ICH who could be monitored on a general neurosurgery ward with a low risk of clinical deterioration., METHODS: We performed a retrospective review of pediatric patients 18 years or younger with mild TBI (Glasgow Coma Scale [GCS] score 14-15) and traumatic ICH admitted to Saint Louis Children's Hospital between 2006 and 2011. We excluded patients with injuries unrelated to the TBI that would require intensive care unit (ICU) admission and those with penetrating intracranial injuries., RESULTS: We identified 118 patients meeting inclusion criteria. Repeat neuroimaging was obtained in 69 (58%) of 118 patients. Radiologic progression was noted in 6 (8.7%) of 69 patients, with a trend toward more frequent progression in patients with epidural hematoma (EDH) versus other ICH (3 [20%] of 15 vs. 3 [5.6%] of 54; $p = 0.11$). Of 118 patients, 8 (6.8%) experienced clinically important neurologic decline (CIND) and 6 (5.1%) required neurosurgical intervention. Both CIND and the need for neurosurgical intervention were significantly higher in patients with EDH (21% each) compared with those with other types of ICH (4% and 2%, respectively) ($p = 0.02$, $p < 0.01$). Based on these results, we developed a preliminary management framework to assist in determining which patients can be safely observed on a neurosurgery ward without an ICU admission. Specifically, those patients without EDH, intraventricular hemorrhage, coagulopathy, or concern for a high-risk neurosurgical lesion (e.g., arteriovenous malformation) may be safely observed on the ward., CONCLUSIONS: These results demonstrate that few children with mild TBI and ICH experience CIND and the preliminary framework we developed assists in identifying which patients can safely avoid ICU admission. This framework should be validated prospectively and externally., LEVEL OF EVIDENCE: Therapeutic/care management, level IV.

2012. Greene, K. A., et al. (1995). "Impact of traumatic subarachnoid hemorrhage on outcome in nonpenetrating head injury. Part I: A proposed computerized tomography grading scale." Journal of neurosurgery **83**(3): 445-452.

The presence of traumatic subarachnoid hemorrhage (tSAH) on admission computerized tomography (CT) scans obtained from patients suffering from severe, nonpenetrating head injury has been shown to be associated with a worse outcome than the injury alone would warrant. However, no previous study has provided a simple means of relating the

amount of tSAH, its location, or other abnormal findings on initial head CT scans to outcome in patients with non-penetrating head injury. In this study, admission head CT scans from 252 patients with tSAH, treated at a single institution, were reviewed to ascertain thickness of the tSAH; its location; evidence of mass lesion(s); shift of midline structures (5 mm); basal cistern effacement; and cortical sulcal effacement. The CT scans were then organized into Grades 1 to 4 with 1 indicating thin tSAH (5 mm); 3, thin tSAH with mass lesion(s); and 4, thick tSAH with mass lesion(s). A stepwise regression analysis of CT features ranked them in descending order of contribution to Glasgow Outcome Scale (GOS) scores at the time of discharge from acute hospitalization as follows: basal cistern effacement, thickness of tSAH, cortical sulcal effacement, presence of mass lesion(s), and location of tSAH. A shift of midline structures was not found to be a significant variable. Further analysis comparing CT grades and admission postresuscitation Glasgow Coma Scale (GCS) scores was highly significant. Patients with lower CT grades had better admission GCS values and discharge GOS scores than those with higher CT grades. From their experience, the authors conclude that their CT grading scale is simple and reliable and relates significantly to outcome at the time of discharge from acute hospitalization.

2014. Greene, W. R., et al. (2010). "Insurance status is a potent predictor of outcomes in both blunt and penetrating trauma." American journal of surgery **199**(4): 554-557.

BACKGROUND: Patients with penetrating injuries are known to have worse outcomes than those with blunt trauma. We hypothesize that within each injury mechanism there should be no outcome difference between insured and uninsured patients., METHODS: The National Trauma Data Bank version 7 was analyzed. Patients aged 65 years and older and burn patients were excluded. The insurance status was categorized as insured (private, government/military, or Medicaid) and uninsured. Multivariate analysis adjusted for insurance status, mechanism of injury, age, race, sex, injury severity score, shock, head injury, extremity injury, teaching hospital status, and year., RESULTS: A total of 1,203,243 patients were analyzed, with a mortality rate of 3.7%. The death rate was significantly higher in penetrating trauma patients versus blunt trauma patients (7.9% vs 3.0%; P < .001), and higher in the uninsured (5.3% vs 3.2%; P < .001). On multivariate analysis, uninsured patients had an increased odds of death than insured patients, in both penetrating and blunt trauma patients. Penetrating trauma patients with insurance still had a greater risk of death than blunt trauma patients without insurance., CONCLUSIONS: Insurance status is a potent predictor of outcome in both penetrating and blunt trauma.

2015. Greenhalgh, D. G., et al. (2013). "A ten-year experience with pediatric face grafts." Journal of burn care & research : official publication of the American Burn Association **34**(5): 576-584.

The authors reviewed their 10-year experience of performing face grafts in children with burns. They sought to compare different methods for aesthetic outcome and need for reconstruction. In addition, they determined the efficacy of using allograft skin or Integra as temporary covers. They performed a review of 160 pediatric patients who underwent acute facial excision and grafting for burns between 2000 and 2010. Of the 160 patients with a mean age of 5.8 +/- 4.8 years, 96 were males. The mean burn size was 39.4 +/- 24.61%, of which 36.5 +/- 25.4% was third degree. Overall length of stay was 72.1 days, intensive care unit length of stay was 44.2 days, and the mortality rate was 13.75%. Ninety patients had their entire face burned, 42 burned half, 15 burned their foreheads, and seven had other combinations. The interval between injury and grafting was 13.9 +/- 13.19 days. Sixty-three percent patients required one face graft, 23% had two, 8% had three, and 6% four or more. For their initial procedure, 105 patients underwent autografting, 28 had allografting, and 23 received Integra. The authors performed a two-stage procedure in 20.4% and a 1-day procedure in 79.6%. Ten patients had a contiguous "U-shaped" graft wrapped around the face. At least partial regrafting was performed in 21.1%. Allograft and Integra were used for massive burns (69.9 +/- 14.5%, 62.6 +/- 18.3%, respectively). Of these, 39% died, 17% developed an Integra infection, and 43% required regrafting before autografting. Overall, 24.5% of patients underwent facial reconstruction during their first admission, and 57.1% during subsequent admissions. No difference in the rate of reconstructive surgery was noted between patients receiving Integra or autografting. Autografting face burns as an initial, one-stage procedure works well. The "wrap-around" autograft leads to excellent cosmetic results. When there is a shortage of autograft, allograft or Integra are good options but Integra does not reduce the need for reconstructive surgery.

2016. Grela, M., et al. (2021). "Post-mortem analysis of gunshot wounds to the head and thorax in dogs by computed tomography, radiography and forensic necropsy." Medicine, science, and the law **61**(2): 105-113.

In view of the scarcity of literature data on the use of radiological imaging techniques in forensic veterinary medicine, while at the same time the number of reported crimes against animals involving the use of firearms is rising, this paper attempts to assess the usefulness of radiography and computed tomography (CT) in the post-mortem diagnosis of gunshot wounds (GSW) in comparison to classic necropsy. The design of the experiment was as follows: preparation of the research material (13 dog carcasses), shooting of the material from different distances (1.5 and 12 m, plus one contact shot to the head) and using different types of ammunition, followed by X-rays and CT scans in each case to examine the injuries resulting from the shot. The final steps of the experiment were photographic documentation and autopsy by the Virchow method. In the examined material, post-traumatic bone lesions and the presence of metallic foreign bodies were successfully imaged by both radiography and CT. GSW analysis using CT provided much better data quality and some additional information. Two general conclusions can be drawn from the results of the experiment. First, damage caused by gunshots is correlated with the calibre, initial velocity and kinetic energy of the projectile, as well as the distance from the muzzle of the gun to the object shot. Second, radiological examination is useful in preparing forensic veterinary opinions. Used as a complement to classic necropsy, they increase the possibility of an accurate post-mortem diagnosis of shooting victims.

2017. Grellner, W., et al. (2019). "Model cannons causing lethal traumata." Forensic science international **302**: 109853.

Model cannons are usually considered to be harmless toys; therefore no legal regulations are required. Nevertheless, suicidal intentions or playful experimentation can turn this toy into a lethal weapon. This paper describes two cases of misuse of model cannons, leading to severe injuries and consequently death: the first case was the result of a suicidal intention, where the cannon caused a bullet injury into the forehead with marked signs of close-firing and intensive brain damage. The second case was an accidental event, where the cannon induced an entry wound at the left chest wall with surrounding carbonization and a fatal rupture of the heart. Circumstances of the lethal situations and mechanisms of the cannons leading to fatal injuries including ballistic considerations are described. The report is supported by a thorough literature research.

2018. Gressot, L. V., et al. (2014). "Predictors of outcome in civilians with gunshot wounds to the head upon presentation." Journal of neurosurgery **121**(3): 645-652.

OBJECT: Prediction of outcome from initial presentation after a gunshot wound to the head (GSWH) is essential to further clinical decision making. The authors' goals are to report the survival and functional outcomes of these patients, to identify prognostic factors, and to propose a scoring system that can predict their outcome., METHODS: The records of 199 patients admitted with a GSWH with dural penetration between 1990 and 2008 were retrospectively reviewed. The inclusion criterion was a CT scan available for review. Patients declared brain dead on presentation were excluded, which yielded a series of 119 patients. Statistical analysis was performed using a logistic regression model., RESULTS: Fifty-eight (49%) of the 119 patients died. Twenty-three patients (19%) had a favorable outcome defined as a 6-month Glasgow Outcome Scale (GOS) score of moderate disability or good recovery, 35 (29%) had a poor outcome (GOS of persistent vegetative state or severe disability), and 3 (3%) were lost to follow-up. Significant prognostic factors for mortality were age older than 35 years, nonreactive pupils, bullet trajectory of bihemispheric (excluding bifrontal), and posterior fossa involvement compared with unihemispheric and bifrontal. Factors that were moderately associated with higher mortality included intracranial pressure (ICP) above 20 mm Hg and Glasgow Coma Scale (GCS) score at presentation of 3 or 4. Upon multivariate analysis, the significant factors for mortality were bullet trajectory and pupillary response. Variables found to be significant for good functional outcome were admission GCS score greater than or equal to 5, pupillary reactivity, and bullet trajectory of unihemispheric or bifrontal. Factors moderately associated with good outcome included age of 35 years or younger, initial ICP 20 mm Hg or lower, and lack of transventricular trajectory. In the multivariate analysis, significant factors for good functional outcome were bullet trajectory and pupillary response, with age moderately associated with improved functional outcomes. The authors also propose a scoring system to estimate survival and functional outcome., CONCLUSIONS: Age, pupils, GCS score, and bullet trajectory on CT scan can be used to determine likelihood of survival and good functional outcome. The authors advocate assessing

patients based on these parameters rather than pronouncing a poor prognosis and withholding aggressive resuscitation based upon low GCS score alone.

2019. Grewal, A. M., et al. (2021). "Long-term ophthalmic anatomical and functional outcomes after surgical removal of intraorbital foreign bodies." European journal of ophthalmology **31**(1): 263-270.

PURPOSE: To analyze the anatomical and functional ophthalmic parameters after the surgical removal of various intraorbital foreign bodies., METHODS: A retrospective analysis of medical records was performed featuring detailed history, ophthalmic examination, orbital computed tomographic scans, treatment details, and outcomes. The analyzed anatomical factors included extraocular movements, the position of the eyeball (proptosis, dystopia, and enophthalmos), and fullness of orbital sulci. The functional assessment was based on visual acuity, pupillary reactions, and diplopia. The outcomes were defined as complete, partial, and failure after a minimum follow-up of 1 year., RESULTS: Of 32 patients, the organic and inorganic intraorbital foreign bodies were surgically removed from 18 (56.25%) and 14 (43.75%) orbits, respectively. At presentation, anatomically the extraocular movement restriction, proptosis/dystopia/enophthalmos, and orbital sulcus fullness were noted in 26 (81.25%), 24 (75%), and 15 (46.88%), respectively. Functionally, diminished visual acuity, diplopia, and pupil abnormalities were seen in 27 (84.38%), 14 (43.75%), and 8 (25%), respectively. After intraorbital foreign body removal at a mean follow-up of 14 months, the improvement of anatomical factors (same sequence) were observed in 8 (30.77%), 20 (83.33%), and 12 (80%), respectively. In functional factors (same sequence), the improvement was noted in none (0%), 13 (92.86%), and 5 (62.5%), respectively. Hence, the majority of patients (n = 20, 62.5%) achieved partial success, while 8 (25%) had complete success. Four (12.5%) had treatment failure despite similar management protocols., CONCLUSION: The anatomical outcomes are better than the functional outcomes after surgical removal of the intraorbital foreign bodies. The visual acuity does not improve considerably after the surgical removal of intraorbital foreign bodies. Overall, the wooden intraorbital foreign bodies have poorer anatomical and functional prognosis.

2021. Grieve, A. W. (2010). "Phineas P Gage - 'The man with the Iron bar'." Trauma **12**(3): 171-174.

Phineas P Gage was a railway construction workman who, in 1848, received a devastating penetrating head injury. A 4 ft long tamping iron was fired by accident through his skull destroying both frontal lobes. He survived the accident through luck, the care he received from colleagues at the scene and through medical care received from doctors. This article examines closely the injury pattern, prehospital care, trauma care and medical and psychiatric sequelae Gage received. © The Author(s), 2010.

2022. Griffin, A. T. and F. W. Arnold (2013). "An unusual etiology of post-traumatic meningitis." The American journal of the medical sciences **346**(4): 331-333.

Clostridium perfringens and related species are well-known culprits of post-traumatic soft tissue and bone infection. However, central nervous system involvement with these organisms spontaneously or subsequent to trauma is unusual. The authors reported a case of post-traumatic meningitis in which both C perfringens and Enterococcus faecium were isolated.

2023. Griffin, L. J. and J. V. Hickey (2012). "Penetrating head injury." Critical care nursing quarterly **35**(2): 144-150.

Traumatic brain injury affects more than 1 million civilians annually. Functional outcomes in this population are less than favorable. This case report describes a patient with a penetrating injury to the head and brain from a gunshot wound including the pathophysiology of injury and outlines evidence-based management guidelines to provide comprehensive care.

2025. Grigoras, I., et al. (2010). "Functional improvement between brain death declaration and organ harvesting." Transplantation proceedings **42**(1): 147-149.

INTRODUCTION: The quality of harvested organs is crucial for graft survival and for posttransplant evolution. This study sought to investigate the evolution of the functional status of brain death (BD) patients during the period between declaration and organ harvesting (BD duration)., MATERIALS AND METHODS: The study included all BD patients who underwent organ harvesting between January 2006 and June 2009. We compared the functional status regarding hemodynamics, respiration, kidney and liver function, coagulation, water, electrolytes, and acid-base balance evaluated at the moment of BD declaration (P1) and just before organ harvesting (P2). The results of the comparison were expressed as improvement, stable, or aggravation. We calculated mean values of the functional parameters in P1 and P2 and the statistical significance of the differences., RESULTS: Twelve BD patients were included in the study. The time interval between P1 and P2 was 16.08 +/- 8.54 hours (range, 6-32). The number of patients with vasopressor support was 9/12 at P1 and 0/12 at P2, oxygenation disturbances 1/12 in P1 and 0/12 in P2, renal dysfunction 9/12 in P1 and 2/12 in P2, liver dysfunction 7/12 in P1 and 1/12 in P2, coagulopathy 4/12 in P1 and 0/12 in P2, hypernatremia 8/12 in P1 and 3/12 in P2, and metabolic acidosis 9/12 in P1 and 1/12 in P2. The overall assessment showed improvement in all patients. The most statistically significant improvement was registered in the cardiovascular, respiratory, renal, liver, and acid-base status ($P < .05$)., CONCLUSION: With early, aggressive, protocolized donor management, functional improvement may be achieved during BD duration.

2026. Grigorian, A., et al. (2019). "Increased risk of head injury in pediatric patients with attention deficit hyperactivity disorder." Journal of child and adolescent psychiatric nursing : official publication of the Association of Child and Adolescent Psychiatric Nurses, Inc **32**(4): 171-176.

OBJECTIVE: The prevalence of attention deficit hyperactivity disorder (ADHD) in the general pediatric population is 7%, whereas the prevalence in trauma is unknown. We hypothesized pediatric patients with ADHD would have a higher risk of involvement in a mechanism of injury (MOI) requiring constant attention to surroundings, such as a bicycle collision., METHODS: The Pediatric Trauma Quality Improvement Program (2014-2016) was queried for patients with ADHD. Patients, less than 16 years of age, with ADHD were compared to those without ADHD., RESULTS: The prevalence of ADHD was 2.5% (2,866). ADHD patients had higher risk for bicycle collision (odds ratio [OR], 1.85; 95% confidence interval [CI], 1.59-2.15; $p < .001$). ADHD bicyclists were less likely to wear a helmet (9.4% vs. 18.2%, $p = .003$) and had a higher rate of traumatic brain injury (TBI; 55.6% vs. 39.7%, $p < .001$), compared to non-ADHD bicyclists., CONCLUSIONS: Pediatric ADHD patients have a 60% higher risk of being involved in a bicycle collision. ADHD patients that are involved in a bicycle collision are less likely to wear a helmet with a higher rate of TBI. Increased public awareness, education, and supervision may help reduce risk of bicycle collisions and TBI in this population.

2027. Grimes, W. R., et al. (1988). "Shotgun wounds involving the head and neck." American journal of surgery **155**(6): 776-779.

Since limited information is available on the management and spectrum of injuries sustained by patients with shotgun wounds to the head and neck, we reviewed the records of 26 patients with shotgun wounds involving the head and neck region. Fifty-four percent of these patients had associated injuries involving the trunk or extremities, and 43 percent of these patients required repair of these associated injuries. Overall, 23 percent of patients with shotgun wounds of the head and neck region had injuries of other anatomic areas that required operative treatment. In these patients, the major life-threatening injuries were not related to the head and neck region but were related to injuries of other anatomic areas. By stratifying the patients according to the anatomic pattern of injury (point blank, close range, or long range) and their hemodynamic status on presentation to the emergency room, it was possible to predict the need for surgery as well as the risk of death.

2028. Grindlinger, G. A., et al. (1987). "Acute paranasal sinusitis related to nasotracheal intubation of head-injured patients." Critical care medicine **15**(3): 214-217.

One hundred eleven head-injured patients were examined for paranasal sinusitis during early convalescence. Glascow coma scale (GCS) was less than 8 in 79 patients. Ninety-three patients had sustained blunt injuries, and 18 had penetrating ones. Sixty-five orotracheal intubations (OTI) and 31 nasotracheal intubations (NTI) were performed at the

scene or on hospital arrival. Fifteen patients were not tracheally intubated. Paranasal sinus air fluid levels (AFL) were present in 30 patients on their admitting computerized tomography scans. Paranasal sinusitis developed in 19 patients with a mean GCS of 5.4 +/- 3.3 (SD). Sixteen of the 19 had NTI, and three had OTI (p less than .05). Of 30 patients with AFL, sinusitis occurred in 13. Ten of these 13 had NTI, and three had OTI (p less than .05). Penetrating injury did not increase the risk of sinusitis (p greater than .1). Seventeen of the 19 infections were polymicrobial. Sinusitis after head trauma is related to NTI, AFL, and severity of head injury.

2029. Grindlinger, G. A., et al. (2016). "Decompressive craniectomy for severe traumatic brain injury: clinical study, literature review and meta-analysis." SpringerPlus **5**(1): 1605.

OBJECTIVE: To examine the clinical and neurological outcome of patients who sustained a severe non-penetrating traumatic brain injury (TBI) and underwent unilateral decompressive craniectomy (DC) for refractory intracranial hypertension., DESIGN: Single center, retrospective, observational., SETTING: Level I Trauma Center in Portland, Maine., PATIENTS: 31 patients aged 16-72 of either sex who sustained a severe, non-penetrating TBI and underwent a unilateral DC for evacuation of parenchymal or extra-axial hematoma or for failure of medical therapy to control intracranial pressure (ICP)., INTERVENTIONS: Review of the electronic medical record of patients undergoing DC for severe TBI and assessment of extended Glasgow Outcome Score (e-GOS) at 6-months following DC., MEASUREMENTS AND MAIN RESULTS: The mean age was 39.3y +/- 14.5. The initial GCS was 5.8 +/- 3.2, and the ISS was 29.7 +/- 6.3. Twenty-two patients underwent DC within the first 24 h, two within the next 24 h and seven between the 3rd and 7th day post injury. The pre-DC ICP was 30.7 +/- 10.3 and the ICP was 12.1 +/- 6.2 post-DC. Cranioplasty was performed in all surviving patients 1-4 months post-DC. Of the 29 survivors following DC, the e-GOS was 8 in seven patients, and 7 in ten patients. The e-GOS was 5-6 in 6 others. Of the 6 survivors with poor outcomes (e-GOS = 2-4), five were the initial patients in the series., CONCLUSIONS: In patients with intractable cerebral hypertension following TBI, unilateral DC in concert with practice guideline directed brain resuscitation is associated with good functional outcome and acceptable-mortality.

2030. Griva, F., et al. (2000). "Spontaneous movement of a metallic intracranial foreign body: case report." Surgical neurology **54**(3): 267-269.

2031. Grobbelaar, A. and J. D. Knottenbelt (1991). "Retained knife blades in stab wounds of the face: is simple withdrawal safe?" Injury **22**(1): 29-31.

A retained knife blade following a stab wound to the face is an uncommon injury that may give anxiety to the doctor managing the case. In 11 patients presenting with retained blades, simple withdrawal was associated with no untoward effect. In two patients the blade was not visible from the outside. The authors recommend that patients presenting with stab wound of the face are radiographed before discharge.

2032. Grocott, H. P. (2014). "Cerebral Oximetry: Better monitoring, improved patient outcomes, both or neither?" Applied Cardiopulmonary Pathophysiology **17**(2): 15-20.

Utilizing some of the same general principles as ubiquitously available and standard of care pulse oximetry, cerebral oximetry is increasingly becoming adopted into cardiovascular (and non-cardiovascular) anaesthetic and critical care practice. Though far from becoming a standard of care itself, the increasingly available information outlining its potential utility in optimizing peri-operative management warrants a careful examination of both its current status and future directions. Cerebral oximetry had its early beginnings in the 1980s with the work of Jöbsis and colleagues. By using multi-wavelength light sources in the near infrared range, these investigators demonstrated the utility of exploiting the ability of the differential absorption of oxygenated and de-oxygenated haemoglobin of these wavelengths in brain (and possibly other) tissue. Differing from pulse oximetry, that discriminates between the pulsatile (i.e. arterial) from non-pulsatile (venous) components in order to calculate arterial saturation, tissue oximetry integrates both signals to give a mixed (in an approximately 3:1 ratio of venous to arterial blood) overall tissue oximetric signal. As opposed to pulse oximetry, this provides a signal regardless of the presence of any pulsatility (ideal in low flow conditions, as well as the relatively non-pulsatile situation of CPB) resulting in an overall oxygen saturation signal of all the blood contained within the interrogated tissue. In the case of the brain, the penetration of photons is likely limited to within 15-20 mm of

the brain surface. This does significantly limit the spatial resolution of the device by only providing information in the most superficial area of the frontal lobe. By integrating this oximetric data and comparing it to validated direct measurements of jugular venous saturation, these devices (with now at least 4 commercial devices on the market worldwide and 3 available in North America), produce a continuous output of tissue (i.e. brain) oxygen saturation. This saturation information can then be integrated with our understanding of oxygenation delivery and utilization conditions to allow modifications to made in peri-operative physiologic conditions with the aim of optimizing overall tissue oxygenation, and ideally, corresponding end-organ function and outcome. However, despite extensive publications (now numbering in the hundreds) highlighting various case reports, observational studies and a few very modestly sized randomized trials, we are far from understanding how this technology can influence neurologic outcome, yet alone overall peri-operative outcomes. A few of these publications are highlighted further on in this text and in the suggested readings at the end of this summary. This list is by no means comprehensive, but it does outline some of the more influential papers in the field. Despite approval by regulatory authorities, the FDA (and other national regulatory bodies) does not require these devices (as opposed to pharmaceuticals) to be linked to an improvement in patient outcome. These devices need only be shown to validly determine the measurements that they claim to measure. That is, they only need demonstrate that they validly measure actual tissue oxygenation, with no proof required that by measuring this (and/or intervening to modify it) that they can improve outcome. This is the irony of the technology approval pathway (as opposed to pharmaceutical approval). That said, those who intermittently (and many who routinely) utilize these devices repeatedly have developed their own understanding of the potential utility of cerebral oximetry and provide case after case of anecdotal evidence of how these devices have averted certain catastrophe. However, these sorts of endorsements are clearly insufficient to confidently warrant wide-scale adoption of this technology. However, proponents of a more wide spread adoption, point to other technologies that we currently cannot do without (such as pulse oximetry) that have never undergone the same scrutiny for which cereb al oximetry is now being considered. It is clear that pulse oximetry has never been demonstrated in a large randomized double blind controlled clinical trial to improve outcome, yet none of us could advocate not using it. The same type of grandfathering process that led to the current use of pulse oximetry will not be afforded to other technologies and it is now in the hands of clinicians, academics, researchers, and device companies to prove the true worth of these devices. We have a history in peri-operative medicine and anaesthesia, of failing to properly examine clinical utility of the devices we now integrate into our everyday practice although we as a specialty are not unique since other specialties also lack the timely yet rigorous evaluation of technologies and interventions. No better an example of this is with BIS technology. Despite its wide availability for almost 15 years, we have only recently undertaken the needed large-scale clinical trials to truly evaluate the utility of its initial stated purpose. If we don't learn from these examples, we will soon be in the same position with cerebral oximetry. In fact, in many respects we are already there, as commercially available oximetric devices have been available since the mid to late 1990s. Complicating the issue of technology utility is the apparent differences in the various devices that are now available. Extrapolating information (and utility) derived from one device, is not necessarily applicable to similar, though subtly different devices. Arguing against this device specific evaluation is again the example of the pulse oximeter where none of us could confidently dismiss a saturation signal from one pulse oximeter manufacturer over the other. Clearly there are subtle differences in these pulse oximetry devices (such as how they deal with artifact induced by movement and low flow states), but essentially pulse oximetry is pulse oximetry, despite which manufacturer has his name on it. It is likely too early, however, to say the same for the 4 devices (and likely more to come) that are now on the market. This makes the design of clinical trials somewhat difficult as until equivalency is determined, we are handicapped in designing trials that should probably have uniformity of technology. As compelling an argument one can make at the present moment for the use of these devices (I personally would not like to do a case without the information that it provides me, though this is clearly an opinion not based on solid scientific grounds), we need hard scientific data to definitely prove this point and outline how best to manage patients. A further handicap is that no technology can improve outcome without being linked to a management strategy. We are still in our relative infancy in understanding how to intervene based on the information that these devices provide for us. Although interventional algorithms (such as the one proposed by Denault et al) have been suggested, they have not yet been subjected to the rigor of corroborative clinical trials. The rationale for using cerebral oximetry developed from multiple sources, an example of which was data from Croughwell et al based on the relationship between jugular bulb desaturation and clinical outcome. However, the invasiveness of jugular bulb saturation and other logistical difficulties have limited its use, making a non-invasive option that can capture some of the same information highly desirable. Cerebral oximeter devices were first used to focus on brain injury after cardiac surgery. As there had been well described pattern of brain injury in this area since the advent of cardiac surgery, to have a monitor to determine when these injurious events occurred was clearly advantageous. What followed in the literature was a logical time course and

pattern with observational and anecdotal case reports of the use of these devices. One of the first of many observational studies published was by Yao et al who reported an observational trial focusing on the relationship between the degree of cerebral desaturation a d functional brain outcome. Specifically, they examined the integral accounting for the amount of time and degree of cerebral desaturation compared to the postoperative mental status examination (MMSE) and other indices of frontal lobe function. What these investigators demonstrated was that the more severe the desaturation the patients experienced, the more impaired their cognitive function was. Numerous case reports continued the discussion of potential overall clinical utility of this device. Because of its fast signal response time, it rapidly became a user friendly (as compared to invasive jugular venous saturation and tedious TCD) monitor of cerebral perfusion, in particular, being excellent at interrogating the symmetry of perfusion across the brain. Without doubt, numerous catastrophic intra-operative events were avoided by the use of this device by the early recognition of perfusion abnormalities in the brain. Both in the adult as well as in the paediatric literature, these types of anecdotal case reports are increasingly prevalent. However, it has only been relatively recently that randomized controlled data specifically defining the utility of cerebral oximetry have been published. Murkin et al published a trial of 200 patients in which an interventional strategy was utilized to maintain the cerebral saturation signals within 75% of their baseline reading. This interventional strategy was based upon optimizing both oxygen supply and utilization in the brain. For example, following establishment of the baseline reading (an initial step in utilizing cerebral oximetry), the investigators instituted an interventional algorithm if the patient's saturation dropped 20% from their baseline. This intervention included ruling out mechanical causes such as cannula malplacement or jugular venous impingement due to head position, and followed with techniques to optimize oxygen supply to the brain. For example, if patients were hypocapnic, PaCO2 was returned to a normal level. In addition, the mean arterial pressure (MAP) was increased modestly, and as well, there were increases in FiO2. If these parameters failed to return the saturation to normal, and if there was significant anaemia, the patients were transfused to improve oxygen carrying capacity. If these efforts to improve oxygen delivery failed, additional methods to suppress cerebral oxygen metabolism were used including administration of additional propofol and modest cooling. This management strategy has been further elucidated by Denault and colleagues. Although the Murkin et al study was not adequately powered to examine neurological outcome (i.e. stroke) the results did demonstrate a trend toward the stroke reduction in patients that were managed with the interventional algorithm. However, what was unique about the study was that not only was there a trend toward an improvement in neurologic outcome, but that there was an improvement in an overall organ outcome as identified by reduction in major organ morbidity. Indeed, this study described that the use of these technologies may have come full circle from only examining brain perfusion (as a means to improve neurologic outcome) to the point of monitoring brain perfusion as an index organ for overall organ function. Interestingly, Murkin et al suggested that the brain simply represents an index organ for overall tissue perfusion. This is partly correct as it is the only major organ that is within reach of the light sources that these devices utilize. However, in some respects its unique protective mechanisms (i.e. autoregulation) make it the last organ to be compromised in a situation of impaired blood flow and oxygenation. It is exactly the opposite of the 'canary in the coal mine' in that its oxygenation status is maintained long after other organs (such as those perfused by the splanchnic vasculature) have been compromised. Thus, although it is probably important to maintain its saturation, covert tissue compromise is likely occurring frequently despite our confidence that we are doing all the right th ngs. This probably accounts for the lack of robust correlation to overall outcome. More recently, Slater et al have also studied the use of cerebral oximetry in cardiac surgery. 265 patients undergoing cardiopulmonary bypass were randomized to either be blinded to cerebral oximetry or unblinded with the aforementioned interventions if cerebral saturations (rSO2) dropped below 20% of baseline. Neurocognitive testing was performed pre-operatively, prior to hospital discharge, and at 3 months. Although the incidence of neurocognitive dysfunction was not decreased in the treatment group (59% vs. 61%), they did find a correlation between prolonged cerebral desaturation below 50% (i.e. 25% below baseline) and increased risk of neurocognitive decline. An rSO2 desaturation score was calculated as the length of time each patient's rSO2 was below 50%. An rSO2 score greater than 3,000%-second below 50% was seen in 33% of patients with postoperative cognitive decline compared to 20% of patients with no decline (P = 0.024). When multivariate analyses were performed, there was a trend towards decreased cognitive decline in the intervention group (OR = 0.81, 95% C.I. 0.46-1.43), but this was not statistically significant (P = 0.47). The authors suggest that the failure to see a treatment effect may have been the result of poor compliance with the protocol when an intraoperative rSO2 desaturation was encountered. Although the study was not powered to study length of hospital stay, they found a significant correlation between prolonged rSO2 desaturation and hospital stay greater than 6 days (OR 2.71, 95% C.I. 1.31-5.60, P = 0.07), which may also add to the data that cerebral oximetry may be a surrogate marker for overall end organ perfusion/oxygenation. There are probably a limited number of clinical situations where there is a distinctly robust relationship of oximetric data to outcome. One of these is in the use of cerebral oximetry for monitoring the

symmetry of brain blood flow during antegrade selective cerebral perfusion (such as during hypothermic circulatory arrest for aortic arch surgery). I would argue that this is the best, most user friendly (certainly compared to transcranial Doppler) and pertinent monitor one can use in this situation. However, due to the limited numbers of these cases, it is unlikely that his will be proven in a large-scale clinical trial. However, it remains an essential monitoring apparatus for these cases. Although most of the studies reported have been in cardiac surgical patients, Casati et al studied cerebral oximetry in an elderly general surgical population, again demonstrating that improvements in neurologic outcome (i.e. postoperative cognitive dysfunction) could be reduced if this type of monitor was used with a similar type interventional strategy. So where are we now, and where do we need to go? We have such compelling data that at this point, I contend that it would do our patients a disservice to abandon (due to the lack of definitive supportive data) this technology. Similarly, it would be a great disservice not to do the work to definitely prove its overall utility. Getting there, however, will take a very well defined and progressive approach that needs to answer in a step-wise fashion, a number of smaller, but contributory questions. I believe that despite its wide availability, we are in the relative infancy in the life of cerebral oximetry as a peri-operative monitor.

2033. Groh, E. M., et al. (2018). "Temporal variations in pediatric trauma: Rationale for altered resource utilization." American Surgeon **84**(6): 820-825.

Trauma is a major cause of morbidity and mortality in the pediatric population. However, temporal variations of trauma have not been well characterized and may have implications for appropriate allocation of hospital resources. Data from patients evaluated at an ACS-verified Level I pediatric trauma center between 2011 and 2015 were retrospectively analyzed. Date and time of injury, type of injury (blunt vs penetrating), and postemergency department disposition were reviewed. To assess temporal trends, heatmaps were constructed and a mixed poisson regression model was used to assess statistical significance. Pediatric trauma from blunt and penetrating injuries occurred at significantly higher rates between the hours of 1800 and 0100, on weekends compared with weekdays, and from May to August compared with November to February. These data provide useful information for hospital resource utilization. The emergency department, operating room, and intensive care unit should be prepared for increased trauma-related volume between May and August, weekends, and evening hours by appropriately increasing staff volume and resource availability.

2035. Grossbach, A. J., et al. (2014). "Impalement brain injury from steel rod causing injury to jugular bulb: case report and review of the literature." Brain injury **28**(12): 1617-1621.

BACKGROUND: The management of impalement penetrating brain injuries (IPBI) from non-missile objects is extremely challenging, especially when vascular structures are involved. Cerebral angiography is a crucial tool in initial evaluation to assess for vascular injury as standard non-invasive imaging modalities are limited by foreign body artifact, especially for metallic objects., CASE STUDY: This study reports a case of an IPBI caused by a segment of steel rebar resulting in injury to the left jugular bulb and posterior temporal lobe. It describes the initial presentation, radiology, management and outcome in this patient and reviews the literature of similar injuries.

2036. Grosse Perdekamp, M., et al. (2008). "Patterned imprint mark due to the folded shoulder stock: a possible finding in contact shots from submachine guns." Forensic science international **178**(1): e1-5.

The muzzle imprint (barrel mark) is a pressure abrasion typically associated with contact shots. Apart from the contours of the actual muzzle profile, other constructional parts such as the front sight and/or the recoil spring guide of semiautomatic pistols may be imprinted next to the bullet entrance wound. In some types of submachine guns the shoulder stock can be folded forward so that its end partly encircles the muzzle. If such a weapon was in contact with the skin at the instant of discharge, a corresponding contusion mark is to be expected. The imprint configuration may point to the type of weapon and to the way in which the gun had been held when firing the shot. The paper presents the injury pattern in a 36-year-old man who committed suicide with a Scorpion SA Vz 61 submachine gun cal. 7.65mm Browning from former Czechoslovakia.

2037. Grosse Perdekamp, M., et al. (2011). "Two-gun suicide by simultaneous shots to the head: interdisciplinary reconstruction on the basis of scene investigation, autopsy findings, GSR analysis and examination of firearms, bullets and cartridge cases." International journal of legal medicine **125**(4): 479-485.

Suicidal shots fired simultaneously to the head from two handguns are rare. The authors report about a recent case in which a Smith & Wesson cal. 9 mm pistol and a Smith & Wesson cal. .357 Magnum revolver were used. Sitting on a sofa, a 33-year-old man (member of a shooting club) fired two simultaneous shots to the head; the pistol held in the left hand was discharged into the left temple, and the revolver held in the right hand was fired into the mouth. Both weapons remained in the respective hands. An upside-down muzzle imprint in the left temporal region and recoil injuries of a mandibular incisor, and the lower lip indicated that both the pistol and the revolver had been held in an inverted manner at the time of discharge. Blood stains (backspatter) and gunshot residues were present on both firing hands, whereas forward spatter originating from the exit wounds was deposited on the wall behind the suicide's head.

2038. Grosse Perdekamp, M., et al. (2001). "[Mandibular fracture caused by absolute close-range gunshot with a blank cartridge fright weapon]." Unterkieferfraktur durch absoluten Nahschuss mit einer Schreckschusswaffe. **208**(3-4): 88-95.

Bony injuries caused by starter's pistols were repeatedly observed in the form of fractures of the temporal squama and other thin osseous lamellae; in experiments rib fractures could also be produced. In the presented case a contact shot from a blank cartridge pistol caused a fracture of the lower jaw (transverse fracture with a bone fragment split off in reg. 46). The friend of the 17-year-old victim had fired a shot to the right mandibular region during an argument. In the depth of the gunshot entrance wound, which communicated with the oral cavity, intense soot deposits were found as signs of the contact shot.

2039. Grossman, A., et al. (2006). "PET scan as an aid for the return of a head-injured aviator to flying duty." Aviation, space, and environmental medicine **77**(10): 1080-1082.

Head injury is not a rare event in aviators, and poses a difficult dilemma for the flight surgeon regarding return to flying duty due to the fear of post-traumatic epilepsy. Positron emission tomography (PET) is a functional neuroimaging modality that provides additional localizing data in epileptic patients in the interictal phase. We describe a case of penetrating head trauma with no loss of consciousness in a military jet fighter pilot in which the magnetic resonance imaging revealed a minimal brain contusion. PET scan was used as an additional tool for predicting the epileptogenic potential of this finding, thus aiding the decision regarding the return of the aviator to flying duty.

2040. Grossman, R., et al. (2012). "Persistent region-dependent neuroinflammation, NMDA receptor loss and atrophy in an animal model of penetrating brain injury." Future neurology **7**(3): 329-339.

Dynamic changes in neuroinflammation and glutamate NMDA receptors (NMDAR) have been noted in traumatic and ischemic brain injury., AIM: Here we investigate the time course and regional distribution of these changes and their relationship with atrophy in a rat model of penetrating brain injury., MATERIALS METHODS: Quantitative autoradiography, with the neuroinflammation marker [3H]PK11195 and the NMDAR antagonist [125I]iodoMK801, was performed on brains of animals subjected to a unilateral wireknife injury at the level of striatum and killed 3 - 60 days later. Regional atrophy was measured by morphometry., RESULTS: The injury produced large increases in [3H]PK11195 binding density in cortical and septal regions adjacent to the knife track by day 7, with modest increases in the striatum. [125I]iodoMK801 binding was reduced in cor tical and hippocampal regions showing marked neuroinflammation, which showed marked atrophy at subsequent time points., CONCLUSION: These results indicate that neuroinflammaton and loss of NMDAR precede and predict tissue atrophy in cortical and hippocampal regions.

2041. Grosso, A. (2021). "The Influence of Extrinsic Variation in Gunshot Wounds in a U.S. Civil War Skeletal Sample." FASEB Journal **35**(SUPPL 1).

Most gunshot studies focus on the propagation of fractures on the cranium or the midshaft of a long bone. However, bone closer to the joint is structurally different from the shaft. Here, I analyzed the morphology of fracture patterns from gunshot wounds to the distal femora of U.S. Civil War soldiers. The individual sample (n=34) of distal femora was obtained from the Civil War Skeletal Collection at the National Museum of Health and Medicine (Silver

Spring, MD). Variables collected included fracture counts, average fracture lengths, combined fracture lengths, location on the femur, registered age of the soldier, and their epiphyseal fusion status. The value in a U.S. Civil War skeletal sample is that the individuals it contains are relatively homogenous in terms of age, sex, ancestry, diet, and lifestyle. The projectiles involved were most commonly “minni balls;” many of which are preserved with the associated skeletal remains. Most of the variation in injury pattern is primarily related to extrinsic variables, such as distance from shooter, interruptions in projectile trajectory, and size, shape, or velocity of the impacting projectile at the time of contact. Intrinsic variables may still play a role, such as the amount of soft tissue present and impact location (indirect or direct contact). All measured individuals were male, with an average age of 24.18±6.84yrs. There was no correlation between age and combined fracture length. The average number of bone fragments and fractures counted were 3.59±2.89 and 7.26±3.94, respectively. The average fracture length was 44.80±19.95mm, with an average combined fracture length of 339.68±207.36mm. A limitation here is that these samples were collected via limb amputation, so some of the fractures extending proximally are incomplete. Interestingly, 7 individuals had an epiphyseal fusion score of 1 or 2 (with 4 being completely fused), with 2 instances in individuals aged 23 and 24yrs. In instances of unfused epiphyses, fractures that initiated in the epiphysis did not propagate into the diaphysis. The results of this study contribute to the understanding of how extrinsically introduced variation may affect what we see and interpret in gunshot wounds as more and longer fractures are usually associated with “higher velocity projectiles.” This study also noted the importance of epiphyseal fusion on ballistic analysis to long bones, but continued research is needed in this area to fully understand this phenomenon.

2042. Groswasser, Z., et al. (2002). "Quantitative imaging in late TBI. Part II: cognition and work after closed and penetrating head injury: a report of the Vietnam head injury study." Brain injury **16**(8): 681-690.

CONTEXT: Functional outcome in relation to CT findings in traumatic brain injured (TBI) patients is not well established in relation to cognitive and vocational outcome., OBJECTIVE: To investigate the possible correlation between relatively simple quantitative radiological measurements and cognitive and vocational outcome., DESIGN: Retrospective analysis of quantitative assessment of CT studies in relation to post-injury cognitive changes and vocational outcome., SETTING: US Army Medical Centre., PATIENTS: 74 penetrating head injured (PHI) and 37 closed head injured (CHI) Vietnam war veterans., OUTCOME MEASURES: The Armed Forces Qualification Test (AFQT); Disability score; Return to work., RESULTS: Total brain volume loss, third ventricle width (3VW), ventricular score (VS), and septum-caudate distance (SCD) were significantly related to cognitive change and return to work in PHI patients. Volume loss and 3VW were the most valuable radiologic predictors of outcome in multivariate linear and logistic regression models for both CHI and PHI., CONCLUSION: 3VW on late CT scans following traumatic brain injury is a powerful predictor of overall long-term cognitive outcomes and potential for return to work.

2043. Grove, A. S., Jr. (1982). "Computed tomography in the management of orbital trauma." Ophthalmology **89**(5): 433-440.

Computed tomography (CT scanning) is a valuable aid in the management of orbital trauma because it provides a method of visualizing tissues and objects of many different densities. CT scanning can be used to study orbital fractures in order to suggest the prognosis for improvement of ocular malpositions after surgery. The extent of fractures and the etiology of many soft tissue abnormalities can be determined by this technique. Foreign bodies can be accurately localized so that the approach to their removal can be planned.

2047. Grundfast, K. M., et al. (1990). "Diverse etiologies of facial paralysis in children." International journal of pediatric otorhinolaryngology **19**(3): 223-239.

Facial paralysis (FP) in children is most often idiopathic, however, many diverse and identifiable etiologies exist. Twenty-five cases of children admitted consecutively to the Children's National Medical Center over 8.5 years for the evaluation of FP were reviewed retrospectively. In 21 (84%) of the patients the FP was discovered to be secondary to a specific etiology or associated with a recognizable syndrome. In 7 cases, the FP was an initial manifestation of a serious underlying disorder. Causes of the FP in this series include: otitis media, mastoiditis, temporal lobe abscess, osteopetrosis, both blunt and penetrating trauma, iatrogenic surgical injury, facial burns, cerebellar astrocytoma, leukemia rhabdomyosarcoma, intracerebral arteriovenous malformation, Goldenhar syndrome, and Melkersson-Rosenthal syndrome. Four (16%) patients were diagnosed as having Bell's palsy. Methods of management, including the use of electrodiagnostic testing are described.

2048. Grunsfeld, A. A. and I. S. Login (2006). "Abulia following penetrating brain injury during endoscopic sinus surgery with disruption of the anterior cingulate circuit: case report." BMC neurology **6**: 4.

BACKGROUND: It is common knowledge that the frontal lobes mediate complex human behavior and that damage to these regions can cause executive dysfunction, apathy, disinhibition and personality changes. However, it is less well known that subcortical structures such as the caudate and thalamus are part of functionally segregated fronto-subcortical circuits, that can also alter behavior after injury. CASE PRESENTATION We present a 57 year old woman who suffered penetrating brain injury during endoscopic sinus surgery causing right basal ganglia injury which resulted in an abulic syndrome., CONCLUSION: Abulia does not result solely from cortical injury but can occur after disruption anywhere in the anterior cingulate circuit--in the case of our patient, most prominently at the right caudate.

2050. Gruss, J. S., et al. (1991). "Early definitive bone and soft-tissue reconstruction of major gunshot wounds of the face." Plastic and reconstructive surgery **87**(3): 436-450.

The use of craniofacial surgical techniques, extended open reduction, rigid fixation with plates and screws, and the replacement of severely damaged or missing bone with immediate bone grafting in the treatment of complex facial fractures has been applied to the management of severe gunshot wounds of the face. Early definitive bone and soft-tissue reconstruction has been performed in 37 patients. One-hundred and seventy-seven primary bone grafts were utilized in 33 patients for orbital, nasal, zygomatic, and maxillary reconstruction. Twenty-six patients required mandibular repair with compression or reconstruction plates. Soft-tissue reconstruction was provided by a combination of flaps. Four patients had extensive soft-tissue loss replaced by free vascularized omental flaps. The omentum provided circumferential coverage of the mandibular reconstruction and reconstruction of the floor of the mouth and was then tunneled in a circle through both cheeks into the middle and upper face. The omentum reconstructed deficits in the hard palate and upper buccal sulcus and was then wrapped around all zygomatic, orbital, and midfacial bone grafts and used to fill in dead space in the maxillary, ethmoid, and frontal sinuses. The omentum is not used to provide contour and bulk, but to cover bone grafts and plates and fill in dead space. Carefully shaped bone grafts provide the correct craniofacial scaffold. Early restoration of a midfacial bony scaffold and the prevention of soft-tissue contraction facilitate secondary reconstruction. Four late total nasal reconstructions with tissue-expanded forehead skin wrapped around bone grafts were performed.

2051. Guazzo, E. P. (1994). "Spontaneous migration of airgun pellet in the brain." Journal of neurology, neurosurgery, and psychiatry **57**(4): 404.

2052. Guckel, C. (1988). "[Possible computed tomographic and magnetic resonance tomographic detection of wood foreign bodies following perforating eye injuries]." Computertomographische und kernspintomographische Nachweismoglichkeit holzerner Fremdkorper nach perforierender Augenverletzung. **28**(7): 334-337.

After perforating eye injury the retention of a foreign body in the orbits has to be excluded. Wooden foreign bodies mostly have negative density on CT, which increases later as a result of granulomatous changes. On MRI, pieces of wood appear with low signal intensity, and only in some cases is a collar-shaped structure recognizable, allowing differentiation from gas. Soon after orbital trauma with splinters of wood, therefore CT allows better differentiation of pieces of wood from intraorbital gas by measurement of their density, whereas MRI, makes it possible to demonstrate wooden foreign bodies in older injuries in spite of granulomatous changes.

2053. Guehl, N. J., et al. (2021). "Evaluation of the potassium channel tracer [18F]3F4AP in rhesus macaques." Journal of cerebral blood flow and metabolism : official journal of the International Society of Cerebral Blood Flow and Metabolism **41**(7): 1721-1733.

Demyelination causes slowed or failed neuronal conduction and is a driver of disability in multiple sclerosis and other neurological diseases. Currently, the gold standard for imaging demyelination is MRI, but despite its high spatial resolution and sensitivity to demyelinated lesions, it remains challenging to obtain specific and quantitative measures of molecular changes involved in demyelination. To understand the contribution of demyelination in different diseases and to assess the efficacy of myelin-repair therapies, it is critical to develop new in vivo imaging tools sensitive to changes induced by demyelination. Upon demyelination, axonal K+ channels, normally located underneath the myelin sheath, become exposed and increase in expression, causing impaired conduction. Here, we investigate the properties of the K+ channel PET tracer [18F]3F4AP in primates and its sensitivity to a focal brain injury that occurred three years prior to imaging. [18F]3F4AP exhibited favorable properties for brain imaging including high brain penetration, high metabolic stability, high plasma availability, high reproducibility, high specificity, and fast kinetics. [18F]3F4AP showed preferential binding in areas of low myelin content as well as in the previously injured area. Sensitivity of [18F]3F4AP for the focal brain injury was higher than [18F]FDG, [11C]PiB, and [11C]PBR28, and compared favorably to currently used MRI methods.

2054. Guekht, A., et al. (2012). "Disorders of brain nitrergic system in the mechanisms of early seizures after ischemic and hemorrhagic stroke." Epilepsy Currents **12**(1).

Rationale: Early poststroke seizures (EPS) occur in 5-10% of stroke patients, more commonly after intracerebral hemorrhage than infarction. EPS are thought to result from cellular biochemical dysfunction leading to electrically irritable tissue. The molecular mechanisms of EPS remain obscure. Pleiotropic effects of nitric oxide proved to be important in stroke. We hypothesized that disorders of brain nitrergic system may play a role in the development of EPS. Methods: In 48 patients with the first-ever stroke (hemorrhagic/ ischemic: 22/26, in each group 50% with EPS) and 10 age-and gender matched controls we studied CSF levels of nitric oxide metabolites, nitrates, and nitrites (NOx), nitric oxide synthase (NOS) activity, products of nitrosative stress, immunoglobulins, and autoantibodies to nitrated proteins in the CSF of patients during the first day after stroke onset. NOS activity was assayed by conversion of radiolabeled arginine to citrulline, NOx levels - using a fluorescent probe diaminonaphtalene. The activity of lactate dehydrogenase (LDH) was assayed by a fluorometric method. Binding of nitrotyrosine-BSA with liquor proteins was assayed by ELISA with the use of a monoclonal antinitrotyrosine antibody. Results: There was a significant increase of NOx level in CSF of ischemic stroke (IS) patients without EPS (5,5±0,64 vs. 2,2±0,43 μmol/l in controls, P<0.01). This phenomenon is believed to reflect compensatory activation of endothelial NOS (eNOS) in cerebral vessels to ensure vasodilatation. Since patients with EPS did not demonstrate NOx increase (2,6±0,40 μmol/l,), we hypothesized that an eNOS defect can underlie EPS after ischemic event. Hemorrhagic stroke (HS) patients with and without EPS demonstrated NOx levels similar to the controls. However, the activity of NOS, virtually absent in the control group, was significant in CSF of patients with HS (p<0.001 vs controls, p< 0.05 in patients with EPS vs without EPS). As release of LDH into the CSF after HS was also significantly higher as compared to controls and correlated with NOS activity (r=0.72, p<0.05) we suggested that NOS is released into CSF from damaged brain cells or cells penetrating damaged blood-brain barrier. In the CSF of stroke patients, the content of immunoglobulins (Ig) of G, M, and A classes was significantly elevated. This increase was more pronounced in patients with HS. Binding to nitrotyrosine-BSA was increased in IS and was substantially higher in HS. Structural modifications of proteins induced by nitrosative stress stimulate the immune response, which develops in the CSF at the early stage of stroke. Conclusions: The mechanisms of EPS are different in IS and HS. Early seizures in IS are

related to the impaired ability to urgently increase eNOS activity in response to an ischemic situation and to provide an effective vasodilatation. Mechanisms of EPS in HS are associated with the BBB damage. Nitrosative stress and stimulation of the immune response might contribute to both mechanisms and should be further investigated.

2055. Guekht, A., et al. (2015). "TBI study in Moscow-predictors of seizures and outcomes." Epilepsy Currents **15**: 218-219.

Rationale: Traumatic brain injury (TBI) is a major cause of acquired epilepsy (Annegers et al., 1998). Epidemiological studies (Guekht et al., 2010) revealed that TBI was the main identified cause of epilepsy in Russia. The purpose of the present study was to evaluate incidence, risk factors for early and late seizures and outcomes after TBI in the prospective study of the consecutive cohort of patients. Methods: A prospective study of consecutive cohort of adult patients hospitalized with TBI in 2 centers in Moscow. Persons with preexisting cognitive decline and/or epilepsy were excluded. Patients were followed from admission (within 24 hours after TBI) for 2 years or until death. Clinical evaluation, CT or MRI, Glasgow coma scale (GCS) assessment were performed in the hospital; clinical, MMSE and HADs assessment -in the follow- up. Severity of TBI has been categorized by the GCS values into mild (13-15), moderate (9-12) and severe (low GCS - 8 or less) Results: 237 patients (178 men, 59 women, age 42.2 (SD 15.2) were included; 49 (20.7%) experienced seizures. 43 (18.1%) had early seizures (ES, up to 7 days after TBI), 15 (6.3%) - late seizures (LS). 9 out of 43 (20%) with ES also experienced LS compared to 0.03% of those who had no ES (p=0.0000). ES was the significant predictor of LS (OR 8.3, 95%CI 2.76 -24.9, p=0.0002). There was significantly higher proportion of patients with low GCS in the ES group (34.9% vs 13% without seizures). In univariate logistic regression low GSC values on admission were significant (p< 0.00001) risk factor of seizures. OR for any seizures was 6.6 (95%CI 2.6- 16.7), for ES - 8.4 (95%CI 3.2-21.5), ES were associated with bilateral lesions or lesion in the left hemisphere (Kruskal-Wallis test, p =0.04). Any seizures and ES were significantly associated with contusions and the volume of hematoma. In multivariate logistic regression, the following parameters were significant predictors of any seizures: depressed skull fracture (OR 25.4, 95%CI 6.1 - 105.7, p=0.0000), midline shift (OR 19.3, 95%CI 4.5 - 82.0, p=0.0000), alcohol at admission (OR 12.2, 95%CI 3.8-39.5, p=0.0000). Penetrating injury was borderline significant (OR 3.3, 95%CI 0.9 - 11.2, p=0.06). For ES only, significant risk factors were: depressed skull fracture (OR 8.4, 95%CI 2.3- 29.9, p=0.0009), midline shift (OR 8, 95%CI 2.1-30.1, p=0.002), alcohol at admission (OR 8.8, 95%CI 2.9 - 26.1, p=0.0000). ES (but not LS) were the important predictor of mortality. 18/43 (41.9%) of patients with ES died vs 8/194 (4.1%) of patients without ES (p=0.0000). MMSE values were significantly lower and HADs anxiety and depression scale values were higher (p<0.01) in the groups of patients with seizures. Conclusions: The occurrence of seizures is a medically and functionally important complication of TBI. Seizures are frequent in patients with TBI. Early seizures are associated with increased risk of mortality. Seizures after TBI are associated with cognitive decline and depression/anxiety.

2056. Guerra Martinez, A. and G. Pino Sanz (2011). "[Penetrating head injury in a pediatric patient]." Traumatismo craneoencefalico con objeto penetrante en paciente pediatrico. **58**(2): 135.

2057. Guerrero, C., et al. (2017). "Intraoral transmucosal rigid fixation to treat severely infected mandibular fractures." International journal of oral and maxillofacial surgery **46**: 80.

Objectives: To combine incision and drainage of facial infections and treat mandibular fractures in a singular surgical stage Methods: Eight patients (aged 16-42 years, five males and three females) with severe multi-spaces facial infections after mandibular fractures secondarily to gun-shot wounds or trauma were treated by Erich arch bars to obtain an ideal occlusion and physiotherapy post surgery, bone reduction was performed either open or closed, transmucosal rigid fixation was apply to avoid internal plates colonisation. The arch bars and plating system were removed 8-12 weeks after, according to bone healing. The infections were treated by incision and drainage with drains installation and removal, either 24 or 48 h after surgery. Results: All infections were cured; the fractured bones were aligned and fixated without complications, ideal dental occlusion, aesthetics and function were obtained. Conclusions: This new method allows the combination of facial infections and fractures treatments in one surgical stage, with major economical savings and less time away from work.

2058. Guerrero, C. A., et al. (2017). "Maxillofacial reconstruction by bone transport and multiple dental implants." International journal of oral and maxillofacial surgery **46**: 22.

Objective: To reconstruct the maxilla or the mandible using pedicled osteotomised segments for major continuity defects. Methods: 10 patients were treated for maxillofacial continuity defects, ranged from 2 to 16 cm, as a result of tumour resection, gunshot wound or trauma. Utilising local osteotomies and bone transport, the bony segments maintained the soft tissue attachments and were mobilised and fixated in position to a reconstruction plate. For minor defects up to 4 cm local osteotomies and immediate fixation to a reconstructive plate were performed, combined with internal bone transport for major defects. Clinical analysis, photographs and radiographs (panoramic, lateral and P-A cephalic) were used to evaluate the bone continuity, facial aesthetics, occlusion and mandibular function. Results: All patients were adequately reconstructed intraorally with radiographic evidence of bony continuity. No soft tissue dehiscence, infection or necrosis of the segments was observed after 2 years of follow up. Conclusions: All reconstruction were successful, and full bony continuity was obtained, using pedicled osteotomised segments. Furthermore, the use of osseointegrated implants allowed functional dental rehabilitation anchorage.

2060. Guevara, A. B., et al. (2016). "Association Between Traumatic Brain Injury-Related Brain Lesions and Long-term Caregiver Burden." The Journal of head trauma rehabilitation **31**(2): E48-58.

OBJECTIVE: To investigate the association between traumatic brain injury (TBI)-related brain lesions and long-term caregiver burden in relation to dysexecutive syndrome., SETTING: National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, Maryland., PARTICIPANTS: A total of 256 participants: 105 combat veterans with TBI, 23 healthy control combat veterans (HCv), and 128 caregivers., OUTCOME MEASURE: Caregiver burden assessed by the Zarit Burden Interview at 40 years postinjury., DESIGN: Participants with penetrating TBI were compared with HCv on perceived caregiver burden and neuropsychological assessment measures. Data of computed tomographic scans (overlay lesion maps of participants with a penetrating TBI whose caregivers have a significantly high burden) and behavioral statistical analyses were combined to identify brain lesions associated with caregiver burden., RESULTS: Burden was greater in caregivers of veterans with TBI than in caregivers of HCv. Caregivers of participants with lesions affecting cognitive and behavioral indicators of dysexecutive syndrome (ie, left dorsolateral prefrontal cortex and dorsal anterior cingulate cortex) showed greater long-term burden than caregivers of participants with lesions elsewhere in the brain., CONCLUSION AND IMPLICATION: The TBI-related brain lesions have a lasting effect on long-term caregiver burden due to cognitive and behavioral factors associated with dysexecutive syndrome.

2061. Gueye, E. M., et al. (1998). "[Spinal cord injuries in Senegal: 16 cases]." Les plaies vertebro-medullaires au Senegal: a propos de 16 cas. **43**(2): 238-242.

Penetrating spinal cord injuries (P.S.C.I.) are rarely described in Sub Saharian countries in spite of an increasing number of wars. To study epidemiology management and prognosis of P.S.C.I. in Senegal, population of 16 patients collected from Fann Hospital in Dakar has been studied. 9 cases were related on gunshot or shrapnel injuries and 6 were stab-wounded. 8 came from war practice and 7 from civilian practice. The point of entry was at the posterior or lateral part of the body and continuous leaking of cerebral spinal fluid from this point was founded only in one patient. Patients showed a clinical picture of a complete spinal cord section syndrome, 3 spinal cord hemisection Brown Sequard syndromes, 3 cauda equina syndromes and 1 monoradicular syndrome. Spinal X-rays or myelography may lead to an accurate evaluation of the extent of bone tissue destruction. Anatomical evaluation of roots and spinal cord lesions were more difficult when C.T. scan or R.M.I. is not available. Penetrating spinal cord injury with foreign body included or myelography stop or showing cauda equina syndrome should be operated on. 9 of our patients has benefited of spine surgical posterior approach (laminectomy). Immediate vital prognosis is good regarding the fact that visceral associated lesions were rare (2 cases). Functional recovery is fair only 46.6% of patients expressed partial or complete recovery. Prognosis factors such as injuring agent and initial neurological status has been discussed. Prognosis of penetrating spinal cord injuries could be improved by immediate and multidisciplinary management.

2062. Guglieri-Lopez, B., et al. (2018). "Rifampin dose optimization in children with tuberculous meningitis using dynamic PET imaging data." Journal of Pharmacokinetics and Pharmacodynamics **45**: S11.

Objectives: Tuberculous meningitis (TBM) is the most devastating form of tuberculosis (TB). Key TB antimicrobials have restricted brain penetration. The objective of this analysis was to optimize rifampin dosing in children with TBM to achieve brain exposures above the target for M. tuberculosis. Methods: A micro-dose (ng) of 11C-rifampin was injected to New Zealand white rabbits (n = 12) and dynamic PET imaging was performed. After imaging, a 30 mg/kg dose of unlabeled rifampin was administered and blood samples were analyzed using mass-spectrometry. A published pharmacokinetic model for rifampin after oral administration in humans 1 was scaled down and used to describe the pharmacokinetics of both rifampin and 11C-rifampin in plasma in rabbits. Then, the pharmacokinetic model was expanded to describe the brain distribution of 11C-rifampin. This pharmacokinetic-brainbiodistribution model was used to perform Monte Carlo simulations of different doses in children in order to predict rifampin exposure in brain. Probability of target attainment curves were generated. The target value for rifampin was assumed to be Cmax[4 times the minimum inhibitory concentration (MIC) (MIC = 1 lg/mL). Results: The developed pharmacokinetic-brain-biodistribution model described the distribution of 11C-rifampin into brain, including a decrease in penetration over time. This decrease, which may represent a return to homeostasis due to decreased infection and improved blood brain barrier integrity, had an estimated half-life of approximately 3 weeks. In children, only an oral dose of C 30 mg/kg would achieve the target exposure in the brain lesions at the initiation of treatment and sustained Cmax[1 lg/mL during the first 6 weeks of TBM treatment. Conclusion: Our integrated pharmacokinetic-brain-biodistribution model predicts that rifampin doses C 30 mg/kg are required to achieve adequate concentrations in brain lesions in children.

2063. Gui, H., et al. (2013). "Image-guided surgical navigation for removal of foreign bodies in the deep maxillofacial region." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **71**(9): 1563-1571.

PURPOSE: Most trauma surgeons encounter numerous penetrating injuries. Some foreign bodies can cause pain, infection, and discomfort to the patient. Serious functional disorders also are likely to occur. Foreign bodies in critical areas must be removed. This report describes the use of image-guided technology for the removal of foreign bodies deep in the maxillofacial region., PATIENTS AND METHODS: From 2008 through 2011, 5 patients with foreign bodies in the maxillofacial area underwent image-guided removal at the authors' department. The STN navigation system (Stryker-Leibinger, Freiburg, Germany) was used for surgical planning and intraoperative navigation. Preoperatively, computerized tomography and digital subtraction angiography were used to create 3-dimensional views of the region to aid surgeons in more accurately defining the spatial location of the foreign object. During surgery, the foreign objects and surgical instruments were visualized on the screen., RESULTS: In all 5 cases, the foreign bodies were removed by minimally invasive access without any complications. Surgical time was approximately 40% shorter compared with the conventional technique of not using image-guided navigation. A 1-year postoperative evaluation showed that the patients' complaints and symptoms had resolved, function was restored, and esthetics were remarkably improved., CONCLUSION: Navigation-guided removal of foreign bodies in the complex, deep maxillofacial region in proximity to vital areas can be regarded an ideal and valuable option for these potentially complicated procedures.

2064. Guilburd, J. N. and A. Rakier (2012). "Reversal of brain herniation in children by dural fenestrations." Child's Nervous System **28**(5): 773.

Object: Decompressive craniectomy is perceived as a last resort for treating uncontrollable intracranial pressure. The role of dural fenestrations in the treatment of Acute Subdural Hematoma was proved to be efficient as a new surgical technique in thirty one patients to avoid abrupt disruption of cerebral tissue during the classical wide opening of the dura, owing to dramatic diminution of ICP. We adopted the same technique in the treatment of desperate situations in children, as the ultimate step of decapitation of increased ICP, in order to try reversal of brain herniation. We consider that “classical” decompression with wide dural opening could be in some cases more deleterious for the patient owing to further deterioration. We stress the importance of keeping intact as much as possible the natural covering of the brain. Methods: 25 patients with GCS 3to5 on admission (13 with severe closed head injuries and 4 with penetrating injuries) were brought to the operating room on emergency for a wide uni or bilateral decompressive craniotomy/ ectomy and multiple fenestrations of the dura (MFD). All the patients were admitted to the emergency department and received primary care as usually recommended by advanced trauma life support guidelines and immediately transferred

to the Pediatric Intensive Care Unit after insertion of ICP monitoring via a subdural catheter or a Codman intraparenchymal device .In all the cases, uncontrolled increased intracranial pressure developed. The surgical technique consisted of elevation of a wide bone flap, multiple small openings of the exposed dura in order to allow brain decompression and reposition of the bone immediately or lately. Results: Twenty one patients survived. Fifteen of them are conscious (five neurologigally normal, eight with mild and two with marked neurological deficit). Five children remained in persistent vegetative state. In all the patients, the ICP became controllable with usual medical measures and the pupils turned smaller and reactive. Conclusions: In spite of disappointing trends of surgical reversal of brain herniation in the past, we think that this simple surgical technique, especially in children could still play an important role to save irreversible situations. The “classical approach” of decompressive craniectomy with wide dural opening and free periosteal graft is not only “unappropriate but even deleterious” in cases of severe increased ICP owing to lower recovery scores and increased immediate and late morbidity.

2065. Guilford, F. R. (1970). "Surgical consideration in disorders of the horizontal and vertical portions of the facial nerve." The Annals of otology, rhinology, and laryngology **79**(2): 241-251.

2066. Guilliard, M. J., et al. (2010). "Corns in dogs; signalment, possible aetiology and response to surgical treatment." The Journal of small animal practice **51**(3): 162-168.

OBJECTIVES: To describe the signalment and response to surgical treatment, and to propose aetiopathogenetic mechanisms for the development of paw pad corns in dogs., METHODS: A combined retrospective and prospective study was conducted on 30 dogs that presented with paw pad corns. The age, breed and gender of the dogs, together with anatomical positions of the corns were recorded. Surgical treatments involved either excision (n=27) or distal digital ostectomy (n=3). The minimum follow-up period was one year., RESULTS: The age at presentation was from two to 15 years. All the breeds in this study were either greyhounds or sighthounds. Males were over-represented. Ninety percent of the corns were found in the digital pads of digits three and four, and 90% were found in the thoracic limbs. The evidence suggests a mechanical aetiology or foreign body penetration. Long-term response to surgical excision resulted in a recurrence rate of more than 50% (n=27). Distal digital ostectomy gave good results in selective cases (n=3)., CLINICAL SIGNIFICANCE: Corns can cause severe chronic lameness in greyhounds and related breeds. Long-term response to surgical treatments is disappointing but it is recommended as an initial treatment as it can be curative.

2067. Gujral, I. B., et al. (2006). "Sex differences in mortality after traumatic brain injury, Colorado 1994-1998." Brain injury **20**(3): 283-291.

PRIMARY OBJECTIVE: The purpose of this study was to assess the relationship between sex and traumatic brain injury (TBI) mortality., METHODS AND PROCEDURES: A total of 20,465 persons with TBI were identified from a Colorado population-based surveillance system for 1994-1998. Case fatality ratios were calculated to identify sex differences for selected risk factors. Unconditional logistic regression was used to determine the relationship between TBI mortality and sex controlling for risk factors., MAIN OUTCOMES AND RESULTS: Adjusting for age, race, metropolitan residence and penetrating injury, the estimated odds of TBI mortality for males compared to females was 1.21 (95% CI 1.10, 1.34) for pre-hospital fatalities and 1.19 (95% CI 1.05, 1.37) for hospital fatalities., CONCLUSION: Results indicate differences in TBI mortality comparing males and females. Future studies are warranted to identify if behaviour and physiological responses are associated with TBI outcomes among males and females.

2069. Gulati, A., et al. (2010). "Penetrating knife injury to the frontal lobe--a case report." Annals of the Royal College of Surgeons of England **92**(6): W41-42.

Penetrating injuries of the craniofacial region are increasing and have the potential to cause severe vascular and neurological deficit. We present our management of a case with a knife stab injury to the infra-orbital region, traversing

the orbit and penetrating into the anterior cranial fossa, the tip lying in close proximity to the anterior cerebral circulation.

2070. Gulsen, S., et al. (2010). "Rapid Development of Brain Abscess Caused by Streptococcus Pyogenes Following Penetrating Skull Injury via the Ethmoidal Sinus and Lamina Cribrosa." Journal of Korean Neurosurgical Society **48**(1): 73-78.

OBJECTIVE: Streptococcus pyogenes is a beta-hemolytic bacterium that belongs to Lancefield serogroup A, also known as group A streptococci (GAS). There have been five reported case in terms of PubMed-based search but no reported case of brain abscess caused by Streptococcus pyogenes as a result of penetrating skull injury. We present a patient who suffered from penetrating skull injury that resulted in a brain abscess caused by Streptococcus pyogenes., METHODS: The patient was a 12-year-old boy who fell down from his bicycle while cycling and ran into a tree. A wooden stick penetrated his skin below the right lower eyelid and advanced to the cranium. He lost consciousness on the fifth day of the incident and his body temperature was measured as 40. While being admitted to our hospital, a cranial computed tomography revealed a frontal cystic mass with a perilesional hypodense zone of edema. There was no capsule formation around the lesion after intravenous contrast injection. Paranasal CT showed a bone defect located between the ethmoidal sinus and lamina cribrosa., RESULTS: Bifrontal craniotomy was performed. The abscess located at the left frontal lobe was drained and the bone defect was repaired., CONCLUSION: Any penetrating lesion showing a connection between the lamina cribrosa and ethmoidal sinus may result in brain abscess caused by Streptococcus pyogenes. These patients should be treated urgently to repair the defect and drain the abscess with appropriate antibiotic therapy started due to the fulminant course of the brain abscess caused by this microorganism.

2071. Gunasena, P., et al. (2010). "Clinical outcome following decompressing craniectomy with minimal brain exploration for ballistic injuries to the brain." Brain injury **24**(3): 182-183.

Objectives: Method of surgery for ballistic brain injuries have been changing from Second World War up to now. At the beginning aggressive decompression and evacuation of hematoma was the practice. However according to the data from the second Iraq war the practice has been changed to less aggressive decompression to deal with hematomas and foreign bodies. A prospective study was conducted to evaluate the clinical outcome following decompressing craniectomy with minimal exploration of the brain for penetrating Brain Injury sustained in a war situation. Method: 150 patients brought to Teaching Hospital Anuradhapura Sri Lanka with penetrating brain injuries during the recently ended civil war over a period of 8 months have been evaluated to assess the clinical outcome. Patients who had ICH, acute SDH, and cerebral contusions due to penetrating Brain Injury with mass effect were included in the study. All patients had decompressing cranictomy with removal of bone flap. Total evacuation of acute SDH were done while only the easily accessible haematomas, bone fragments and contusions were allowed to come out. All patients had fascia lata on lay dural graft and creation of SCF fistula before closure. Clinical outcome was evaluated using Glasgow outcome scale and Glasgow coma scale at the end of 2 weeks and 6 months time. Results: 30% of the patients had bullet injuries and 70% had shrapnels.6 patients died due to injuries. 80% of patients had ICH, 70% had contusions and 55% had acute SDH. 40% of the patients had GCS 6/15- 8/15, 50% had GCS 9/15-11/15, and 10% had GCS 12/15- 13/15. At the end of 2 weeks 5% of the of patients had GOS 1/5, 95% GOS 3/5. At the end of 6 months 40% of patients had GOS 5/5, 45% had 4/5, 10% had 3/5. Conclusions: Minimal damage surgery with decompressing craniectomy is a satisfactory way to manage penetrating brain injuries during war situation. Clinical outcome was evaluated using Glasgow outcome scale and Glasgow coma scale at the end of 2 weeks and 6 months time. Results: 30% of the patients had bullet injuries and 70% had shrapnels.6 patients died due to injuries. 80% of patients had ICH, 70% had contusions and 55% had acute SDH. 40% of the patients had GCS 6/15- 8/15, 50% had GCS 9/15-11/15, and 10% had GCS 12/15- 13/15. At the end of 2 weeks 5% of the of patients had GOS 1/5, 95% GOS 3/5. At the end of 6 months 40% of patients had GOS 5/5, 45% had 4/5, 10% had 3/5. Conclusions: Minimal damage surgery with decompressing craniectomy is a satisfactory way to manage penetrating brain injuries during war situation.

2072. Gunasena, P., et al. (2010). "Evaluation of risk of developing EDH associated with large craniectomy closure without hitching the dura." Brain injury **24**(3): 129.

Objectives: Since Walter Dandy described tenting suture to the dura before craniotomy closure to prevent post operative development of EDH has been practiced over many decades. Many authors in the past have described the

incidence of developing EDH has not been higher though the dura has not been hitched. Method: A prospective study has been conducted during the recently concluded civil war in Sri Lanka to evaluate the incidence of developing EDH following decompressive craniectomy for Acute SDH and intracerebral hematomas due to penetrating brain injuries. 300 patients brought to a single unit over a period of two years have been evaluated. Patients who had craniectomies more than 8cm in its largest diameter were included in the study. All these patients had bulging brain at the time of closure. No patients had tenting suture to the dura to prevent post op extradural hematomas. All the patients had post operative CT scanning from 24 hours to 72 hours post operatively. Results: Not a single patient developed an extradural hematoma. Two patients out of 300 developed intracerebral hematomas and underwent reoperation. Conclusions: Closure of large craniectomy in the presence of brain bulging does not require Dural tenting sutures to prevent post operative Extradural hematomas.

2073. Gunasena, P., et al. (2010). "On lay dural graft without suturing and creation of CSF fistula to prevention of CSF leak following decomprssive craniectomy for penetrating brain injury in a war setting." Brain injury **24**(3): 128.

Objectives: CSF leak through the surgical incision or through air sinuses is a significant problem association with penetrating brain injuries where arachnoid and pia mater is injured. It has been reported as high as 28% in the Korean War. Method: A prospective study has been conducted during the recently ended civil war in Sri Lanka to evaluate the incidence of CSF leaks following decompressive craniectomies for penetrating brain injury. Patients arrived at a single station for a period of one and half years from January 2008 have been evaluated. Out of 995 patients 650 patients underwent decommpressive craniectomies. All patients having had the definitive procedure underwent dural plasty using facia late as an on lay graft between the brain and the dura without suturing to the dura. A CSF fistula has been created using a suction drain. The drain was removed around the 14th post operative day. Results: Only 12 patients had CSF leak through the surgical wound no patients had CSF ottorrhoea or rhinorrhoea. All 12 patients required reoperation and managed successfully. 8 patients had confirmed intracranial sepsis. The incidence of CSF leak with our technique was 1.8%. Conclusions: Creation of CSF fistula and on lay dural graft without suturing is a successful way of preventing CSF leak following decompressive craniectomies for penetrating brain injuries done in a war situation where the time and the resources are limited factors.

2074. Gund, V. A. and B. Hammer (1975). "[A rare type of transorbital brain injury]." Eine seltene Art der transorbitalen Hirnverletzung **36**(2): 101-107.

Case report of transorbital brain injury from a mortar shot. A bolus of powder particles and iron had penetrated the right orbit and then the roof of the orbit and led to the formation of an intracerebral abscess. Diagnostic and therapeutic approach is described.

2075. Gundogmus, U. N., et al. (2013). "[Residual pellet in fetal brain tissue following a gunshot injury to a pregnant woman: a case report]." Gebe bir kadinda av tufegi yaralanmasi sonucu fetus beyin dokusunda reziduel sacma tanesi: Bir olgu sunumu. **19**(4): 371-374.

Vital functions and the effect of injuries on quality of life are important from a viewpoint of causation in willful injury crimes committed against a pregnant woman. In such conditions, which should be evaluated separately in criminal law and compensation law, permanent losses of organ function that may negatively affect the woman's fertility, the features of permanent functional impairments and premature birth of the fetus can be additive factors for the indemnification amount. In scientific literature, case reports addressing the morphological and physiological changes to the fetus due to firearm injury are rare. In the presented case, we aimed to evaluate the fetus's situation, following firearm injury to a 41-year-old woman at 27 weeks gestation. While the mother was living a healthy life, the significant problem of the child in the first four-year period of his development was hyperactivity. Evaluating the effect of the frontal lobe lesion on the psychiatric findings of the child is important.

2076. Gunkel, S., et al. (2009). "[Facial perforation trauma: an unusual injury in a skiing accident]." Perforatationstrauma im Gesichtsschadel : Eine ungewohnliche Verletzung beim Skifahren. **112**(12): 1075-1078.

Facial perforation injuries are very rare. We describe a case of a 48-year-old man who sustained a perforation trauma from an 11 cm long wooden tree branch in the middle of the face in a skiing accident. He suffered from

additional injuries, such as fractures of the ribs and hand, but was neurologically without pathologic findings and was cardiopulmonary stable. The branch penetrated the head from the sinus maxillaris through the maxilla just missing the internal and external carotid arteries and ending just short of the cervical vertebra. The patient was transported to a center for oral and maxillofacial surgery and underwent several operations.He could return to his normal social and professional life 8 months after the accident.

2077. Gunther, M., et al. (2015). "Neuroprotective effects of N-acetylcysteine amide on experimental focal penetrating brain injury in rats." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **22**(9): 1477-1483.

We examined the effects of N-acetylcysteine amide (NACA) in the secondary inflammatory response following a novel method of focal penetrating traumatic brain injury (TBI) in rats. N-acetylcysteine (NAC) has limited but well-documented neuroprotective effects after experimental central nervous system ischemia and TBI, but its bioavailability is very low. We tested NACA, a modified form of NAC with higher membrane and blood-brain barrier permeability. Focal penetrating TBI was produced in male Sprague-Dawley rats randomly selected for NACA treatment (n=5) and no treatment (n=5). In addition, four animals were submitted to sham surgery. After 2 hours or 24 hours the brains were removed, fresh frozen, cut in 14 mum coronal sections and subjected to immunohistochemistry, immunofluorescence, Fluoro-Jade and terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) analyses. All treated animals were given 300 mg/kg NACA intraperitoneally (IP) 2 minutes post trauma. The 24 hour survival group was given an additional bolus of 300 mg/kg IP after 4 hours. NACA treatment decreased neuronal degeneration by Fluoro-Jade at 24 hours with a mean change of 35.0% ($p<0.05$) and decreased TUNEL staining indicative of apoptosis at 2 hours with a mean change of 38.7% ($p<0.05$). Manganese superoxide dismutase (MnSOD) increased in the NACA treatment group at 24 hours with a mean change of 35.9% ($p<0.05$). Levels of migrating macrophages and activated microglia (Ox-42/CD11b), nitric oxide-producing inflammatory enzyme iNOS, peroxynitrite marker 3-nitrotyrosine, NFkappaB translocated to the nuclei, cytochrome C and Bcl-2 were not affected. NACA treatment decreased neuronal degeneration and apoptosis and increased levels of antioxidative enzyme MnSOD. The antiapoptotic effect was likely regulated by pathways other than cytochrome C. Therefore, NACA prevents brain tissue damage after focal penetrating TBI, warranting further studies towards a clinical application.

2078. Günther, M., et al. (2013). "COX-2 Regulation differs between sexes in the secondary inflammatory response following experimental penetrating brain injury in rats." Journal of neurotrauma **30**(15): A93-A94.

Introduction Traumatic brain injury (TBI) is followed by a secondary inflammatory response. Females are better protected from adverse effects of this process in animal models and human epidemiological studies. The reason for this is not fully known. We examined the inflammatory response following experimental TBI in male and female rats. Methods Parietal contusions using a penetrating brain injury model were produced in male and female rats (n = 5). The rats were placed in a stereotactic frame and positioned with a probe directly above the exposed dura mater. A pin with a tip radius of 1mm and depth of penetration 5mm was accelerated into the brain. After 24 h and 72 h the brains were removed, cut in 14 lm coronal and transversal sections and subjected to immunohistochemical analyses for protein expression and in situ hybridization for mRNA detection. We analyzed the expression of the proinflammatory enzymes Cox-2 and iNOS, markers of astrogliosis (GFAP), microgliosis (Osteopontin), peroxynitrite levels by surrogate measure 3-Nitrotyrosine, and neuronal degeneration (Fluoro Jade). Results The region of interest (ROI) was in coronal sections defined medially by the interhemispheric fissure, basally by the inferior border of corpus callosum, and laterally by the lateral border of the right hemisphere. ROI was in transversal sections defined by the interhemispheric fissure and the lateral borders of the ipsilateral hemisphere. GFAP mRNA was upregulated in the ROI at 24 h and 72 h. Minor upregulation was seen on the contralateral side. No difference was seen between sexes. Osteopontin was upregulated in the ROI at 24 h. No upregulation was seen on the contralateral side. No difference was seen between sexes. Cox-2 mRNA was elevated in the cortical areas of the ROI. Minor upregulation was seen on the contralateral side. mRNA levels were significantly upregulated in male rats in the ROI at 24 and 72 h ($p < 0.05$). iNOS mRNA levels and protein expression was upregulated in the ROI at 24 h. No upregulation was seen on the contralateral side. No difference was seen between sexes. 3-Nitrotyrosine was upregulated in the ROI after 24 h. No upregulation was seen on the contralateral side. No difference was seen between sexes. Fluoro Jade stained neuronal degeneration was upregulated in the ROI at 24 h. No upregulation was seen on the contralateral side. No difference was seen between sexes. Conclusions We found that the Cox-2 mediated inflammatory response differed between female and male rats following TBI. Cox-2 is partly expressed

under physiological conditions in the brain but mainly induced by proinflammatory mediators. It is suspected to be involved in various neurodegenerative diseases, and the regulation of Cox-2 and iNOS has been shown to be interconnected. The nitric oxide producing enzyme iNOS is induced following trauma, leading to oxidative stress through the creation of peroxynitrite. iNOS and peroxynitrite expression did not differ between sexes. Astrogliosis and microgliosis was found in the perilesional area with a similar expression between sexes. Our findings from this pilot study indicate that the sex specific trait of the secondary inflammatory response may be connected to prostaglandin regulation. The difference did not lead to altered neuronal death at 24 h. This heterogeneity may in part explain sex dependent variances in outcome after TBI.

2079. Gunther, M., et al. (2015). "COX-2 regulation and TUNEL-positive cell death differ between genders in the secondary inflammatory response following experimental penetrating focal brain injury in rats." Acta neurochirurgica **157**(4): 649-659.

INTRODUCTION: Traumatic brain injury is followed by secondary neuronal degeneration, largely dependent on an inflammatory response. This response is probably gender specific, since females are better protected than males in experimental models. The reasons are not fully known. We examined aspects of the inflammatory response following experimental TBI in male and female rats to explore possible gender differences at 24 h and 72 h after trauma, times of peak histological inflammation and neuronal degeneration., METHODS: A penetrating brain injury model was used to produce penetrating focal TBI in 20 Sprague-Dawley rats, 5 males and 5 females for each time point. After 24 and 72 h the brains were removed and subjected to in situ hybridization and immunohistochemical analyses for COX-2, iNOS, osteopontin, glial fibrillary acidic protein, 3-nitrotyrosine, TUNEL and Fluoro-Jade., RESULTS: COX-2 mRNA and protein levels were increased in the perilesional area compared to the uninjured contralateral side and significantly higher in males at 24 h and 72 h ($p < 0.05$). iNOS mRNA was significantly increased in females at 24 h ($p < 0.05$) although protein was not. TUNEL was increased in male rats after 24 h ($p < 0.05$). Glial fibrillary acidic protein, osteopontin, 3-nitrotyrosine and Fluoro-Jade stained degenerating neurons were increased in the perilesional area, showing no difference between genders., CONCLUSIONS: COX-2 regulation differed between genders after TBI. The increased COX-2 expression in male rats correlated with increased apoptotic cell death detected by increased TUNEL staining at 24 h, but not with neuronal necrosis measured by Flouro-Jade. Astrogliosis and microgliosis did not differ, confirming a comparable level of trauma. The gender-specific trait of the secondary inflammatory response may be connected to prostaglandin regulation, which may partially explain gender variances in outcome after TBI.

2080. Guo, Y., et al. (2022). "Characteristics and Visual Prognosis of Pediatric Open Globe Injury in Shanghai, China." Ophthalmic research **65**(3): 328-334.

INTRODUCTION: The aim of the study was to describe the characteristics of open globe injury (OGI) and the relationship between the complications and visual outcomes in children with this type of injury., METHODS: This was a retrospective chart review of 1,664 children, under the age of 16 years, who were hospitalized for OGI between January 1, 2007, and December 31, 2015. Each patient's age, sex, cause and agent of injury, complications, visual acuity, and classification of ocular trauma were collected for review and analysis., RESULTS: The mean age was 5.6 +/- 3.4 years. Right eyes were particularly vulnerable to injury (right eye:left eye ratio = 1.2:1). Traumatic cataract was the most common complication. The average initial and final best corrected visual acuity were logarithm of the minimum angle of resolution (logMAR) 2.04 +/- 0.78 and logMAR 1.74 +/- 0.88, respectively. Logistic regression analysis showed that hyphema (odds ratio [OR] = 1.850), iris prolapse (OR = 1.702), vitreous hemorrhage (OR = 9.703), retinal detachment (OR = 11.938), endophthalmia (OR = 5.377), intraocular foreign body (OR = 3.346), and initial visual acuity <0.05 (OR = 9.017) were risk factors for visual acuity <0.05 at hospital discharge., CONCLUSION: OGI was most frequent in preschool children and boys. Right eyes were more vulnerable than left eyes. Poor visual outcomes were associated with hyphema, iris prolapse, vitreous hemorrhage, retinal detachment, endophthalmia, intraocular foreign body, and an initial visual acuity <0.05.

2081. Guo, Y. W., et al. (2004). "Vital signs changes and survival curve analysis of cats after craniocerebral injury under different environments of temperature and humidity." Chinese Journal of Clinical Rehabilitation **8**(1): 76-78.

Aim: To investigate the changing characteristic of vital signs and survival time of cats after craniocerebral injury in the environment of high temperature and humidity. Methods: Thirty-two cross-bred cats were randomly divided into

four groups and put into the following environments respectively after fire-arm injury: A (25 °C, relative humidity 50%); B(35 °C, relative humidity 85%); C(38 °C, relative, humidity 90%); D(40 ° C, relative humidity 95%). The blood pressure, heart rate, respiratory frequency and body temperature were recorded every 10 minutes until 6 hours later. Results: The vital signs in the gunshot wound under normal temperature group observed in the experiment were stable, and along with the increase of temperature and humidity, the body temperature and respiratory frequency and heart rate of cats in each group were significantly different at the same point of time ($P < 0.05$). The cats in group A and B were survival in 6 hours, while the cats in group C began to die after 1.5 - 2.0 h and all died 5 hours later, and the mean survival time was (3.4 ± 0.8) h. The cats in group D began to die 0.5 - 1 h later and all died after 2.5 hours, and the mean survival time was (2.0 ± 0.5) h. Conclusion: The environment of high temperature and humidity can significantly affect the changes of vital signs and survival time of the cats with craniocerebral injury.

2082. Guo, Y.-w., et al. (2004). "Bacterial growth characteristics in craniocerebral gunshot wound of cat in a hot and humid environment." Di 1 jun yi da xue xue bao = Academic journal of the first medical college of PLA **24**(2): 201-203.

OBJECTIVE: To investigate the growth behavior of characteristics in craniocerebral gunshot wound of cats in a hot and humid environment., METHODS: Twenty-three cross-bred cats were randomly divided into 4 groups: group A, the gunshot wound control group at normal temperature, in which tissue sampling was performed immediately after the wounding; group B, another gunshot wound control group at normal temperature, in which the samples were taken 6 h after the wounding; group C, the gunshot wound group subjected to a hot and humid environment, in which the tissue samples were obtained 6 h after the wounding; group D, the control group without undergoing the wound. The tissues from the wound tract and the surrounding tissues were sampled for bacterial culture and counting., RESULTS: The bacterial counts of the tissues from the wound tract, the tissues within 5 mm and within 5-10 mm from wound tract varied insignificantly between groups A, B and C ($P>0.05$). In each group, the bacterial counts declined in the tissues as the distance of the sampling sites from the wound tract increased ($P<0.01$). The bacterial counts of the tissues from the wound tract and within 5 mm from the wound tract in group A, B and C were significantly different from those in group D ($P<0.01$)., CONCLUSION: Hot and humid environment does not significantly affect the bacterial growth in the craniocerebral gunshot wound within the first 6 h, which is a safe period against rapid bacterial growth and suitable for debridement.

2083. Guo, Z., et al. (2013). "Bone augmentation in a titanium cap with a porous surface modified by microarc oxidation." The International journal of oral & maxillofacial implants **28**(3): 767-773.

PURPOSE: To compare bone augmentation on pure titanium-machined surfaces and surfaces that have been modified by microarc oxidation (MAO) using titanium caps., MATERIALS AND METHODS: Twenty caps were manufactured from rods of commercially pure titanium. The control group (CG) consisted of 10 titanium caps with machined inner walls. The test group (TG) consisted of 10 titanium caps that were modified by MAO in an electrolyte solution containing calcium phosphate ions. The two types of titanium caps were fixed on the calvaria of 10 New Zealand rabbits. Each rabbit received two different caps. Although each cap was unfilled, the marrow and blood from the wound of the rabbit skulls could penetrate into the caps. After 4 weeks, the rabbits were sacrificed, and the skulls were removed for observation. The zenith of new bone was measured directly after the caps were removed from the skulls; subsequently, the bone volume was calculated by microcomputed tomography., RESULTS: Little bone augmentation could be observed in the CG caps, and the new bone height of the CG group was inconspicuous. In contrast, the new bone extended along the inner walls of the TG caps. The mean height of new bone of the TG group was 2.3 +/- 0.28 mm. The mean volume of new bone in the TG group was 18.63 +/- 3.80 mm(3)., CONCLUSIONS: New bone formation in a titanium cap surface modified by MAO was greater than that of a nonmodified cap. A titanium cap allowed new bone formation on the MAO surface to be observed and is a promising device for bone augmentation. Additionally, this finding suggests that observation through a titanium cap is a feasible method for biomaterial testing in hard tissue.

2084. Guppy, K. H. and C. Ochi (2018). "Self-Inflicted Drywall Screws in the Sagittal Sinus." World neurosurgery **110**: 323-325.

A 30-year-old right-handed man with a history of schizophrenia presented with 2 self-inflicted drywall screws in the skull. The patient was sleepy but easily arousable; blood tests showed he had taken methamphetamines. Computed

tomography and computed tomography angiography of the head showed the frontal screw abutted left of the superior sagittal sinus, and the posterior screw went through the superior sagittal sinus with no extravasation of contrast material at either site. Both screws were removed with exposure of the sagittal sinus using U-shaped craniectomies. There was no bleeding on the removal of the screws. It appears the posterior screw entered between the leaflets of the sagittal sinus dura mater. The patient had returned to work without any sequelae 1 month after injury.

2085. Gupta, A., et al. (2011). "Pencil in the brain: a case of temporal lobe abscess following an intracranial penetrating pencil injury." Pediatric neurosurgery **47**(4): 307-308.

The case of a 7-year-old girl with an intracranial penetrating injury due to a pencil is presented. The difficulties in diagnosis and the need for a high degree of suspicion and for prompt adequate surgical treatment are highlighted.

2086. Gupta, A. K., et al. (2005). "High-flow traumatic carotico-jugular fistula manifesting as venous hypertensive encephalopathy. A case report." Interventional Neuroradiology **11**(3): 261-268.

We report the clinical and angiographic findings in a patient who presented with venous hypertensive encephalopathy secondary to a traumatic carotico-jugular fistula. Endovascular entrapment of the fistula by occluding the common carotid artery and internal jugular vein at the base of the skull resulted in near total improvement of the patient's neurological status.

2087. Gupta, B., et al. (2011). "Facial and spinal impalement injury: An airway challenge." Indian Journal of Critical Care Medicine **15**(4): 236-237.

2088. Gupta, M., et al. (2010). "Accidental deaths due to coffee making machine blast: Two unusual case reports." Journal of Forensic Medicine and Toxicology **27**(1): 4-6.

In these reports the authors present two separate rare incidents of accidental explosion of country made coffee making machines. These machines maintain steam under pressure, which is used to make coffee. These machines which were old and not well maintained could not support the high steam pressure inside, resulting in explosion. Two persons died and five others were injured in the explosions. Such cases are of interest as a number of devices, which work on similar principles, are in use in the market. In this case report, we discuss the circumstances leading to the explosion of machines, the autopsy findings, brief review of the literature and methods of prevention of such incidents.

2089. Gupta, N., et al. (2018). "Results of simple limbal epithelial transplantation in unilateral ocular surface burn." Indian journal of ophthalmology **66**(1): 45-52.

PURPOSE: This study aimed to report the long-term outcomes of autologous Simple Limbal Epithelial Transplantation (SLET) performed for unilateral limbal stem cell deficiency (LSCD) following chemical burn at a tertiary eye center in North India., METHODS: This was a single-center prospective interventional case series of patients who developed unilateral LSCD after suffering from ocular surface burns and who underwent SLET between October 2012 and May 2016 with a follow-up period of at least 6 months. The primary outcome measure was restoration of a completely epithelized, stable, and avascular corneal surface. The secondary outcome measure was percentage of eyes, which reported visual gain., RESULTS: The study included 30 eyes of 30 patients, 18 adults and 12 children, at a median follow-up of 1.1 years (range: 6 months to 3.5 years), 21 of 30 eyes (70%; 95% confidence interval, 53.6%-86.2%) maintained successful outcome. Visual acuity gain was seen in 71.4% of successful cases. The clinical factors associated with failure were identified as acid injury, severe symblepharon at the time of presentation, and SLET combined with penetrating keratoplasty (PK)., CONCLUSION: Autologous SLET is an effective limbal cell transplantation technique for the treatment of unilateral LSCD. It is especially beneficial for centers where cell cultivation laboratory is unavailable. Presence of severe symblepharon, which requires PK peroperatively , has poor outcome.

2090. Gupta, P. K., et al. (2008). "Penetrating intracranial injury due to crochet needle." Pediatric neurosurgery **44**(6): 493-495.

Penetrating head injury is uncommon and is always a curiosity in terms of the mechanism involved. The complete extent of the damage can only be known with CT scan of the brain, which at times may be difficult to get, due to the large size of the foreign body. The management of such patients is always a challenge and requires innovative planning. A case of crochet needle injury is described in which the needle entered through the mouth and passed through the jugular foramen into the cerebellum. This patient, fortunately, escaped without any neurological deficit and complications. The principles of management are highlighted. Copyright 2008 S. Karger AG, Basel.

2091. Gupta, P. P., et al. (2017). "Patterns of Injury and Mortality in Pediatric Patients Attending Emergency Department in a Tertiary Care Center in Eastern Nepal." JNMA; journal of the Nepal Medical Association **56**(207): 331-334.

INTRODUCTION: Trauma is a major and increasing global health concern in the recent world. It is now the leading cause of death among people less than 18 years old. The aim of this study is to analyze all injuries from trauma-related causes among children and adolescents under 18 years old of age., METHODS: This is a retrospective cross sectional study done in Emergency Department of B.P. Koirala Institute of Health Sciences. Patients aged less than 16 years were included with history of trauma from January 1st 2013 to 31st December 2013. The details of patient were taken from computerized medical records of the hospital. The demographic data, pattern of injury, mode of injury, diagnosis and outcomes were tabulated in Microsoft Excel., RESULTS: Total 3958 pediatrics patient were enrolled in this study with Male: Female=3.6:1 and Mean age 9.6+/-3.2 years. The common modes of injury were fall injury 2596 (65.6%) and RTAs 1176 (29.7%). Whereas the commonest patters were Fractures 1385 (35%) and Soft Tissue Injuries 784 (19.8%)., CONCLUSIONS: Fall Injury and Road Traffic Accidents are major and serious problem for children in Low Income countries like Nepal.

2092. Gupta, S., et al. (2019). "Firearm injuries cause disproportionate mortality in pediatric traumatic brain injury." Clinical neurosurgery **66**: 85.

INTRODUCTION: Traumatic brain injury is a major cause of mortality and long-term morbidity in the pediatric population. Given renewed legislative efforts aimed at reducing firearm violence and harm, we sought to investigate the impact of firearms on mortality associated with TBI. METHODS: Amulticentric, retrospective cohort analysis of pediatric patients with TBI was conducted using the National Trauma Data Bank from 2011 to 2014. The primary outcome was mortality within the hospital; the primary exposure was firearm-related vs. non-firearmrelated TBI. RESULTS: Pediatric patients with firearm-related TBI (n = 1,417; median [IQR] age 16 [13-17]) and non-firearm-related TBI (n = 123,740; median [IQR] age 11 [5-15]) were included. Firearm injuries included intentional harm by others (56%), suicide attempts (29%), and accidental harm by others (15%). The majority of African- American firearm-related TBIs presented after assault (79.6%), whereas the majority of White cases presented after suicide attempts (55.6%). Firearm-related cases presented with an average adjusted GCS 3.4 points lower than non-firearm-related TBI. 50.0% of firearm-related cases died while in the hospital compared to 2.8% of non-firearm cases. The firearm injury type with the highest rate of mortality was self-harm/suicide attempts (69.8%). Relative to non-firearm cases, firearm injuries were identified to be an independent predictor of in-hospital mortality (OR 8.3; 95% CI 7.1-9.7); firearm suicide attempt injuries were the most lethal (OR 13.0; 95% CI 9.9-17.0). Although firearm injuries comprised only 1.1% of all TBIs, they were the cause of injury in 16.7% of all deaths. Male sex, Black race, and public and self-pay insurance predicted firearm injuries. CONCLUSION: Firearm-related injuries are associated with disproportionately high mortality in pediatric TBI, especially in suicide attempts. African-Americans are at disproportionately high risk of firearm assault relative to Whites. Public health and policy interventions could target youth firearm injuries and potentially prevent a significant portion of TBI deaths.

2093. Gupta, S. K. and A. A. Umredkar (2012). "Juxtapontine abscess around a retained wooden fragment following a penetrating eye injury: surgical management via a transtentorial approach." Journal of neurosurgery. Pediatrics **9**(1): 103-107.

Penetrating injury through the orbit with a retained intracranial wooden foreign body is rare. The authors report the case of a child with a juxtapontine brain abscess secondary to a retained foreign body. The pitfalls in diagnosis and the surgical management for removal of the wooden fragment and drainage of the abscess are discussed.

2094. Guranda, A. I., et al. (1994). "[Experience of anesthesiology and intensive care services in mass admission of victims with fight injuries]." Opyt anesteziologo-reanimatsionnogo obespecheniia massovogo postuplenia postradavshikh s boevymi travmami.(1): 44-47.

In mass admission of wounded patients quick rational medical sorting is of primary importance. Anesthesiology and intensive care service performs organization and specific medical work. Gun-shot peritonitis is characterized by initial multiorgan insufficiency and instability of central hemodynamic index. We used planned neuroplegia and sedatives of benzodiazepine type in severe craniocerebral trauma. In fat embolism of cerebral vessels we used lipostabil and heparin. There were also cases of heart wounds and injuries.

2095. Gurunluoglu, R. and J. Gatherwright (2019). "Microsurgical reconstruction of complex maxillofacial gunshot wounds: Outcomes analysis and algorithm." Microsurgery **39**(5): 384-394.

BACKGROUND: Satisfaction with appearance, functional outcomes (speech, swallowing), work status after microsurgical reconstruction for maxillofacial gunshot wounds (GSW) remain largely unknown. The purpose of this study is to report these parameters. By investigating these outcomes, we also aimed to provide microsurgical algorithms for complex maxillofacial GSW., METHODS: Forty-two consecutive maxillofacial GSW patients between 2006 and 2014 were analyzed for outcomes. Mean age was 41.3 years ranging 14 to 77 years. There were 33 males and 9 females., RESULTS: Twenty-four patients received 36 free flaps for early reconstruction in 1 to 2 weeks, two patients in a delayed manner. Fifteen fibula flaps for mandible reconstruction, five fibula, there radial forearm (RF), and two scapular osteocutaneous (OC) flaps for maxilla reconstruction, two RF flaps for palate reconstruction, one RF for cheek reconstruction were used. Four patients underwent innervated gracilis flap for total lower lip and one for cheek reconstruction. Rectus abdominis myocutaneous flap was used for mid-face defects in two patients. One anterolateral thigh flap was used for lower lip/chin reconstruction. Nine free flaps were performed to treat a complication and/or to improve function. All flaps survived except for three partial skin paddle loss to fibula flaps. Mean follow-up was 17.2 months. Return to work/school was 70%. Surveys noted 58% "satisfied". All patients but two achieved perceptible speech, the majority had no difficulty with swallowing, all patients had oral competence., CONCLUSIONS: Favorable outcomes were obtained in most maxillofacial GSW. After investigating these outcomes, microsurgical algorithms were developed for clinical practice for reconstruction of composite mandible and total-lower lip defects, and maxilla/mid-face defects.

2096. Gurunluoglu, R., et al. (2012). "Functional reconstruction of total lower lip defects using innervated gracilis flap in the setting of high-energy ballistic injury to the lower face: preliminary report." Journal of plastic, reconstructive & aesthetic surgery : JPRAS **65**(10): 1335-1342.

BACKGROUND: Reconstruction of total full-thickness lower lip defects combined with extensive composite mandibular defects particularly in the setting of close-range high-energy ballistic injury presents a formidable challenge for the reconstructive plastic surgeon. While the fibular flap has been widely accepted for its usefulness in the reconstruction of composite mandibular defects, to date, there is no definitive widely established method of total lower lip reconstruction. The article presents authors' approach using innervated gracilis muscle flap for total lower lip reconstruction in the setting of high-energy gunshot injuries to the face., METHODS: Three patients underwent composite mandibular defect reconstruction using fibular osteocutaneous flap and functional lower lip reconstruction using innervated gracilis muscle flap. Lip lining was reconstructed using the skin paddle of the fibular flap. The external surface of the gracilis muscle was skin-grafted. Facial artery myomucosal flap provided vermilion reconstruction in two patients., RESULTS: All fibular (n=3) and gracilis flap transfers (n=3) were viable. An electromyographic study at 1 year postoperatively demonstrated successful re-innervation of the gracilis muscle. Starting at about 10 weeks postoperatively, patients exhibited voluntary lip movements and oral competence. In addition, all patients achieved near-normal speech, evidence of recovered protective sensitivity and satisfactory appearance. The mean follow-up was 16.1 months., CONCLUSIONS: Our preliminary report in three patients demonstrated that innervated gracilis muscle transfer combined with fibular flap provides a successful reconstruction of extensive composite mandibular and total lower lip defects resulting from gunshot injuries to the face. Oral continence was achieved by combination of regained tonicity and voluntary movement of the gracilis muscle following re-innervation and assistance of the cheek muscles on

the gracilis muscle. The described technique was reliable and the results were promising.

2097. Gussack, G. S. and G. J. Jurkovich (1988). "Penetrating facial trauma: a management plan." Southern medical journal **81**(3): 297-302.

Penetrating wounds of the face present a spectrum of injuries and multiple management dilemmas. The surgeon's first concern remains the establishment of a proper airway and control of life-threatening injuries. Selected ancillary diagnostic procedures should be used to confirm vascular, aerodigestive, or central nervous system injuries. Diagnosis of injuries may require arteriography, endoscopic examination, barium studies, computerized tomography, and detailed ophthalmologic examination. We review 16 cases of penetrating facial trauma treated at the University of South Alabama Trauma Center over a one-year period. The injuries resulted from 13 gunshot wounds and three stab wounds. Injuries of the central nervous system occurred in three patients, mandibular fractures in four, optic nerve or globe injury in three, and maxillary sinus fracture in seven. Our experience with these patients demonstrates the spectrum of injuries and serves as a basis for a management algorithm.

2098. Guthrie, E., et al. (1999). "Traumatic brain injury in children and adolescents." Child and adolescent psychiatric clinics of North America **8**(4): 807-ix.

Traumatic brain injury is an insult to the brain caused by an external force that results in an impairment (transient or permanent) of cognitive, behavioral, emotional, or physical function. Traumatic brain injury encompasses shearing injury, which might be seen in a shaken infant, as well as penetrating injury from a foreign body, such as a bullet. This article addresses the recovery phase and functional sequelae following traumatic brain injury. Research and clinical experience over the past decade have led to a better understanding of the pathophysiology of head injury and, in turn, improved management.

2099. Gutierrez, A., et al. (1983). "Unusual penetrating craniocerebral injury." Surgical neurology **19**(6): 541-543.

We report a 29-year-old patient who was operated on for a penetrating craniocerebral injury caused by an underwater fishing harpoon. It had penetrated through the roof of the left orbit, upward toward the calvaria. The patient was immediately operated upon and the foreign body was easily removed through a small left parietal craniectomy. In spite of the spectacular appearance of the injury on admission to the hospital, neurological impairment before and after the operation was minimal.

2100. Gutierrez-Aceves, G. A., et al. (2018). "Posterior bi-parietal decompressive craniectomy in refractory intracranial hypertension secondary to civilian gunshot wound. Case report and review of literature." International journal of surgery case reports **53**: 291-294.

Background: Decompressive craniectomy is recommended as second tier therapy for unresponsive intracranial hypertension in Traumatic Brain Injury. There have been reports of a Bi-Occipital craniectomy in cases where the focal injury is posterior. Case description: The work has been reported in line with the SCARE criteria. There is a 56-year-old male with Traumatic brain injury secondary to gunshot and intracranial hypertension, managed with biparietal craniectomy, after place a intracranial pressure monitor, whit good response to surgical and medical treatment, even with good outcome after hospitalization. Conclusions: In selected cases a posterior bi-parietal craniectomy can be performed in a safe way with acceptable results to treat refractory Intracranial hypertension. We propose that this neurosurgical technique can be used in patients with posterior focal injuries.

2101. Gutierrez-Gonzalez, R., et al. (2008). "Penetrating brain injury by drill bit." Clinical neurology and neurosurgery **110**(2): 207-210.

Non-missile low velocity penetrating brain injuries are unusual among civilian population. They show specific characteristics different from missile wounds. In this paper we describe a rare case of self-inflicted penetrating head trauma by electric drill. We document neuroimaging studies and review the management concerning this pathology. To our knowledge, this is the first case of intracranial retained drill bit with such radiological findings reported in the

literature. An 80-year-old male with no previous psychiatric disorder presented at our hospital after suffering an accident while working with an electric drill. Physical examination revealed right lower extremity plegia and three penetrating scalp wounds to the left parasagittal region. Skull X-ray and computed tomography demonstrated an intracranial metallic foreign body located in the left parietal lobe and an intraparenchymal hematoma with no mass effect close to the foreign body. The patient was taken to the operating room to remove the drill bit fragment. Antibiotic and antiseizure prophylaxis were administered. Postoperative computed tomography confirmed no residual metallic fragments and functional recovery was excellent. After psychiatric assessment, suicide attempt was confirmed and antidepressive therapy was then started. On follow-up, no complication was documented. It is essential to exclude penetrating brain trauma whenever a scalp wound is noticed in order to provide proper treatment and prevention care. The permanent neurological deficit in low velocity injuries is related to the degree and location of the primary injury. It also depends on an early diagnosis and treatment and the absence of delayed complications.

2102. Guven, S. and A. H. Durukan (2018). "Terroristic sniper shot ocular injuries: military and police casualties: case series." Journal of the Royal Army Medical Corps **164**(5): 318-321.

INTRODUCTION: Sniper shot ocular injuries (SSOI) are rare and result in poor ocular outcomes due to high energy transfer both to the eye and the adjacent brain. To our knowledge, no reports of such injuries in terms of outcomes have been previously described in the literature. The aim of this case series was to describe the treatment performed and ocular outcomes of such injuries., METHODS: Five cases of terroristic SSOIs referred to Gulhane Military Medical Academy Department of Ophthalmology between 22 July 2015 and 30 January 2017 were reviewed. Comparisons were made between the location and mechanism of injury, initial and final ocular signs, interventions and additional extraocular injuries., RESULTS: Two cases were of police officers and the remaining were Turkish military soldiers. All of our cases were injured in urban district by terrorist snipers hidden in apartments. Four individuals were injured in the right eye and the other was injured bilaterally. Initial visual acuities (VA) ranged from no light perception (NLP) to 0.0 with logMAR. Final VA raised to 0.0 in three patients whereas in two of NLP patients it remained the same. Mean Ocular Trauma Score was 2.2. Two eyes necessitated evisceration and the others underwent vitrectomy surgery., CONCLUSIONS: The prognosis of SSOI is unpredictable and is highly dependent on the trajectory and energy deposition. Primary evisceration or enucleation should be reserved to severely ruptured globe cases with no chance of globe-saving procedures. If the globe remains intact, retinal and vitreal damage should be repaired. Due to risk of associated intracranial injury, all patients should be referred for neurosurgical opinion.

2103. Guvenc, Y., et al. (2021). "Penetrating Craniocerebral Injury by the Hook of a School Desk." Pediatric neurosurgery **56**(2): 152-156.

INTRODUCTION: Although penetrating cranial injuries are rare in pediatric patients, these injuries can lead to morbidity and mortality. Removal of a gigantic foreign body from the cranium requires proper management as it has high risk of further brain damage and seizures., CASE PRESENTATION: We report the case of a patient with cranial injury caused by hitting the head to the hook of a school desk. Due to the extreme nature of the injury, the following additional steps were necessary: taking help from a local firefighter team to cut the desk, surgical removal of the foreign body, and cranioplasty after 6 months. Following this, he was discharged without neurological deficits., DISCUSSION/CONCLUSION: Neurotrauma is one of the major causes of death in children. The damage and effect of the injuring foreign body depends on its size, shape, velocity, trajectory, and entry point. It should be kept in mind that any high-frequency processes applied on the extracranial parts of conductive objects, such as metal bars, may trigger seizures. Preoperative extracranial intervention for huge penetrating foreign bodies should be performed under anticonvulsant administration and intubation to decrease the risk of epileptic seizures and its complications.

2104. Guzman-Almagro, E., et al. (2021). "Open-globe-injury: A single center Spanish retrospective 5-year cohort study." European journal of ophthalmology **31**(5): 2710-2716.

PURPOSE: To review and analyze the epidemiological profile, clinical characteristics and visual outcomes in patients attended for traumatic open globe injury (OGI) at our hospital over a 5-year period., DESIGN: Retrospective chart review study., METHODS: Retrospective analysis of all patients attended at Fundacion Jimenez Diaz University Hospital for OGI between 2011 and 2015. Data from 104 patients including demographics, ocular examination, medical

and surgical treatment, visual outcomes, and complications were analyzed., RESULTS: Most patients were male (79.8%) and the median age at the time of injury was 41 years (interquartile range 31.5-58 years). Work-related accidents represent more than half of the cases and their main mechanism was penetrating trauma or foreign body. This type of accident had good prognosis (median final visual acuity in decimal scale 0.8; interquartile range 0.4-1). Falls were the second most common cause of OGI, predominantly affecting senior women (50%), with a high incidence of ocular rupture (50%) and associating a poor visual prognosis (median final visual acuity 0.01; interquartile range 0-0.5). There was a strong correlation (0.75; $p < 0.001$) between ocular trauma score (OTS) and final best corrected visual acuity., CONCLUSIONS: Two different patterns of OGI were identified in our sample. Work-related trauma in young males was the most common form of OGI and was associated with good prognosis. However, falls in senior women were associated with poor prognosis.

2105. Haas, B., et al. (2009). "Survival advantage in trauma centers: expeditious intervention or experience?" Journal of the American College of Surgeons **208**(1): 28-36.

BACKGROUND: Trauma patients who receive care at designated trauma centers have a decreased risk of death, but the processes of care that lead to improved outcomes are unknown. We set out to examine the relationship between trauma center care, rapidity of assessment and intervention, and mortality among trauma patients with indications for immediate operative intervention., STUDY DESIGN: Data were collected from a multicenter prospective cohort study of adult patients cared for in trauma centers (TC) and nondesignated centers (NTC). From this cohort, we identified patients with two patterns of injury: hypotensive penetrating trauma (PT) and blunt traumatic brain injury (TBI) with mass effect. Times from admission to relevant interventions were assessed, as were relative risks of in-hospital death in TC compared with NTC. Relative risks were adjusted for differences in case mix using propensity analysis., RESULTS: Among 1,331 patients who met inclusion criteria, 23.5% died in hospital. Relative risk of death was 0.61 (95% CI, 0.43 to 0.86) among patients managed at TC compared with those admitted to NTC. This survival advantage was greatest among patients in the PT group managed at TC (relative risk: 0.43; 95% CI, 0.19 to 0.94). Relative risk of death at TC among patients in the TBI group was 0.72 (95% CI, 0.50 to 1.0). Within the first 24 hours of admission, however, there was no statistically significant difference between median times to radiographic assessment or operative intervention at TC as compared with other hospitals., CONCLUSIONS: Risk of death is considerably lower among patients requiring early operative intervention if they are treated at a designated Level I trauma center. These outcomes are not a result of more rapid assessment and intervention alone, and emphasize the complex factors that contribute to the survival benefit of trauma center care.

2106. Habal, M. B. and R. A. Rasmussen (1993). "Osseointegrated implants in cranial bone grafts for mandibular reconstruction." The Journal of craniofacial surgery **4**(1): 51-57.

Branemark osseointegrated implants were used in combination with a cranial bone graft that was harvested from the outer table of the skull in a patient with a discontinuity defect of the anterior aspect of the mandible. First, a staged procedure allowed reconstruction of the defect. The second stage was placement of the Branemark osseointegrated implant fixtures, followed by contouring the interior genial area by adding more bone grafts. The initial stabilization was done with an adoption plate that was used to stabilize the mandibular fragments during the healing phase. This plate was subsequently removed when the osseointegrated implants were placed. The patient had a full course of oral rehabilitation and a satisfactory final outcome.

2107. Haberkamp, T. J., et al. (1995). "Gunshot injuries of the temporal bone." The Laryngoscope **105**(10): 1053-1057.

Despite an increasing incidence of gunshot wounds to the temporal bone, there is little in the literature regarding management of survivors of these serious injuries. Twelve patients were treated for such wounds between 1986 and 1994. The most frequent presentations were cranial nerve injury, especially facial paralysis (9 patients), hearing loss (7), vascular injury (4), and vestibular dysfunction (3). Persistent cerebrospinal fluid otorrhea was uncommon (1 patient) in this series. Computed tomography and audiovestibular testing were helpful in evaluating the severity of injury and guiding the surgical approach when necessary. Electroneurography was helpful in evaluating facial nerve function; however, documented disruption of the facial nerve canal in itself was considered an indication for surgical exploration. Other indications for surgical intervention included evidence of dural tear, vascular injury, and severe disruption of the external auditory canal.

2108. Hachemi, M., et al. (2007). "Delayed rupture of traumatic aneurysm after civilian craniocerebral gunshot injury in children." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **23**(3): 283-287.

BACKGROUND: There are few published large series on civilian craniocerebral gunshot injuries in children. Traumatic intracranial aneurysms (TICAs) are rare and highly unstable lesions. They represent less than 1% of all aneurysms and can either rupture within minutes after formation or remain quiescent for several weeks or years, manifesting with delayed hemorrhage and neurologic deterioration., CASE HISTORY: We report the case of a 10-year-old girl who was referred for coma after high-velocity craniocerebral gunshot wound and neurological deterioration 7 days after the initial injury. A massive right posterior occipital hematoma caused by the rupture of an unsuspected right posterior cerebral artery TICA was discovered. TICA was treated by coil embolization, with a good neurological recovery at 6-month follow-up., DISCUSSION: We discuss the pathogenesis and the management of TICA in a child after civilian craniocerebral gunshot injuries., CONCLUSIONS: TICAs should be suspected in patients with civilian craniocerebral gunshot injuries, presenting with secondary neurological deterioration, to carry out emergent CT scan and angiographic exploration before contemplating definitive endovascular treatment. Endovascular management may be a prompt safe-to-use technique and a valuable option, especially when surgery is highly risky.

2109. Hackett, M. J., et al. (2015). "In situ biospectroscopic investigation of rapid ischemic and postmortem induced biochemical alterations in the rat brain." ACS chemical neuroscience **6**(2): 226-238.

Rapid advances in imaging technologies have pushed novel spectroscopic modalities such as Fourier transform infrared spectroscopy (FTIR) and X-ray absorption spectroscopy (XAS) at the sulfur K-edge to the forefront of direct in situ investigation of brain biochemistry. However, few studies have examined the extent to which sample preparation artifacts confound results. Previous investigations using traditional analyses, such as tissue dissection, homogenization, and biochemical assay, conducted extensive research to identify biochemical alterations that occur ex vivo during sample preparation. In particular, altered metabolism and oxidative stress may be caused by animal death. These processes were a concern for studies using biochemical assays, and protocols were developed to minimize their occurrence. In this investigation, a similar approach was taken to identify the biochemical alterations that are detectable by two in situ spectroscopic methods (FTIR, XAS) that occur as a consequence of ischemic conditions created during humane animal killing. FTIR and XAS are well suited to study markers of altered metabolism such as lactate and creatine (FTIR) and markers of oxidative stress such as aggregated proteins (FTIR) and altered thiol redox (XAS). The results are in accordance with previous investigations using biochemical assays and demonstrate that the time between animal death and tissue dissection results in ischemic conditions that alter brain metabolism and initiate oxidative stress. Therefore, future in situ biospectroscopic investigations utilizing FTIR and XAS must take into consideration that brain tissue dissected from a healthy animal does not truly reflect the in vivo condition, but rather reflects a state of mild ischemia. If studies require the levels of metabolites (lactate, creatine) and markers of oxidative stress (thiol redox) to be preserved as close as possible to the in vivo condition, then rapid freezing of brain tissue via decapitation into liquid nitrogen, followed by chiseling the brain out at dry ice temperatures is required.

2110. Hada, M., et al. (2016). "An unusual case of protruding retro-orbital metallic foreign body." Indian journal of ophthalmology **64**(8): 604-606.

A 34-year-old female presented with firecracker injury with curved metallic foreign body embedded in the left orbit and protruding out through the upper eyelid. The report highlights notable aspects in diagnosis, decision-making, and successful removal of this unusual case of retro-orbital foreign body.

2111. Hadas, N., et al. (1990). "Tangential low-velocity missile wound of the head with acute subdural hematoma: case report." The Journal of trauma **30**(3): 358-359.

Tangential missile wounds of the head without skull fracture are a known entity. Usually, references in the literature indicate that this type of injury results from a high-velocity missile impact. We present a case of a tangential missile head wound caused by a low-velocity missile. As the range of fire was short, the quantity of energy that might be released could be equated with that released by a high-velocity missile fired from a much longer range. This possibility

should be brought to the attention of clinicians as an essential element in this pre-treatment clinical evaluation. We propose a pathomechanical explanation for the development of the clinical state.

2113. Haddad, F. S. (1978). "Nature and management of penetrating head injuries during the civil war in Lebanon." Canadian Journal of Surgery **21**(3): 233-240.

During the recent war in Lebanon, at one hospital one fifth of all casualty admissions were patients with skull injuries associated with penetrating brain damage. Wounds inflicted by high velocity missiles carried the greatest mortality. The patient's state of consciousness afforded the best guide to prognosis. Craniotomy, when feasible, was found preferable to the accepted technique of craniectomy in the management of these cases. Thorough debridement and complete hemostasis are essential, and when these have been accomplished, deeply placed bony fragments may be left in situ with impunity. Traumatic aneurysm develop by no means rarely and therefore postoperative arteriography is advisable.

2114. Haddad, F. S. (1978). "Wilder Penfield Lecture: nature and management of penetrating head injuries during the Civil War in Lebanon." Canadian journal of surgery. Journal canadien de chirurgie **21**(3): 233-240.

During the recent war in Lebanon- at one hospital one fifth of all casualty admissions were patients with skull injuries associated with penetrating brain damage. Wounds inflicted by high velocity missiles carried the greatest mortality. The patient's state of consciousness afforded the best guide to prognosis. Craniotomy, when feasible, was found preferable to the accepted technique of crainectomy in the management of these cases. Traumatic aneurysms develop by no means rarely and therefore postoperative arteriography is advisable.

2115. Haddad, F. S. (2002). "Penetrating missile head injuries: Personal experiences during the Lebanese conflict." Neurosurgery Quarterly **12**(4): 299-306.

This is an overview of the experience of the author during 18 years of civil strife in Lebanon. What can be worse than brain missile injury is the psychologic effect on the people caused by such wars. Unfortunately, these wars are common and have been going on uninterruptedly since World War II. With an experience of more than 1,000 cases, the author has attempted to give a simple classification of these injuries and presents the essence of their treatment. Four main topics are discussed: 1) craniotomy versus craniectomy; 2) the importance of retained fragments in the brain; 3) traumatic aneurysms; and 4) a rapid, easy, and helpful grading system.

2116. Haddad, F. S., et al. (1991). "Traumatic intracranial aneurysms caused by missiles: their presentation and management." Neurosurgery **28**(1): 1-7.

Only 30 cases of traumatic intracranial aneurysm (TICA) secondary to missile injury have been reported to date. To these we add 15 more cases. Missile TICAs are often seen on a secondary branch of the middle cerebral artery and are usually accompanied by a intracerebral hematoma (80%) or by an acute subdural hematoma (26%). Fourteen of our cases were secondary to shrapnel injuries and only one was secondary to a bullet. None of the injuries was through-and-through. TICAs may enlarge in time and, seemingly inoffensive, may rupture and lead to death. All seven TICAs studied histologically proved to be false aneurysms. TICAs are best treated through trapping and excision. The outcome depends on the patient's status and level of consciousness before surgery. Indications for angiography are discussed.

2118. Hadjizacharia, P., et al. (2009). "The impact of intoxication on the number of organs available for transplantation after brain death." The American surgeon **75**(5): 416-420.

A significant number of head-injured trauma patients are likely to present with a positive toxicology. The purpose of this study is to investigate whether intoxication with substances such as cocaine, amphetamine, alcohol, and opiates on admission has any influence on the number of organs that are recovered after brain death in these patients. We conducted a retrospective review of all organ donor patients admitted to a Level I trauma center over a 4-year period (2002 to 2005). Patients with positive toxicology screens on admission were compared to counterparts with negative screens with regard to the number of organs harvested. There were 90 organ donor patients during the 4-year period. There were 63 (70%) patients to negative toxicology screens. The remaining 27 (30%) were found to be intoxicated with a variety of substances, including alcohol (18%), cocaine (4%), amphetamines (9%), benzodiazepines (4%), opiates (4%), and polysubstances (10%). A comparison of total organs and individual organs donated by both intoxicated and nonintoxicated patients showed no overall statistical difference in the number or type of organs donated between the two groups. Thus, the prospect of organ procurement should not be overlooked in intoxicated patients.

2119. Haegen, T. W., et al. (2005). "Use of image-guided systems in the reconstruction of the periorbital region." Archives of facial plastic surgery **7**(4): 266-271.

The conflict in the Middle East has led to an increase in the incidence and severity of facial trauma evaluated at tertiary military medical facilities. The Naval Medical Center San Diego, San Diego, Calif, has treated 5 patients with penetrating injuries to the orbit with associated comminuted fractures. We have used the technology of image-guided surgery to assist in reconstructing these injuries. Image-guided surgery has many applications in the head and neck. This review consists of a series of traumatic applications of the image-guided system with a focus on orbital and midfacial trauma. We will discuss the benefits and drawbacks of this technique compared with previously described techniques.

2120. Haeren, R. H. L., et al. (2012). "Posttraumatic skull hemangioma: case report." Journal of neurosurgery **117**(6): 1082-1088.

Intraosseous cavernous hemangiomas of the skull are rare lesions for which the origin is unclear. The authors present a case in which there was a radiologically documented history of trauma preceding the development of a hemangioma in the frontal bone. In a review of the literature the authors found 83 cases of skull hemangiomas, and 43% of the lesions were located in the frontal bone. In 25% of these lesions, previous trauma was reported anamnestically. The present case and radiological findings related to it suggest a causal relationship between trauma and the development of intraosseous hemangioma.

2122. Hagai, B., et al. (2014). "Exploring the meaning of the Subthalamic Nucleus's neural signal in Parkinson." Stereotactic and Functional Neurosurgery **92**: s192-s193.

Objective: Exploring the meaning of the Subthalamic Nucleus's neural signal in Parkinson. Methods: We studied the impact of the neurophysiological and surgical properties of DBS of the subthalamic nucleus (STN-DBS) on motor, neuropsychological (NPSY), and speech outcome in Parkinson. We included 48 patients (19 female, 29 male), excluding brain injuries, DBS of other targets, infections, and hardware complications. Presenting symptoms and outcomes were correlated with STN-DBS laterality/dominance, micro-electrode recordings (MER) and surgical properties at 3.8 months before STN-DBS and 16.2 months after respectively. Principle components analysis (PCA) of the pre-/post-DBS scores in the 3 outcome categories was used to design a simplified evaluation protocol. Results: We had a homogenous group of patients in terms of symptoms' types and severity, brain dominance and gender. STN-DBS worsen frontal neuropsychological faculties and speech intelligibility, however in a rather acceptable degree in the scope of the significant improvement in the overall quality of life. In addition to the known impact of laterality, it seems that both STN-dominance and STN-neural-signal have a crucial clinical impact. Pre-DBS analyses showed that UPDRS I-III (Tremor, Rigidity/Bradykinesia, Axial Deficit), duration of PD (10.5±4.3y, p=0.9) and levodopaequivalent drug dosage (LEDD;

1225±611, p=0.9) were indifferent to laterality/dominance. Mean age was lower in the bilateral STN-DBS (Bi-STN) group (54.5y) than the unilateral right-STN (Uni-Rt; 60.7y) and unilateral left-STN (Uni-Lt; 63.8y). Bi-STN patients had worse scores for activities of daily living (ADL) (Bi-STN 58, Uni-Rt 70, Uni-Lt 73, p=0.02) and UPDRS-IV (Bi-STN 7.30, Uni-Rt 5.38, Uni- Lt 3.69, p=0.0037). Voice and neuropsychology scores were normal in all groups. Following DBS, the Uni-Lt group least improved in ADL (Uni-Lt 11.7% <Uni-Rt 20.5% < Bi-STN 48.5%, p<0.05) and LEDD (Uni-Lt -16.9% < Uni-Rt -35% < Bi-STN -43.5%, p<0.05). ADL improvement was explained by the ON/OFF fluctuations (Uni-Lt -1, Uni-Rt -1.2, Bi-STN -4.2, p<0.05) rather than by the absolute scores (both before and after surgery). DBS was associated with a greater improvement in rigidity and bradykinesia than in tremor; the opposite result was for drugs. The ipsilateral effect of DBS was more prominent for bradykinesia than tremor. Axial deterioration was resistant to DBS (2.5, p=0.03). We also showed a trend of better improvement among patients undergoing DBS at earlier PD-stages. Speech intelligibility and NPSY deteriorated from normal before DBS to abnormal after Bi-STN and Uni-Lt DBS (p<0.03) only. Frontal-NPSY properties were more DBS-vulnerable. There was an overall unexplained increase in the use of anti-psychotic/anti-depressive drugs. DBS most significantly improved ON/OFF fluctuations will drugs improved motor symptoms. Last we PCA which yielded six clinically and mathematically independent factors: Bradykinesia-Rigidity, Tremor, Speech-intelligibility, Memory-Language, Executive functioning and Attention-Concentration. Wider STNs (p<0.001), higher normalized-neuronal signal (p=0.03), and presence of active cathodes within the β-oscillatory STN regions (p=0.2) were more common in patients with greater motor improvement and less speech/NPSY deterioration. As for the number of brain penetrations, we found no significant and consistent trend. Conclusion: Within the constraints of the population size and time to survey, it seems plausible to suggest the following. ON/OFF fluctuations are affected by STN laterality and dominance and have a prominent impact on ADL. Not only STN and LEDD impacts differ (bradykinesia and rigidity for the first and tremor for the latter) but moreover Bi-STN showed the most significant effect upon ON/OFF fluctuation (compared with both unilateral groups), possibly suggesting different underlying mechanisms. Besides laterality per se clinicians should consider dominant vs non-dominant STN involvement (which might prominently impact the speech-neuropsychology profiles). On the b sis of our findings, we designed an innovative and simplified evaluation protocol using representative motor, speech, and neuropsychology. We introduce a novel surgical-neurophysiological STN-score (composed of STN width, normalized neuronal signals, and β oscillations) to facilitate the decision- making process during surgery in terms of target selection and the final location of the chronic stimulation cathode.

2123. Hagan, R. E. (1971). "Early complications following penetrating wounds of the brain." Journal of neurosurgery **34**(2 Pt 1): 132-141.

The experience of an evacuation hospital in Japan in treating 506 consecutive patients from Vietnam with penetrating wounds of the brain is reported with particular reference to early complications. Sixty-eight patients were operated on for still retained intracranial foreign bodies. Thirty-five of the 62 patients with retained intracranial bone fragments had positive microbial cultures of the fragment, which in 63% showed Staphylococcus epidermis. All of the metallic fragments cultured revealed microbial growth. Superficial infections were noted in 32 patients. Superficial plus deep infections were found in eight patients with no retained bone fragments. Eighteen patients had meningitis proven by culture, while an additional 12 patients with CSF sugars of less than 40 mg% were assumed to have meningitis. Twelve patients developed CSF leaks requiring surgery. Twenty-three patients (4.54%) died as a result of their wounds. The neurosurgical treatment recommended for these patients is described.

2124. Hage, T., et al. (2020). "Does the type of explosive brain-death correlate with outcome after heart transplantation?" Journal of Investigative Medicine **68**(1): A34.

Purpose of study In heart transplantation, the origin of brain death may have an impact on outcome after heart transplantation. It has been reported that explosive brain death, including head trauma, gunshot to the head, and subarachnoid hemorrhage (SAH), may lead to increased catecholamine surge with damage to the donor heart as well as upregulation of inflammatory markers. Other forms of brain death such as hanging, drowning, and drug overdose may also impact outcome, but this has not been firmly established. Therefore, we sought to evaluate explosive brain death and its relationship to outcomes in the current era. Methods used Between 2010 and 2018, we assessed 823 heart transplant patients and divided them into two groups based on whether the heart donor underwent explosive or non-explosive brain death. Endpoints included 1-year survival, freedom from the development of cardiac allograft vasculopathy (CAV, as defined by stenosis >30% by angiography), non-fatal major adverse cardiac events (NF-MACE: myocardial infarction, new congestive heart failure, percutaneous coronary intervention, implantable cardioverter

defibrillator/pacemaker implant, stroke), any treated rejection (ATR), acute cellular rejection (ACR), antibody-mediated rejection (AMR), donor specific antibodies (DSA), and severe primary graft dysfunction (PGD). Summary of results Patients from both explosive and non-explosive brain death mechanisms have comparable outcomes in terms of survival and freedom from severe PGD, CAV, NF-MACE, and rejection. Conclusions Explosive brain death does not appear to be associated with less than optimal outcomes after heart transplantation.

2125. Hagemeier, L., et al. (2009). "Extended suicide using an atypical stud gun." Forensic science international **189**(1-3): e9-12.

Suicides with stud guns are uncommon, but are well documented in the literature. On rare occasions, stud guns are also used as a homicide weapon. This case report describes an extended suicide in which a husband killed his wife and their two dogs, which lived on the property. The husband then committed suicide with a shot from the stud gun into his skull. He was a 70-year-old pensioner, a retired butcher, who was found by his son. He was lying in a supine position on a carpet in the living room, with the stud gun stuck in his skull. During autopsy, high concentrations of an antihistamine were found in the blood of each corpse; this drug is used as a soporific. In contrast to the literature, which mainly describes powder deposits due to the use of conventional stud guns, in this case a stud gun was used in which the expanding gases and powder escaped together with the central bolt at the front of the device; powder drains were not involved. Detailed findings of the autopsy are given with reference to this type of stud gun.

2127. Haghi, M. R., et al. (2009). "A penetrating trauma to the temple." Emergency medicine journal : EMJ **26**(10): 746.

2128. Hagos, F., et al. (2014). "Probenecid increases n-acetylcysteine brain levels: Implications for brain-directed therapeutics." Critical care medicine **42**(12): A1511.

Learning Objectives: A major hurdle in the translation of pharmacological therapies for treatment of CNS diseases is penetration of drugs across the blood-brain barrier (BBB) and sustained bioavailability. For example, Traumatic Brain Injury (TBI) is a leading cause of death in children and young adults, yet there are no FDA-approved drugs to treat neuronal damage after TBI. Lack of consideration for pharmacokinetics and penetration into the brain may be one of the reasons for failure of previous TBI drug trials. N-acetylcysteine (NAC) is an antioxidant with limited BBB penetration. Given that oxidative stress contributes to the pathogenesis of TBI, a strategy augmenting brain bioavailability of drugs like NAC could prove efficacious. We hypothesized that the organic acid transporter and multidrug resistance-associated protein inhibitor, probenecid (PB), increases plasma and brain levels of the antioxidant NAC in rats. Methods: Naive 16-18 d.o. male Sprague-Dawley rats (n=4/time point) received NAC (163 mg/kg) with or without PB (150 mg/kg) i.p. Plasma and brain tissue were collected at 0.5, 1, 2, 4, 6 and 8h after injection for analysis. NAC concentrations in plasma and brain homogenate were measured using a validated LC-MS/MS assay. Results: Plasma exposure of NAC was increased by 1.65 fold in the NAC+PB group compared to the NAC only group (AUC0-inf: 2.42 ± 0.2×105 vs 1.46 ± 0.06×105 ng∗h/mL; p=0.0037). Brain exposure of NAC was increased by 2.41 fold in the NAC+PB group (AUC0-inf: 341.1 ± 40.5 vs 822.2 ± 82.1 ng∗h/mL; p=0.0028). PB reduced apparent plasma clearance of NAC by 65% (CL/F: 1113 ± 29 vs 674 ± 8.2 mL/h/ kg). Conclusions: Both plasma and brain exposure of NAC were significantly increased by co-administration of PB. The decrease in apparent plasma clearance of NAC is a novel finding that strongly suggests that NAC is a transporter substrate. PB increased brain exposure by 1.46 fold more than the plasma exposure implying possible transporter-related effects at the BBB. Both NAC and PB are FDA approved and thus provide an attractive therapeutic strategy for CNS diseases including TBI.

2129. Hagos, F. T., et al. (2019). "Membrane transporters in traumatic brain injury: Pathological, pharmacotherapeutic, and developmental implications." Experimental neurology **317**: 10-21.

Membrane transporters regulate the trafficking of endogenous and exogenous molecules across biological barriers and within the neurovascular unit. In traumatic brain injury (TBI), they moderate the dynamic movement of

therapeutic drugs and injury mediators among neurons, endothelial cells and glial cells, thereby becoming important determinants of pathogenesis and effective pharmacotherapy after TBI. There are three ways transporters may impact outcomes in TBI. First, transporters likely play a key role in the clearance of injury mediators. Second, genetic association studies suggest transporters may be important in the transition of TBI from acute brain injury to a chronic neurological disease. Third, transporters dynamically control the brain penetration and efflux of many drugs and their distribution within and elimination from the brain, contributing to pharmacoresistance and possibly in some cases pharmacosensitivity. Understanding the nature of drugs or candidate drugs in development with respect to whether they are a transporter substrate or inhibitor is relevant to understand whether they distribute to their target in sufficient concentrations. Emerging data provide evidence of altered expression and function of transporters in humans after TBI. Genetic variability in expression and/or function of key transporters adds an additional dynamic, as shown in recent clinical studies. In this review, evidence supporting the role of individual membrane transporters in TBI are discussed as well as novel strategies for their modulation as possible therapeutic targets. Since data specifically targeting pediatric TBI are sparse, this review relies mainly on experimental studies using adult animals and clinical studies in adult patients.

2131. Haider, G., et al. (2020). "Intracranial Hypertension Following Gunshot Wound to the Torcula: Case Report and Literature Review." World neurosurgery **137**: 94-97.

BACKGROUND: Elevation of bone for the treatment of depressed skull fractures overlying venous sinuses is rarely required or performed. The neurosurgical literature only describes a handful of cases of surgical intervention in which the posterior two-thirds of the superior sagittal sinus was involved. Clinical course is variable, signs and symptoms suggest increased intracranial pressure, and all conservative measures should be exhausted before proceeding with the surgical route., CASE DESCRIPTION: A 27-year-old man presented with a self-inflicted gunshot wound to posterior head. On presentation, there were no neurologic complaints. On imaging, the bullet fragment was associated with a comminuted anteriorly displaced fracture over the torcula. Vessel imaging showed tapering of the superior sagittal sinus and transverse sinuses near the torcula, suggesting narrowing due to mass effect. The patient did not respond to initial conservative management and developed worsening diplopia and papilledema concerning for increased intracranial pressure. Occipital/suboccipital craniectomy was performed with elevation of depressed skull fracture, decompression of dural venous sinus, removal of bullet, and mesh cranioplasty. Repeat ophthalmology examination postoperatively showed improvement in optic disc edema and diplopia., CONSLUSIONS: This case confirms that the approach of surgical management of superior sagittal venous sinus injuries associated with skull fractures described in the literature also can be used successfully for injuries over the torcula if conservative management does not help alleviate the symptoms and results in good outcome. It was felt that delayed surgery also plays an important role, as it gives time for scar tissue to form, which may help to protect the sinus from injury during surgery.

2132. Haley, A. C. and C. Abramson (2009). "Traumatic pneumocephalus in a dog." Journal of the American Veterinary Medical Association **234**(10): 1295-1298.

CASE DESCRIPTION: A 17-month-old dog was evaluated because of progressive tetraparesis. The dog had a history of craniofacial trauma at 2 months of age., CLINICAL FINDINGS: Results of a neurologic examination were suggestive of a lesion localized to the medulla. Computed tomography revealed extensive pneumocephalus extending throughout the ventricular system and into the cranial cervical subarachnoid space., TREATMENT AND OUTCOME: Because of the deterioration in the dog's clinical condition, an emergency bilateral transfrontal craniectomy was performed. A large amount of pyogranulomatous material was found intraoperatively. Neurologic and computed tomographic abnormalities were no longer evident during a recheck examination 8 weeks after surgery., CLINICAL RELEVANCE: Findings suggested that pneumocephalus should be considered in the differential diagnosis for dogs with neurologic signs of an intracranial abnormality, particularly if the dog has a history of craniofacial trauma.

2134. Haller, I., et al. (2019). "Severe craniofacial trauma after multiple pistol shots." Open Medicine (Poland) **14**(1): 629-632.

A 48-year-old woman suffered from life-threatening injuries in head and chest caused by six pistol shots fired at close range in an attempted homicide. We report here on our successful airway management and bleeding control at the scene of crime and the multidisciplinary surgical treatment of the associated head and neurovascular injuries.

2135. Haller, J. R. and C. Shelton (1997). "Medial antebrachial cutaneous nerve: a new donor graft for repair of facial nerve defects at the skull base." The Laryngoscope **107**(8): 1048-1052.

When grafting a facial nerve defect after resection of a skull base cancer, the use of the greater auricular nerve is generally contraindicated because of concern of malignant involvement. In the past, the sural nerve was used as a donor graft for reconstruction of the facial nerve. We have found a sensory branch of the median nerve of the upper arm, the medial antebrachial cutaneous (MAC) nerve, to be a suitable option for facial nerve grafting. The MAC nerve provides a good diameter match for the facial nerve and has branching to allow reconstruction of the distal facial nerve in the parotid bed. The length is adequate to graft from the brainstem to the distal facial branches. Loss of sensation is limited and well tolerated by the patient. The MAC nerve has been used in grafting in 15 patients with skull base disease and facial nerve defects. No complications have been encountered, and the functional return appears to be similar to other grafts. In our practice the MAC nerve is a valuable option for facial nerve repair at the skull base.

2136. Hallock, G. G. (1995). "Self-inflicted gunshot wounds of the lower half of the face: the evolution toward early reconstruction." The Journal of cranio-maxillofacial trauma **1**(3): 50-55.

The self-inflicted gunshot wound of the lower half of the face traditionally has been treated by multistaged and prolonged reconstructive maneuvers that often left significant and uncorrectable secondary deformities. Modern cranio-maxillofacial methods for reduction and rigid fixation of the facial skeleton, using immediate autogenous bone grafts when required, also has been efficacious for the acute management of these severe gunshot injuries. These methods can reduce the previously expected morbidity. Today's improved outcomes also are a consequence of the use of more reliable regional flaps and microsurgical techniques, which permit the early and simultaneous restoration of bone and soft tissue loss once all devitalized tissues have been adequately debrided.

2137. Halloran, L. G. and S. A. Levinson (1973). "Extra-cranial carotid artery injury following non-penetrating cervical trauma." Virginia medical monthly **100**(9): 811-passim.

2138. Halmy, C., et al. (2011). "[Mandibular reconstruction with free osteocutaneous fibula flap using the occipital artery as recipient vessel]." Mandibularekonstrukcio arteria occipitalisra varrt szabad osteocutan fibulalebennyel. **152**(16): 642-645.

Authors performed reconstructive surgery for extensive skin and mandibular bone defect following gunshot injury to the left side of the face. The soft tissue and bone defect was reconstructed with the free osteocutaneous fibula flap harvested from the left lower leg, as suitable local reconstructive flap was not available. The bony continuity was reestablished with a 7 cm long fibula segment. Microvascular anastomoses were performed to the left occipital artery and the left internal jugular vein. The occipital artery was chosen as the external carotid system was completely missing on the right side and was missing several branches on the left side due to the trauma. The fibular segment became fully incorporated and 95% of the flap healed by primary intention.

2139. Hamblin, M. (2014). "Can transcranial low-level laser light therapy induce the brain to repair itself?" Lasers in surgery and medicine **46**: 52.

Background: A multitude of brain disorders could be benefited if the brain could be stimulated to heal and repair itself. Transcranial low-level laser light therapy (LLLT) at near-infrared wavelengths (810 nm) penetrates the scalp and skull and provides many beneficial effects to the brain. These include neuroprotection, anti-apoptosis, anti-

inflammation, angiogenesis, neurogenesis and synaptogenesis. Study: We used mice that had received a traumatic brain injury either by a controlled cortical impact or by a closed head injury to test the beneficial effects of LLLT. Mice were followed with neurological severity score, wire grip test, forced swim test, tail suspension test, Morris water maze, and numerous immunofluorescence studies on brain sections removed at sacrifice. Results: The neurological functioning of mice was improved as demonstrated by the neurological severity score and the wire grip and motion test. Learning and memory was improved as shown by the Morris Water Maze Test. Immunofluorescence studies in brain sections showed increased incorporation of BrdU in the hippocampus and subventricular zone as an indicator of neurogenesis-the formation of new brain cells. The pleiotropic neurotrophin-brain derived neurotrophic factor (BDNF) was increased at early time points while synapsin1 was increased at later time points indicating that new connections were being formed between existing neurons. Conclusion: The beneficial effects in stimulating neurogenesis, synaptogenesis and BDNF after transcranial LLLT suggest the treatment may have wider applications beyond TBI to neurodegenerative diseases such as Alzheimer's and psychiatric diseases such as major depression.

2140. Hamblin, M., et al. (2013). "Transcranial low-level laser (light) therapy in mice: Tramautic brain injury and beyond." Lasers in surgery and medicine **45**: 50-51.

Background: Traumatic brain injury (TBI) has no good treatment at present. Transcranial low-level laser (light) therapy at near-infrared wavelengths (810 nm) penetrates the scalp and skull and provides many beneficial effects to the brain. These include neuroprotection, anti-apoptosis, anti-inflammation, angiogenesis, neurogenesis and synaptogenesis. These effects could also be beneficial in numerous brain disorders. Study: Mice were subjected to two different types of TBI (closed head and controlled cortical impact (CCI)) and treated with LLLT to the head starting at 4 hour post-injury. The wavelength, fluence, power density, pulse structure and treatment repetition were varied. Mice were followed with neurological severity score, wire grip test, forced swim test, tail suspension test, Morris water maze, and numerous immunofluorescence studies on brain sections removed at sacrifice. Results: In the closed head model a single treatment 4-hours post-TBI with CW lasers at 660nm and 810nm were effective, while 730nm and 980nm were not. In the CCI model 810-nm laser pulsed at 10Hz was superior to 810nm laser at CW or pulsed at 100 Hz. In another study we compared a single treatment 4 hours post TBI with three daily treatments and with fourteen daily treatments. Three daily treatments gave best results while 14 treatments gave no benefit. This result was explained by the lack of neurogenesis after 14 treatments that was apparent after 3 treatments. Upregulation of a neurotrophin (BDNF) and markers for synaptogenesis was also seen. Conclusion: The beneficial effects in stimulating neurogenesis, synaptogenesis and BDNF after transcranial LLLT suggest it may have wider applications beyond TBI to neurodegenerative diseases such as Alzheimer's and psychiatric diseases such as major depression.

2141. Hamblin, M., et al. (2012). "Mechanisms of action of transcranial LLLT for traumatic brain injury." Lasers in surgery and medicine **44**: 49.

Background: Low-level laser (or light) therapy (LLLT) is attracting growing interest to treat both stroke and traumatic brain injury (TBI). The fact that near-infrared light can penetrate into the brain allows non-invasive treatment to be carried out with a low likelihood of treatment-related adverse events. It is proposed that red and NIR light is absorbed by chromophores in the mitochondria of cells leading to changes in gene transcription and upregulation of proteins involved in cell survival, antioxidant production, leading to preservation of brain tissue and new brain cell formation. Study: Two models of TBI in mice were developed; a closed head weight drop and an open skull controlled cortical impact. Transcranial 810nm laser therapy consisting of a 36 J/-2 given as single exposure 4-hours post TBI or as 3 or 14 similar daily exposures. Mice were followed by neurological performance tests for 28 days and were sacrificed at various times post-TBI for histological and immunofluorescence studies. Results: A single laser treatment gave a positive benefit in neurological severity score and 3 daily laser treatments a greater benefit, but 14 laser treatments gave no benefit over sham TBI control. Histological studies at necropsy suggested that the cortical lesion was repaired by neural progenitor (stem) cells (BrdU+, NeuN+) from the subgranular zone of the dentate gyrus and the sub-ventricular zone, possibly stimulated by the laser. We also found reduced caspase-3 expression at 4 days suggesting lower brain cell apoptosis, increased BDNF at 7 days suggesting a mechanism of neurogenesis, and increased synapsin-1 at 28 days suggesting formation of new synapses. Increased GFAP was seen after 14 laser treatments suggesting an explanation for the ineffectiveness of that regimen. Conclusion: Transcranial laser therapy is a promising treatment for acute (and chronic TBI) and the lack of side-effects and paucity of alternative treatments encourages early clinical trials.

2142. Hamblin, M., et al. (2011). "In vitro and in vivo studies of lllt for traumatic brain injury." Lasers in surgery and medicine **43**: 951.

Background: Low-level laser (or light) therapy (LLLT) is attracting growing interest to treat both stroke and traumatic brain injury (TBI). The fact that near-infrared light can penetrate into the brain allows non-invasive treatment to be carried out with a low likelihood of treatment-related adverse events. It is proposed that red and NIR light is absorbed by chromophores in the mitochondria of cells leading to changes in gene transcription and upregulation of proteins involved in cell survival, antioxidant production, collagen synthesis, reduction of chronic inflammation and cell migration and proliferation. Study: We cultured primary cortical neurons from embryonic mouse brains and studied the effects of red and near-infra-red laser light on the generation of reactive oxygen species, nitric oxide release, transcription factor activation, intracellular calcium and ATP. Two models of TBI in mice were developed; a closed head weight drop and an open skull controlled cortical impact. Transcranial laser therapy consisting of a single exposure 4-hours post-TBI to 36 J/cm2 of various lasers was delivered. Results: There was a biphasic dose response in cultured cortical neurons for generation of ROS, NO, intracellular calcium, mitochondrial membrane potential and ATP. 810-nm or 660-nm laser significantly improved neurological severity score in TBI up to 4-weeks post-TBI. Laser therapy at 730 or 980nm was ineffective. Histological studies at necropsy suggested that the cortical lesion was repaired by neural progenitor (stem) cells from the subgranular zone of the dentate gyrus, possible stimulated by the laser. Conclusion: Transcranial laser therapy is a promising treatment for acute (and chronic TBI) and the lack of side effects and paucity of alternative treatments encourages early clinical trials.

2143. Hamedani, H., et al. (2022). "Traumatic carotid-cavernous fistula: A case report." Radiology Case Reports **17**(6): 1955-1958.

Direct carotid-cavernous fistulas are a rare complication of craniofacial trauma that often presents with proptosis, chemosis, and other visual symptoms. Disruption of blood flow from a carotid-cavernous fistula can cause cortical and cranial nerve ischemia which requires emergent intervention. Upon clinical suspicion of a carotid-cavernous fistula, patients should undergo computed tomography angiography (CTA) or magnetic resonance angiography (MRA), and digital subtraction angiography (DSA) if no other etiology is suspected. We present a case of a middle-aged patient with a gunshot wound in the posterior pharynx that resulted in a direct carotid-cavernous fistula of the left internal carotid artery.

2144. Hamilton, A., et al. (2014). "An unusual case of intraorbital foreign body and its management." International ophthalmology **34**(2): 337-339.

A 36-year-old aboriginal female presented following an assault with a wooden fence paling. Examination revealed a wooden object protruding lateral to the left eyebrow. CT scan showed a blow-in fracture of lateral orbital wall and a hypodense foreign body causing indentation of the globe and stretching of the optic nerve. The case was managed successfully with complete recovery of the visual acuity on day 1 post-surgery. This case highlights the importance of prompt removal of large lateral wooden intraorbital foreign body to achieve an excellent visual outcome.

2146. Hammed, A., et al. (2021). "Spontaneous migration of a falling bullet in the cerebellum reveals the importance of intraoperative skull X-ray." Journal of Surgical Case Reports **2021**(4).

Cranial gunshot wounds (CGSWs) are the most lethal types of the cranial traumas and they are usually mortal. Falling bullets or gravitational bullets are the ones that move under the effect of the gravity force after the muzzle force diminished. CGSWs constitute a major clinical challenge for neurosurgeons dealing with trauma in both the military and civil experience. We report the case of a 21-year-old man with a falling bullet wound to the head. The decision of surgical treatment of a bullet injury is difficult if it is in close proximity to vital structures; removal of the bullet may cause significant neurological damage; however, migration can lead to a worsening of the neurological status of the

patient. Before surgical removal of any intracranial bullet, as valuable information, it is recommended that a plain skull X-ray be obtained after final positioning of the head.

2147. Hammed, A., et al. (2022). "Spontaneous Migration of a Falling Bullet in the Cerebellum Reveals the Importance of Intraoperative Skull X-Ray." Brain injury **36**(SUPPL 1): 1.

Cranial gunshot wounds (CGSWs) are the most lethal types of the cranial traumas and they are usually mortal. Falling bullets or gravitational bullets are the ones that move under the effect of the gravitational force after the muzzle force diminished. CGSWs constitute a major clinical challenge for neurosurgeons dealing with trauma in both the military and civil experience. We report the case of a 21-year-old man with a falling bullet wound to the head-falling bullet wound to the head. In his physical examination, there was a single-entry wound situated on the left side of the parietal bone, about 2 cm left of the midline. Brain tissue was seen through the open wound. In the first neurological examination, the patient was confused and GCS at the time of admission was 14. Pupils were equally reactive, and his vitals were stable. Cranial computerized tomography (CT) revealed a bone defect of 0.5 cm in the left parietal region and a metallic object located between left occipital bone and inferior side of left cerebellar hemisphere. The patient underwent a left unilateral retrosegmoid craniectomy. Intraoperative skull X-ray was obtained and it revealed that the bullet had inversed and migrated upward inside the left cerebellar hemisphere and the bullet was removed. The decision of surgical treatment of a bullet injury is difficult if it is in close proximity to vital structures, removal of the bullet may cause significant neurological damage; however, migration can lead to a worsening of the neurological status of the patient.

2148. Hammon, W. M. (1971). "Analysis of 2187 consecutive penetrating wounds of the brain from Vietnam." Journal of neurosurgery **34**(2 Pt 1): 127-131.

A series of 2187 cases of penetrating wounds of the brain, treated in a U.S. Army Hospital in Vietnam, is analyzed according to operability, wounding agents, sites of cranial penetration, associated organ system injuries, operative and postoperative complications, and mortalities. A detailed description of the operative technique of thorough intracranial debridement and dural repair is presented and stressed. The previously established principles of combat neurosurgery are confirmed and their continued use recommended.

2149. Hammond, F., et al. (2015). "Safety, tolerability, and effectiveness of dextromethorphan/quinidine for pseudobulbar affect in patients with traumatic brain injury: PRISM-II." PM and R **7**(9): S112.

Objective: A multicenter, open label study (PRISM-II) was conducted to assess effectiveness, safety, and tolerability of dextromethorphan and quinidine (DM/Q) combination for the treatment of pseudobulbar affect (PBA) in patients with stroke, dementia, or traumatic brain injury (TBI). Enrollment has now completed for the cohort of patients with PBA secondary to dementia (results already reported), stroke, and TBI; results for the TBI cohort will be presented. Design: 12-week, open-label, single active treatment arm. Setting: U.S. multicenter trial. Participants: Eligible patients had a clinical diagnosis of PBA, a Center for Neurologic Study-Lability Scale (CNS-LS) score ≥13 (range 7-35), and a clinical diagnosis of non-penetrating TBI which was stable and non-evolving. Patients with unstable medical illness or contraindications to DM/Q were excluded. Interventions: Enrolled patients received DM 20 mg/Q 10 mg twice daily for 12 weeks (once daily in week 1). Concomitant mood/behavioral medications were allowed if stable for ≥2 months. Main Outcome Measures: Primary endpoint was change in CNS-LS from baseline to Day 90/early withdrawal. Additional endpoints included the change in PBA episodes/week, QOL VAS, Clinical and Patient Global Impression of Change (CGI-C and PGI-C), MMSE, the TBI Neurobehavioral Functioning Inventory (NFI), patient treatment satisfaction, and the Patient Health Questionnaire (PHQ-9) assessing depressive symptoms. Vital signs and adverse events were monitored throughout. Results or Clinical Course: Enrollment in the PRISM II TBI cohort completed on January 30, 2015, with 120 patients. The last patient will complete the trial in April 2015. Final results will be available July 2015 and will be presented. Conclusion: PRISM-II is the first prospective open-label study to systematically evaluate DM/Q safety, tolerability, and effectiveness in patients with PBA secondary to TBI as well as the impact of symptom relief on other patient reported measures.

2150. Hammoudeh, Z. S. (2012). "Mandibular gunshot wound with bullet aspiration." The Journal of craniofacial surgery **23**(6): e540-541.

Urban violence continues to be an important source of penetrating craniofacial injuries in major trauma centers. Gunshot wounds to the mandible are a commonly treated condition by craniofacial surgeons. Some gunshot wounds are through-and-through injuries, but in many patients, the bullet enters with no visible exit wound. In such situations, the bullet's trajectory and final destination are certainly important to the craniofacial surgeon in the extent of bony damage but may also be of unforeseen consequence to the patient's airway and respiratory condition. We present a case of a patient who had a gunshot wound to the face with comminuted mandibular ramus fracture in which the bullet was unexpectedly found to be aspirated down the right mainstem bronchus. This is the first reported case of a completely intact bullet being aspirated after gunshot wound to the face in an adult patient. We present this case to illustrate a rare possible complication after penetrating mandibular injury and offer a strategy for management of such an occurrence.

2151. Hampton, D. W., et al. (2007). "A potential role for bone morphogenetic protein signalling in glial cell fate determination following adult central nervous system injury in vivo." The European journal of neuroscience **26**(11): 3024-3035.

Bone morphogenetic proteins (BMPs) and their endogenous inhibitors, including noggin, chordin and follistatin, have roles in pattern formation and fate specification of neuronal and glial cells during nervous system development. We have examined their influence on glial reactions in the injured central nervous system (CNS). We show that penetrating injuries to the brain and spinal cord resulted in the upregulation of BMP-2/4, BMP-7, and noggin, with the latter being expressed almost exclusively by reactive astrocytes at the injury site, and we show that astrocytes in vitro produce noggin. As BMPs have been shown to drive cultured NG2-positive oligodendrocyte precursors (OPCs) towards a multipotential phenotype (type II astrocytes), we investigated the effects of inhibiting noggin with a function-blocking antibody (noggin-FbAb). In vitro, BMP-driven conversion of OPCs to type 2 astrocytes was inhibited by noggin, an effect that was reversed by noggin-FbAb. Noggin-FbAb also increased the number of type 2 astrocytes generated from cultured OPCs exposed to an astrocyte feeder layer, consistent with astrocytes producing both BMPs and noggin. In knife cut injuries in vivo, noggin-FbAb treatment resulted in an increase in the number of NG2-positive cells and small GFAP-positive cells in the injury site, and the appearance of glial cells with the morphological and antigenic characteristics of type 2 astrocytes (as generated in vitro), with coexpression of both GFAP and NG2. This potential conversion of inhibitory OPCs to type 2 astrocyte-like cells in vivo suggests that endogenous BMPs, unmasked by noggin antagonism, might be exploited to manipulate cell fate following CNS trauma.

2152. Hampton, J. O., et al. (2015). "A simple quantitative method for assessing animal welfare outcomes in terrestrial wildlife shooting: The European rabbit as a case study." Animal Welfare **24**(3): 307-317.

Shooting is widely used to reduce the abundances of terrestrial wildlife populations, but there is concern about the animal welfare outcomes ('humaneness') of these programmes. Management agencies require methods for assessing the animal welfare outcomes of terrestrial wildlife shooting programmes. We identified four key issues in previous studies assessing the animal welfare outcomes of shooting programmes: (i) biased sampling strategies; (ii) no direct ante mortem observations; (iii) absence of quantifiable parameters for benchmarking; and (iv) no evaluation of explanatory variables that may cause adverse welfare outcomes. We used methods that address these issues to assess the welfare outcomes of a European rabbit (Oryctolagus cuniculus) shooting programme in south-eastern Australia. An independent observer collected ante mortem (distance, timing and outcome of each shot fired) and post mortem (locations of bullet wounds) data. The ante mortem data were used to estimate three critical animal welfare parameters: apparent time to death (ATTD); instantaneous death rate (IDR); and wounding rate (WR). The post mortem data were used to evaluate the location of bullet wounds relative to the Australian national standard operating procedure (SOP). For rabbits, the mean IDR was 0.60, ATTD was 12 s and WR was 0.12. A large proportion of rabbits (0.75) were shot in the cranium or thorax, as required by the SOP. Logistic regression indicated that the proportion of rabbits wounded and missed increased with shooting distance. Hence, reducing shooting distances would increase the humaneness of European rabbit shooting programmes. Our approach enables the animal welfare outcomes of terrestrial shooting programmes to be independently quantified.

2153. Han, Y., et al. (2009). "Endophthalmitis due to inadvertent globe penetration during retrobulbar injection of saline solution for laser in situ keratomileusis." Journal of cataract and refractive surgery **35**(6): 1132-1133.

A 31-year-old woman presented with visual acuity of counting fingers and presumed bacterial endophthalmitis in the left eye 10 days after refractive surgery. During the procedure, a retrobulbar injection of balanced salt solution had been performed to assist with globe suction by the microkeratome. A perforation site was identified in the inferonasal retina. Following intravitreal antibiotic injection and surgical intervention, the visual acuity returned to 20/20. Retrobulbar injection to facilitate laser in situ keratomileusis carries risks. Careful monitoring for signs of infection is recommended if globe perforation is recognized.

2155. Hand, W. L. and J. P. Sanford (1970). "Posttraumatic bacterial meningitis." Annals of internal medicine **72**(6): 869-874.

2156. Handlos, P., et al. (2019). "Necessary Defense or Homicide?: The Importance of Crime Scene Reconstruction in Crossbow Injuries." The American journal of forensic medicine and pathology **40**(3): 293-297.

Reconstruction of a criminal offense is a crucial approach in forensics and criminalistics allowing for the verification of the location, the particular method used, or the use of a specific instrument. This report describes the case of a young man who was killed by an arrow shot from a crossbow. The autopsy revealed a penetration of the head and significant damage to the brain stem. Although the cause of death was evident from the outset, it was necessary to clarify whether or not the arrow was shot as necessary self-defense. Ballistic investigation of the seized weapon and reconstruction of the crime was absolutely essential to bring forth conclusive evidence to convict the perpetrators of the murder.

2157. Handlos, P., et al. (2019). "Axe injury pattern in homicide." Forensic science, medicine, and pathology **15**(3): 516-518.

Chop or slash wounds are produced by sharp-edged tools such as an axe, or a machete. This paper presents a case of a violent death of a 57 year-old-man. Autopsy revealed deformation of the right side of the head. A total of 23 slash, stab and cut wounds as well as contused lacerations were identified on the scalp as well as the face and the neck. In addition, superficial abrasions and bruises were identified on the skin. The immediate cause of death was due to extensive brain contusion following fragmentation of the neurocranium. The injuries resulting in the death of the victim were sustained during an assault on the head with an axe, which was used both as a slashing tool and a blunt instrument.

2158. Haney, L. J., et al. (2020). "Characteristics and Distribution of Extremity Vascular Injuries in a Wartime Military Cohort." Journal of vascular surgery **72**(1): e165-e166.

Objectives: Combat-related extremity vascular injuries (EVI) in service members pose a significant challenge to clinicians due to the complex, long-term health care needs of these Veterans after repair and limb salvage. This study determined characteristics of service members, mechanisms of injury and distribution of vascular injuries in Operation Enduring Freedom/Operation Iraqi Freedom/Operation New Dawn veterans. Methods: Veterans with EVI undergoing an initial attempt at repair were identified using the Department of Defense Trauma Registry, validated by chart abstraction and merged with Veterans Administration data. Results: Our cohort of 527 service members with EVI averaged 25.3 ± 6.5 years old (range, 18-56 years) at time of injury, >95% of the service members were male, and 30% were married. The distribution of race was 82% white, 6% African American and 3% Asian; independently, 10% were of Hispanic ethnicity. Cohort members were enlisted (95%) in the Army (68%) or Marines (28%), and most graduated from high school (84%) with 13% reporting some college. Service members were injured in Operation Iraqi Freedom/Operation New Dawn (66%) and Operation Enduring Freedom (33%). Explosive injury mechanism was most common (63%), with gunshot wounds accounting for 32%; 73% were penetrating versus 27% blunt injuries. The composite Injury Severity Score was

15.9 ± 9.2 (range, 1.0-59.0) with a distribution of 60% mild, 25% moderate, and 15% severe injuries. Abbreviated Injury Scale-Extremities distribution included 12% moderate, 67% serious, and 17% severe. The 527 service members experienced 741 vascular injuries: 246 arterial and 38 venous upper and 317 arterial and 140 venous lower extremity injuries with many Veterans also suffering concurrent soft tissue, bone and nerve injuries. Brachial (43%), radial (24%), and ulnar (21%) arteries and brachial (37%) veins were most frequently injured in the upper extremity (Table I). Superficial femoral (29%), tibial (25%), and popliteal (25%) arteries and superficial femoral (28%) and popliteal (23%) veins were the most common lower extremity injuries (Table II). All 527 service members were alive upon discharge with >99% surviving at 5 years of injury. Sixty-five percent were discharged/medically retired for disability, 52% were diagnosed with PTSD at 5 years of injury, and 82% had traumatic brain injury (TBI) including 14% with moderate, severe or penetrating TBI. Conclusions: EVI caused by explosive mechanism represents a large cause of morbidity with high rates of disability and TBI. Many service members undergo successful vascular repair and all survived their EVI, however, the overall health of this cohort requires complex and holistic care beyond initial surgical repair and stabilization. [Formula presented] [Formula presented]

2159. Haney, L. J., et al. (2021). "Persistent Pain, Physical Dysfunction, and Decreased Quality of Life After Combat Extremity Vascular Trauma." Annals of vascular surgery **71**: 167-180.

BACKGROUND: Combat-related extremity vascular injuries (EVI) have long-lasting impact on Iraq/Afghanistan veterans. The purpose of this study is to describe long-term functional outcomes in veterans with EVI using survey measures and identify modifiable factors that may be improved to reduce chronic pain and injury-related dysfunction., METHODS: Veterans with upper and lower EVI undergoing an initial limb salvage attempt were identified using the Department of Defense Trauma Registry and validated with chart abstraction. Surveys measured pain; Short Musculoskeletal Function Assessment (SMFA) for self-reported bother and dysfunction; and Veterans RAND 12-Item Health Survey (VR-12) physical and mental component scores (PCS; MCS) for quality of life, depression, post-traumatic stress disorder, and the potentially modifiable factors of reintegration into civilian life, resilient coping, resilience, and family functioning., RESULTS: Eighty-one patients responded with an average time since injury of 129 months (SD: 31; range 67-180 months). Mechanism of injury included 64% explosions and 31% gunshot wounds; 16% of the respondents were diagnosed with moderate/severe/penetrating traumatic brain injury. Limb salvage rates were 100% and 77% for upper and lower extremities, respectively (P = 0.004). Respondents screened positive for probable depression (55%) and post-traumatic stress disorder (51%). Compared with population norms, SMFA bother and dysfunction indices were higher (worse), MCS was lower (worse), and PCS was similar. The multivariable models adjusted for age, marital status and pain. The higher SMFA is part of the results of the multivariable models. MCS decreased with difficulty reintegrating into civilian life and was positively correlated with increased resilience and resilient coping. SMFA scores were greater for patients with high pain intensity and increased 6-11 points per point increase in difficulty with civilian-life reintegration. SMFA dysfunction was associated with better family functioning., CONCLUSIONS: EVI results in significant long-term disability with lasting deficits in physical function, frequent depressive symptoms, and below average self-reported quality of life. Strengthening modifiable factors including resiliency and resilient coping, and providing ongoing assistance to improve reintegration into civilian life, may ameliorate the functional disabilities and chronic pain experienced by veterans with EVI. 2160. Hanieh, A. (1971). "Brain injury from a spent bullet descending vertically. Report of five cases." Journal of neurosurgery **34**(2 Pt 1): 222-224.

This is a report of five cases in which a bullet penetrated the vertex of the skull and brain, apparently during its vertical descent after having been fired into the air.

2161. Hanigan, W. C., et al. (1986). "Lawn dart injury in children: report of two cases." Pediatric emergency care **2**(4): 247-249.

Two cases of intracranial penetration by lawn darts are presented in this report. Both patients were children who developed infectious sequelae following primary closure of cutaneous puncture wounds. These injuries suggest that the darts produced a high-energy impact force that resulted in skull fractures and focal cerebral injury. When children present with puncture wounds or lacerations produced by lawn darts, intracranial penetration must be ruled

out, using appropriate medical imaging. Parents should be advised regarding the need for medical reassessment should fever, headache, or local signs of infection occur.

2162. Hanigan, W. C. and C. Sloffer (2004). "Nelson's wound: treatment of spinal cord injury in 19th and early 20th century military conflicts." Neurosurgical focus **16**(1): E4.

During the first half of the 19th century, warfare did not provide a background for a systematic analysis of spinal cord injury (SCI). Medical officers participating in the Peninsular and Crimean Wars emphasized the dismal prognosis of this injury, although authors of sketchy civil reports persuaded a few surgeons to operate on closed fractures. The American Medical and Surgical History of the War of the Rebellion was the first text to provide summary of results in 642 cases of gunshot wounds of the spine. The low incidence of this injury (0.26%) and the high mortality rate (55%) discouraged the use of surgery in these cases. Improvements in diagnoses and the introduction of x-ray studies in the latter half of the century enabled Sir G. H. Makins, during the Boer War, to recommend delayed intervention to remove bone or bullet fragments in incomplete injuries. The civil experiences of Elsberg and Frazier in the early 20th century promoted a meticulous approach to treatments, whereas efficient transport of injured soldiers during World War I increased the numbers of survivors. Open large wounds or cerebrospinal fluid leakage, signs of cord compression in recovering patients, delayed clinical deterioration, or intractable pain required surgical exploration. Wartime recommendations for urological and skin care prevented sepsis, and burgeoning pension systems provided specialized longterm rehabilitation. By the Armistice, the effective surgical treatment and postoperative care that had developed through decades of interaction between civil and military medicine helped reduce incidences of morbidity and dispel the hopelessness surrounding the combatant with an SCI.

2163. Haninec, P., et al. (1996). "Shotgun pellet embolus of the middle cerebral artery treated by emergency embolectomy." British journal of neurosurgery **10**(3): 311-314.

We report a case of traumatic embolization of a shotgun pellet in the middle cerebral artery. The patient was successfully treated by emergency embolectomy performed 12 h after the accident. The literature seems to support the protective role of surgical treatment against cerebral ischaemia and subsequent infarction in such cases.

2164. Hanna, B. C., et al. (2006). "Surgical debridement of craniocervical necrotizing fasciitis: the window of opportunity." The Journal of laryngology and otology **120**(8): 702-704.

Craniocervical necrotizing fasciitis (CCNF) has a potentially high morbidity and mortality. Late presentation, shock and disseminated intravascular coagulation are associated with a particularly poor prognosis. Early recognition and aggressive treatment is advised. A case report is presented of a late presentation of necrotizing fasciitis of the face, neck and anterior thoracic wall. Despite adverse prognostic indicators, surgical debridement was performed. Intensive medical treatment included continuous renal replacement therapy and intravenous immunoglobulin. Survival in this case illustrates that the window of opportunity for surgically treating CCNF extends to the advanced stages of the disease, albeit with increased morbidity.

2165. Hanna, P. J. and M. D. Baker (2014). "Point of care ultrasound identification of an intracranial foreign body." Journal of Investigative Medicine **62**(2): 480-481.

Purpose of Study: To describe how point of care ultrasound was used to describe skull fracture and intracranial foreign body Methods Used: Case Report Summary of Results: A 7 year old male presented to the emergency department 1 day following a gunshot wound to the forehead. Patient was reportedly shot by an air rifle (760 Pump Master ®) at close range by a 4 year old relative. There was no alteration of mental status or loss of consciousness. Vital signs, Glasgow Coma Scale (15), and neurological exam were all normal. A 1 mm puncture wound was noted in the right frontal scalp without palpable foreign body, soft tissue swelling, or bony step off. Plain radiograph revealed a metallic foreign body without evidence for skull fracture. Point of care ultrasound demonstrated a right frontal skull cortical discontinuity with hyperechoic foreign body with ring artifact. Computed tomography revealed small open calvarial frontal skull fracture with frontal cerebral hemorrhage. The patient was admitted to the Pediatric Neurosurgery service and underwent removal of an intracranial, extradural foreign body. The patient had an uneventful recovery and was discharged the following day. Conclusions: Utility of Point of care Ultrasound has been well described for soft tissue

foreign bodies and fractures. Ultrasound is not generally useful for identifying foreign bodies embedded in bone. Bone acts as a strong reflector of sound waves making foreign body identification with ultrasound difficult. We described a case in which a metallic foreign boy was localized immediately beneath a skull fracture. (Figure presented).

2166. Hanna, W. C., et al. (2008). "The current status of traumatic diaphragmatic injury: lessons learned from 105 patients over 13 years." The Annals of thoracic surgery **85**(3): 1044-1048.

BACKGROUND: Our understanding of traumatic diaphragmatic injury (TDI) is based primarily on outdated retrospective series. We sought to reexamine present day patterns of diagnosis, associated injuries, predictors of mortality, and long-term outcomes of this condition., METHODS: A prospectively entered trauma database from the Montreal General Hospital was reviewed for patients admitted with a TDI from 1993 to 2006. Hospital charts were reviewed, and patient characteristics, mechanism of injury, associated injuries, operative management, and postoperative outcomes were recorded. Logistic regression was used to identify predictors for mortality., RESULTS: Identified were 105 patients with TDI consisting of blunt in 37% and penetrating in 63%. Only 23% of TDI were diagnosed on initial chest roentgenogram. External wounds in penetrating TDI cases were found in the abdomen alone in 19%, in the chest alone in 46%, and in both in 35%, which was associated with intraabdominal organ injury in 83%, 55%, and 87%, respectively. Less than half of patients had a diaphragmatic hernia. Lung, chest wall, and thoracic organ injuries were more common in blunt trauma, but there was no significant difference between abdominal injuries in both mechanisms. Overall mortality from TDI was 18%, and there was no difference between blunt and penetrating injury. In blunt trauma, brain injury and an Injury Severity Score (ISS) exceeding 15 were independently associated with increased death. In penetrating trauma, only an ISS exceeding 15 predicted death., CONCLUSIONS: Traumatic diaphragmatic injury remains a challenge to diagnose and treat, primarily due to the presence of associated injuries. The high incidence of intraabdominal organ injury, irrespective of the site of penetrating wound, dictates a transabdominal approach for exploration and repair. Severity of associated injuries (ISS) predicts death.

2167. Hanot, E. M., et al. (2020). "Traumatic orbital ligament avulsion diagnosed with cross-sectional imaging in three dogs." Veterinary Record Case Reports **8**(3).

The aim of the study was to describe the clinical and imaging findings of three dogs diagnosed with orbital ligament avulsion. Three immature dogs presented following a facial bite trauma, including multiple skull fractures and ventral, ventrolateral or rostrolateral displacement of the affected eye. The extent of lesions and orbital ligament avulsion were assessed and diagnosed using CT (n=2) or MRI (n=1). Orbital ligament avulsion was identified as an interruption of the linear structure between the zygomatic process of the frontal bone and the frontal process of the zygomatic bone. One dog was treated surgically to correct a visual axis alteration, while the remaining two dogs were managed conservatively. Orbital ligament avulsion is an uncommon condition that should be considered following a facial trauma. Concurrent lesions might necessitate surgical intervention, but it remains unclear if the avulsion of the orbital ligament itself requires a specific treatment.

2168. Hansen, J. E., et al. (1988). "Penetrating intracranial wood wounds: clinical limitations of computerized tomography." Journal of neurosurgery **68**(5): 752-756.

The case history of a patient with a periorbital penetrating wooden foreign body is presented. The computerized tomography (CT) densities of several different sources of wood were compared using an experimental model. The clinical usefulness and practical limitations of CT in the evaluation of intracranial foreign bodies is discussed, and the management of this type of injury is reviewed.

2169. Hansen, M. L. U., et al. (2020). "Penetrating Orbital Sphenoid Sinus Trauma with a Wooden Stick: A Challenging Case Report." Case Reports in Ophthalmology **11**(3): 540-545.

Transorbital and intra-sphenoidal traumas are relatively uncommon, can be challenging to manage, and are associated with a high risk of complications and potentially fatal outcome. Transorbital and intra-sphenoidal trauma pose a medical challenge due to close relationship to delicate and critical anatomical structures, such as the globe, optic nerve, the ophthalmic internal carotid arteries, and central nervous system. Rapid admission to a level 1 trauma center with a high surgical expertise level is essential to ensure the best possible treatment and outcome. We present a case of

a 75-year-old man who had a severe orbital trauma, where a wooden foreign object penetrated the orbit into the sphenoid sinus without penetrating its posterior wall. This case is important because of the rare trauma presentation with a wooden foreign object, which can easily be missed on computed tomography. The case also illustrates the importance of close collaboration between ophthalmologists and rhinologists when challenged with severe orbital sphenoid sinus trauma.

2170. Hanson, E. K. and J. Ballantyne (2013). "Highly specific mRNA biomarkers for the identification of vaginal secretions in sexual assault investigations." Science & justice : journal of the Forensic Science Society **53**(1): 14-22.

The inability to definitively determine the tissue source of origin of forensically relevant biological fluids could result in a failure to provide crucial information necessary to the investigation and prosecution of the case. For example, in instances of sexual assault with a foreign object or digital penetration, the identification of vaginal secretions (VS) transferred to such objects or the perpetrators might be critical in establishing the circumstances of the assault. Conventional serological and immunological methods for body fluid identification can confirm the presence of human blood and semen. However, currently none of the routinely used biochemical tests can definitively identify the presence of human saliva or VS. It has been demonstrated that mRNA (or miRNA) profiling of body fluid stains can provide a degree of identification specificity of tissue and body fluids heretofore unattainable by conventional means. Early promising VS candidate RNA biomarkers, however, failed to exhibit the required degree of specificity or sensitivity and thus, at present, it is not possible for the forensic scientist to definitively identify VS using molecular genetics techniques. The aim of this work was to find novel highly specific RNA biomarkers for the identification of VS. Whole transcriptome profiling (RNA-Seq) of vaginal swab samples from different donors resulted in the identification of a number of putative VS-specific mRNA candidates. After detailed evaluation of >200 candidates from the tens of thousands of mRNA species found in VS, six promising candidates were identified. From these, two gene transcripts, namely CYP2B7P1 and MYOZ1, consistently demonstrated high specificity and sensitivity for VS when used in a qualitative capillary electrophoresis-based assay. Importantly these two biomarkers are able to differentiate between VS and other body fluids containing significant numbers of epithelia, particularly saliva and skin. Significantly, CYP2B7P1 is exceedingly specific with no detectable cross reactivity with other forensically relevant body fluids/tissues noted to date. The other four putatively specific biomarkers are expressed at higher levels in VS compared with saliva and will be more suitable for use with a quantitative (i.e. qRT-PCR) assay format.

2171. Hanson, H. R., et al. (2019). "Trends of ED visits, admissions, and deaths for pediatric traumatic brain injury comparing sport and non-sport mechanisms." Injury Epidemiology **6**.

Background: Traumatic brain injuries (TBI) in children result in significant morbidity and mortality. There are many mechanisms, both sport and non-sport related, which cause these injuries. Studies have reported that Emergency Department (ED) visits for pediatric TBI caused by sports are increasing; however, no subsequent study has evaluated the trend in non-sport TBI. The objective of this study was to evaluate ED visits, admissions, and deaths for non-sport TBI compared to those caused by sports. Methods: A retrospective study of children 5-19 years of age was performed at a pediatric, level 1 trauma center from 2002 to 2012. Subjects with a primary or secondary diagnosis of TBI were identified from the hospital's trauma registry, and mechanism of injury, disposition, injury severity score, and length of stay were recorded. Frequencies were used to characterize the population, Chi-square analysis was performed to determine differences between groups, and linear trend lines were calculated for sport-related and non-sport TBI by year. Results: Thirteen thousand two hundred ninty one subjects were seen in the ED between 2002 and 2012 for a TBI; 9527 (72%) were from a non-sport mechanism, and 3764 (28%) were from a sport mechanism. Subjects with a non-sport TBI were more likely to be younger ($p < 0.001$), African American ($p < 0.001$), and have Medicare/Medicaid ($p < 0.001$). Subjects with a non-sport TBI were admitted to the hospital 15% of the time, and subjects with a sport-related TBI were admitted 10% of the time ($p < 0.001$). When evaluating all TBI by mechanism of injury, sport had the lowest injury severity score (mean 4.4) and the shortest length of stay (mean 1.6 days) of any mechanism. There were six deaths reported from non-sport TBI and none from sport-related TBI. ED visits for sport-related TBI increased 92%, and non-sport TBI increased 22% over 10 years. There was a peak in TBI, in both groups, seen in 2009. Conclusions: ED visits for both sport and non-sport TBI have increased over the past 10 years. TBI from a non-sport mechanism was more likely to result in hospitalization or death. Prevention efforts should be expanded to include all high-risk TBI mechanisms, not just sports.

2172. Harada, K., et al. (2014). "An unusual case of suicide by handcrafted shotgun and slug." Legal medicine (Tokyo, Japan) **16**(2): 95-97.

Injuries by handcrafted firearms are uncommon, and those by handcrafted shotguns are very rare. We present an unusual case of suicide using a handcrafted shotgun and slug. A 73-year-old male, who was a glass-grinding artisan, was found dead at a workshop on the premises of his residence. Autopsy showed a contact shotgun wound to the forehead, which perforated the cranium and caused extensive damage to the brain. The handcrafted shotgun was found in the proximity of the body. The shotgun consisted of metal pipes fixed to the vise and did not take the form of a conventional gun. The recovered slug was also found to be manufactured manually. It appeared that the handcrafted shotgun was only intended for committing suicide using his ballistics knowledge, skills, and resources.

2173. Harada, T. (2004). "Y-shaped vein grafting to Stensen duct defect." Annals of plastic surgery **53**(3): 299-300.

2174. Harat, M., et al. (2000). "[Facial-cerebral gunshot wounds]." Postrzaly twarzowo-mozgowe. **34**(3): 487-500.

The current frequency increase of gunshot wounds to the head is directly proportional to the access to firearms and to amount of firearm-related crimes. This risk is increasing especially in population groups that have not been threatened before. Hence the aim of this study was to analyse and resume our experiences in the management of faciocerebral gunshots. We retrospectively reviewed a series of 9 consecutive patients who were treated in the Department of Neurosurgery, Military Clinical Hospital in Bydgoszcz with the diagnosis of gunshot wound to the head from 1994 to 1999. All the cases were young males (mean, 26 yr). There were six suicidal attempts and three accidents at firearm service. KbkAK, that is a standard machine gun in the Polish Army, was most frequently related to gunshots in the analysed series. All the patients were assessed according to Glasgow Coma Scale (GCS) at arrival to hospital. Average of admission GCS Score was 6.1. The patients were also assessed after treatment using Glasgow Outcome Scale (GOS). One patient was dead (GOS Score 1), and 7 (78%) improved to good, independent functional status (GOS Score 4 or 5). The authors emphasize the necessity of multispecialistic initial operative management of faciocerebral gunshots wounds and aggressive pre- and postoperative care (tracheostomy, gastrostomy, treatment of encephalitis), which makes it possible to obtain good and very good outcomes. Furthermore, we stress the role of minimal primary debridement for the sake of frequent secondary reconstructive operations.

2175. Hardman, J. M. (1979). "The pathology of traumatic brain injuries." Advances in neurology **22**: 15-50.

2176. Hardy, T. L. and J. Aldridge (1981). "Traumatic transient Kluver-Bucy syndrome." Surgical neurology **15**(5): 338-340.

A case of transient Kluver-Bucy syndrome after a gunshot wound through the head is presented. We have found no other case of posttraumatic Kluver-Bucy syndrome described in the literature. The original criteria for the syndrome are reviewed and compared with findings in previously reported human cases.

2177. Hargrave, K., et al. (2016). "Accidental Transorbital Penetrating Brainstem and Carotid Injury with CB Antenna: A Case Report." The Journal of the Louisiana State Medical Society : official organ of the Louisiana State Medical Society **168**(3): 95-98.

The authors present an unusual case of a transorbital penetrating injury of the internal carotid artery and brainstem. A young man accidentally ran into a 10-foot long citizens band (CB) antenna, and presented to the emergency department with nausea, dizziness and right periorbital ecchymosis. The nature and full extent of the injury were not appreciated at the time of initial examination and computed tomography scan. Magnetic resonance imaging subsequently demonstrated an unusual brainstem lesion. Neurology consultation was obtained. The neurologist and neuroradiologists reviewed the neurological and imaging findings together. This collaboration proved critical to understanding the true nature and extent of the injury and planning evaluation and treatment. Cerebral angiography

revealed a traumatic internal carotid artery dissection and pseudoaneurysm, which was treated by placement of a covered stent. The clinical symptoms remained mild and 7-year follow up shows clinical and angiographic stability.

2178. Harmon, L. A. (2020). "Response to "Letter to the Editor"-Infection after penetrating brain injury-An Eastern Association for the Surgery of Trauma multicenter study oral presentation at the 32nd annual meeting of the Eastern Association for the Surgery of Trauma, January 15019, 2019, Austin, Texas." The journal of trauma and acute care surgery **88**(3): e119-e120.

2179. Harmon, L. A., et al. (2019). "Infection after penetrating brain injury-An Eastern Association for the Surgery of Trauma multicenter study oral presentation at the 32nd annual meeting of the Eastern Association for the Surgery of Trauma, January 15-19, 2019, in Austin, Texas." The journal of trauma and acute care surgery **87**(1): 61-67.

BACKGROUND: Fatality rates following penetrating traumatic brain injury (pTBI) are extremely high and survivors are often left with significant disability. Infection following pTBI is associated with worse morbidity. The modern rates of central nervous system infections (INF) in civilian survivors are unknown. This study sought to determine the rate of and risk factors for INF following pTBI and to determine the impact of antibiotic prophylaxis., METHODS: Seventeen institutions submitted adult patients with pTBI and survival of more than 72 hours from 2006 to 2016. Patients were stratified by the presence or absence of infection and the use or omission of prophylactic antibiotics. Study was powered at 85% to detect a difference in infection rate of 5%. Primary endpoint was the impact of prophylactic antibiotics on INF. Mantel-Haenszel chi and Wilcoxon's rank-sum tests were used to compare categorical and nonparametric variables. Significance greater than p = 0.2 was included in a logistic regression adjusted for center., RESULTS: Seven hundred sixty-three patients with pTBI were identified over 11 years. 7% (n = 51) of patients developed an INF. Sixty-six percent of INF patients received prophylactic antibiotics. Sixty-two percent of all patients received one dose or greater of prophylactic antibiotics and 50% of patients received extended antibiotics. Degree of dural penetration did not appear to impact the incidence of INF (p = 0.8) nor did trajectory through the oropharynx (p = 0.18). Controlling for other variables, there was no statistically significant difference in INF with the use of prophylactic antibiotics (p = 0.5). Infection was higher in patients with intracerebral pressure monitors (4% vs. 12%; p = <0.001) and in patients with surgical intervention (10% vs. 3%; p < 0.001)., CONCLUSION: There is no reduction in INF with prophylactic antibiotics in pTBI. Surgical intervention and invasive intracerebral pressure monitoring appear to be risk factors for INF regardless of prophylactic use., LEVEL OF EVIDENCE: Therapeutic, level IV.

2180. Harna, B., et al. (2020). "Epidemiology of trauma patients admitted to a trauma center in new delhi, india." Indian Journal of Critical Care Medicine **24**(12): 1193-1197.

Introduction: The rapid economic and automobile growth in India leads to a rapid increase in road traffic accidents (RTAs) and factors affecting it. This study evaluates the epidemiology of trauma patients' reports to the major trauma center in New Delhi, India. Materials and methods: The 1,583 patients over 6 months reporting to the casualty of the trauma center attached to Lok Nayak Hospital, New Delhi were included in the study. The patients reporting to the outpatient department as follow-up visits were not included in the study. The data were collected with the help of a structured pro forma. Results: The data depicted the RTAs as the most common cause affecting adults between 20 years and 40 years. The study reports other risk factors like alcohol intoxication and motorcycle riders. Mostly, the patients present in a semiconscious and disoriented state requiring fluid resuscitation. Abrasions and bruises in the extremities stand out as the most common injury pattern. The fractures suffered were the most common injury suffered by the patients. Conclusion: Our study shows that RTAs and workplace injuries are the predominant causes of trauma affecting mostly the adults. This study defines the correlation of various parameters with causation and distribution of the trauma in the sample population. This study was performed to improve the understanding of the mode of trauma, severity of injuries, and outcome in our hospital, so that effective prevention and comprehensive management strategies could be made. Clinical significance: This study signifies the fundamental study for the occurrence, distribution, and prevention of trauma in the society. The acquisition of knowledge of different patterns of trauma patients along with other descriptive factors helps to understand the causation of this disease as well as development of preventive measures. This can form the basis of hospital and regional trauma management strategies.

2181. Harnish, C., et al. (2015). "An alarming presentation of Creutzfeldt-Jakob disease following a self-inflicted gunshot wound to the head." Injury **46**(5): 926-928.

Transmissible spongiform encephalopathies (TSE), also known as prion diseases, are characterized by rapid and fatal neurological decline. They not only detrimentally affect the patient, but also present additional challenges to healthcare systems due to the infectivity of the tissues and the difficulty of inactivating the prion. The most common TSE is Creutzfeldt-Jakob disease (CJD), which can occur after familial, spontaneous or acquired transmission. TSEs received more attention after the development of variant CJD (vCJD), also known as Mad Cow Disease, in the UK during the mid-1990s. Unlike familial or spontaneous CJD, this variant was connected to consumption of cattle contaminated with the prion disease, bovine spongiform encephalopathy. This development increased interest in the etiology of CJD and other TSEs and the risk it presents as an infectious disease. The following details the case of a 59-year-old male infected with CJD presented to our level II trauma center for treatment following a self-inflicted gunshot wound to the head.

2182. Harputluoglu, M., et al. (2018). "Endoscopic treatment of biliary complications after living donor liver transplantation in a high volume transplant center in Turkey; a single-center experience." Acta gastro-enterologica Belgica **81**(2): 283-287.

BACKGROUND AND AIM: Biliary complications are an important cause of mortality and morbidity after living donor liver transplantation (LDLT). We present our endoscopic treatment results after LDLT as a single center with high volume., METHODS: Patients who underwent endoscopic retrograde cholangiopancreatography (ERCP) after LDLT between 2005 and 2015 were included. Clinical data included patient demographics, ERCP indications (stricture or leak), and treatment outcomes, including need for percutaneous and surgical interventions., RESULTS: ERCP was performed in 446 (39.2%) patients with duct-to-duct anastomosis of 1136 LDLT patients. The most common biliary complication was stricture +/- stone (70.6%, 315/446). Stricture and leak occurred in 60 (13.4%) patients. Only biliary leak was found in 40 (8.9%) patients. Our endoscopic treatment success rate in patients with biliary stricture after LDLT was 65.1%. Overall endoscopic success rates in our patients were 55.0% in patients with both leak and stricture, and only leak. In all, our percutaneous transhepatic biliary interventions (PTBI) and ERCP success rate was 90.6% in patients with biliary complications after LDLT., CONCLUSIONS: Endoscopic treatments are highly effective for biliary complications after LDLT. Effective use of percutaneous interventions in collaboration with endoscopic treatments significantly reduces the need for surgical treatment.

2183. Harrahill, M. (2011). "An unusual case of cerebral venous sinus thrombosis in a trauma patient." Journal of emergency nursing **37**(2): 203-204.

2184. Harrar, D. B., et al. (2019). "Clinical Determination of Brain Death in Children Supported by Extracorporeal Membrane Oxygenation." Neurocritical care **31**(2): 304-311.

BACKGROUND/OBJECTIVE: Children supported by extracorporeal membrane oxygenation (ECMO) are at risk of catastrophic neurologic injury and brain death. Timely determination of brain death is important for minimizing psychological distress for families, resource allocation, and organ donation. Reports of successful determination of brain death in pediatric patients supported by ECMO are limited. The determination of brain death by clinical criteria requires apnea testing, which has historically been viewed as challenging in patients supported by ECMO. We report eight pediatric patients who underwent a total of 14 brain death examinations, including apnea testing, while supported by veno-arterial ECMO (VA-ECMO), resulting in six cases of clinical determination of brain death., METHODS: We performed a retrospective review of the medical records of pediatric patients who underwent brain death examination while supported by VA-ECMO between 2010 and 2018 at a single tertiary care children's hospital., RESULTS: Eight patients underwent brain death examination, including apnea testing, while supported by VA-ECMO. Six patients met criteria for brain death, while two had withdrawal of technical support after the first examination. During the majority of apnea tests (n = 13/14), the ECMO circuit was modified to achieve hypercarbia while maintaining oxygenation and hemodynamic stability. The sweep flow was decreased prior to apnea testing in ten brain death examinations, carbon dioxide was added to the circuit during three examinations, and ECMO pump flows were increased in response to hypotension during two examinations., CONCLUSIONS: Clinical determination of brain death, including apnea testing,

can be performed in pediatric patients supported by ECMO. The ECMO circuit can be effectively modified during apnea testing to achieve a timely rise in carbon dioxide while maintaining oxygenation and hemodynamic stability.

2185. Harrington, B. M., et al. (2020). "Complications, outcomes, and management strategies of non-missile penetrating head injuries." Journal of neurosurgery **134**(5): 1658-1666.

OBJECTIVE: While high-velocity missile injury (gunshot) is associated with kinetic and thermal injuries, non-missile penetrating head injury (NMPHI) results in primary damage along the tract of the piercing object that can be associated with significant secondary complications. Despite the unique physical properties of NMPHI, factors associated with complications, expected outcomes, and optimal management have not been defined. In this study, the authors attempted to define those factors., METHODS: Consecutive adult patients with NMPHI who presented to Tygerberg Academic Hospital (Cape Town, South Africa) in the period from August 1, 2011, through July 31, 2018, were enrolled in a prospective study using a defined treatment algorithm. Clinical, imaging, and laboratory data were analyzed., RESULTS: One hundred ninety-two patients (185 males [96%], 7 females [4%]) with 192 NMPHIs were included in this analysis. The mean age at injury was 26.2 +/- 1.1 years (range 18-58 years). Thirty-four patients (18%) presented with the weapon in situ. Seventy-one patients (37%) presented with a Glasgow Coma Scale (GCS) score of 15. Weapons included a knife (156 patients [81%]), screwdriver (18 [9%]), nail gun (1 [0.5%]), garden fork (1 [0.5%]), barbeque fork (1 [0.5%]), and unknown (15 [8%]). The most common wound locations were temporal (74 [39%]), frontal (65 [34%]), and parietal (30 [16%]). The most common secondary complications were vascular injury (37 patients [19%]) and infection (27 patients [14%]). Vascular injury was significantly associated with imaging evidence of deep subarachnoid hemorrhage and an injury tract crossing vascular territory ($p <= 0.05$). Infection was associated with delayed referral (> 24 hours), lack of prophylactic antibiotic administration, and weapon in situ ($p <= 0.05$). A poorer outcome was associated with a stab depth > 50 mm, a weapon removed by the assailant, vascular injury, and eloquent brain involvement ($p <= 0.05$). Nineteen patients (10%) died from their injuries. The Glasgow Outcome Scale (GOS) score was linearly related to the admission GCS score ($p < 0.001$). One hundred forty patients (73%) had a GOS score of 4 or better at discharge., CONCLUSIONS: The most common NMPHI secondary complications are vascular injury and infection, which are associated with specific NMPHI imaging and clinical features. Identifying these features and using a systematic management paradigm can effectively treat the primary injury, as well as diagnose and manage NMPHI-related complications, leading to a good outcome in the majority of patients.

2186. Harris, C. M. and R. Laughlin (2013). "Reconstruction of hard and soft tissue maxillofacial defects." Atlas of the oral and maxillofacial surgery clinics of North America **21**(1): 127-138.

Reconstruction of maxillofacial composite defects is a technically demanding and time-demanding process. It also requires a prolonged treatment course, a team approach, and meticulous planning that is prosthetic and esthetically driven. The use of vascularized flap reconstruction, dental implants, and computer-aided technology and advances in maxillofacial prosthetics has contributed immensely toward the goal of fully reconstructing victims of large avulsive wounds. Further advances in technology, surgical training, and maxillofacial prosthodontics will undoubtedly aid in minimizing the number of surgical interventions and maximize the final functional and esthetic results of these patients.

2187. Harris, E. W. and C. W. Cotman (1984). "Brain tissue transplantation research." Applied neurophysiology **47**(1-2): 9-15.

2188. Harris, J. H., Jr. (1975). "The significance of soft tissue injury in the roentgen diagnosis of trauma." CRC critical reviews in clinical radiology and nuclear medicine **6**(3): 295-368.

Soft tissue damage is an integral part of trauma. This basic fact is commonly ignored in the evaluation of roentgenograms obtained because of trauma. The soft tissue component of the traumatic lesion may produce the most obvious roentgen sing of injury and is, in these instances, fundamental to the correct roentgen diagnosis. In many instances, the soft tissue lesion is frequently of greater clinical significance that the more obvious skeletal injury. An awareness of the roentgen signs that signal soft tissue injury, and of those skeletal lesions that are commonly associated with radiographically silent, but clinically more significant, soft tissue damage, leads to prompt institution of appropriate

additional diagnostic studies or therapeutic measures. Thus, the soft tissue injury in the roentgen diagnosis of trauma has both diagnostic and therapeutic significance. Each will be discussed in this article.

2189. Harris, J. H., Jr. (2001). "Re: Lanoix R et al. C-spine injury associated with gunshot wounds to the head: retrospective study and literature review. J Trauma.2000;49:860--863." The Journal of trauma **51**(1): 179-180.

2190. Harris, J. P., et al. (2021). "Open-globe wounds in operation Iraqi Freedom and Operation Enduring Freedom: risk factors for poor visual outcomes and enucleation." Acta ophthalmologica **99**(8): 904-908.

PURPOSE: To determine the rates and types of open-globe wounds in soldiers admitted to Walter Reed Army Medical Center from 2001 to 2011 after sustaining combat injuries., METHODS: Data were collected in the Walter Reed Ocular Trauma Database. Inclusion criteria were patients who suffered open-globe injuries. Open-globe injuries were classified by type of wound: corneal, corneo-scleral or scleral, or type of open-globe injury: perforating, rupture, penetrating or intraocular foreign body. The primary analysis assessed the effect on final visual acuity (VA) and the risk of enucleation., RESULTS: In this study, 285 (32.02%) open-globe injuries were recorded in 890 eyes in the data set. Corneal wounds were noted in 127 (44.56%) eyes, corneo-scleral wounds in 78 (27.37%) and scleral wounds in 129 (45.26%) eyes. The involvement of both the corneal and sclera was associated with poorer visual outcome (BCVA < 20/200) compared to injuries with an injury confined to either the cornea or scleral alone ($p = 0.038$). At a wound length of greater than approximately 14 mm, patients had 75% chance of having a poor final VA. Enucleation was performed in 64 (22.46%) eyes of patients with wounds. The type of wound was not found to be predictive of enucleation in multivariate analysis, but rather the type of open-globe injury was predictive. Perforating (OR: 1.58, 95% CI: 1.43-1.72) and globe rupture injuries (OR: 1.49, 95% CI: 1.33-1.66) were more likely to undergo enucleation., CONCLUSIONS: Open-globe injuries occur frequently in combat ocular trauma. Poor final VA was noted most with corneo-scleral wounds with approximately 50% of patients having a final VA less than 20/200.

2191. Harris, L. S. (1991). "Postmortem magnetic resonance images of the injured brain: effective evidence in the courtroom." Forensic science international **50**(2): 179-185.

Magnetic resonance images (MRI) of the whole, formalin-fixed brain produce details of pathologic changes deep within brain substance not apparent on external examination. Photographs of these radiographic images present pathologic features in a black-and-white, 2-dimensional format which has proven particularly effective in court before judge and jury. This pathologist has noted acceptance of such photographs in explaining to jurors the details of his testimony in selected cases where brain trauma resulted in a wrongful death. Penetrating missile wounds and blunt impact injuries are particularly well documented by this method.

2192. Harris, R. and S. Press (2012). "Intraoperative computed tomography for complex midfacial and orbital Trauma." Journal of oral and maxillofacial surgery **70**(9): e-18.

Advanced intraoperative imaging provides the clinician the ability to have real-time feedback while navigating their way through complex surgical procedures. Navigational systems have the benefit of allowing preoperative planning to be integrated into the intraoperative system; however, they do not account for the threedimensional changes that occur in tissue volumes and positioning after surgical manipulation of the initial anatomy. This can lead to unexpected clinical inaccuracies. Intraoperative computed tomography (CT) has been used in the neurosurgical arena for three-dimensional angiography. Since the use of intraoperative CT allows for immediate evaluation, the use in oral and maxillofacial surgery for dealing with the complex anatomy of midfacial and orbital trauma may be beneficial. Inaccurate reduction of the zygomaticomaxillary complex (ZMC) can lead to increased orbital volume with resultant enopthalamos and facial asymmetry due to lack of malar projection. Incorrect placement of orbital floor fixation can lead to hypoglobus, diplopia, continued entrapment of periorbital tissues, and increased posterior vertical orbital height. These conditions are very difficult to address secondarily often requiring osteotomies, custom designed implants, and multiple procedures, all with less than ideal outcomes. Ten patients were selected who presented to the Vanderbilt University Emergency Department with complex midfacial and/or orbital trauma from July 2011 through February 2012. All patients underwent surgical reconstruction of their injuries with the adjunctive use of intraoperative CT guidance. All

procedures and imaging were performed in the same operative suite utilizing the same Phillips Allura Xper FD20 CT unit. Axial, coronal, and sagittal images were obtained and analyzed on each patient prior to procedure completion. Objective analysis intraoperatively focused on the following outcome variables: adequate reduction, comparison of bony symmetry to uninjured side, positioning of inferior rectus muscle, comparison of posterior vertical orbital height, and extraocular movements. Subjective analysis postoperatively focused upon patient satisfaction with esthetics and function. Etiology of injury included gunshot wounds, sporting accidents, assault, and motor vehicle collisions. Ten patients (9 male and 1 female), with a mean age of 39, ranged in age from 18 to 72. Six of the patients had a ZMC fracture while all patients had an orbital fracture. Intraoperative imaging was evaluated prior to completion of the procedure with no patients requiring alteration of their fixation. Based upon intraoperative imaging all patients had clinically acceptable: 1) bony symmetry and fracture reduction compared to the uninjured side; 2) horizontal position of the inferior rectus muscle; 3) posterior vertical orbital height when compared to uninjured side; 4) extraocular movements when forced duction tests were performed. Subjectively all patients were satisfied with their outcomes functionally and esthetically with no reported diplopia. One patient complained of continued left infraorbital nerve (V2) dysesthesia. While intraoperative navigational systems can be helpful, we have found that the use of intraoperative CT predictably improves functional and esthetic outcomes of complex midfacial and orbital trauma. The use of this technology also helps the overall reduction in healthcare costs by eliminating the need for reoperation in complex cases.

2193. Harrop, J. S., et al. (2014). "Evaluating initial spine trauma response: injury time to trauma center in PA, USA." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **21**(10): 1725-1729.

Historical perceptions regarding the severity of traumatic spinal cord injury has led to considerable disparity in triage to tertiary care centers. This article retrospectively reviews a large regional trauma database to analyze whether the diagnosis of spinal trauma affected patient transfer timing and patterns. The Pennsylvania Trauma database was retrospectively reviewed. All acute trauma patient entries for level I and II centers were categorized for diagnosis, mechanism, and location of injury, analyzing transportation modality and its influence on time of arrival. A total of 1162 trauma patients were identified (1014 blunt injuries, 135 penetrating injuries and 12 other) with a mean transport time of 3.9 hours and a majority of patients arriving within 7 hours (>75%). Spine trauma patients had the longest mean arrival time (5.2 hours) compared to blunt trauma (4.2 hours), cranial neurologic injuries (4.35 hours), and penetrating injuries (2.13 hours, $p<0.0001$). There was a statistically significant correlation between earlier arrivals and both cranial trauma ($p=0.0085$) and penetrating trauma ($p<0.0001$). The fastest modality was a fire rescue (0.93 hours) or police (0.63 hours) vehicle with Philadelphia County (1.1 hour) having the quickest arrival times. Most trauma patients arrived to a specialty center within 7 hours of injury. However subsets analysis revealed that spine trauma patients had the greatest transit times. Present research trials for spinal cord injuries suggest earlier intervention may lead to improved recovery. Therefore, it is important to focus on improvement of the transportation triage system for traumatic spinal patients.

2194. Harshith, K., et al. (2019). "Transcalvarial and Transdural Involvement of Skull Actinomycosis with Recurrence." Indian Journal of Neurosurgery **8**(3): 185-187.

Actinomycosis is caused by anaerobic gram-positive bacteria of Actinomyces genus, generally found as commensals in the human body and infection occurs when the immune system is compromised. We present the case of a 35-year-old diabetic woman, who presented with headache and sudden onset of left-sided weakness apart from scalp swelling, which on imaging showed transcalvarial transdural involvement, and subsequent surgical debridement and histopathologic analysis confirmed actinomycosis. Follow-up showed recurrence of the lesion at the same site following a period of remission. Calvarial involvement of actinomycosis is rare and can mimic even neoplastic or malignant lesions, hence requiring prompt diagnosis, treatment with surgery, and long-term antibiotic treatment to prevent complications.

2195. Hart, K. L. and D. Bowles (2012). "Reconstruction of alveolar defects using titanium-reinforced porous polyethylene as a containment device for recombinant human bone morphogenetic protein 2." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **70**(4): 811-820.

PURPOSE: The use of recombinant human bone morphogenetic protein 2 (rhBMP-2) in a collagen carrier is a proven alternative to autogenous bone grafting for certain cases. One of the principle limitations of rhBMP-2 at present, however, is the lack of a reliable rigid containment system to prevent soft tissue collapse of the collagen carrier sponge.

The present case series describes the use of titanium-reinforced porous polyethylene as a containment device for rhBMP-2-grafted alveolar defects., PATIENTS AND METHODS: A case review was performed of 8 patients who had undergone rhBMP-2 bone grafting using porous polyethylene as the containment device. Eight maxillary and two mandibular alveolar defects were grafted using rhBMP-2 and titanium-reinforced porous polyethylene as a soft tissue barrier. One patient received autologous ramus bone in addition to the rhBMP-2. All patients were followed up by clinical examination and periodic radiographic studies for 6 months to 2 years. Implant-borne prostheses were fabricated on all successful grafts., RESULTS: Of the 10 grafted alveolar defects, 2 (20%) resulted in early exposure of the containment devices, were removed, and resulted in no bone formation. One of the 10 defects (10%) became exposed 3 months postoperatively and resulted in only moderate bone formation. In the 7 nonexposed cases (70%), bone formation was excellent, and implants were successfully placed., CONCLUSIONS: Titanium-reinforced porous polyethylene might be a useful alternative containment device for rhBMP-2-grafted alveolar defects. The exposure rate of 30% in the present case series is comparable to that for titanium alone. Modifications to the shape and thickness of the material might improve its use in alveolar reconstruction and further reduce the incidence of exposure. Further studies are needed; however, titanium-reinforced porous polyethylene could become a new addition to the armamentarium of clinicians grafting alveolar defects. 2196. Hartwig, S., et al. (2009). "Black powder handgun deaths remain an uncommon event." The American journal of forensic medicine and pathology **30**(4): 350-353.

Although it was predicted that there would be an increase in the use of black powder guns due to their greater ease of procurement with less government control on sales, this does not seem to have been the general experience. To determine the rate of use of black powder handguns in shooting deaths in Berlin, Germany, review of the files of the Institute of Legal Medicine and Forensic Sciences, Charite-Universitatsmedizin Berlin was conducted over a 10-year period from 1997 to 2006. Out of total 85 gunshot deaths, there were only 3 where black powder handguns were used (3.5%). The cases involved 3 males aged 55, 62, and 63 years, respectively, all of whom had committed suicide with black powder percussion handguns, using 0.45, 0.56, and 0.36 caliber weapons. The source of the guns could not be determined. Wounds were characterized by excessive soot and propellant soiling and tattooing. The low number of fatalities involving black powder guns in a large forensic institution in Berlin, Germany, suggests that limiting access to such weapons would have little effect on total numbers of gunshot deaths. Simple loading mechanisms and reliability appear to be more important features influencing the choice of a handgun, rather than mere availability.

2197. Hartwig, S., et al. (2010). "Self-constructed shooting devices utilizing manually-impacted firing-pins (suicide machines)." The American journal of forensic medicine and pathology **31**(2): 192-194.

Three cases of suicide are described where deaths were due to single gunshot wounds to the head from self-constructed shooting devices. The victims were twin brothers aged 27 years, and a 53-year-old male. The firearms were manufactured by the victims who used machined metal tubes with 12-gauge shotgun and 7.65 mm ammunition, respectively. The mechanism of action in all cases relied upon direct impact on the firing pin rod; with a hammer in 2 cases, and a rock in the third. Homemade firearms are manufactured globally for use in criminal activities, although they tend to be found more often in countries and among groups where there is limited access to commercially manufactured weapons due to economic or legal constraints. Most devices use either a standard sprung hammer or trigger mechanisms. Given the unusual and cumbersome nature of the firing mechanism in the reported cases, it is likely that these firearms were specifically manufactured for the purpose of suicide.

A case of traumatic foreign body embolism into the right intracranial carotid artery with stenosis of the right middle cerebral artery in a 9-year-old boy is presented. Initial hemiparesis and a consecutive asymptomatic interval of 12 months were followed by a period of frequent transient ischemic attacks. After an extracranial-intracranial arterial

bypass had been performed 18 months later, symptoms ceased without relapse. A thorough review of the literature demonstrates the rare incidence of this entity.

2200. Hashimoto, K., et al. (2017). "Vitronectin Regulates the Fibrinolytic System during the Repair of Cerebral Cortex in Stab-Wounded Mice." Journal of neurotrauma **34**(22): 3183-3191.

Vitronectin (VN), one of the serum proteins, is known to be involved in the regulation of blood coagulation, fibrinolysis, and cell migration. It has been proposed that the regulation of fibrinolysis by VN promotes the blood-brain barrier (BBB) recovery from brain injuries such as traumatic injury and subarachnoid hemorrhage. The effects of VN on fibrinolysis in the injured brain remain unclear, however. We examined the effects of VN on the fibrinolytic system in the stab-wounded cerebral cortex of VN-knockout (KO) mice. First, hemorrhage and recovery from BBB breakdown in the wounded regions were assessed by serum immunoglobulin G (IgG) extravasation. The level of IgG extravasation increased 3-7 days after the stab wound (D3-7) in the cortex of VN-KO mice, compared with that in wild type mice, indicating that VN deficiency inhibited the recovery from BBB breakdown. The VN deficiency decreased fibrin fiber deposition at D1-3, suggesting that VN deficiency tilts the balance between fibrinogenesis and fibrinolysis toward fibrinolysis. Next, the effects of VN deficiency on the fibrinolytic factors were analyzed in the stab-wounded cortex. The VN deficiency impaired the activity of plasminogen activator inhibitor-1, an inhibitor of the fibrinolytic system, at D3-5. Further, VN deficiency up-regulated the mRNA and protein expression levels of tissue-type plasminogen activator, and urokinase-type plasminogen activator. These results demonstrate that VN contributes to the regulation of the fibrinolytic system and recovery from BBB breakdown in the wounded brain.

2201. Hashmi, Z. G., et al. (2014). "Unequal burden of injury at level I trauma centers: The case for efficiency in resource allocation for optimal trauma care." Journal of the American College of Surgeons **219**(3): S104-S105.

INTRODUCTION: Trauma centers (TCs) are frequently designated and verified based on the availability of resources to optimally care for the injured. However, anecdotal evidence suggests that even between similarly-resourced facilities, some centers treat different proportions of specific injuries than others, raising concerns regarding efficiency of equal resource allocations. The objective of this study was to explore the existence of potential differences in the proportion of specific injuries treated at level I trauma centers. METHODS: We analyzed data from the National Trauma Data Bank 2007-2011. Patients ≥16 years of age, with blunt/penetrating injuries and an Injury Severity Score ≥9 admitted to level I trauma centers were included. The Barell Injury Diagnosis Matrix was utilized to characterize proportions of specific injuries treated at each center. TCs were then classified into proportional quintiles for each specific injury, which were then used to compare inter-quintile variations (lowest vs highest quintile). RESULTS: A total of 720,563 patients from 172 TCs were analyzed. Significant interquintile variations were observed for all cohorts (Table). The greatest variation was found between lowest and highest quintile TCs for penetrating (6.7-fold difference, $p<0.01$) and firearm injuries (9.4-fold difference, $p<0.01$). An average of two fold difference was observed for specific injuries based on the Barell classification including traumatic brain injury, spinal cord, thoracic, abdominal, pelvic and hand injuries. CONCLUSIONS: Similarly-resourced level I trauma centers differ substantially in the proportions of specific injuries treated. Current TC designation and verification strategies may need to be reconsidered to improve efficiency in resource allocations for optimal trauma care. (Table Presented).

2203. Hassan Osman, M. and S. Shaltout (2013). "Maxillofacial firearm injuries: A protocol for management in Asyut University hospital." International journal of oral and maxillofacial surgery **42**(10): 1225.

Purpose: This study discusses the firearm injuries in the maxillofacial region, protocol for primary care and management, the complications encountered and the outcome of the patients in Asyut University Hospital in upper Egypt. Patients and methods: 47 cases were received the primary care and treatment in Assiut University Hospital - were admitted and treated, the results were recorded and analysed. Results: Mandible (area III) was the common site of injury, the CNS and ocular injury have the same frequency of association. The most common complications were deformed commissure and scars. Cases with bone loss of the mandible leads to mal-occlusion and associated with

mandibular and cervical branch facial nerve injury. Conclusion: Recommendation of simple approach, post operative safe air way and avoidance of sophisticated technique in the stage of primary care and treatment.

2204. Hassan, S. (2022). "Innovation of new surgical technique to contour the missing bone in the face of survivors of traffic and war injuries by new modified Problast painted with a mixture of biocompatible materials." Journal of Population Therapeutics and Clinical Pharmacology **29**(3): e109-e111.

The bone grafts taken from the patient himself (Auto genius graft) to restore the contour of the lost facial bone lost is the ideal technique on the road to recovery from injuries of war or traffic accidents. This novel surgical procedure utilizes a new modified Problast painted with a mixture of a biocompatible materials to restore the lost parts of the zygomatic bones, due to traffic accidents, shell injuries, or bullet injuries.

2205. Hassfeld, S., et al. (1997). "Intraoperative guidance in maxillofacial and craniofacial surgery." Proceedings of the Institution of Mechanical Engineers. Part H, Journal of engineering in medicine **211**(4): 277-283.

The authors' experiences with intraoperative computer assisted guidance in interventions in oromaxillofacial and craniofacial surgery are reported. The guidance system SPOCS (Surgical Planning and Orientation Computer Systems, Aesculap, Germany) consists of an infrared light emitting system of diodes and camera, an imaging workstation and assorted freehand instruments. The software is an updated version of the well-known Viewing Wand software (ISG Technologies, Canada). In tests on phantoms, the system proved a mean accuracy of less than 1.5 mm. Within the last 15 clinical tests, the system has achieved an accuracy better than 3 mm which, at the moment, the authors estimate to be sufficient to proceed with its clinical evaluation. Using bone screws to register the patient's position, an accuracy in the range of less than 2 mm in relation to bony reference points has been achieved. By visualizing the tip of the instrument in real time, this technique allows surgical interventions, even in anatomically complicated situations, without endangering vital neighbouring structures. The 'offset' function of the software, by which the surgeon can elongate the tip of the instrument virtually, allows the surgeon to analyse structures before they are penetrated by the instrument as in a 'look ahead' operation. The authors expect computer assisted simulation and guidance systems to improve surgical quality and reduce the risks associated with surgical interventions.

2206. Hatano, M., et al. (2016). "Combination management by C-arm fluoroscopy and extraocular muscle severance for penetrating ocular trauma with a retrobulbar foreign body." Orbit (Amsterdam, Netherlands) **35**(3): 167-169.

We report here the successful removal of a retrobulbar metallic foreign body in a patient with penetrating ocular trauma by a transconjunctival approach and combination management with C-arm fluoroscopy and extraocular muscle severance. A 37-year-old man sustained a penetrating injury to the right eye while using an iron hammer. Initial slitlamp examination revealed a corneoscleral laceration, iridocele, anterior chamber collapse, and a traumatic cataract. Visual acuity in the right eye was limited to the perception of hand motion. Computed tomography revealed an orbital foreign body in the retrobulbar area. The patient underwent corneoscleral suturing, severance of extraocular muscles, removal of the foreign body with guidance by C-arm fluoroscopy, pars plana lensectomy, and pars plana vitrectomy. Combination management with C-arm fluoroscopy and extraocular muscle severance may thus be a suitable approach to the removal of a retrobulbar metallic foreign body.

2207. Hatefi, M., et al. (2016). "Association of serum uric acid level with the severity of brain injury and patient's outcome in severe traumatic brain injury." Journal of Clinical and Diagnostic Research **10**(12): OC20-OC24.

Introduction: The prognostic value of serum Uric Acid (UA) levels in Traumatic Brain Injury (TBI) is unclear. Aim: To investigate the relationship between serum UA levels and prognosis of patients with TBI when in hospital and at six months after discharge. Materials and Methods: All patients attended our emergency department during July 2014 and December 2015 and were consecutively entered into the study and among 890 evaluated candidates based on inclusion criteria we finally investigated the serum UA levels of 725 TBI patients. Computed Tomography (CT) images of the brain were obtained within the first 24 hours of hospitalization. Outcome was assessed using the Glasgow Outcome Scale (GOS) score at discharge and at six months after discharge. Results: Data of 725 patients (42.89% men; mean age: 54.69 ± 12.37 years) were analyzed. Mean ± Standard Deviation (SD) of GCS scores was 4.65 ± 1.76. Serum levels of UA, when in hospital and at six months after discharge, among those who died were lower than those who survived (in hospital:

0.126 ± 0.026 vs. 0.243 ± 0.942 mmol/l, p = 0.000; 6 months post-discharge: 0.130 ± 0.044 vs. 0.286 ± 0.069 mmol/l, p<0.001). The mean UA plasma was significantly different between deceased and alive patients according to GOS scores (p<0.001 and p=0.030, respectively). The UA levels showed a significant relationship with GCS scores and severity of brain injury assessed using the Marshall Classification Score (p=0.005). Conclusion: Our results showed a strong relationship between UA levels and patients' outcomes either in hospital or at six months after discharge. Serum UA level could be considered as a valuable marker for evaluating the severity of brain injury and outcomes of TBI.

2208. Hatfield, S. and V. R. Challa (1980). "Embolism of cerebral tissue to lungs following gunshot wound to head." The Journal of trauma **20**(4): 353-355.

The case history of a 28-year-old man who sustained a gunshot wound to the head and developed multiple pulmonary emboli composed of cerebral tissue is presented. The brain tissue fragments probably entered the severed end of a bridging vein, traveled along the superior sagittal sinus, and gained access to the internal jugular vein and systemic venous return.

2209. Hauer, T., et al. (2011). "[Bullet and shrapnel injuries in the face and neck regions. Current aspects of wound ballistics]." Schuss- und Splitterverletzungen im Gesichts- und Halsbereich. Aktuelle Aspekte zur Wundballistik. **59**(8): 752-764.

A basic understanding of the ballistic behaviour of projectiles or fragments after entering the human body is essential for the head and neck surgeon in the military environment in order to anticipate the diagnostic and therapeutic consequences of this type of injury. Although a large number of factors influence the missile in flight and after penetration of the body, the most important factor is the amount of energy transmitted to the tissue. Long guns (rifles or shotguns) have a much higher muzzle energy compared to handguns, explaining why the remote effects beyond the bullet track play a major role. While most full metal jacket bullets release their energy after 12-20 cm (depending on the calibre), soft point bullets release their energy immediately after entry into the human body. This results in a major difference in extremity wounds, but not so much in injuries with long bullet paths (e.g. diagonal shots). Shrapnel wounds are usually produced with similarly high kinetic energy to those caused by hand- and long guns. However, fragments tend to dissipate the entire amount of energy within the body, which increases the degree of tissue disruption. Of all relevant injuries in the head and neck region, soft tissue injuries make up the largest proportion (60%), while injuries to the face are seen three times more often than injuries to the neck. Concomitant intracranial or spinal injury is seen in 30% of cases. Due to high levels of wound contamination, the infection rate is approximately 15%, often associated with a complicated and/or multiresistant spectrum of germs.

2210. Haughey, F. (2012). "Post traumatic brain injury fatigue-finding a focus." Brain injury **26**(4-5): 327.

Objectives: Due to its subjective nature, post traumatic brain injury fatigue (PTBIF) is considered difficult to treat. In some cases this may lead to fatigue being overlooked or ignored by the clinician. Fatigue is often neglected as a target for treatment, perhaps because it typically appears unrelated to the severity of the central disease process. PTBIF is very topical in the literature. The number of people presenting with fatigue both as an inpatient and outpatient in our facility is high and it's impact on occupational performance is evident. A formalised pathway of assessment and treatment for patients presenting with PTBIF did not exist in our unit. This exploratory study serves to explore the knowledge base of cliniicans working with persons with PTBIF and their current practices. The study also looked at the evidence in relation to the assessments and interventions used with this population. Methods: A review of the literature was completed to explore the different types of fatigue, the impact of fatigue on occupational performance, assessments and interventions used for people experiencing PTBIF. A number of interviews were completed with clients to establish the subjective experience of PTBIF. A survey was drawn up and distributed to 16 members of the occupational therapy department and 24 members members of the wider interdisciplinary team working in the brain injury programme in this national centre. The purpose of this was to explore current practice and thinking in relation to PTBIF and to compare this with empirical evidence related to same. Results: Survey participants noted that PTBIF was reported by 50-75% of clients. There was varying levels of knowledge between diciplines relating to the etiology, epidemiology and prevalence of PTBIF. Over half of the participants surveyed did not report a question relating to PTBIF as forming part of their initial assessment. There was no established assessment or intervention procedure or fatigue management protocol relating to PTBIF. The literature was reviewed and despite its prevalence and impact on quality of

live, there is little evidence regarding the effectiveness of fatigue management interventions for PTBIF. There was little evidence available to support current practices by clinicians. A fatigue managment protocol is currently being established in the programme which includes: 1. The identification of a Quantitative/Qualitative Measure 2. A compulsory question regarding PTBI fatigue on initial assessment/interview 3. Development of an educational booklet for patients, friends and family 4.Scheduling/Timetabling breaks in therapy schedules Conclusions: PTBIF impacts occupational performance. The importance of treating this deficit early in the inpatient admission is essential. If not acknowledged and addressed as an inpatient it can impact negatively on the client's ability to maximise their potential within their inpatient stay. If a rehabilitation team are to effectively address the needs of people who have sustained a TBI it is essential that this impairment is addressed.

2211. Hausmann, R. and P. Betz (2002). "Thermally induced entrance wound-like defect of the skull." Forensic science international **128**(3): 159-161.

A case of death due to car fire is described where the carbonised skull of the cremated corpse showed an ovoid defect of the cranial bone. The question arose whether this formed fracture was caused by a gunshot. But the reconstruction of the cranial remains with detached parts of the tabula externa provided evidence that the suspicious defect was to be classified as an uncommon heat-induced post-mortem artefact.

2212. Havel, J., et al. (2006). "[Using of scanning electron microscopy for detection of gunshot residue]." Pouziti skenovaci elektronove mikroskopie pri detekci povystrelovych castic. **51**(3): 42-46.

Scanning electron microscope improves the possibility of investigation of surroundings near of gunshot wounds in forensic medicine, it is the next subsequent method for differentiating of area of entrance and exit wound, supplemental method for determination of firing distance, permit of detection (GSR) on the hand of shooter and ensured describing of samples and their stored. Detection of GSR provides many information about composition of bullet and primer. Authors are demonstrating the possibility of detection of GSR on experimental shooting to the krupon (pigs' skin) in different situation (such as in a room and in outside area) and using of different weapon (hand gun CZ No.75 and machine gun No.58).

2213. Haworth, C. S. and J. C. de Villiers (1988). "Stab wounds to the temporal fossa." Neurosurgery **23**(4): 431-435.

Stab wounds to the temporal fossa appear as a characteristic clinical entity. Patients admitted with stab wounds to the head during the period 1970 to 1986 were reviewed retrospectively. Of these, 10 met the criteria of having suffered a stab wound that penetrated the skull and dura mater of the temporal fossa. Injury to the internal carotid artery-cavernous sinus complex (3 patients) or to the basilar artery-pons region (5 patients) was frequent. Two other patients experienced injury to the trigeminal nerve and the petrous ridge. The mechanical, neurological, radiological, and prognostic features of knife wounds to this region are discussed.

2214. Hawramy, T. A. (2007). "Role of pre-hospital care in reducing mortality rate among victims of gunshot injuries." Middle East Journal of Emergency Medicine **7**(2): 61-66.

This study can be regarded as the first research done solely on autopsy findings in the Iraqi Kurdistan region. It is a prospective study on (106) cadavers who were victims of gunshot injuries (included those who died at the scene and those who died as in-patients) seen in Sulaimani Forensic Department from February 2003 to February 2004. A classical approach by dissection was used to determine cause of death in each victim, with age and sex incidence in order to clarify role and importance of pre-hospital care in reducing death for victims of gunshot injuries. In general, victims were either received from the scene after an average period of two to four (2-4) hours from the event or directly from the hospital. The main causes of death among those received from the scene were severe bleeding due to vascular or organic injuries [account for (53/106) 50.02%] , laceration of brain tissue (47/106) 44.34%, and spinal cord transaction (1/106) 0.94%. While septicemia is the only cause of death among those received from hospital, accounting for (5/106) 4.7%. Deaths occurred from injuries to different anatomical sites of the body: head alone (42/106) 39.62%, head with extremity (6/106) 5.66%, neck alone(1/106) 0.94%,chest alone (16/106) 15.92%, chest with extremity (8/106) 7.54%, abdomen alone (15/106) 14.15%, abdomen with extremity(4/106) 3.77%, thigh alone (11/106) 10.37%, and pelvis alone (3/106) 2.83%. The most significant finding is that life almost always could be preserved in at least (11/106) 10.37% with

a single bullet injury to thigh if pre-hospital care was present. Death from gunshot injuries can be regarded as a second major cause of death after road traffic accidents in our region with sex distribution of 86.79% males and 13.21% females. The peak age incidence for females was between 14-44 years and for males 14-54 years, regardless of the type of events, i.e. criminal, suicidal or accidental. Incidence of gunshot injuries are more common in rural areas than urban ones in a ratio of 5.5:1.

2216. Hawryluk, G. W. J. (2016). "Comments." Neurosurgery **78**(5): E760.

2217. Hawryluk, G. W. J., et al. (2022). "Rationale and Methods for Updated Guidelines for the Management of Penetrating Traumatic Brain Injury." Neurotrauma reports **3**(1): 240-247.

Penetrating traumatic brain injury (pTBI) affects civilian and military populations resulting in significant morbidity, mortality, and healthcare costs. No up-to-date and evidence-based guidelines exist to assist modern medical and surgical management of these complex injuries. A preliminary literature search revealed a need for updated guidelines, supported by the Brain Trauma Foundation. Methodologists experienced in TBI guidelines were recruited to support project development alongside two cochairs and a diverse steering committee. An expert multi-disciplinary workgroup was established and vetted to inform key clinical questions, to perform an evidence review and the development of recommendations relevant to pTBI. The methodological approach for the project was finalized. The development of up-to-date evidence- and consensus-based clinical care guidelines and algorithms for pTBI will provide critical guidance to care providers in the pre-hospital and emergent, medical, and surgical settings.

2218. Hay, A., et al. (1991). "Needle penetration of the globe during retrobulbar and peribulbar injections." Ophthalmology **98**(7): 1017-1024.

The charts of 23 patients with needle penetration of the globe during retrobulbar or peribulbar injections between January 1980 and May 1990 were reviewed. Possible needle penetration risk factors included high myopia, previous scleral buckling procedures, injection by nonophthalmologists, and poor patient cooperation during the injection. Of the 23 cases of ocular penetration, 16 (70%) were from sharp (22-, 23-, and 25-gauge) needles, and 7 (30%) were from blunt (23- and 25-gauge) needles. Management options depended on the severity of the intraocular injury. Retinal breaks without retinal detachment were treated by laser photocoagulation (four cases) or cryopexy (one case) and were observed in three cases. More advanced complications (retinal detachment and vitreous hemorrhage) were usually treated by pars plana vitrectomy with or without a scleral buckle (12 of 14 cases). The final visual acuity was 20/400 or better in only 2 of the 14 retinal detachment cases. In cases without retinal detachment, the final visual acuity was 20/50 or better in 7 of 9 cases.

2219. Hayashi, N. (2000). "[Brain hypothermia treatment for the management of severe pediatric brain injury]." No to hattatsu = Brain and development **32**(2): 122-131.

In the management of severe pediatric brain injury, attention has previously been paid to brain edema, ICP elevation and low cerebral perfusion pressure (CPP). However, in the acute stage within 3-6 hours after trauma, brain hypoxia and hyperglycemia associated with diffuse brain injury are often observed. We have pointed out brain thermo-pooling (elevation of brain tissue temperature) and brain hypoxia caused by defective release of oxygen from hemoglobin (due to decrease in red blood cell enzyme (DPG)) as a new mechanism of brain injury. To treat these pathologic changes, we have developed a brain hypothermia treatment, the major purpose of which is to prevent brain hypoxia, brain thermo-pooling, neurohormonal changes causing cytokine encephalopathy, and a selective, radical-mediated damage of the dopamine A10 nervous system. The brain tissue temperature is initially adjusted to 35 degrees C with adequate cerebral oxygenation, followed by brain hypothermia at 34 degrees C for 1 weeks to prevent brain hypoxia, free radical reactions, brain edema and ICP elevation. What is most difficult in the pediatric brain hypothermia treatment is to maintain metabolic balance in the injured brain tissue and pulmonary infections associated with an

immune crisis. When a rapid elevation of serum glucose is noted it is critical to lower the value because glucose quickly penetrates the blood-brain barrier and increases pyruvate and lactate by inhibiting the TCA cycle metabolism. Thus, hyperglycemia during brain hypothermia treatment is one of the major target of management. Another problem is immune crisis associated with secondary pulmonary infections. To prevent them, early enteral nutrition and replacement of L-arginine were most useful, as well as preconditioning for rewarming as follows: serum albumin > 3.0 g/dl; lymphocyte > 1500/mm3; T-H (CD4) lymphocytes > 55%; serum glucose, 120-140 mg/dl; vitamin A > 50 mg/dl; Hb > 12 g/dl and 2,3 DPG, 10-15 mumol/gHb; O2 ER, 23-25% and AT-III, > 100%. The clinical benefit of this therapy is still controversial.

2220. Hayashi, S., et al. (1990). "Treatment of a mandibular gunshot wound." Japanese Journal of Plastic and Reconstructive Surgery **33**(4): 355-358.

A 20-year-old man with mandibular gunshot wound has been treated. AX ray examination revealed that the left side of his mandible was fractured and that the neck was swollen, thoush the carotid artery and vein were still intact. In the case of gunshot wounds, shock waves way cause soft tissue damage far from the primary missile track. Thus for the treatment of gunshot wounds, extensive debridement is needed. For such cases, a vascularlized tissue transfer has proven sucessful in the reconstruction of defective tissue, In this instance, the authors used a free iliac bone graft for the reconstruction of the mandible and the results were excellent.

2224. Haynes, Z. A., et al. (2021). "Risk factors of persistent insomnia among survivors of traumatic injury: a retrospective cohort study." Journal of clinical sleep medicine : JCSM : official publication of the American Academy of Sleep Medicine **17**(9): 1831-1840.

STUDY OBJECTIVES: Insomnia is a diagnosis with broad health and economic implications that has been increasingly recognized in military service members. This trend was concurrent with an increase in traumatic wartime injuries. Accordingly, we sought to determine longitudinal predictors of persistent insomnia in combat veterans who sustained traumatic injuries., METHODS: Retrospective cohort study of service members deployed to conflict zones from 2002 to 2016, with longitudinal follow-up in the Veterans Affairs and Military Health Systems. Two cohorts were derived: (1) service members who sustained traumatic injuries and (2) an age-, sex-, and service component-matched cohort of uninjured service members who deployed to a combat zone. Insomnia was defined using International Classification of Diseases, Ninth Revision or International Classification of Diseases, 10th Revision-Clinical Modification codes., RESULTS: The final population of 17,374 service members was followed from date of injury (or date of matched participant's injury) for a median of 8.4 (interquartile range, 5.3-10.7) years. Service members with traumatic injury were at significantly greater risk of developing insomnia than uninjured service members (hazard ratio = 1.43; 95% confidence interval, 1.30-1.58) after adjustment. Traumatic brain injury was associated with insomnia compared with patients without traumatic brain injury in the multivariable model: mild/unclassified traumatic brain injury (hazard ratio = 2.07; 95% confidence interval, 1.82-2.35) and moderate/severe/ penetrating traumatic brain injury (hazard ratio = 2.43; 95% confidence interval, 2.06-2.86). Additionally, burn injury (hazard ratio = 1.95; 95% confidence interval, 1.47-2.59) and amputation (hazard ratio = 1.61; 95% confidence interval, 1.26-2.06) significantly increased the risk of a diagnosis., CONCLUSIONS: Traumatic injuries significantly predicted a diagnosis of insomnia after controlling for mental health disorders. Our findings strongly suggest the need for long-term surveillance of sleep disorders in trauma survivors., CITATION: Haynes ZA, Collen JF, Poltavskiy EA, et al. injury: a retrospective cohort study. J Clin Sleep Med. 2021;17(9):1831-1840. Copyright © 2021 American Academy of Sleep Medicine.

2225. Hazama, A., et al. (2018). "Full Recovery After a Bihemispheric Gunshot Wound to the Head: Case Report, Clinical Management, and Literature Review." World neurosurgery **117**: 309-314.

BACKGROUND: Nearly 33,600 people die each year in the United States as a result of gunshot wounds (GSWs). Penetrating craniocerebral GSWs are often fatal with a nearly 70% death rate at the scene of the trauma. Overall combined mortality rate for patients who die at the scene or at the hospital is almost 91%. Poor outcome is associated with initial low Glasgow Coma Scale score and bihemispheric and transventricular gunshot trajectory. We summarize current understanding in management, prognostic factors, and survival outcomes in patients with a penetrating GSWs to the head. We report a patient with return to full function despite bihemispheric, multilobar involvement. Full function is defined here as ability to return to previous work and perform activities of daily living., CASE DESCRIPTION: A 33-year-old man sustained a GSW to the head under unknown circumstances. On initial presentation, he had a Glasgow Coma Scale score of 15. He was verbalizing and communicating but was amnestic for the event. From a left frontal entry wound, the bullet traversed both frontal lobes of the brain reaching the right frontal-parietal junction. Physical examination and vital signs were normal. Appropriate surgical and medical management resulted in complete recovery., CONCLUSIONS: Craniocerebral GSWs have a high mortality rate and usually require aggressive management. Evaluation of most GSWs requires appropriate imaging studies followed by proactive treatment against infection, seizure, and increased intracranial pressure. Surgical intervention is often necessary and ranges from local wound debridement to craniectomy, decompression, and wound exploration.

2226. He, L., et al. (2012). "Pharmacokinetics of bendamustine in patients with brain metastases from solid tumors: Evaluation of bendamustine blood-brain barrier penetration." Clinical Pharmacology and Therapeutics **91**: S130.

BACKGROUND: Bendamustine (BM) is a dual functioning DNA alkylating and cross-linking reagent approved by the US FDA for treatment of CLL and NHL. It is currently in clinical evaluation for treatment of various hematologic and solid tumor malignancies. The ability of BM to penetrate the BBB has not been directly evaluated in humans. The purpose of our study was to evaluate the plasma pharmacokinetics (PK) of BM and determine if BM could be detected and quantified in resected brain lesions after dosing. METHODS: Our team is evaluating BM as a radiosensitizer combined with fractionated stereotactic radiotherapy for treatment of patients with up to 4 brain metastases from solid malignancies. Patients were dosed with a 30 min. IV infusion of BM days 1 to 3 with surgical resection of lesions following dosing on day 3. Plasma samples were collected on day 1 or 2. Surgeries were conducted after infusion on day 3 with collection of plasma, cerebro-spinal fluid (CSF) and brain tumor tissues. Two highly sensitive LC-MS/MS assays for quantification of BM in human plasma and mouse brain tissue (as a surrogate for human brain tissue) were developed and fully validated. RESULTS: Plasma PK data from 3 patients treated with 40 mg BM demonstrated peak concentrations near 13 M at the end of infusion with rapid decline to nM levels within 2 hours and half-lives near 0.8 hrs. CSF and tumors collected 4.5 to 9 hours after BM infusion indicated BM could be detected in the earliest samples collected, although levels were below quantifiable limits. CONCLUSION: Plasma PK for BM is consistent with previous clinical studies. Data from day 3 of treatment suggests BM is present at detectable levels in CSF and brain tumors up to 6 hours after dosing. Additional patients are being accrued with efforts to reduce time delays between BM dosing and surgery.

2227. Healey, D. L. and J. A. Kieser (2005). "Unusual fatal dog attack in Dunedin, New Zealand." The Journal of forensic odonto-stomatology **23**(2): 51-54.

A case of a fatal dog attack on a middle aged woman is presented. The offending dog was her own Bull-mastiff, which had previously shown signs of aggression towards her. Most of the injuries were found on the victim's face, neck and skull. A noteworthy feature of this attack was that the victim was known to suffer from Huntington disease. It is postulated that the involuntary movements, progressive dementia and increased moodiness characteristic of the disease may have had a significant role in triggering the attack.

2228. Healy, J. F. (1982). "Computed tomography of orbital trauma." The Journal of computed tomography **6**(1): 1-10.

Ten cases of trauma to the orbit and orbital region are presented to illustrate the efficacy of computed tomography in the radiologic evaluation of these injuries. CT was able to detect subarachnoid hemorrhage, retrobulbar hematoma, orbital cellulitis, foreign bodies, intraglobal and intraorbital air, dislocated lens, blowout, and tripod fractures in these patients.

2230. Heath, D. L. and R. Vink (1999). "Optimization of magnesium therapy after severe diffuse axonal brain injury in rats." The Journal of pharmacology and experimental therapeutics **288**(3): 1311-1316.

A number of studies have demonstrated that magnesium salts given after traumatic brain injury improve subsequent neurologic outcome. However, given that these earlier studies have used a number of different salts, dosages, and routes of administration, follow-up studies of the neuroprotective properties of magnesium are complicated, with comparisons to the earlier literature virtually impossible. The present study has therefore characterized the dose-response characteristics of the most commonly used sulfate and chloride salts of magnesium in a severe model of diffuse traumatic axonal injury in rats. Both magnesium salts improved neurologic outcome in rats when administered as a bolus at 30 min after injury. The i.v. and i.m. optima of each salt was 250 micromol/kg and 750 micromol/kg, respectively. The identical concentrations required for improved neurologic outcome suggest that improvement in outcome was dependent on the magnesium cation and not the associated anion. Subsequent magnetic resonance studies demonstrated that the administered magnesium penetrated the blood-brain barrier after injury and resulted in an increased brain intracellular free magnesium concentration and associated bioenergetic state as reflected in the cytosolic phosphorylation potential. Both of these metabolic parameters positively correlated with resultant neurologic outcome measured daily in the same animals immediately before the magnetic resonance determinations.

2231. Hebecker, R., et al. (2009). "An unusual case of a penetrating skull-base injury caused by a wild deer's antler." Central European neurosurgery **70**(1): 48-51.

Injuries relevant to neurosurgeons in central Europe are rarely caused by wild animal attacks, whereas dog bites in urban areas and farm-related attacks from cattle and horses are well-known to cause sometimes fatal head injuries. The authors describe the first case of a perforating frontobasal injury caused by a wild deer's antler. Associated lesions involved the endonasal area and the left orbit. A multidisciplinary approach was used to address all lesions in a one-stage operation resulting in a full recovery of the patient. Apart from the problem of a possible contamination of the head wound, injuries caused by wild animal attacks should be treated the same way as comparable "regular" cases. Adequate coverage of dural and bone defects with autologous material via a bifrontal intradural approach and meticulous debridement of the intracranial wound usually gives good functional and cosmetic results.

2232. Hecimovic, I., et al. (2000). "Intracranial infection after missile brain wound: 15 war cases." Zentralblatt fur Neurochirurgie **61**(2): 95-102.

OBJECTIVES: The present study describes 15 cases of intracranial infections developed in a group of in patients with missile brain wound (MBW), during the war in Croatia in the region of East Slavonia., METHOD: The retrospective study included 88 MBW casualties. There were 11 females and 77 males aged 2-80 years. The projectile penetration of the cranial dura was confirmed and the presence of intracranially retained foreign bodies was evaluated with computerized tomography (CT) in all the patients. The wounded were treated according to the modern recommendations of neurotrauma care. However, we extracted only accessible bone/metallic fragments during intracranial debridement. All intracranial infections were documented by cultures, CT, surgery or autopsy. The mean follow-up period of wounded with intracranial infections was 2.4 years (range, 10 days to 7 years)., RESULTS: Intracranial infection developed in 14 patients (17%) as "early intracranial infections". Among 14/15 cases, infection developed within the first 8 weeks, and in 1 case 5 months after wounding. We recorded 4 cases of isolated bacterial meningitis, whereas in 9 cases brain abscess had developed. In 6 cases brain abscess was associated with concomitant meningitis and epidural empyema. Local cerebritis developed in one case, as well as subdural empyema with the concomitant

meningitis in one case. There were 8 deaths in total of 15 cases. Glasgow Outcome Score 3 was observed in 2 and good outcome in 5/15 cases. The infectious organisms were isolated in 8 cases. Gram-positive bacteria were found in 12 different specimens. Gram-negative bacteria were found in 9 specimens. The most frequently isolated organism was Staphylococcus aureus. beta-hemolytic streptococcal and clostridial infections were not observed. Among the 15 patients with intracranial infection, just one did not have intracranially retained bone and/or metallic fragments. However, among the 73 head injuries without intracranial infections only 10 did not have retained fragments. CSF fistula and/or dehiscence developed in 13/15 patients with intracranial infection. In 67/73 wounded without intracranial infections, wound complications were not registered., CONCLUSIONS: The liberal use of post-contrast CT of the brain within the first 2 months after injury, especially if performed early in the clinical course, can lead to a prompt diagnosis of most of "early intracranial infections". The surgical procedures in order to prevent wound CSF fistula/dehiscence development are absolutely necessary. The immediate scalp and dural wound repair in case of wound complications are absolutely indicated and if needed, the procedures can be repeated. However, it seems that retained fragments are not responsible for an increased rate of intracranial infection.

2233. Hedberg, K. M., et al. (2001). "The glioma-associated gangliosides 3'-isoLM1, GD3 and GM2 show selective area expression in human glioblastoma xenografts in nude rat brains." Neuropathology and applied neurobiology **27**(6): 451-464.

This work describes the in vivo expression and distribution of glioma-associated gangliosides (GD3, GM2, 3'-isoLM1) in a novel human brain tumour nude rat xenograft model. In this model, the tumours, which are established directly from human glioblastoma biopsies, show extensive infiltrative growth within the rat brain. This model therefore provides an opportunity to study ganglioside expression not only within the macroscopic tumour, but also in brain areas with tumour cell infiltration. The ganglioside expression was studied by confocal microscopy of immunostained brain sections using antiganglioside monoclonal antibodies. Xenografts from four human glioblastoma multiformes were established in rats and the brains removed after 3-4 months. Ganglioside GD3 was expressed in the tumour parenchyma while ganglioside 3'-isoLM1 was more abundantly expressed in the periphery of the tumour associated with areas of tumour cell invasion. GM2 expression was only seen in one tumour, where it was located within the main tumour mass. Double staining with a pan antihuman monoclonal antibody (3B4) and the antiganglioside monoclonal antibodies confirmed that the ganglioside expression was associated with tumour cells. This work supports the concept of different biological roles for individual gangliosides and indicates that antibodies or ligands directed against GD3 and 3'-isoLM1 might be complementary when applied in the treatment of human glioblastomas.

2234. Hee, J. K., et al. (2008). "Tuberculin survey to estimate the prevalence of tuberculosis infection of the elementary schoolchildren under high BCG vaccination coverage." Tuberculosis and Respiratory Diseases **65**(4): 268-276.

Background: Although the prevalence of tuberculosis infections (PTBI) is one of the basic epidemiologic indices, no survey has been carried out since 1995 because the nation-wide tuberculosis prevalence survey was changed to a surveillance system. Subjects without a BCG scar are examined in a tuberculin survey. However, it is very difficult to select these subjects under high vaccination coverage. It is important to evaluate the impact of BCG vaccinations on the tuberculin response and estimate the PTBI regardless of the BCG vaccination status. Methods: A nation-wide, school-based cross-sectional tuberculin survey was carried out among first graders in elementary school in 2006. A total of 5,148 children in 40 schools were selected by quota sampling. Tuberculin testing with 0.1 ml of two tuberculin units of PPD RT23 was carried out on 4,018 children. The maximum transverse diameter of induration was measured 48 to 72 hours later. The presence of a BCG scar was checked separately. Results: There were no BCG scars in 6.3% of the subjects. The mean induration size of tuberculin testing was 3.7±4.4 mm, which included 1,882 (46.8%) subjects with an induration size of 0 mm. The PTBI was 10.9% (439 subjects) using a cut-off point of ≥10 mm (conventional method). The annual risk of tuberculosis infections (ARTI) was 1.9% when the mean age of the subjects was assumed to be 6 years. There was no difference in the PTBI according to the presence or absence of a BCG scar [11.2% vs 7.6% (OR: 1.54, 95% CI: 0.98-2.43)]. Using a mirror image technique with 16 mm as the cut-off point, the PTBI and ARTI had decreased to 2.4% and 0.4% respectively. Conclusion: PTBI and ARTI, as estimated by conventional methods, appear to be high among BCG vaccinated children. A mirror image technique is more suitable for estimating the indices in a country with an intermediate burden of tuberculosis than the conventional method.

2235. Heffern, E., et al. (2021). "Anatomic Subunit Approach to Composite Reconstruction of Facial Gunshot Wounds." The Journal of craniofacial surgery **32**(7): 2487-2490.

ABSTRACT: With a rise in gun violence in the United States, surgeons are tasked with effectively managing penetrating facial trauma. The purpose of this study is to assess methods used for successful composite reconstruction of each anatomical facial subunit following penetrating trauma. A retrospective chart review was performed in subjects undergoing craniofacial reconstruction following penetrating trauma. Reconstructive methods were analyzed through operative reports. Subjects were categorized by anatomical subunit reconstructed (mandible, maxilla (malar complex and roof/palate), orbit, and cranium) and method of reconstruction (open reduction internal fixation only, bone graft, free flap, implant, and tissue expansion). Thirty-six subjects underwent reconstruction for penetrating facial trauma. Involved subunits include 24 mandible, 11 malar complex, 13 palate, 18 orbit, and 11 cranium. Predominate reconstruction method was open reduction internal fixation only for mandible (45.8%), bone grafting for malar complex (81.8%), implant for orbit (66.7%) and cranium (63.6%), and local tissue rearrangement for palate (84.6%). The predominate bone graft donor site was iliac for mandible (42.9%), rib for malar complex (36.3%) and orbit (40.0%), and frontal bone for cranium (42.8%). The predominate free flap was osteocutaneous for all mandible, orbit, and cranium and 7 of 10 (70.0%) palate reconstructions. Tissue expansion was used in all subunits except cranium. In conclusion, bone grafting, implants, free tissue transfer, and tissue expansion are all viable reconstruction options for penetrating trauma. There is no single approach to use, and decisions regarding definitive reconstruction method should be based upon anatomical subunit involved and the size/area of defects. 2236. Hegde, V., et al. (2005). "Cranio-orbital injury with internal carotid artery laceration and a missing eyelid." Ophthalmic plastic and reconstructive surgery **21**(6): 467-469.

A 37-year-old man presented to the emergency department with a visor impacted in the left orbit after a motorbike accident. His initial injury appeared to be limited to the orbit. Because the bleeding appeared disproportionate to the orbital injury, an intracranial injury was suspected. Subsequently, on hemicraniotomy, the tip of the visor was found at the bifurcation of the internal carotid artery. The avulsed upper eyelid was found under the frontal lobe. The patient underwent the clipping of internal carotid artery and middle and anterior cerebral artery with replantation of the upper eyelid. Neurologic damage was limited to loss of vision, right foot drop, and bowel and bladder incontinence. This case of penetrating orbital trauma demonstrates that the absence of focal neurologic deficit and radiologic signs suggestive of intracranial injury may not rule out life-threatening intracranial injury.

2238. Heiferman, D. M., et al. (2016). "Bilateral Through-and-Through Trajectory of a Low-Velocity Transcranial Penetrating Foreign Object in a Twelve-Month-Old." Pediatric neurosurgery **51**(1): 25-29.

A 12-month-old girl sustained a penetrating intracranial trauma of a thin aluminum rod traversing from the left frontal bone and exiting the right occipital bone. The rod entered the left anterior frontal lobe, traveled through the ventricular system, narrowly missed the right posterior cerebral artery by less than 1 mm and exited through the right cerebellum. The rod was surgically extracted, and the child remained neurologically intact. Pre- and postoperative vascular imaging, antibiotics, seizure prophylaxis and surgical planning are paramount to successful care of these delicate cases. Copyright © 2015 S. Karger AG, Basel.

2239. Heimer, J., et al. (2017). "Antemortem identification by fusion of MR and CT of the paranasal sinuses." Forensic science, medicine, and pathology **13**(3): 375-378.

Radiologic forensic identification is usually performed by comparing antemortem and postmortem radiographs. While computed tomography (CT) has become a valuable addition to radiologic identification, magnetic resonance (MR) imaging has only rarely been used for this purpose. In our case, identification was accomplished using fused MR- and CT images in a survivor of a gunshot injury to the head. This case supports and highlights the possibility to perform intermodality radiologic identification comparing preexisting MR imaging to subsequently aquired CT data in living (or

deceased) humans as long as manual modifications of windowing, color and contrast enable differentiation of the two modalities in the fused image.

2241. Hejna, P. (2010). "Multiple suicidal injuries with shotgun slugs." International journal of legal medicine **124**(1): 79-82.

Shotguns are usually used to fire multiple pellets, but they are capable of firing single projectiles. Shotgun slug injuries are rare, severe, and fully comparable to those inflicted by high-velocity projectiles. A case of gunshot suicide of a 59-year-old man with a shotgun loaded with shotgun slugs is presented. The first two shots were fired into the heart region, but did not hit the vital organs of the victim's thorax and did not cause immediate incapacitation. The man was able to reload and refire. The third shot was fired into the region of right temple; the last shot caused severe cerebrocranial gunshot injury and was fatal. The victim did not pull aside his clothing to expose his skin before shooting into the heart region.

2242. Hejna, P. and M. Bohnert (2013). "Decapitation in suicidal hanging--vital reaction patterns." Journal of forensic sciences **58 Suppl 1**: S270-277.

Complete or incomplete decapitation as a consequence of suicidal hanging is very rare, few cases having been reported in the worldwide literature. Posthanging decapitation is typically related to a drop of several meters. Three cases of complete decapitation and one case of incomplete decapitation by suicidal hanging are reported with particular emphasis on internal findings and vital reaction patterns. Personal, circumstantial, autopsy, and toxicological data were analyzed to define basic characteristics of such extreme injuries. The crucial factor for the state of decapitation itself is the kinetic energy of the falling body, the strength of the human neck tissue, and the diameter and elasticity of the used ligature. Results of our case study suggest Simon's hemorrhage and air embolism as useful autopsy findings in posthanging beheading cases. Simon's hemorrhage was demonstrated in three cases of four. The test for air embolism was positive in all four cases.

2243. Hejna, P. and M. Safr (2010). "An unusual zip gun suicide--medicolegal and ballistic examination." Journal of forensic sciences **55**(1): 254-257.

Home-made guns are imitations of typical firearms and usually have handgun characteristics. This article presents an unusual case of a suicide carried out by means of a fatal gunshot wound to the head using a home-made zip gun. A 49-year-old male, with a history of paranoid psychosis was found dead in the dwelling place of a family house. The investigation at the crime scene did not lead to suspicion of a gunshot wound because of the unusual nature of the firearm used. A medical examiner diagnosed an opened head injury as the primary cause of the victim's death. The autopsy findings provided immediate grounds for further inspection of the crime scene. Subsequently, a simple zip gun, which had been overlooked during the scene investigation, was discovered. An undeformed projectile recovered from the victim's head was consistent with the use of the home-made firearm. Following the completion of the investigations and autopsy, the death was classified as a suicide.

2244. Hejna, P., et al. (2011). "Reconstruction of devastating head injuries: a useful method in forensic pathology." International journal of legal medicine **125**(4): 587-590.

Crushing head injuries usually do not allow direct visual identification of individuals, and above all, it constitutes an obstacle to comprehensive evaluation of discrete traumatic changes of the skin and soft tissues. We present our experience with the plastic adaptation of devastating head injuries in the two exemplary cases. The principal of the reconstruction is manual repositioning of bone fragments of the cranial and facial parts of the skull and careful approximation of the wound edges and their gradual suture using suture material. The reconstruction method can be recommended as an auxiliary technique in the identification of unknown victims with crushing head injuries and in the evaluation of devastating gunshot wound of the head.

2245. Hejna, P., et al. (2012). "The ability to act--multiple suicidal gunshot wounds." Journal of forensic and legal medicine **19**(1): 1-6.

Multiple self-inflicted gunshot wounds are rare and usually present a challenge to the forensic pathologist in determining the manner of death. Determining a person's capability to act following a gunshot wound can be of major importance in crime scene reconstruction and in differentiation between homicide and suicide. Questions concerning the possibility of physical activity following a given gunshot wound are repeatedly raised in court. We report herein three unusual cases of suicide involving multiple gunshot wounds; all the victims suffered gunshot wounds of the head without immediate incapacitation. In the first two cases, the head was target for two gunshots. Third case was a combination of two gunshots to the head and chest. In the text, we focus on the victim's ability to act after the first shot, with regards to the character and localization of the gunshot wound. Also, we focus on findings that are typical for a repeated suicidal shot.

2246. Hejna, P., et al. (2012). "Complex suicide with black powder muzzle loading derringer." Forensic science, medicine, and pathology **8**(3): 296-300.

Planned complex suicide is defined as the combination of more than one method of suicide, previously planned by the victim, to prevent failure of the first method. Herein, we present a case of planned complex suicide, committed by a black powder muzzle loading handgun and hanging. A 39-year-old man was found dead in the bathroom of his flat, hanging by the neck with a huge atypical gunshot entrance in the right temporal region of his head with extensive backspatter. The skin defects, as well as soft tissues in the subcutaneous pocket undermining, were heavily burnt. Along the wound canal were multiple bone fragments, and at the end of the path at the left temple was an embedded lead ogival projectile with a cross shaped artificial incision at its tip. The hanging was incomplete. There were no fractures of the hyoid bone and laryngeal cartilages. Cervical muscles and vessels were intact. Simon's sign was negative. Signs of asphyxia were not present. This is the first reported case of complex suicide with a black powder derringer and manipulated projectile.

2247. Helán, M., et al. (2020). "Ischaemic Stroke Caused by a Gunshot Wound to the Chest." EJVES Short Reports.

Introduction: Pneumatic weapons rarely cause severe trauma. However, pellet embolisation can cause severe and unexpected injuries. Report: This is the case study of a 32 year old man, who was shot in the chest with a pneumatic rifle. Initially, urgent damage control surgery was performed to resolve pneumothorax and pericardial tamponade, but no projectile was found. Subsequent atypical symptomatology led to more extensive imaging that found a pellet embolised into the right carotid artery, thrombosis of the middle cerebral artery, and development of a large right hemispheric ischaemic area. After an unsuccessful endovascular intervention, the projectile was removed during an open surgical procedure. The right hemisphere oedema required decompressive hemicraniectomy, but long term intensive care and physiotherapy resulted in a satisfactory recovery with moderate neurological sequelae. Conclusion: An unusual clinical presentation in combination with an absent exit wound might be symptomatic of projectile embolisation and should lead to a search for it. When the projectile position is convenient, surgical removal is the treatment of choice while an endovascular approach should be reserved for inaccessible locations or asymptomatic cases.

2248. Helbig, H. and H. P. Iseli (2002). "Traumatic rupture of the globe caused by cow horns." European journal of ophthalmology **12**(4): 304-308.

PURPOSE: We investigated the epidemiology, clinical findings and functional outcome of open-globe injuries caused by cow horns over a 50-year period in eastern Switzerland., METHODS: We retrospectively evaluated the files of cases with ruptures of the globe caused by cow horns between 1950 and 1999., RESULTS: We found 59 cases with ruptures of the globe by cow horns, accounting for 5% of all open-globe injuries. The incidence of these accidents did not change during the observation period. Twenty-two eyes (37%) were enucleated. Only 7 eyes (12%) retained a vision of > or = 0.1. Between 1950 and 1989 only 2/43 eyes (5%) reached a vision of > or = 0.1. In the 1990's, with the introduction of vitreous surgery 5/16 eyes (31%) had a vision of > or = 0.1. Four patients (7%) had blinding eye disease in the partner eye, and three (5%) had a second open-globe trauma., CONCLUSIONS: In rural regions, with cattle breeding,

open-globe injuries by cow horns are relatively common and the frequency is still the same as 50 years ago. The visual prognosis of these eyes is still guarded, but functional results have improved with the introduction of vitreous surgery. Patients who have had a rupture of the globe appear to have an increased risk for partner eye trauma. Therefore, all efforts are justified to preserve even limited vision in severely injured eyes.

2250. Helling, E. and A. J. McKinlay (2005). "Considerations for the head-injured air-evacuated patient: a case report of frontal sinus fracture and review of the literature." Military medicine **170**(7): 577-579.

Head and neck injuries are not uncommon in combat environments and may be increasing due to survivable injuries from the use of kevlar helmets and body armor. With the current capability of rapid evacuation from the battlefield, acutely injured patients with frontal sinus injuries may undergo further barometric challenges. Proper care during transport can prevent the occurrence of secondary injury (increased intracranial pressure, tension pneumocephalus) that would complicate the patient's management at the next level of care. Management principles (importance of low-level flight/pressurized cabin, preflight use of decongestants, avoidance of valsalva, and ability to manage complications either procedurally or by landing) are reviewed. In addition, we propose a simple mechanism for pressure equilibration of a compromised frontal sinus during air evacuation using an angiocatheter placed through the wound before closure.

2251. Helling, T. S., et al. (1992). "The role of early surgical intervention in civilian gunshot wounds to the head." The Journal of trauma **32**(3): 398-400.

Surgical management of gunshot wounds of the head has remained a controversial issue in the care of civilian patients. In an attempt to determine who might benefit from aggressive surgical intervention, we examined 89 patients over a 3-year period who had suffered cranial gunshot wounds and had at least one computed tomographic scan of the head after admission. Patients were divided into those receiving early (less than 24 hours) surgical intervention (ES, n = 27), late (greater than 24 hours) surgical intervention (LS, n = 6) or no surgical intervention (NS, n = 56). Overall mortality was 63%. Ten of 27 patients (37%) in the ES group died compared with 46 of 56 patients (82%) in the NS group (p less than 0.0001). Glasgow Coma Scale (GCS) scores in the ES group averaged 7.86 +/- 4.72 and in the NS group 5.59 +/- 4.42 (p less than 0.05). The GCS scores in the LS group (all of whom survived) were significantly higher than those of the other two groups, 12.17 +/- 4.10. The number of patients with GCS scores of 3 or 4 on admission was significantly less in the ES (41%) than in the NS group (66%, p = 0.035) and survival was better with surgery (36%) than without (3%, p = 0.007). Patients with mass lesions (clot, ventricular blood) were more often found in the ES group (17/27) than in the NS group (18/56) (p = 0.008). Patients with bihemispheric injuries fared better with surgery (7 of 14 survivors) than without (2 of 33 survivors, p = 0.0003). Only one infectious complication (brain abscess) was encountered in the LS group. No delayed intracranial complications in survivors in the NS group were seen.(ABSTRACT TRUNCATED AT 250 WORDS)

2252. Helmick, K., et al. (2012). "Traumatic brain injury: next steps, research needed, and priority focus areas." Military medicine **177**(8 Suppl): 86-92.

Traumatic brain injury (TBI) has been not only a major focus of concern during the recent conflicts in Afghanistan and Iraq, but also among our garrison service members. The prevalence of these injuries has compelled the nation and Congress to invest in the development of policies and programs that support evidence-based care for the full continuum of TBI, from mild (otherwise known as concussion) to severe and penetrating brain injuries. Although, the Department of Defense has made great strides in the areas of TBI clinical care, education, and research, there remains a great need to leverage scientific, policy, and clinical advancement to maximize care of the service member. The purpose of this article is to outline the 7 major areas of work currently being undertaken to help advance the field of TBI. The 7 areas include: (1) eliminating undetected mild traumatic brain injury through prompt early diagnosis, (2) ensuring force readiness and addressing cultural barriers, (3) improving collaborations with the Department of Veterans Affairs, other federal agencies, and academic and civilian organizations, (4) improving deployment-related assessments, (5) deploying effective treatments, (6) conducting military-relevant and targeted research, and (7) enhancing information technology systems.

2253. Helmick, K. M., et al. (2015). "Traumatic brain injury in the US military: epidemiology and key clinical and research programs." Brain imaging and behavior **9**(3): 358-366.

Traumatic brain injury (TBI), and particularly concussion, is a major concern for the U.S. Military because of the associated short term disability, long term cognitive and pain symptoms suffered by some, and risk of prolonged or permanent neurologic injury if the Service member incurs a second TBI before full recovery from the first. Concussions were seen more often during the recent conflicts in Afghanistan and Iraq than in prior conflicts, such as the Vietnam War, because of the use of improvised explosive devices that typically caused non-penetrating closed head injury. Since 2000 more than 300,000 Service members were diagnosed with TBI, of which more than 80 % were concussions. Improved TBI screening tools also have identified a higher than expected incidence of concussions occurring in garrison. In this review we summarize current epidemiologic data for TBI in the Military, and describe contemporary Military procedures and strategies for TBI prevention, identification, evaluation, and acute and chronic care. Key TBI clinical research priorities and programs are described, and innovative organizational plans to address future TBI needs are summarized.

2254. Helmy, A. (2017). "Neuroinflammation in traumatic brain injury." British journal of neurosurgery **31**(2): 128-129.

Trauma is an everyday part of the life of every surgeon. Specifically, Traumatic Brain Injury (TBI, head injury) is the cause of death in half of all cases of trauma mortality. TBI is a complicated disease with several interacting facets of injury including disrupted metabolism, excitotoxicity, loss of cerebral autoregulation and increased intracranial pressure. Current treatments have focussed on promoting physiological stability to avoid further 'secondary' injury rather than dealing with the underlying injurious processes. Until recently, the brain was incorrectly thought to be immunoprivileged. In fact, inflammation plays a key role following TBI. Cytokines and chemokines are important mechanistic drivers of the pathological processes that occur after TBI and are therefore potential therapeutic targets. As well as the role of inflammation in the acute injury following TBI, there is also increasing evidence that inflammation has a role in some of the late complications of TBI such as pituitary dysfunction, epilepsy and depression. There is an increasing recognition that as the physiological response to injury, inflammation is in fact a key mechanism in TBI and brain injury in general. Our work has focussed on exploring the underlying mechanisms that are responsible for neuronal damage and death after TBI. Our TBI patients are routinely monitored with a microdialysis catheter in order to measure a wide range of soluble mediators. In the clinical setting, metabolic intermediaries such as glucose, lactate and pyruvate are used to infer the metabolic state of the brain. The same microdialysis technique, can be expanded to recover a wide range of other molecules in a research setting. We have used microdialysis to systematically characterise the inflammatory response to TBI in the human brain over several days following injury. Cytokines and chemokines carry out a range of functions including recruiting and activating inflammatory cells, biasing them towards certain functions such as promoting inflammation versus repair as well as having direct effects on neurones. Evidence from animal models suggests that these inflammatory molecules provide a link between the deforming force applied to the brain at the time of injury and wide range of injurious processes that follow. All previous studies of neuroprotective drugs in TBI have failed, despite promising pre-clinical studies: the complex reasons behind this include understanding the biology of TBI in humans, determining whether a drug penetrates the blood brain barrier in a timely fashion and ultimately determining whether it has any biological effect. To address these issues we have carried out a randomised control trial of a potential neuroprotective agent, Interleukin-1 Receptor Antagonist, together with microdialysis monitoring to show that the drug crossed the blood brain barrier and is able to modify the inflammatory response to TBI. This paradigm is a promising model for future research in brain injury that combines an assessment of the biological processes that cause injury with a pharmacokinetic assessment to optimise therapeutic drug dosage and delivery. In this way, a new front has been opened up in our search for new therapies for this devastating and deadly condition.

2255. Helmy, A., et al. (2014). "Recombinant human interleukin-1 receptor antagonist in severe traumatic brain injury: a phase II randomized control trial." Journal of cerebral blood flow and metabolism **34**(5): 845.

Traumatic brain injury (TBI) is the commonest cause of death and disability in those aged under 40 years. Interleukin-1 receptor antagonist (IL1ra) is an endogenous competitive antagonist at the interleukin-1 type-1 receptor (IL-1R). Antagonism at the IL-1R confers neuroprotection in several rodent models of neuronal injury (i.e., trauma, stroke and excitotoxicity). We describe a single center, phase II, open label, randomized-control study of recombinant human

IL1ra (rhIL1ra, anakinra) in severe TBI, at a dose of 100 mg subcutaneously once a day for 5 days in 20 patients randomized 1:1. We provide safety data (primary outcome) in this pathology, utilize cerebral microdialysis to directly determine brain extracellular concentrations of IL1ra and 41 cytokines and chemokines, and use principal component analysis (PCA) to explore the resultant cerebral cytokine profile. Interleukin-1 receptor antagonist was safe, penetrated into plasma and the brain extracellular fluid. The PCA showed a separation in cytokine profiles after IL1ra administration. A candidate cytokine from this analysis, macrophage-derived chemoattractant, was significantly lower in the rhIL1ra-treated group. Our results provide promising data for rhIL1ra as a therapeutic candidate by showing safety, brain penetration and a modification of the neuroinflammatory response to TBI by a putative neuroprotective agent in humans for the first time.

2256. Hemphill, J. C., 3rd, et al. (1999). "Endovascular therapy of traumatic injuries of the intracranial cerebral arteries." Critical care clinics **15**(4): 811-829.

Traumatic intracranial arterial injuries represent uncommon complications of both closed-head injury and penetrating head trauma. These injuries include arterial dissections, pseudoaneurysms, and fistulas, both direct and indirect. Although these lesions may be identified while still asymptomatic, they usually present in a delayed fashion with intracranial hemorrhage, focal cerebral ischemia, or, occasionally, severe epistaxis. Endovascular therapy has assumed a major role in the management of this diverse group of lesions. Embolization of pseudoaneurysms with balloons or detachable coils, the use of embolic particles for small arterial injuries, and large vessel occlusion with detachable balloons represent current treatment strategies that have evolved over the past three decades. Angioplasty and stent deployment may have a future role to play in the management of arterial dissection. Principles of neurologic critical care that minimize secondary brain injury are essential adjuncts in the management of these patients before, during, and after endovascular treatment.

2257. Henderson, V. W. (1987). "Outcome prediction after severe closed head injury in adults." Bulletin of clinical neurosciences **52**: 47-63.

Disability after severe closed head injury (CHI) differs from that of penetrating trauma or other causes of more focal cerebral damage, but its symptoms can be understood in terms of the pathophysiology and the usual pathology of CHI. Outcome can be quantified by means of specific, narrowly-defined measures, which may fail to reflect other serious sequelae, or by means of functional rating scales, which bear little logical relation to CHI pathophysiology and lump together patients with diverse deficits. The choice of appropriate intake measures of CHI severity in turn depends on which aspects of outcome are to be determined. As the cardinal symptom of CHI is altered consciousness, logical intake measures of CHI severity include measures of the depth and the duration of the abnormal state of consciousness. Confounding factors in outcome prediction include secondary complications of CHI, premorbid characteristics, and effects of acute and rehabilitative therapy. Most research has focused on functional outcome predictions based on simple intake measures obtained shortly after injury, but intake measures that permit accurate prediction of rehabilitation potential or of specific cognitive and behavioral outcomes are also needed.

2258. Hendricks, A. M., et al. (2013). "Screening for mild traumatic brain injury in OEF-OIF deployed US military: an empirical assessment of VHA's experience." Brain injury **27**(2): 125-134.

BACKGROUND: VHA screens for traumatic brain injury (TBI) among patients formerly deployed to Afghanistan or Iraq, referring those who screen positive for a Comprehensive TBI Evaluation (CTBIE)., METHODS: To assess the programme, rates were calculated of positive screens for potential TBI in the population of patients screened in VHA between October 2007 through March 2009. Rates were derived of TBI confirmed by comprehensive evaluations from October 2008 through July 2009. Patient characteristics were obtained from Department of Defense and VHA administrative data., RESULTS: In the study population, 21.6% screened positive for potential TBI and 54.6% of these had electronic records of a CTBIE. Of those with CTBIE records, evaluators confirmed TBI in 57.7%, yielding a best estimate that 6.8% of all those screened were confirmed to have TBI. Three quarters of all screened patients and virtually all those evaluated (whether TBI was confirmed or not) had VHA care the following year., CONCLUSIONS: VHA's TBI screening process is inclusive and has utility in referring patients with current symptoms to appropriate care. More than 90% of those evaluated received further VHA care and confirmatory evaluations were associated with significantly higher average utilization. Generalizability is limited to those who seek VHA healthcare.

2259. Hendrickson, S., et al. (2014). "Neurosurgical management of indirect brain injury in penetrating trauma: A stab in the right direction." Brain injury **28**(5-6): 726.

Introduction: Penetrating trauma is traditionally the domain of the vascular/general surgeon; however, focal ischaemic neurological consequences are amenable to neurosurgical intervention. This study presents two patients (one knife wound victim, one gunshot victim) who required emergency decompressive craniectomies for malignant middle cerebral artery infarcts following penetrating trauma not involving the head, brain or spine. Both cases describe unique injury patterns and are supported by novel radiological findings. Case description: The first patient was a 22-year old Caucasian male who received a single stab wound to the precordium, necessitating an emergency thoracotomy, release of cardiac tamponade and repair of myocardial lacerations. Two days post-operatively the patient was noted to have a left hemiparesis. A Computed Tomography (CT) scan revealed a large right middle cerebral artery (MCA) territory infarct, probably resulting from embolic left ventricular thrombus. He underwent an urgent decompressive craniectomy. The patient made an excellent recovery and returned to part time work 3 months post-injury. The second patient was a 56-year old male who received a shotgun wound to the right side of his neck. He was noted to have a dense left hemiplegia on admission. A CT scan subsequently demonstrated migration of one shotgun pellet into the MCA via the internal carotid, which resulted in a large right MCA territory infarct and radiological evidence of raised intracranial pressure. Similarly, this patient underwent an emergency decompressive craniectomy. The patient made a limited neurological recovery with a persistent left hemiplegia 4 months post-injury. Discussion: The benefits of decompressive craniectomy have been clearly demonstrated for malignant middle cerebral artery territory infarcts; however, there is limited literature on infarcts resulting from trauma. These cases demonstrate that the role of neurosurgery in a major trauma centre extends beyond the management of direct traumatic brain injury and that early intervention in embolic infarction secondary to trauma can improve outcome.

2261. Hengzhu, Z., et al. (2014). "A rare case of penetrating brain injury by crossbow in a 22-month-old child." Pediatric emergency care **30**(6): 421-423.

Nonmissile penetrating brain injuries are exceedingly uncommon among civilian population and are most often associated with inflicted injury. They show specific characteristics different from that of missile wounds. In this article, we describe a rare case of a 22-month-old child who experienced accidental penetrating head trauma caused by a crossbow. We document neuroimaging studies and review the management concerning this pathology. To our knowledge, this is the youngest survived case of penetrating brain injury by a crossbow with such radiological findings reported in the literature.

2262. Henion, A., et al. (2022). "Epilepsy Risk Factors in One Million Post-9/11 U.S. Veterans: Impact of Traumatic Brain Injury, Deployment and Physical and Mental Comorbidities." Brain injury **36**(SUPPL 1): 109.

Objectives: We examined predictors of epilepsy in over a million Post 9/11 Veterans. We hypothesized that individuals with epilepsy would be more likely to have a history of TBI or deployment, where blast-related injury/military exposures are common. We also evaluated other established risk factors for epilepsy including brain tumor, stroke, and other neurological conditions, as well as mental and physical health comorbidities. Methods: We compiled and merged Veterans Health Administration (VHA) (2002-2018) and Department of Defense health data (2000-2019) for Veterans who entered VHA care between 2002 and 2014. We identified epilepsy using convulsions/epilepsy specific ICD9/10 codes, and concomitant use of anti-seizure medications (ASM). We identified TBI severity using self-reports (VHA comprehensive TBI screening evaluation) and ICD9/10 codes. Mental and physical health comorbidities were identified using ICD9/10 codes before the index date (Epilepsy: date of the first ASM after epilepsy diagnosis or the first seizure date if there was no ASM use; No Epilepsy: first care in VHA plus mean time to epilepsy [978 days]). We used logistic regression to calculate adjusted odds ratios and their 95% confidence intervals presented as (AOR; 95% CI). Results: In this cohort (N = 1,055,873; mean age at index date = 34.6 years), 27,438 (2.6%) were veterans with epilepsy (VWE). Compared to those without epilepsy, fewer VWE were deployed (61% vs.71%) and more had TBI (39% vs. 18%). In

analyses controlling for demographics, and mental/physical health comorbidities, the odds of epilepsy were significantly lower for deployed (vs. non-deployed; 0.66; [0.63-0.69]). Odds of epilepsy were significantly higher for people with all levels of TBI severity compared to no TBI: mild TBI (1.49; 1.43-1.54), moderate/severe TBI (2.43; 2.31-2.56), or penetrating TBI (5.59; 5.15-6.08). Other strong predictors included brain tumor (17.24; 15.51-19.16), encephalopathy (6.03; 5.22-6.97), Alzheimer's disease or frontotemporal dementia (3.88; 2.81- 5.35), stroke (3.74; 3.58-3.91), Parkinson's disease (2.75; 2.2- 3.75), multiple sclerosis (2.53; 2.17-2.95), headache (2.32; 2.25-2.39), anoxic brain damage (2.17; 1.69-2.78) and cardiovascular disease (1.96; 1.89-2.04). Smoking history, opioid abuse, sedative abuse, and overdose were also significantly associated with epilepsy. Conclusions: As expected, TBI severity (including mild TBI) was significantly associated with epilepsy even after controlling for brain tumor and other neurologically related conditions. However, our hypothesis regarding deployment history as a risk factor for epilepsy was not supported, perhaps due to chronic physical and mental health conditions that preclude deployment. This is consistent with the finding that cardiovascular disease, smoking, overdose and opioid or sedative abuse were strong risk factors for epilepsy in this relatively young cohort. More sophisticated statistical models using longitudinal data (or extremely large observational cohort studies) are needed to better understand the interactions among TBI, deployment and chronic mental/physical comorbidities.

2264. Hennington, G., et al. (2011). "Effect of aerobic exercise on cortical activation and working memory following traumatic brain injury." Journal of Head Trauma Rehabilitation **26**(5): 435-436.

Introduction/Rationale TBI is on the rise in the active duty US military population and is frequently associated with impairments in working memory. Cortical regions currently considered to play a role in this system includes the dorsolateral prefrontal cortex (DLPFC), anterior cingulate (ACC) and precuneus (PreC). In animal and human models, these regions have shown improved levels of activity in human and animal models following aerobic exercise as well as improved cognitive performance. The aim of this study was to investigate changes in the cortical activity and working memory performance in three TBI survivors after following a 12 week aerobic exercise program. Method/Approach Three male subjects (mean age 39.6 ± 16.9) with severe, non-penetrating TBI (6.3 ± 5.0 years post-injury). Cortical activation was obtained using 3T fMRI during performance of a visual fixation condition (control), 0-back and 2-back conditions of the N-back working memory task. Scans were performed on 3 different days prior to and after a 12 week aerobic exercise program consisting of 3, 40 minute sessions per week. Analysis of changes in activation during the N-back task was performed using Brain Voyageur. Measurements of working memory were measured through the accuracy and reaction time on the N-back task. Results/Effects Following completion of the 12-week exercise program all 3 subjects demonstrated a decrease in the intensity of the caudal ACC and PreC and right DLPFC areas during the 0- back task compared to the control task. However, an increase in the intensity and voxel count in the left DLPFC was noted during the 0-back task compared to the 2-back task. In 2 of the subjects, an increase in the intensity of the ACC and the right DLFPC was also noted during the 2-back task when compared to the 0-back task. Conclusions/Limitations Participation in aerobic exercise resulted in significant changes in cortical activation in the ACC, PreC & DLPFC and working memory. This pilot study contributes to emerging evidence supporting the use of aerobic exercise following severe TBI and indicates the need for further research to determine if these findings exist in a larger population.

2265. Henry, B., et al. (2012). "Cerebral microdialysis and PtiO2 to decide unilateral decompressive craniectomy after brain gunshot." Journal of Emergencies, Trauma and Shock **5**(1): 103-105.

Decompressive craniectomy (DC) following brain injury can induce complications (hemorrhage, infection, and hygroma). It is then considered as a last-tier therapy, and can be deleteriously delayed. Focal neuromonitoring (microdialysis and PtiO2) can help clinicians to decide bedside to perform DC in case of intracranial pressure (ICP) around 20 to 25 mmHg despite maximal medical treatment. This was the case of a hunter, brain injured by gunshot. DC was performed at day 6, because of unstable ICP, ischemic trend of PtiO2, and decreased cerebral glucose but normal lactate/pyruvate ratio. His evolution was good despite left hemiplegia due to initial injury.

MATERIALS AND METHODS: Examples of defects including mandibular continuity defects, preprosthetic atrophic alveolar ridge deficiencies, traumatic defects, and maxillary clefts were included., RESULTS: All patients demonstrated osseous regeneration stimulated by rhBMP-2., CONCLUSION: rhBMP-2 is successful in regenerating bone in a variety of maxillofacial defects. In the future, rhBMP-2 will play a significant role in the treatment of bone deficiencies.

2268. Herman, T. E., et al. (1995). "Unrecognized retention of intraorbital graphite pencil fragments: the role of computerized tomography." Pediatric radiology **25**(7): 535-537.

Children with unrecognized intraorbital pencil fragments may come to attention because of surrounding abscess and granuloma formation, after a long delay, and may be suspected to have an intraorbital neoplasm. Two such patients are reported, with emphasis on CT findings. Recognition of the CT manifestations of intraorbital pencil fragments may allow a more conservative surgical intervention than that for presumed intraorbital neoplasm.

2269. Hermann, A. L. and A. Lecler (2021). "Post-traumatic retained foreign body in the cavernous sinus." Interdisciplinary Neurosurgery: Advanced Techniques and Case Management **23**.

The case of a post-traumatic organic foreign body incarcerated in the cavernous sinus is described herein. Trans-orbital post-traumatic foreign bodies are very rare and can present varying clinical features. The objective is to show the danger of this type of foreign body and to suggest a diagnostic approach using imaging.

2270. Hernandez, S., et al. (2020). "Endonasal resection of the cartilaginous eustachian tube with nasoseptal flap closure for refractory CSF fistula following previous mastoid and middle ear obliteration." Journal of Neurological Surgery, Part B Skull Base **81**.

Background: Lateral skull base approaches or previous temporal bone trauma can lead to persistent encephaloceles or CSF fistula despite appropriate management with mastoid obliteration and attempted occlusion of the bony eustachian tube through the middle ear space. These patient scenarios may present a reconstructive dilemma. Objective/Case Presentation: We present a challenging case of a young male with a remote history of penetrating injury to the lateral skull base. He had resultant cholesteatoma and encephalocele requiring transmastoid repair and obliteration with closure of the external auditory canal. He had persistent infectious complications and subcutaneous emphysema over the temporal scalp when blowing his nose, indicating a persistently patent eustachian tube. There was also some concern for intermittent CSF rhinorrhea on history and examination. Technique: A submucous resection and partial turbinectomy was first performed to facilitate appropriate exposure and uninarial two-handed technique. Cuts were designed around the torus, extending into the fossa of Rosenmuller posteriorly. The cartilaginous eustachian tube was then resected and surrounding mucosa meticulously removed. The remaining visible lumen was packed with Surgicel. An ipsilateral nasoseptal flap was then harvested and rotated for inset with excellent coverage. Care was taken to avoid covering any native mucosa as to avoid mucocele formation. Results: The cavity was carefully packed and the patient observed overnight. He has done well in the immediate postoperative setting with no recurrent subcutaneous emphysema and no evidence to suggest CSF rhinorrhea. Conclusions: Endonasal closure of the eustachian tube may be an option in cases of recalcitrant CSF fistula and infectious complications. Employing a vascularized septal flap ensures optimal wound healing and ample closure.

2271. Hernesniemi, J., et al. (1986). "[Can mortality in severe traumatic brain damage be generally reduced?]." Kann die Mortalitat bei schweren traumatischen Hirnschaden uberhaupt mehr reduziert werden? **47**(2): 99-104.

A total of 272 cases with fatal traumatic brain injuries were retrospectively analysed. 68% of the cases were outside of any form of therapy. Only the third of these fatal cases are ever seen by a neurosurgeon. In 12% of these fatal

cases the outcome might have been improved by an optimum diagnosis and therapy. Prevention of these severe head injuries seems to be the only potential therapy.

2272. Herrera, M. L., et al. (2021). "Intramuscular insulin-like growth factor-1 gene therapy modulates reactive microglia after traumatic brain injury." Brain research bulletin **175**: 196-204.

Reactive gliosis is a key feature and an important pathophysiological mechanism underlying chronic neurodegeneration following traumatic brain injury (TBI). In this study, we have explored the effects of intramuscular IGF-1 gene therapy on reactive gliosis and functional outcome after an injury of the cerebral cortex. Young adult male rats were intramuscularly injected with a recombinant adenoviral construct harboring the cDNA of human IGF-1 (RAd-IGF1), with a control vector expressing green fluorescent protein (RAd-GFP) or PBS as control. Three weeks after the intramuscular injections of adenoviral vectors, animals were subjected to a unilateral penetrating brain injury. The data revealed that RAd-IGF1 gene therapy significantly increased serum IGF1 levels and improved working memory performance after one week of TBI as compared to PBS or RAd-GFP lesioned animals. At the same time, when we analyzed the effects of therapy on glial scar formation, the treatment with RAd-IGF1 did not modify the number of glial fibrillary acidic protein (GFAP) positive cells, but we observed a decrease in vimentin immunoreactive astrocytes at 7 days post-lesion in the injured hemisphere compared to RAd-GFP group. Moreover, IGF-1 gene therapy reduced the number of Iba1+ cells with reactive phenotype and the number of MHCII + cells in the injured hemisphere. These results suggest that intramuscular IGF-1 gene therapy may represent a new approach to prevent traumatic brain injury outcomes in rats.

2273. Herring, C. J., et al. (1988). "Transcranial stab wounds: a report of three cases and suggestions for management." Neurosurgery **23**(5): 658-662.

Transcranial stab wounds are uncommon. Three such cases are presented. The severity of the wounds may vary from innocuous to devastating. Skull films are useful in delineating the depth of penetration. The presence of the knife blade in situ may make the computed tomographic scan impossible to perform or difficult to interpret. Cerebral angiography may be indicated if injury to a major cerebral vessel is suspected or if the patient suffers a delayed subarachnoid or intracerebral hemorrhage. Provided that the patient's clinical status indicates a positive prognosis, transcranial stab wounds should be explored surgically. The weapon should be removed in the operating room immediately before or at the time of operation.

2274. Herzog, M., et al. (2005). "[Injuries of the head and neck in suicidal intention]." Verletzungen des Kopfes und des Halses in suizidaler Absicht. **84**(3): 176-181.

BACKGROUND: Injuries of the head and neck with suicidal intention might create serious situations that require rapid and interdisciplinary treatment., METHODS AND PATIENTS: Twenty-seven patients with suicidal head and neck injuries were treated at the Department of oto-rhino-laryngology, head and neck surgery, University of Wurzburg/Germany, between 1991 and 2002. The medical histories were analyzed retrospectively., RESULTS: Twenty-three of them were male, 4 female. Mean age at time of attempted suicidal was 48 years (18 - 90). One patient was already treated for a psychiatric disorder. None of the patients had a suicidal attempt in the history. Nine patients suffered from a pharynx or larynx trauma after strangulation. Four out of seven patients with cutting or stabbing injuries showed a perforation of the upper airways. Nine patients had gunshot traumas, one of them with perforation of the pharynx. Thirteen patients underwent immediate endoscopy under general anaesthesia followed by a neck exploration in 3 patients. Six patients received a temporary tracheotomy. All patients were considered suicidal for the duration of stay in the ENT-department resulting in a permanent supervision. All patients were transferred to a psychiatric unit as soon as possible for further treatment. A statistically significant accumulation was observed during the last third of a year. Over the period of 11 years, suicidal injuries of the head and neck tend to occur more frequently., CONCLUSIONS: The presented study emphasizes the need of immediate surgical and intensive care treatment of patients with head and neck injuries due to suicide attempts as well as an adequate psychiatric supervision during as well as after the surgical treatment.

2275. Hess, U., et al. (2000). "[The radiological diagnosis of an intraorbital bullet projectile]." Radiologische Diagnostik eines intraorbitalen Geschossprojektils. **40**(4): 404-407.

Beside conventional X-ray examination, ultrasound and computer tomographic examination are accepted radiologic techniques to assess the extend of damage of intraorbital injuries. With the exception of a few reports in the literature there is agreement that intraorbital metallic foreign bodies and gun-shot bullets represent a contraindication for magnetic resonance (MR) imaging examination because of artificial imaging side effects and the potential of secondary dislocation of the metallic foreign body due to ferromagnetism. By means of the case reported here it is shown that this general opinion is not universally valid. Depending on the elemental metallic composition of foreign bodies and gun-shot bullets it is demonstrated that MR examination allows high-resolution illustration and in some cases is advantageous compared with other radiologic imaging techniques.

BACKGROUND: Small metallic foreign bodies may easily be identified by conventional x-ray. The Comberg shell is a useful tool to discriminate between extra-respectively intraocular localization of the foreign body. However, poor results are common when evaluating the x-ray films., METHODS: We have improved evaluation of the radiographs by means of a program for a personal computer, regarding the following aspects: To avoid errors of measurement the relevant points of the radiograms are read by a digitizer-tableau. The different projection failure of the lateral respectively posteroanterior x-ray is calculated separately. For the calculation of the modell the true axial length of the eye is considered., CONCLUSION: A three dimensional image from varying points of view gives an instructive impression of the foreign body and its relation to structures of the eye. Handling of the presented computer program is easy. It standardizes analysis of the Comberg radiograms.

2278. Hesselink, L., et al. (2020). "New automated analysis to monitor neutrophil function point-of-care in the intensive care unit after trauma." Intensive Care Medicine Experimental **8**(1).

Background: Patients often develop infectious complications after severe trauma. No biomarkers exist that enable early identification of patients who are at risk. Neutrophils are important immune cells that combat these infections by phagocytosis and killing of pathogens. Analysis of neutrophil function used to be laborious and was therefore not applicable in routine diagnostics. Hence, we developed a quick and point-of-care method to assess a critical part of neutrophil function, neutrophil phagosomal acidification. The aim of this study was to investigate whether this method was able to analyze neutrophil functionality in severely injured patients and whether a relation with the development of infectious complications was present. Results: Fifteen severely injured patients (median ISS of 33) were included, of whom 6 developed an infection between day 4 and day 9 after trauma. The injury severity score did not significantly differ between patients who developed an infection and patients who did not ($p = 0.529$). Patients who developed an infection showed increased acidification immediately after trauma ($p = 0.006$) and after 3 days ($p = 0.026$) and a decrease in the days thereafter to levels in the lower normal range. In contrast, patients who did not develop infectious complications showed high-normal acidification within the first days and increased tasset to identify patients at risk for infections after trauma and to monitor the inflammatory state of these trauma patients. Conclusion: Neutrophil function can be measured in the ICU setting by rapid point-of-care analysis of phagosomal acidification. This analysis differed between trauma patients who developed infectious complications and trauma patients who did not. Therefore, this assay might prove a valuable asset to identify patients at risk for infections after trauma and to monitor the inflammatory state of these trauma patients. 2279. Hessler, C., et al. (2012). "[Fatal crossbow injury in an adolescent]." Todliche Armbrustverletzung im Jugendalter. **229**(3-4): 90-95.

The authors present the case of a 14-year-old boy who died while handling a crossbow, which was a gift from a friend's mother. The bolt passed through the right nostril, penetrated the sinus sphenoidalis, the brain stem, the left occipital lobe and the occipital calvaria. Immediately after the accident, the victim was taken to a maximum care hospital. In spite of neurosurgical treatment and intensive care the victim died 4 days later. The case presented demonstrates that crossbows are not suitable as toys for underage persons, as they are deadly weapons which can cause serious penetrating injuries. In Germany, no license is required to buy and/or possess crossbows. In the authors' opinion, legal restrictions on the sale of crossbows and a special training of the users would be reasonable measures to reduce such accidents.

2280. Hettige, S., et al. (2010). "Chopstick injury penetrating the skull base: A case report." Skull Base **20**(3): 219-222.

We describe an unusual case of a foreign body penetrating the skull base and lodging in the posterior fossa. A 38-year-old woman fell onto a chopstick while eating, causing it to impact into her mouth. The chopstick penetrated the oropharynx and the occipital bone via the jugular foramen to enter the posterior fossa intracranially, piercing the tentorium cerebelli and leaving a fractured tip in the occipital lobe. Three-dimensional reconstructive computed tomographic scans were obtained to view the trajectory and position of the chopstick. Reconstructed angiography revealed the proximity of the carotid artery and the jugular vessels to the foreign object. Safe access to the chopstick was via an occipital craniotomy to retrieve the distal portion and an ipsiplateral retrosigmoid craniectomy to remove the proximal end. Provision was made to gain proximal control of all major nearby vessels in the event of any hemorrhage. Trauma causing penetration of a foreign body into the posterior fossa of the skull is rare due to its surrounding thick bone. Appropriate preoperative planning, including 3-D computed tomographic images and angiograms, are integral in the surgical approach for the safe removal of such objects. 2281. Heuer, A., et al. (2016). "hESC-derived neural progenitors prevent xenograft rejection through neonatal desensitisation." Experimental neurology **282**: 78-85.

Stem cell therapies for neurological disorders are rapidly moving towards use in clinical trials. Before initiation of clinical trials, extensive pre-clinical validation in appropriate animal models is essential. However, grafts of human cells into the rodent brain are rejected within weeks after transplantation and the standard methods of immune-suppression for the purpose of studying human xenografts are not always sufficient for the long-term studies needed for transplanted human neurons to maturate, integrate and provide functional benefits in the host brain. Neonatal injections in rat pups using human fetal brain cells have been shown to desensitise the host to accept human tissue grafts as adults, whilst not compromising their immune system. Here, we show that differentiated human embryonic stem cells (hESCs) can be used for desensitisation to achieve long-term graft survival of human stem cell-derived neurons in a xenograft setting, surpassing the time of conventional pharmacological immune-suppressive treatments. The use of hESCs for desensitisation opens up for a widespread use of the technique, which will be of great value when performing pre-clinical evaluation of stem cell-derived neurons in animal models. 2286. Hickman, Z. L., et al. (2019). "Efficacy of seizure prophylaxis following complicated mild traumatic brain injury: A retrospective pilot study." Journal of neurosurgery **131**(1): 102.

Introduction: Complicated mild TBI (mTBI) is defined as GCS 13-15 with a head CT demonstrating a traumatic intracranial lesion (hemorrhage/contusion/edema) or depressed skull fracture. Studies investigating the necessity/efficacy of seizure prophylaxis following complicated mTBI to prevent post-traumatic seizures (PTS) are limited and guidelines for antiepileptic drug (AED) administration in these patients are lacking. We examined PTS incidence following complicated mTBI in patients that either received, or did not receive, seizure prophylaxis. Methods: A Level 1 trauma center database was retrospectively reviewed to identify consecutive subjects aged 15+ years that presented with complicated mTBI between Apr-Dec 2016. Exclusion criteria included a history of seizures; prior or penetrating TBI; neurological decline to GCS<13; need for invasive neurosurgical intervention. Demographic data was collected and prophylactic AED administration information was obtained, including AED type/dose/duration. Medical records were queried to determine the incidence of early/late PTS from in-hospital events and on follow-up. Data was analyzed using unpaired Student's t, Fisher's exact, or Chi square tests, as appropriate. Results: 86 consecutive complicated mTBI patients (mean age 58.7+/-2.3y, 62% male, mean GCS 14.8+/-0.1) were included in our cohort. 79.1% of patients received prophylactic AEDs, median AED duration was 8 days (range 1-98). There were no in-hospital PTS (0/86, 0%). For patients with 7+ days follow-up (n=62), the incidence of early PTS was 1.9% (1/52) in the AED group and 10.0% (1/10) in the no AED group (P=0.30). There were 3 late PTS in both the AED/no AED groups (4.4% versus 16.7%) (P=0.10). Overall PTS incidence was 8.1% (7/86). Conclusion: No patients in our cohort had an immediate PTS during their initial hospital visit. The early PTS rate was low (3.2%), but there was a non-trivial incidence of late PTS (8.1%). The incidence of both early/late PTS trended lower in patients that received prophylactic AEDs immediately after injury.

2287. Hida, K., et al. (1978). "[Brain abscess discovered 38 years after head injury (author's transl)]." No shinkei geka. Neurological surgery **6**(8): 811-813.

We reported a case of delayed brain abscess following a penetrating gun-shot injury. The brain abscess surrounding retained intracranial fragments of bone and shell was found 38 years after head injury. The patient's only symptom had been minimal weakness of the right arm. This case was treated surgically with good results. The long period of silent infection was discussed.

OBJECTIVE: To describe 3 cases of pneumolabyrinth after penetrating injury to the middle ear and to review previously reported cases, comparing precipitating factors and hearing outcomes., DATA SOURCES: Three cases we encountered and the PubMed and Japan Medical Abstracts Society databases., STUDY SELECTIONS: In addition to our 3 cases, we identified 48 cases from 41 articles regarding pneumolabyrinth. DATA EXTRACTIONS: All articles describing cases of pneumolabyrinth were used for this review., DATA SYNTHESIS: Among the 51 cases, audiologic evaluation was not available in 16 cases. In the remaining 35 cases, hearing outcomes were analyzed focusing on 3 factors: 1) differences in and interval until medical intervention, 2) existence of stapes lesions, and 3) extension of air bubble into the inner ear. We failed to find any significant differences in interventions, although operation less than 2 weeks after injury tended to be associated with a higher rate of hearing recovery (54%) than operation 2 weeks or longer after injury (25%). Furthermore, 11 (48%) of 23 cases with pneumolabyrinth limited to the vestibule or semicircular canals showed improved hearing, whereas none of 6 cases (0%) with pneumolabyrinth extending from the vestibular organs to the cochlea showed hearing recovery. This difference was statistically significant ($p < 0.05$)., CONCLUSION: Assessment of the location and extension of pneumolabyrinth appears important in predicting hearing outcomes and planning the management of middle and inner ear trauma.

2292. Hillered, L., et al. (2005). "Translational neurochemical research in acute human brain injury: the current status and potential future for cerebral microdialysis." Journal of neurotrauma **22**(1): 3-41.

Microdialysis (MD) was introduced as an intracerebral sampling method for clinical neurosurgery by Hillered et al. and Meyerson et al. in 1990. Since then MD has been embraced as a research tool to measure the neurochemistry of acute human brain injury and epilepsy. In general investigators have focused their attention to relative chemical changes during neurointensive care, operative procedures, and epileptic seizure activity. This initial excitement surrounding this technology has subsided over the years due to concerns about the amount of tissue sampled and the complicated issues related to quantification. The interpretation of mild to moderate MD fluctuations in general remains an issue relating to dynamic changes of the architecture and size of the interstitial space, blood-brain barrier (BBB) function, and analytical imprecision, calling for additional validation studies and new methods to control for in vivo recovery variations. Consequently, the use of this methodology to influence clinical decisions regarding the care of patients has been restricted to a few institutions. Clinical studies have provided ample evidence that intracerebral MD monitoring is useful for the detection of overt adverse neurochemical conditions involving hypoxia/ischemia and seizure activity in subarachnoid hemorrhage (SAH), traumatic brain injury (TBI), thromboembolic stroke, and epilepsy. There is some data strongly suggesting that MD changes precede the onset of secondary neurological deterioration following SAH, hemispheric stroke, and surges of increased ICP in fulminant hepatic failure. These promising investigations have relied on MD-markers for disturbed glucose metabolism (glucose, lactate, and pyruvate) and amino acids. Others have focused on trying to capture other important neurochemical events, such as excitotoxicity, cell membrane degradation, reactive oxygen species (ROS) and nitric oxide (NO) formation, cellular edema, and BBB dysfunction. However, these other applications need additional validation. Although these cerebral events and their corresponding changes in neurochemistry are important, other promising MD applications, as yet less explored, comprise local neurochemical provocations, drug penetration to the human brain, MD as a tool in clinical drug trials, and for studying the proteomics of acute human brain injury. Nevertheless, MD has provided new important insights into the neurochemistry of acute human brain injury. It remains one of very few methods for neurochemical measurements in the interstitial compartment of the human brain and will continue to be a valuable translational research tool for the future. Therefore, this technology has the potential of becoming an established part of multimodality neuro-ICU monitoring, contributing unique information about the acute brain injury process. However, in order to reach this stage, several issues related to quantification and bedside presentation of MD data, implantation strategies, and quality assurance need to be resolved. The future success of MD as a diagnostic tool in clinical neurosurgery depends heavily on the choice of biomarkers, their sensitivity, specificity, and predictive value for secondary neurochemical events, and the availability of practical bedside methods for chemical analysis of the individual markers. The purpose of this review was to summarize the results of clinical studies using cerebral MD in neurosurgical patients and to discuss the current status of MD as a potential method for use in clinical decision-making. The approach was to focus on adverse neurochemical conditions in the injured human brain and the MD biomarkers used to study those events. Methodological issues that appeared critical for the future success of MD as a routine intracerebral sampling method were addressed.

2293. Hilton, G. D., et al. (2004). "Neuroprotective effects of estradiol in newborn female rat hippocampus." Brain research. Developmental brain research **150**(2): 191-198.

Perinatal brain injury, consequent to hypoxic/ischemic events, is associated with the release of excess excitatory neurotransmitters, including glutamate. We have previously shown that administration of a glutamate receptor agonist, kainic acid (KA), to postnatal day 0 (PN0) and PN1 rats results in damage selective to the dentate gyrus of females. Pretreatment with the gonadal steroid estradiol prevents KA-induced damage to the female dentate gyrus. To begin to

elucidate the cellular mechanism of the neuroprotective effects of estradiol in neonatal females, we have employed the estrogen receptor antagonists Tamoxifen and ICI 182,780 in vivo and in vitro, respectively. Peripheral administration of Tamoxifen, which crosses the blood-brain barrier, prevented estradiol-mediated neuroprotection against KA-induced damage in the dentate gyrus. The highly selective estrogen receptor antagonist ICI 182,780, which does not penetrate into the brain from the periphery, also prevented estradiol's protective effects on KA-induced cell death in cultured hippocampal neurons but only late in the time course of injury. The data suggest that the neuroprotection afforded by estradiol against KA-induced injury in the female is estrogen receptor mediated but may include an additional mechanism that is not antagonized at the receptor.

2294. Hilton-Jones, D. and C. P. Warlow (1985). "Non-penetrating arterial trauma and cerebral infarction in the young." Lancet (London, England) **1**(8443): 1435-1438.

In a retrospective study of 60 patients under the age of 45 with ischaemic stroke the commonest likely predisposing factor was trauma, which applied to 13 (22%) patients. In 9 of these patients neck movement was the most likely factor that precipitated the stroke and was the factor identified in all the 3 who had damage to the vertebral artery. The other 4 patients had sustained direct trauma in the neck area, 2 as a result of attempted strangulation and 2 by carrying heavy loads on the shoulder. There may be a delay between the traumatic event and manifestation of the stroke, probably because the initial damage, which is most likely a small tear, is of no immediate consequence, and the stroke results after thrombus has formed over the tear and subsequently embolised.

2295. Hinderer, K. H. (1976). "Nasal problems in children." Pediatric annals **5**(8): 499-509.

Nasal problems in children are very common. The factors that affect the embryologic development have been discussed. Injuries that occur in prenatal, natal, and postnatal periods affect normal development. Prompt treatment of minor injuries is necessary to prevent airway problems later. The "wait and see" attitude toward nasal deformity is ill advised. X-ray findings are not conclusive, as the nasal pyramid in a child is largely cartilaginous. Obstructive nasal breathing can result in facial asymmetry, malocclusion, and cardiopulmonary problems. Allergy and sinusitis are frequently causes of obstruction.

2296. Hindman, H. B., et al. (2007). "Traumatic globe luxation and enucleation caused by a human bite injury." Ophthalmic plastic and reconstructive surgery **23**(5): 422-423.

A 55-year-old woman presented to the emergency room with complete loss of vision in the left eye after being bit in the face by her autistic grandson. She had a small upper eyelid laceration and an anophthalmic socket on the left side. A thorough history revealed that the bite had caused traumatic luxation of her globe, which had allowed the child to transect the optic nerve with his teeth. Careful attention was directed toward the prevention of retrograde infection in this unusual case of traumatic enucleation.

2297. Hink, A. B., et al. (2022). "Adolescent Suicide—Understanding Unique Risks and Opportunities for Trauma Centers to Recognize, Intervene, and Prevent a Leading Cause of Death." Current Trauma Reports **8**(2): 41-53.

Purpose of Review: This provides up-to-date epidemiology of adolescent suicide and risk factors for suicide and highlights the overlap of risks for suicide and injury. It reviews signs and symptoms, and the up-to-date evidence on screening for depression, post-traumatic stress disorder (PTSD), suicide, substance abuse, and lethal means, and offers strategies of implementation in trauma centers. Recent Findings: The incidence of adolescent suicide has continued to rise in the USA to 6.5 per 100,000, with notable racial disparities. The risk factors are complex, but many pre-existing risk factors and sequela after injury such as exposures to violence, suicidal behaviors, substance abuse, depression and post-traumatic stress disorder, and specific injuries including traumatic brain injury and spinal cord injury have further emerged as risks. Studies show rates of suicidality as high as 30% in the acute care setting. There are short screening instruments that can be used to universally screen for depression and suicidality in adolescent trauma patients. Step-up models of care for PTSD are promising to increase screening and services after injury. Lethal means counseling, secure firearm storage practices, and firearm safety policies can reduce the risk of suicide. Summary: Suicide is the second leading cause of death in US adolescents, and trauma patients have significant risk factors for mental illness and

suicidality before and after injury. Trauma centers should strongly consider screening adolescents, establish strategies for mental health support and referrals, and provide lethal means counseling to help prevent suicide.

2298. Hinkelbein, J., et al. (2007). "Local cerebral blood flow is preserved in sepsis." Current neurovascular research **4**(1): 39-47.

Sepsis is often complicated by encephalopathy, neuroendocrine dysfunction and cardiovascular autonomic failure. The cause of septic brain dysfunction is not fully understood. The aim of the present study is to explore whether septic brain dysfunction in a common septic model in the rat correlates with abnormalities either of local cerebral blood flow (LCBF) of defined brain areas or of whole brain blood flow (CBF). 45 male Wistar rats (320+/-13 g) were randomly assigned to a sepsis group (31 rats, cecal ligature and puncture, CLP) or a control group (14 rats, sham operation). Of these 45 rats, 16 rats were used for blood analysis; the remaining 29 rats were used for CBF/LCBF measurements. LCBF measurements were performed 24h after initial surgery using quantitative autoradiography with 4-iodo[N-methyl-(14)C]antipyrine, which allows to analyze CBF on a regional/local and global basis. In 42 different brain regions bilateral optical density measurements were performed. Septic rats (vs. control) presented tachycardia (507+/-37 vs. 452+/-44 min(-1), P<0.05), leukocytopenia (2.96+/-2.37 vs. 8.83+/-2.9710(9) x L(-1), P<0.05), hypocapnia (29.3+/-4.6 vs. 36.4+/-3.9 mmHg, P<0.05), and higher serum lactate concentrations (5.7+/-3.9 vs. 2.2+/-2.0 mmol x L(-1), P<0.05). LCBF of all 42 areas, as well as, CBF (116+/-59 vs. 115+/-52 m x 100 g(-1)min(-1), n.s.) did not differ. The results showed that severe sepsis (mortality rate of 43 %) did not induce alterations in mean CBF and LCBF. It is concluded that brain dysfunction is not reflected in changes of CBF during severe sepsis.

2299. Hiraishi, T., et al. (2009). "Unstable stenosis of the internal carotid artery caused by a craniofacial nail-gun injury-case report." Neurologia medico-chirurgica **49**(12): 590-593.

A 30-year-old carpenter suffered accidental piercing of his jaw by a 3-inch nail from a nail gun. No neurological deficits were found on admission. Computed tomography showed that the tip of the nail had reached the foramen lacerum. Cerebral angiography revealed severe stenosis at the C(4) portion of the left internal carotid artery (ICA) and marked decrease in the flow of the distal ICA. He had developed right hemiparesis and sensory aphasia by the following morning. T(2)-weighted and fluid-attenuated inversion recovery magnetic resonance imaging showed a focal hyperintense signal in the left central region indicating cerebral infarction. Repeat angiography demonstrated that the antegrade blood flow from the occluded point on the admission day had partially resumed, and endovascular trapping of the ICA was successfully carried out. The nail was then removed safely without problematic bleeding. The patient suffered no additional deficit, and his sensory aphasia and right hemiparesis gradually improved. The fluctuating blood flow through the unstable stenosis of the ICA related to nail movement possibly caused the delayed cerebral infarction. To avoid the occurrence of such events, rapid treatment after necessary investigations is recommended in patients with craniofacial penetrating injuries that affect the ICA.

2300. Hiraishi, T., et al. (2007). "[Delayed brain abscess after penetrating transorbital injury]." No shinkei geka. Neurological surgery **35**(5): 481-486.

We report a case of brain abscess caused by a penetrating head injury that occurred 9 years earlier. A 14-year-old girl presenting with fever, headache, and stiff neck was admitted to our hospital. She was diagnosed with aseptic meningitis and treated conservatively. Seven days after admission she became stuporous and showed left hemiparesis. Computed tomography (CT) revealed two ring-enhancing masses with perifocal edema in the right frontal lobe. We diagnosed brain abscess and performed right fronto-temporal decompressive craniectomy and stereotactic aspiration, followed by systemic antibiotic therapy. Post-surgery bone window CT revealed a well-defined, low-density foreign body passing from the left orbita to the right frontal lobe through the ethmoid sinus. We learned that the patient had been struck with a plastic chopstick in the left medial eyelid at the age of 5 years. No particular symptoms developed during the following 9 years. After the cerebral edema had diminished over the next 10 days, a second surgery was performed to remove the residual chopstick, repair the fistula at the base of the skull, and perform cranioplasty. The patient was discharged with only slight hyposmia after a 4-week course of antibiotics. This case showed that it is necessary to remove a residual foreign body and to close the dural fistula if there is a possibility of recurrent central nervous system infection. When a child presents with brain abscess, previous penetrating head injury should be considered.

2301. Hiramatsu, T. (2020). "Bullet fragments spontaneously migrating in opposite directions after a cardiac arrest treated with extracorporeal cardiopulmonary resuscitation following a gunshot wound to the head: A case report." Trauma case reports **28**: 100330.

Gunshot injuries to the head are associated with a poor neurological prognosis, have a high risk of mortality, and make the return of spontaneous breathing and circulation after cardiopulmonary arrest difficult. Bullets or bullet fragments can cause penetrating injuries to the brain tissue and sometimes remain in the skull, potentially migrating within the skull. Herein, we describe a rare patient who achieved a return of spontaneous circulation after cardiopulmonary (ROSC) arrest caused by a gunshot wound, following extracorporeal cardiopulmonary resuscitation. After ROSC, repeated computed tomography (CT) identified spontaneously migrating bullets/fragments in the right hemisphere and the metal fragment was excreted from the skull, while another fragment had moved from the left temporal to the occipital fossa. The patient died on the 15th day of hospitalization. The present case had a rare clinical course, suggesting that ROSC may be achieved under adequate respiratory and circulation management in cases of cardiac arrest with a head injury. The scans showed differing movements of the bullet fragments at each lesion, which was difficult to predict from the first CT scan. When surgical treatment is required to remove bullet fragments remaining in the skull (due to lead poisoning, or infection, among others), it may be useful to be aware that fragments may move in various directions, even out of the skull. Furthermore, we recognized the usefulness of CT scanning for detecting the location of the foreign body in cases of gunshot injury to the head. Copyright © 2020 The Author.

2302. Hirsch, M., et al. (1975). "Delayed hemopericardium following penetrating foreign body into the aorta." Pediatric radiology **3**(2): 111-113.

A four and a half year old girl with delayed appearance of traumatic hemopericardium, detected radiologically despite misleading clinical manifestations, is presented. The presence of cardiomegaly and a needle in the right upper mediastinum on the chest roentgenogram and its partial motion together with diminished cardiac pulsations at fluoroscopy led to angiocardiography. The radiological demonstration of hemopericardium due to the needle penetrating the aortic root, enabled successful surgical intervention.

2303. Hirsch, S. A. (1978). "Cervicofacial actinomycosis following surgical trauma in rats." Oral surgery, oral medicine, and oral pathology **46**(6): 827-830.

Cervicofacial actinomycosis in man is often associated with physical trauma. The presence of intrabony abscesses in rat mandibles following surgical trauma supports the clinical observation that antecedent trauma is an important factor in the pathogenesis of cervicofacial actinomycosis.

2304. Hitchcock, E. and R. Cowie (1983). "Stereotactic removal of intracranial foreign bodies: review and case report." Injury **14**(5): 471-475.

A 13-year-old boy presented himself with an airgun injury with a track from an entry wound in the left temporal region to the right thalamic pulvinar. The patient made a good recovery following stereotactic removal of the pellet. The literature is reviewed and the indications for stereotactic removal of intracranial foreign bodies discussed.

2305. Hobson, H., et al. (2018). "Language and alexithymia: Evidence for the role of the inferior frontal gyrus in acquired alexithymia." Neuropsychologia **111**: 229-240.

The clinical relevance of alexithymia, a condition associated with difficulties identifying and describing one's own emotion, is becoming ever more apparent. Increased rates of alexithymia are observed in multiple psychiatric conditions, and also in neurological conditions resulting from both organic and traumatic brain injury. The presence of alexithymia in these conditions predicts poorer regulation of one's emotions, decreased treatment response, and increased burden on carers. While clinically important, the aetiology of alexithymia is still a matter of debate, with several authors arguing for multiple 'routes' to impaired understanding of one's own emotions, which may or may not result in distinct subtypes of alexithymia. While previous studies support the role of impaired interoception (perceiving bodily states) in the development of alexithymia, the current study assessed whether acquired language impairment following traumatic brain injury, and damage to language regions, may also be associated with an increased risk of

alexithymia. Within a sample of 129 participants with penetrating brain injury and 33 healthy controls, neuropsychological testing revealed that deficits in a non-emotional language task, object naming, were associated with alexithymia, specifically with difficulty identifying one's own emotions. Both region-of-interest and whole-brain lesion analyses revealed that damage to language regions in the inferior frontal gyrus was associated with the presence of both this language impairment and alexithymia. These results are consistent with a framework for acquired alexithymia that incorporates both interoceptive and language processes, and support the idea that brain injury may result in alexithymia via impairment in any one of a number of more basic processes. 2306. Hoey, A., et al. (2022). "Delayed-Onset Seizures Following Self-Inflicted Nail Gun Injury to the Head: A Case Report and Literature Review." Journal of neurological surgery reports **83**(2): E54-E62.

Nail gun use and its associated incidence of injury have continued to increase since it was first introduced in 1959. While most of these injuries involve the extremities, a subset of patients suffer intracranial trauma. The most recent comprehensive review on this particular subject referenced 41 cases and advocated for further discussion regarding proper treatment plans for these individuals. We present the case of a 25-year-old who suffered 35 self-inflicted penetrating head wounds from a nail gun after suffering an amputation injury at his job site. No neurological deficits were present on his arrival to the emergency room. He underwent surgery to treat his arm wound and remove 13 of the 35 nails. The patient was discharged from the hospital on levetiracetam and made a full recovery. Nearly 1 year later, he experienced a seizure at his workplace. However, after resuming his antiepileptic medication, he reports no further complications. This case is distinct for not only being the most nails in a patient's head at presentation, but also following surgery. Utilizing this case, prior review, and 27 subsequent cases, we propose an updated algorithm for diagnosis and treatment of nail-gun-related penetrating head trauma.

2307. Hofbauer, M., et al. (2010). "Predictive factors influencing the outcome after gunshot injuries to the head-a retrospective cohort study." The Journal of trauma **69**(4): 770-775.

BACKGROUND: Civilian gunshot injuries to the head are relatively rare in the irenical European Union, and studies of treatment and outcomes are seldom for this region in the current literature., METHODS: A cohort of 85 patients with civilian head gunshot injuries, who were admitted to our University hospital over a period of 16 years, was reviewed retrospectively. Clinical manifestation, computed tomography scan findings, and surgical treatment were described, with special regard to prognostic factors and outcome., RESULTS: The mean age was 48 years (range, 17.8-98.4 years), and 87% were men. Sixty patients sustained penetrating craniocerebral injuries (P-group) and 25, nonpenetrating gunshot wounds (NP-group). The overall mortality was 87% in the P-group and 4% in the NP-group. The Glasgow Coma Scale (GCS) score at admission was recorded to be 3 to 5 in 58 patients (96%) and 7 patients (28%) in the P-group and NP-group, respectively. Only 8 patients (13%) survived in the P-group compared with 24 patients (96%) in the NP-group. Excluding wound debridement, there were 16 surgical procedures in the P-group and 8 in the NP-group, with a mortality rate of 63% and 13%, respectively., CONCLUSIONS: Glasgow Coma Score at admission and the status of pupils and hemodynamic situation seem to be the most significant predictors of outcome in penetrating craniocerebral gunshot wounds. Computed tomography scans, bi- or multilobar injury, and intraventricular hemorrhage were correlated with poor outcome. Patients with a GCS score >8, normal pupil reaction, and single lobe of brain injury may benefit from early aggressive management.

2308. Hoff, S. F. (1986). "Lesion-induced transneuronal plasticity in the adult rat hippocampus." Neuroscience **19**(4): 1227-1233.

The process of reactive synaptogenesis has been demonstrated in several areas of the central nervous system, including the hippocampal dentate gyrus. After a complete unilateral entorhinal lesion, approximately 85% of the input to the outer two-thirds of the ipsilateral dentate molecular layer is lost. Bilateral fluctuations in synaptic density within non-denervated zones of the dentate molecular layer predict further alterations in neural circuitry at sites located transneuronally to the denervated dentate granule cells. Using quantitative electron microscopy, our study demonstrates a complete cycle of synapse loss and reacquisition within the ipsilateral but not contralateral CA4/hilus region of the hippocampal formation. This area is one of the terminal fields for the dentate granule cell mossy fiber axons. In addition the granule cell mossy fiber axons sprout during the postlesion time course and form a significantly increased number of new mossy fiber terminals within the ipsilateral and contralateral CA4/hilus area. Our results

indicate that responses to brain injury may no longer be confined to a local denervated site, but probably include polyneuronal circuitry loops, which may encompass one or more areas of the central nervous system. Previous difficulties in providing a close behavioral or functional correlation to localized structural events may be explained by a more global brain response to an injury.

2309. Hoffman, J. F., et al. (2021). "Brain region- and metal-specific effects of embedded metals in a shrapnel wound model in the rat." Neurotoxicology **83**: 116-128.

The health effects of prolonged exposure to embedded metal fragments, such as those found in shrapnel wounds sustained by an increasing number of military personnel, are not well known. As part of a large collaborative effort to expand this knowledge, we use an animal model of shrapnel wounds originally developed to investigate effects of embedded depleted uranium to investigate effects of military-relevant metals tungsten, nickel, cobalt, iron, copper, aluminum, lead, and depleted uranium compared to an inert control, tantalum. Rats are surgically implanted with pellets of one of the metals of interest in the gastrocnemius (leg) muscle and tracked until 1 month, 3 months, 6 months, or 12 months from the time of implant, at which point they are euthanized and multiple organs and tissue samples are collected for inspection. Here we focus on four regions of the brain: frontal cortex, hippocampus, amygdala, and cerebellum. We examined changes in accumulated metal concentration in each region as well as changes in expression of proteins related to blood brain barrier tight junction formation, occludin and ZO-1, and synapse function, PSD95, spinophilin, and synaptotagmin. We report few changes in metal accumulation or blood brain barrier protein expression, but a large number of synapse proteins have reduced expression levels, particularly within the first 6 months of exposure, but there are regional and metal-specific differences in effects. 2310. Hoffmann, B. and A. Sepehrnia (2005). "Taylored implants for alloplastic cranioplasty--clinical and surgical considerations." Acta neurochirurgica. Supplement **93**: 127-129.

Traumatic loss of bone substance or post - decompression defects require the reconstruction of the skull. In cases of simple geometry there are handy, secure and cost effective procedures such as using autologuous cryopreserved bone flaps or polymerized Methylmethacrylat. For large sized defects CAD - taylored implants developed to provide a comfortable procedure to ensure high biocompatibility and perfect anatomical results by one - stage surgery. Furthermore cranioplasty does not only imply anatomical reconstruction but also functional recovery of awareness, cognition and motoric functions as shown in several studies according to changes in cerebral hemodynamics and metabolism. In our series of 286 patients who underwent cranioplasty during the past 10 years (1993-2003) we used taylored implants in 15 cases starting in 1999. All the patients included showed large sized defects > 64 cm2, complications did not occur neither during surgery nor the postoperative course, cosmetical results were excellent in all the patients. Neurological findings and the functional state improved in 11/15 patients, 4/15 patients showed no change, nevertheless these patients had reached a good recovery before surgery. Application of this technique is limited by cost, nonetheless it is recommended for extensive reconstruction of the skull.

2311. Hoffmann, C., et al. (2014). "Successful management of a severe combat penetrating brain injury." Journal of the Royal Army Medical Corps **160**(3): 251-254.

We report the case of successful management of a transcranial penetrating high-energy transfer injury in a 20-year-old soldier. The bullet traversed both cerebral hemispheres and lacerated the superior sagittal sinus rendering him unconscious. We detail the care received at all stages following injury from 'Buddy Aid' on the battlefield, resuscitation by a forward medical team through to prompt neurosurgery within 2 h of injury. Subsequent aeromedical evacuation and continuing aggressive critical care has allowed the patient to survive with acceptable neurological impairment after what is generally considered an unsurvivable injury. 2312. Hohenegger, M., et al. (1990). "Serum vasopressin (AVP) levels in polyuric brain-dead organ donors." European archives of psychiatry and neurological sciences **239**(4): 267-269.

Hydromineral metabolism and serum arginine-vasopressin (AVP) levels were investigated in 11 patients who sustained brain death. They showed various degrees of polyuria with low osmolality and low fractional sodium excretion. Urine osmolality was always below that of serum, and AVP levels were between 1.3 and 50.0 pg/ml vs 0.7-8.0 pg/ml in ten normal subjects. Thus central diabetes insipidus was excluded. A renal mechanism inducing water diuresis has to be assumed. The type of renal lesion, however, remains unclear.

2313. Hohl, A., et al. (2012). "Acute hypogonadism in male patients with severe traumatic brain injury." Endocrine Reviews **33**(3).

Objectives: The hypothalamic-pituitary axis may change in traumatic brain injury (TBI), with subsequent hypopituitarism(1,2). Late gonadotrophin deficiency after TBI has been demonstrated frequently: 1-32% (3,4). The present study evaluates the total testosterone and calculated free testosterone in male patients with severe TBI in acute phase and its relationship with mortality. Methods: We included 60 consecutive male patients with severe TBI (Glasgow Coma Scale score 8 or lower after acute neurosurgical resuscitation, or deterioration to that level within 48 hours of impact), admitted to the intensive care unit of the Hospital Governador Celso Ramos between April 2006 and April 2008. This is a public reference hospital for TBI covering a population of approximately 1 million, in the metropolitan area of Florianopolis, Brazil. Victims of gunshot injury and patients who evolved to brain death before 24 hours of admission were excluded. Total testosterone and SHBG (for calculation of free testosterone) were determined in blood plasma on the first, second, and third day after TBI (12, 30 and 70 hours after TBI, respectively). The study was approved by the ethics committee and the family responsible for the patient signed a consent form. Results: Of 60 male patients evaluated, the average age of patients was 35 years. Outcome for 40 patients survived and 20 died, during hospitalization (33.3%). The causes of TBI were traffic accidents (60%), fall (28%), aggression (6%) and others (6%). The mean total testosterone (normal range > 300 ng/dL) fell significantly from first to last evaluation: 438, 278 and 196 ng/dL, respectively. The same situation was observed with the calculated free testosterone (normal range > 6.5 ng/dL): 12.3, 7.9 and 5.0 ng/dL, respectively. Both analyzed hormones showed a high prevalence of abnormalities ranging from 36.5% of patients with low total testosterone in first sample up to 83.3% of cases with low total and calculated free testosterone in the last sample. However, there was no statistically significant difference between the group of patients who survived and those who died during hospitalization ($p \geq 0.13$). Conclusion s: Testosterone decreased progressively in the first 70 hours after severe TBI in male patients. A probable recovery occurs at a later period, since only a few of these men develop permanent hypogonadism. There was no relationship between levels of total and free testosterone and mortality among the patients studied.

2314. Hoit, D. A., et al. (2008). "Angiographic detection of carotid and vertebral arterial injury in the high-energy blunt trauma patient." Journal of spinal disorders & techniques **21**(4): 259-266.

BACKGROUND AND OBJECTIVE: Injury to the carotid and vertebral arteries is an identified risk to patients after blunt high-energy cranio-cervical trauma with an associated risk of thromboembolic stroke. We sought to determine the incidence, features, and risk factors of arterial injury using selective cerebral angiography in a high-risk trauma patient subset., METHODS: Blunt trauma patients with a high-energy mechanism were selected to undergo screening cerebral angiography if they met one of the following criteria: (1) cervical spine hyperextension/hyperflexion injury, (2) skull-base or facial fracture, (3) lateralizing neurologic deficit, ischemic deficit, or cerebral infarction, or (4) hemorrhage of arterial origin., RESULTS: Of 69 screened patients 20 were found to have a vascular injury (28.9%), including 13 carotid and 15 vertebral; 9 of the 20 patients with vascular injury were symptomatic (45%). The most frequent injuries were intimal dissections (8/28), pseudoaneurysms (6/28), and vessel occlusions (5/28); 8 lesions were intracranial and 20 cervical. Displaced facial fractures ($P<0.02$) but not skull-base fracture were predictive of carotid injury; multilevel cervical spine fractures ($P<0.001$) and transverse foraminal fractures ($P<0.02$) were associated with vertebral injury., CONCLUSIONS: Cerebral angiography in a selected group of trauma patients was found to yield a significant rate of carotid and vertebral arterial injury, a finding that had implications to subsequent clinical management.

2315. Hokl, J., et al. (2004). "Modality of brain death and serum troponin T levels in donors and their heart transplant recipients." Annals of transplantation **9**(3): 42-43.

Cardiac troponin T levels and inotropic requirements were assessed in the sera of 39 heart donors immediately before heart harvesting and, in their recipients, during the first two days after transplantation. In the donors who died of

cranial trauma (n=21), serum troponin T levels as well as inotropic support were lower (P<0.05 and P<0.025, respectively) than in the donors (n= 18) in whom death was caused by spontaneous intracranial haemorrhage. In the recipients, no differences in troponin T or inotropic support levels were found in relation to the modality of their donors' brain death.

2316. Holbrook, E. R. and J. Thompson (2013). "The longest journey is from the head to the heart." Journal of Investigative Medicine **61**(1): 178.

Case Report: Introduction Approximately 50% of intravascular missiles enter the venous circulation, and have the potential for central migration toward the heart.We present a case with embolization of a bullet from the head to the distal pulmonary bed. We then reviewed our own institutional experience and the world's literature to help determine the best treatment strategy for patients with projectile embolization to the pulmonary artery. Case Report: A 25-year-old male sustained a gunshot wound to the left eye. Computed tomography (CT) scan of the head disclosed rupture of the left globe and lens, complex fractures of the boney structures, and a 5 mm, well-circumscribed metallic foreign body consistent with a bullet fragment in the right superior aspect of the posterior fossa just caudad to the tentorium. Aside from the head injuries, there was no evidence of additional trauma. Soon after arrival to the emergency department, a right lateral ventricular external drain was placed into the calvarium. In order to monitor the progression of the cerebral injury, repeat CT scan of the head was performed a few hours later, and the bullet fragment was gone. Chest x-ray revealed a dense object in the region of the pulmonary artery that had not been present on the prior chest film. CT scan of the chest showed that the bullet fragment was now in the left lower lung field (figure 1). There was consolidation of the lung parenchyma in the area of the bullet fragment. Broad spectrum antibiotics that had previously been started were continued. Several days later, the patient was transferred to another institution for continued neurologic treatment. At the time of transfer the patient had no complications due to the retained bullet. Discussion: Review of our institution's medical record revealed two additional cases of bullet fragments having embolized from penetrating head injuries to the pulmonary arteries. Both patients were managed conservatively, and had no pulmonary sequelae at 2 years and 18 months respectively. Assessment of the world's literature demonstrates that controversy still exists as regards the need for and appropriate timing of extraction of projectiles that have embolized to the pulmonary circulation.

2317. Holds, J. B., et al. (1993). "Hydraulic orbital injection injuries." Ophthalmology **100**(10): 1475-1482.

BACKGROUND: A high-pressure stream from mechanical equipment may inject gas or liquids deep into the orbit with few initial clinical signs. Aggressive surgical debridement as used in the extremities for the treatment of injection injuries is not possible in the orbit., METHODS: Four patients with orbital injection injuries from farm or industrial equipment are presented. Previously reported cases of high-pressure injection injury are reviewed., RESULTS: Two patients suffered localized anterior orbital inflammation partially responsive to steroidal and nonsteroidal anti-inflammatory agents. Late debridement was required in one patient for a persistent lipogranuloma. Two patients suffered more dramatic and diffuse injections of hydrocarbon mixtures, requiring emergent early surgical debridement and decompression for compressive orbital signs. All patients attained an adequate functional outcome, with one patient's vision limited by a coexisting ocular injury., CONCLUSIONS: High-pressure orbital injection injuries manifest a spectrum of signs ranging from acute inflammation with tissue necrosis and compressive visual loss to late chronic inflammation with a pseudotumor-like course. The authors recommend the initial treatment of orbital injection injuries with systemic antibiotics followed by prompt neuroradiologic imaging. Systemic corticosteroids should be added for confirmed injection injuries with surgical debridement of discrete masses and orbital decompression when indicated. Continued therapy with anti-inflammatory medication may be required to suppress chronic inflammation with selective late surgical debridement of lipogranulomas.

2318. Holland, P., et al. (2004). "Should airguns be banned?" British journal of neurosurgery **18**(2): 124-129.

In this article, we express concerns regarding the availability of airguns, the injuries that they cause and their abuse as weapons of assault. We wish to stimulate debate on this topic and report a 5-year retrospective analysis of all airgun injuries to the head and neck, presenting to Alder Hey Children's Hospital, Liverpool, from June 1998 to June 2003. We identified 16 patients who suffered such injuries with ages ranging from 5 to 15 years. The majority of cases were violent assaults, which is not in accordance with previous published reports. All of these occurred in public places

outside the home. Most incidents occurred through the spring and summer period. Six patients required overnight stay in hospital. Nine patients required operative procedures to remove the airgun pellets. Two patients had serious eye injuries resulting in loss of vision. Two patients had penetrating neck injuries requiring exploration of the wound. The remaining group had either skin-penetrating injuries with lodgement of fragments in subcutaneous tissues or non-skin penetrating injuries. This study highlights serious injuries arising from the abuse of airguns as weapons of assault. Airguns are readily available to people without license. Recent legislation has increased the minimum age at which airguns can be carried in a public place, but we believe that stricter legislation is required to produce a reduction in the number of airgun-related injuries.

2319. Hollerhage, H. G. and G. Dorfmuller (1992). "[Extensive brain injury caused by attempted suicide with an airgun and ultrasound controlled removal of the deep intracranial projectile]." Ausgedehnte Hirnverletzung durch Suizidversuch mit Luftgewehr und ultraschallgestutzte Entfernung des tief intrakraniellen Projektils. **63**(10): 641-643.

A 65-year-old man attempted suicide by shooting himself in the right temple with an air-gun. There was no loss of consciousness. He remained neurologically asymptomatic. On plain x-rays, the pellet was found in the left frontal lobe and CT-scans revealed a vast cerebral injury with a large hematoma in the right frontotemporal region and along the bullet track. The entry wound was opened and the hematoma was evacuated after removal of small bone fragments and limited osteoclastic enlargement of the bullet hole under the view of the microscope. No attempt was made to remove the pellet through the bullet track in order to avoid additional injury to delicate frontal midline structures. A left frontal burr hole was made and a thin silastic tube, as used for ventricular drainage, was placed with its tip at the projectile under ultrasonic guidance. Along the tube, the pellet was removed through a 5 mm cortical incision with the use of the microscope. The postoperative course was uneventful, the patient had no neurological deficit and early postoperative CT-scans showed complete removal of the hematoma and the bullet without additional brain injury.

2320. Hollier, L., et al. (2001). "Facial gunshot wounds: a 4-year experience." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **59**(3): 277-282.

PURPOSE: Facial gunshot wounds can result in devastating functional and aesthetic consequences for patients. In an attempt to evaluate the management and outcome in these patients, a 4-year retrospective review was undertaken of all patients presenting with facial gunshot wounds at a level I trauma center., PATIENTS AND METHODS: A total of 121 patients were identified. Medical documentation could be obtained on 84 of those patients. The patients' maxillofacial injuries were treated by the 3 participating services: plastic surgery, oral and maxillofacial surgery, and otorhinolaryngology. The patients ranged in age from 6 to 64 years, with a mean age of 27 years., RESULTS: The gunshot wounds were single in 64% of the cases and multiple in 36% of the cases. Overall mortality in the series was 11%. Sixty-seven percent (56/84) of the patients suffered an injury to the underlying craniofacial skeleton. Seventy-five percent of these patients required surgical intervention. Twenty-one percent of the patients (16/75) required tracheostomy emergently for management of the airway. Eighteen percent (15/84) of these patients had an intracranial injury, with 50% of these patients requiring surgery. Fourteen percent of the patients in the series (12/84) had great vessel injuries diagnosed at the time of angiography, with 50% of these patients requiring surgery for treatment., CONCLUSION: Contrary to much of the published literature, most patients in this series required surgical intervention for treatment of their facial gunshot wounds. Reconstructive procedures were performed early in the patient's course and, when possible, addressed both the soft tissue and underlying bony injury in a minimum number of stages.

2321. Holmes, A. D. and K. A. Marshall (1979). "Use of the temporalis muscule flap in blanking out orbits." Plastic and reconstructive surgery **63**(3): 336-343.

We report the use of the temporalis muscle as a transposition flap to obliterate the orbit in 5 patients. In 4 of the cases we split the muscle coronally and passed the anterior part through a window in the lateral orbital wall. In two of these patients, skin grafts were put on both sides of the temporalis muscle-fascia flap, to restore nasal lining and to cover the facial surface simultaneously. In the remaining patients, the muscle was split sagittally to provide a large surface for coverage. The temporalis muscle flap is a versatile one for filling orbits after exenteration.

2322. Holmes, P.-J., et al. (2005). "Intraoperative imaging techniques: a guide to retrieval of foreign bodies." Oral surgery, oral medicine, oral pathology, oral radiology, and endodontics **100**(5): 614-618.

Foreign bodies are frequently introduced into the tissues of the head and neck by various mechanisms, and oral and maxillofacial surgeons are often called upon to retrieve these embedded objects. Retrieval may be quite challenging depending on many factors such as the size of the object, the location, and the surrounding anatomical structures. Preoperative imaging is very important in deciding upon the surgical approach. Computerized tomography is considered the gold standard for detection of foreign bodies because of the ability to localize an object in multiple planes and the creation of a 3-dimensional image. Difficulty arises when looking for a small object in an area with multiple important anatomical structures, such as the infratemporal fossa or the neck. Surgery can become tedious secondary to the risk of postoperative morbidity with injury to various anatomical structures. Foreign bodies in the head and neck are often difficult to manage even when a plan has been formulated from static preoperative images. Intraoperative feedback or guidance, especially when navigating through troublesome locations, can be extremely useful. In this paper, we report 2 cases and discuss the various modalities used for intraoperative imaging as a guide for surgical retrieval of foreign bodies.

2324. Holt, G. R. and J. E. Holt (1976). "Lacerations of the lacrimal apparatus, parotid duct, and facial nerve: case report." The Journal of trauma **16**(5): 414-419.

Diagnosis and surgical treatment of a male patient with severe facial lacerations involving the lacrimal duct, parotid duct, and buccal branch of facial nerve are presented. Careful wound care and localization of severed nerves and ducts, and repair under microscope are emphasized.

2325. Hon, K., et al. (2022). "A case report of blunt intraoral cerebrovascular injury in a child following intraoral trauma: The pen is mightier than the sword." Trauma case reports **37**.

Carotid artery dissection in the paediatric population is uncommon and in rare cases it can be due to intraoral blunt trauma associated with a stick-like object such as pen or chopstick in the mouth at the time of injury. Given the rarity of the condition, there is significant knowledge gap in evidence-based diagnosis and management of paediatric blunt cerebrovascular injury (BCVI). This case report presents a rare case of asymptomatic carotid artery dissection due to intraoral blunt trauma in a young patient and the successful conservative management. This report also demonstrated the sonographic progression of the carotid artery dissection on follow up imaging.

2326. Hon, K. L., et al. (2020). "Brain death in children: a retrospective review of patients at a paediatric intensive care unit." Hong Kong medical journal = Xianggang yi xue za zhi **26**(2): 120-126.

PURPOSE: Among patients in paediatric intensive care units (PICUs), death is sometimes inevitable despite advances in treatment. Some PICU patients may have irreversible cessation of all brain function, which is considered as brain death (BD). This study investigated demographic and clinical differences between PICU patients with BD and those with cardiopulmonary death., METHODS: All children who died in the PICU at a university-affiliated trauma centre between October 2002 and October 2018 were included in this retrospective study. Demographics and clinical characteristics were compared between patients with BD and patients with cardiopulmonary death., RESULTS: Of the 2784 patients admitted to the PICU during the study period, 127 died (4.6%). Of these 127 deaths, 22 (17.3%) were BD and 105 were cardiopulmonary death. Length of PICU stay was shorter for patients with cardiopulmonary death than for patients with BD (2 vs 8.5 days, P=0.0042). The most common mechanisms of injury in patients with BD were hypoxic-ischaemic injury (40.9%), central nervous system infection (18.2%), and traumatic brain injury (13.6%). The combined proportion of accident and trauma-related injury was greater in patients with BD than in patients with cardiopulmonary death (27.3% vs 3.8%, P<0.001). Organ donation was approved by the families of four of the 22 patients with BD (18.2%) and was performed successfully in three of these four patients., CONCLUSIONS: These findings emphasise the importance of injury prevention in childhood, as well as the need for education of the public regarding acceptance of BD and support for organ donation.

2327. Hon, K. L. E., et al. (2013). "Pediatric ICU mortality: Communicable or non-communicable diseases." Intensive care medicine **39**: S103-S104.

Objectives: We investigated the pattern of mortality at a PICU and explored if any unusual pathogens are associated with these deaths. Methods: Demographic data of all PICU deaths were analyzed. Results: There were 81 deaths (males 59 %; infants 25 %) over the 10-year period between 2002 and 2012. The mean annual mortality rate of PICU admissions was 5.7 %. Septicemia with common gram positive (commonest coagulase negative staphylococcus), gram negative (commonest pseudomonas) and fungal (commonest candida species) pathogens were present in 12 (15 %), 13 (16 %) and 5 (6 %) of these patients, respectively. Viruses (commonest CMV) were isolated in 20 patients (25 %). 91 % of these patients were ventilated, 73 % required inotropes, 91 % received broad spectrum antibiotic coverage, 31 % received systemic corticosteroids, 52 % blood transfusion and 38 % anticonvulsants. 36 patients (44 %) had a DNAR (Do-Not-Attempt-Resuscitation order) prior to their death at the PICU. Oncological diagnoses (n = 24) were predominant diagnoses. In the trauma category (n = 9), patients were more likely to present with cardiac arrest preceding ICU admission, and to have brain death subsequently. Trauma deaths typically affected healthy boys and not involving any pathogens. There was no gunshot or asthma death. Postmortem examination was performed in 30 % deaths. Conclusions: Death in the PICU is a heterogeneous event that involves infants and children of both genders. These patients may have a premorbid condition but healthy children are not spared. Infections are important associations only in non-traumatic PICU mortality. Nearly half of the patients did not receive active resuscitation against medical futility in honor of caregivers' wishes.

2328. Hong, K., et al. (2021). "Patterns of Pediatric Facial Fractures." Craniomaxillofacial Trauma and Reconstruction.

Objective: The aim of this study was to assess patterns of maxillofacial trauma in the pediatric population in Atlanta. This information is important to help guide management and allocate resources for treatment of maxillofacial injuries at Children's Healthcare of Atlanta (CHOA). Methods: This study was a retrospective chart review of children who presented from 2006 to 2015. Inclusion criteria were: (1) age 18 years old or younger, (2) presentation to emergency department, (3) diagnosis of maxillofacial fractures, and (4) evaluation by Oral and Maxillofacial Surgery, Otolaryngology, or Plastic Surgery services. Medical records were reviewed to record demographic, mechanism of injury, fracture location, and yearly incidence of injury. Descriptive statistics were computed to summarize findings and overall trends. Results: During the study period, 39,833 patients were identified. Of them, 1995 met the inclusion criteria. The majority were male (n = 1359, 68%) with an average age of 9.4 years old (range of 1 month to 18 years old). Mechanisms of injury were motor vehicle collisions (MVC) (n = 597, 29.9%), fall (n = 565, 28.3%), sports injury (n = 317, 15.9%), pedestrian struck (n = 215, 10.8%), assault/abuse (n = 204, 10.2%), other (n = 81, 4.1%), or gunshot wound (n = 16, 0.8%). Fracture sites were mandible (n = 519, 26%), complex (n = 479, 24%), nasal (n = 419, 21%), dentoalveolar (n = 279, 14%), orbital (n = 259, 13%), and maxilla (n = 40, 2%). Males had a higher incidence of assault than females (n = 185, 91% of assaults). The incidence of maxillofacial trauma increased with age with a peak incidence in 13 to 16-year-olds (n = 566, 28.3%). During the years examined, there was an upward trend in MVCs as the etiology with a peak incidence of facial fractures due to MVCs occurring in 2015. All other mechanisms remained constant during this time period. Conclusions: There was an increase in pediatric facial fractures secondary to motor vehicle collisions from 2007 to 2015 despite improvements in regulations, traffic safety, and technology.

2329. Hong, M. H., et al. (2017). "YH25448, a highly selective 3rd generation EGFR TKI, exhibits superior survival over osimertinib in animal model with brain metastases from NSCLC." Journal of Thoracic Oncology **12**(1): S1265-S1266.

Background: Currently-available EGFR TKIs are ineffective for the treatment of brain metastases (BrM) due to limited blood-brain barrier (BBB) penetration. YH25448 is a potent, highly mutant-selective and irreversible 3rd generation EGFR TKI that is able to penetrate the BBB, and targets both the T790M mutation and activating EGFR mutations while sparing wild type (wt). Methods: The biochemical and pharmacological activity of YH25448 were characterized through in vitro kinase assays, and functional cell assays. The animal model with brain metastases from NSCLC was established by implanting luciferase-transfected NCI-H1975 human NSCLC cells carrying the L858R/T790M mutation both subcutaneously and intracranially into nude mice. In this animal model, YH25448 was compared with osimertinib in terms of tumor growth inhibition, survival, weight loss and clinical signs. The correlation of PK profiles (plasma, CSF and tumor tissues) with biological activity using inhibition of EGFR phosphorylation (pEGFR) in the tumor tissue was evaluated. Results: YH25448 selectively inhibited EGFR single and double mutant kinase activity with IC50

values of 2 nM for L858R/T790M against 76 nM for wt-EGFR. In the cell proliferation assays, GI50 values were 6 nM, 5 nM, and 711 nM for H1975 cells (L858R/T790M), PC9 cells (del19) and H2073 cells (wt), respectively. In primary cancer cells from patients harboring EGFR mutations, YH25448 showed more potent inhibition of cancer cell growth compared to osimertinib. YH25448 treatment at the once-daily doses of 1-25 mg/kg resulted in dosedependent tumor regression in both subcutaneous and intracranial lesions in mice implanted with H1975 cells. Given its high selectivity against wild type and wide safety margin, there were no changes in body weight and no abnormal clinical signs. At 10-25 mg/kg, YH25448 achieved more significant, complete tumor growth inhibition and longer overall survival compared to same doses of osimertinib. Dose-dependent inhibition of pEGFR expression in tumor tissue by YH25448 treatment was well translated into the in vivo efficacy. Plasma half-life of YH25448 was 5.9-6.8 hr and tumor to plasma AUC0-last ratio was 3.0-5.1. YH25448 also showed excellent penetration of the BBB, achieving CSF concentrations exceeding the IC50 value for pEGFR inhibition. Conclusion: The strong in vitro potency and high selectivity of YH25448 for mutant EGFR translated into robust in vivo efficacy. These findings indicate that YH25448 will be able to address the urgent unmet needs for EGFR mutant-positive patients with brain metastases.

2331. Hoover, D. A. and A. Mahmood (2001). "Ossification of autologous pericranium used in duraplasty. Case report." Journal of neurosurgery **95**(2): 350-352.

Pericranium is frequently used in duraplasty and is considered superior to the many other alternatives because of its easy availability and because it offers a watertight dural closure while minimizing the problems of adhesion, infection, and rejection. Although the osteogenic potential of all periosteal tissues is recognized, a review of the literature did not reveal a reported case of osseous formation following use of pericranium for duraplasty. The authors report the case of a 17-year-old man who presented with a self-inflicted gunshot wound to the head. He was obtunded, but moving all extremities purposefully. Computerized tomography scanning demonstrated bifrontal injury. A bicoronal craniotomy with debridement was performed on an emergency basis, with vascularized pericranium used for a duraplasty. Follow-up cranioplasty demonstrated significant ossification of the pericranium 5 months after the original surgery. Pericranium is an attractive material for duraplasty; however, its osteogenic potential may interfere with future cranioplasty and cosmesis. This may be especially relevant in young persons.

2332. Hoppe, I. C., et al. (2014). "Pediatric facial fractures as a result of gunshot injuries: an examination of associated injuries and trends in management." The Journal of craniofacial surgery **25**(2): 400-405.

INTRODUCTION: Facial fractures are relatively uncommon in the pediatric population, especially those inflicted as a result of interpersonal violence in the form of gunshot injuries. Few studies have examined the unique management of such high-energy injuries in the pediatric population. Oftentimes the resultant damage to soft tissue and bony structures is so great that it challenges the previously accepted standards in the management of pediatric facial fractures. This study will examine a level 1 trauma center's experience with these unique injuries., METHODS: A retrospective review of all facial fractures occurring in a pediatric population (those 18 years of age or younger) as a result of gunshot wounds in a level 1 trauma center in an urban environment was performed for the years 2000 to 2012. Descriptive information was collected regarding each case as well as information regarding concomitant injuries, treatment modalities, and selected outcomes., RESULTS: During this time period, there were 3147 facial fractures treated at our institution, 353 of which were in pediatric patients. Of these, 17 were the results of gunshot wounds. Three patients were excluded due to insufficient data, leaving a total of 14 patients. The average age of patients was 16.5 (range 14-18); all patients were African-American males. The most common fracture was that of the mandible (n = 10), with 2 of those patients exhibiting panfacial fractures. The average Glasgow Coma Scale on admission was 13.5 (range 3-15). Six of the patients were intubated in the emergency department. The most common concomitant injury was a skull fracture (n = 3), followed by cervical spine fractures (n = 2) and intracranial hemorrhages (n = 2). All patients were admitted to the hospital for reasons other than fracture management. Seven patients ultimately went to the operating room for fracture management. The treatment modalities employed were conservative management with closed techniques (n = 11), rigid internal fixation (n = 2), and the use of an external fixator device (n = 1). Minimal to no soft-tissue debridement was performed in 10 of the 14 patients, 2 of which presented between 6 months and 10 years

post-injury with soft-tissue complications related to retained material. The mean hospital length of stay was 8.2 days (range 1-18 days). One patient expired., DISCUSSION: Pediatric facial fractures as a result of gunshot wounds represent a unique and fortunately rare entity that presents a challenge to all disciplines involved in treatment. In our patients, there was a tendency towards conservative management, with only 3 patients undergoing some form of fixation and only 7 undergoing some form of operative debridement. Concomitant injuries and the high-energy nature of gunshot wounds often preclude traditional management with rigid fixation to ensure adequate bony healing. However, it is important to adequately debride devitalized soft tissue and remove all foreign material to avoid future soft tissue-related complications.

2333. Horan, J., et al. (2019). "Transient Incomplete Locked-In Syndrome Secondary to Supratentorial Gunshot Wound." World neurosurgery **126**: 560-563.

BACKGROUND: Locked-in syndrome (LIS) is a rare neurologic disorder characterized as quadriplegia with anarthria. The diagnosis of LIS is challenging and requires a high index of suspicion. The syndrome is typically caused by an infratentorial lesion to the ventral pons, regardless of etiology. LIS secondary to supratentorial injury is extremely rare, and to our knowledge, this is the first reported case., CASE DESCRIPTION: We report the case of a 26-year-old woman who sustained a gunshot to the left suboccipital area, with supratentorial extension. A diagnosis of incomplete LIS was made on the day of admission, with eye movement preservation. Imaging studies confirmed bilateral injury of the motor homunculus. The clinical course was that of progressive improvement, aided by intensive care unit (ICU) supportive care and early physiotherapy rehabilitation. Her condition improved, and she was discharged to a rehabilitation facility at the end of week 7 postadmission., CONCLUSIONS: This is a unique case of incomplete LIS after supratentorial injury. Initial ICU care and early rehabilitation likely played a major role in the full recovery of this patient. The influence of etiology and site of injury on outcome prognosis is also suggested. Although severe diffuse brain injury may occur in the face of an unremarkable computed tomography (CT) scan, the emerging role of magnetic resonance imaging in optimally evaluating traumatic brain injury with discordant clinical and CT information is highlighted and is useful in cases of LIS where prognosis prediction is important.

2334. Hori, A. and H. Akiyama (2012). "Rare head trauma. Report 1: Gunshot wound." Neuropathology **32**(3): 328.

Seven autopsy cases of gunshot wound were analyzed in three groups. Group 1: Acute death (3cases), group 2: two subacute cases, and group 3: two survived cases and death through unrelevant diseases. In Group 1, multiple/diffuse cortical contusion lesions were found, probably due to peracute swelling of the brain by the flying bullet. Eosinophilic neuronal degeneration could be found at the perifocal area of the injury. The main finding in Group 2 was a bacterial infection. In Group 3, the lesion was not different from the conventional scar formation of the brain. Due to different chronological course of the individual cases, microglial and macroglial reaction was different from each other. This fact suggests the forensic usefulness of the chronological pathology.

2335. Horowitz, M. B., et al. (1999). "Multidisciplinary approach to traumatic intracranial aneurysms secondary to shotgun and handgun wounds." Surgical neurology **51**(1): 31-32.

BACKGROUND: Traumatic intracranial aneurysms (TICAs) may develop following gunshot injuries to the head. Management of these lesions often combines various aspects of microneurosurgical and endovascular techniques to safely repair or obliterate vessel defects., METHODS: We reviewed our experience over the last 18 years and identified five cases of intracranial aneurysms following gunshot and handgun wounds that were treated surgically and/or endovascularly., RESULTS: All patients had successful obliteration of their lesions using a variety of therapeutic modalities aimed at preserving neurologic function while at the same time eliminating the aneurysm from the circulation., CONCLUSION: Both microneurosurgery and endovascular surgery have important roles to play in the management of TICAs. In some cases, both methods can be combined to eliminate lesions and maximize patient recovery in a safe, efficient, and effective fashion.

2336. Horton, J. C., et al. (1996). "Confirmation by magnetic resonance imaging of optic nerve injury after retrobulbar anesthesia." Archives of ophthalmology (Chicago, Ill. : 1960) **114**(3): 351-353.

2337. Horvat, A., et al. (2001). "A novel role for protein tyrosine phosphatase shp1 in controlling glial activation in the normal and injured nervous system." The Journal of neuroscience : the official journal of the Society for Neuroscience **21**(3): 865-874.

Tyrosine phosphorylation regulated by protein tyrosine kinases and phosphatases plays an important role in the activation of glial cells. Here we examined the expression of intracellular protein tyrosine phosphatase SHP1 in the normal and injured adult rat and mouse CNS. Our study showed that in the intact CNS, SHP1 was expressed in astrocytes as well as in pyramidal cells in hippocampus and cortex. Axotomy of peripheral nerves and direct cortical lesion led to a massive upregulation of SHP1 in activated microglia and astrocytes, whereas the neuronal expression of SHP1 was not affected. In vitro experiments revealed that in astrocytes, SHP1 associates with epidermal growth factor (EGF)-receptor, whereas in microglia, SHP1 associates with colony-stimulating factor (CSF)-1-receptor. In postnatal and adult moth-eaten viable (me(v)/me(v)) mice, which are characterized by reduced SHP1 activity, a strong increase in reactive astrocytes, defined by GFAP immunoreactivity, was observed throughout the intact CNS, whereas neither the morphology nor the number of microglial cells appeared modified. Absence of (3)[H]-thymidine-labeled nuclei indicated that astrocytic proliferation does not occur. In response to injury, cell number as well as proliferation of microglia were reduced in me(v)/me(v) mice, whereas the posttraumatic astrocytic reaction did not differ from wild-type littermates. The majority of activated microglia in mutant mice showed rounded and ameboid morphology. However, the regeneration rate after facial nerve injury in me(v)/me(v) mice was similar to that in wild-type littermates. These results emphasize that SHP1 as a part of different signaling pathways plays an important role in the global regulation of astrocytic and microglial activation in the normal and injured CNS.

2338. Hosein, K. K., et al. (2013). "Engraftment of fetal cell transplants in rat model of penetrating brain injury-a “proof of concept” study." Journal of neurotrauma **30**(15): A90.

Introduction In the US, over 1.7 million traumatic brain injury (TBI) cases occur annually. Treatments to ameliorate chronic brain damage after severe TBI do not exist. The purpose of this study was to assess longitudinal survival of genetically modified fetal rat precursor cells transplanted into rat brains following penetrating ballistic-like brain injury (PBBI). Methods Male Sprague-Dawley rats were subjected to unilateral frontal PBBI (10% injury severity). Fetal cortical neural precursor cells (NPCs) were isolotated from D14 rat embryos and lentivirally doubletransduced to express green fluorescent protein and multineurotrophin (GFP/MNTS1). GFP/MNTS1-positive NPCs (400,000 cells in 4ll of stem cell media) were stereotactically microinjected into the injured penumbra. Animals were immunosuppressed with cyclosporine A for the duration of the study and perfusion-fixed at either 1, 6 or 8 weeks post-transplant. The brains were sectioned on a freezing microtome and processed for mature neuronal NeuN and glial GFAP markers using immunofluorescent labeling. Quantitative (unbiased stereology) and confocal microscopy was used to assess NPC transplant survival, neurite outgrowth, and phenotypic differentiation. Results The NPC transplants produced a robust graft spanning a millimeter square (mm2). Engrafted NPC neurite lengths were ∼150lm at 1 week post-transplant. However, by 8 weeks post they displayed elongated extensions out to ∼3 millimeters from the transplant site and showed maximal engraftment of the lesion site. Notably, numerous varicosities were observed on the dendritic processes of the transplanted cells, suggestive of synaptic densities on neurites. The majority of the grafted NPCs were NeuN positive while a few labeled ambiguously with GFAP. Unbiased stereology (calibrated to mean section 30 lm thickness) demonstrated an increase in the estimated population of surviving GFP-positive NPCs from 1 week (22,000) to 8 weeks post-transplant (∼42,000). The volume of the GFP signal increased ∼4-fold over the 8 weeks. Conclusions This pilot study suggests that PBBI brains are conducive to NPC transplants out to 8 weeks post-njury. In addition, the GFP/MNTSpositive NPC transplants survived well, exhibited a strong proliferative profile and a propensity towards a neuronal phenotype in response to severe TBI. Although the NPC transplants did not appear to be migratory, the prolific growth of the neurites and varicosities suggest a capacity for synaptic connections that warrants further investigation.

2339. Hoshide, R., et al. (2018). "Management of Through-and-Through Penetrating Skull Injury: A Railroad Spike That Transgressed the Anterior Skull Base." World neurosurgery **110**: 65-70.

BACKGROUND: Penetrating injuries involving foreign objects that transgress the entirety of the human skull present challenges in the management of vascular injuries, infectious risk, cerebrospinal fluid leak, and cosmetic repair. Ultimately, effective management of these injuries requires a multidisciplinary team and judicious surgical planning., CASE DESCRIPTION: Here we present the treatment of a patient who experienced a penetrating injury from a railroad

spike, with entry and exit points involving the left and right anterior aspects of the temporal fossa, respectively., CONCLUSIONS: The rationale for management decisions is reviewed in the context of the published literature.

2340. Hoshmand, M., et al. (2013). "Intraorbital foreign bodies: Diagnosis, management and imaging mimics." Emergency radiology **20**(5): 363.

Purpose/Aim: - Understand the clinical presentation of intraorbital foreign bodies (IOFBs) and importance of accurate diagnosis - Recognize the imaging features of different types of IOFBs mainly on computed tomography - Become familiar with the complications and ocular comorbidities associated with IOFBs - Learn about the surgical management of IOFBs - Recognize imaging mimics of IOFBs Background: Intraorbital foreign bodies are an important cause of ocular morbidity especially in the younger population. They may occur in various settings including high velocity injury such as gunshot wounds, from glass fragments or minor trauma such as wood stick or pencil penetration. Intraorbital foreign bodies may or may not be well tolerated based on the nature of the object. Surgical removal depends on the nature of IOFB, its location within the orbit, and associated injuries or complications. Content Organization: - Background - Learning objectives - Orbital foreign bodies - Metallic versus nonmetallic objects: Case-based demonstration - Surgical Indications and postoperative findings: Case-based demonstration - Complications: Discuss examples including infection, abscess, and fistula - Ocular comorbidities: Discuss and illustrate cases of IOFB comorbidities such as orbital bone fracture, globe rupture, and corneal and retinal hemorrhage, extraoccular muscle injury and optic nerve injury - Differential diagnosis: Cover imaging mimics of IOFBs such including surgical material, Drusen bodies, dislocated prosthetic lens, arcus senilis, and trochlear apparatus calcifications - Summary Summary/Conclusion: Computed tomography is the most sensitive imaging modality for detection of metallic and glass intraorbital foreign bodies. Dry wood is harder to detect on CTandmay be confused with air column. If there is a suspicion of wooden foreign body, MRI can be pursued if initial CT is negative. Organic foreign bodies are more likely to induce cellulitis and abscess. The type of foreign body and its location within the orbit guides surgical decisions. Entities that can mimic foreign bodies in the orbit include surgical devices, Dursen bodies, phthisis bulbi, arcus senilis and trochlear apparatus calcifications which have typical imaging characteristic that allow their differentiation from foreign bodies.

2341. Hossain, S., et al. (2016). "Prevalence of post-concussion symptoms in an Asian country; Base rates and the effects of mild traumatic brain injury." Brain injury **30**(5-6): 618-619.

Objectives: To develop a Bengali version of the Rivermead Post Concussion Symptom Questionnaire (RPCSQ) and use this in Bangladesh to ascertain base rates of symptoms in a normal sample and to investigate the effects of mild traumatic brain injury (MTBI), with a view to clarifying the aetiological basis of post-concussional symptoms. Methods: The Bengali RPCSQ was developed using backtranslation procedures; a 16-item checklist using a 5-point scale of symptom severity relative to previous status. Group results are typically expressed as the percentage symptomatic on a particular item. Four groups comprised 524 participants, 18 years of age or older with no history of neurological disorder, substance abuse or significant psychiatric disorder: Mild Traumatic Brain Injury (MTBI; n = 124, mean age = 34.2 years, 85% males), seen 7-14 days post-accident; Orthopaedic Patient Controls (PC; n = 84, age = 34.2 years, 81% males), seen 7-14 days post-accident; Normal Controls (NC; n = 272, age = 29.25 years, 67% males) with no recent history of accident or injury; Previous TBI (pTBI, n = 44, age = 27.6 years, 64% males) who were approached to be normal controls but were found to have had previous TBIs. Results: Cronbach's Alpha was 0.93, item-total correlations ranging from 0.31-0.81. Of the MTBI group 27% were illiterate or just literate. The mechanism of injury included assault (32%), struck by falling or flying objects (23%), pedestrian struck by a vehicle (23%) and accident while in a vehicle (19%). On average, 44% of the MTBI group and 42% of the PC group was symptomatic on each item. Both behavioural and cognitive symptoms were common in both groups, e. g. 59.7% of MTBI and 58.3% of PC reported fatigue, 45.2% in both groups reported being irritable and 40.3% and 48.8% reported taking longer to think. NC yielded the lowest symptom rates on 10 of the 16 items, but still an average of 37.9% were symptomatic on each item. NC ratings on cognitive symptoms at least matched those of MTBI, e. g. 43.4% vs 37.9% on forgetfulness, 49.3% vs 41.5% on poor concentration and 51.5% vs 40.3% on taking longer to think. MTBI patients and normal controls in Bangladesh were both approximately twice as symptomatic as TBI patients in the UK and US (where an average of only 14-31% are symptomatic on each item). Conclusions: The experience of post-concussion symptoms is not caused by brain injury; it is a non-specific response to injury and life stresses. The clinical management of post-concussion symptoms after mild

brain injury should focus on addressing adjustment rather than provision of brain injury rehabilitation. There are culturally determined ways of expressing adjustment issues and this will influence symptom base rates and again will need to be taken into account in clinical management.

2342. Hossfeld, B., et al. (2014). "[Primary treatment of penetrating injuries. Part 1: blast trauma]." Primarversorgung penetrierender Verletzungen. Teil 1: Explosionstrauma. **63**(5): 439-450.

Blast injuries may result from a variety of causes but the biomechanical impact and pathophysiological consequences do not differ between domestic or industrial accidents or even terrorist attacks. However, this differentiation relevantly affects the tactical procedures of the rescue teams. Focusing on further detonations, top priority is given to the personal safety of all rescue workers. The rareness of blast injuries in a civilian setting results in a lack of experience on the one hand but on the other hand the complexity of blast injuries to the human body places high demands on the knowledge and skills of the entire rescue team for competent treatment. The purpose of this article is to explain the physicochemical principles of explosions and to convey tactical and medical knowledge to emergency medical services.

2343. Hotz, G., et al. (2001). "Development of the pediatric test of brain injury." The Journal of head trauma rehabilitation **16**(5): 426-440.

OBJECTIVE: The Pediatric Test of Traumatic Brain Injury (PTBI) (currently in its research edition) is a tool for assessing the cognitive-linguistic skills of school-aged children and adolescents in acute care and rehabilitation settings after traumatic brain injury. Development of the PTBI was motivated by the fact that, to date, no standardized test has been available to assess the full range of cognitive-linguistic impairments associated with pediatric brain injury. In this article we describe how the research edition of the PTBI was developed, provide rationale for the areas of assessment, discuss a plan for standardization, and illustrate its use with three children with TBI., DESIGN: The PTBI was constructed to sample the attention, memory, language, reading, writing, metalinguistic, and metacognitive skills that are particularly at risk in pediatric brain injury and that are relevant to the general education curriculum., MATERIAL: The test material for the PTBI was selected on the basis of clinical and experimental evidence that children and adolescents with TBI demonstrate a wide range of cognitive and language deficits. These first appear in the early stages of recovery and often persist but change over time., CONCLUSION: Our goal is to standardize the PTBI so it can be used to establish baseline behaviors and track cognitive-linguistic recovery.

2344. Hotz, G. A., et al. (2000). "Neurobehavioural outcomes of penetrating and tangential gunshot wounds to the head." Brain injury **14**(7): 649-657.

OBJECTIVE: The objective of this study was to compare penetrating and tangential gunshot wounds to the head with regards to demographic, neurobehavioural and clinical outcome measures., METHODS: Twenty-nine patients with penetrating gunshot wounds (P-GSW) and 11 patients with tangential gunshot wound (T-GSW) to the head admitted to an acute neurotrauma service were compared using standardized neurobehavioural and clinical outcome measures., RESULTS: The mean GCS was 10.5 +/- 0.79 for the P-GSW group and 13.4 +/- 0.72 for the T-GSW group. The mean AIS-CNS for the P-GSW group was 5.00 +/- 0 and for the T-GSW group was 3.7 +/- 0.27. Significance was found on Digit Span ($p < 0.05$) and Block Design ($p < 0.009$) subtests. Outcomes between the two groups were similar, except for significant differences were found for acute length of stay (LOS) (P-GSW was 47.72 +/- 13.2 and T-GSW group was 13.0 +/- 1.3, $p = 0.005$) and for acute care charges (P-GSW group was $150,533 +/- 23,834 and T-GSW group was $70,712 +/- 16,587, $p = 0.05$)., CONCLUSIONS: Initially, a penetrating gunshot wound is a more severe and costly injury than a tangential gunshot wound to the head, however T-GSW possess significant deficits and, if the patient survives past the acute phase of recovery, the two groups have similar functional outcomes. Future standard classification, neuropsychological, and clinical outcome measures.

2345. Howaldt, H. P., et al. (1994). "Transnasal approach to the orbit, the interorbital space, and the nasopharynx." The Journal of craniofacial surgery **5**(2): 130-135.

We present a surgical procedure that provides exposure to the medial part of the orbit, the interorbital space, and the nasopharynx. A midline incision of the nose is followed by a pedicled osteotomy of the lateral nasal wall and the

medial wall of the orbit in one piece. This transnasal approach provides good exposure to the medial parts of the craniofacial junction to remove foreign bodies or benign tumors.

2346. Hoz, S. S., et al. (2020). "Fatal Penetrating Head Injuries Caused by Projectile Tear-Gas Canisters." Clinical neurosurgery **67**(SUPPL 1): 151.

INTRODUCTION: Since their advent in the 1920s, tear gas canisters have been frequently used in crowd-control. Previous studies have focused on their chemical toxicities on the eyes, skin, and respiratory system. Few case reports have documented non-penetrating injuries attributed directly to the tear gas canisters (TGC). METHODS: We conducted a retrospective medical chart review of all the patients who were admitted to the Neurosurgery Teaching Hospital (NTH) since the start of the anti-government protests (October/2019). All patients who suffered a penetrating head trauma caused by the TGC were included in our study. We collected variables such as patients' demographics, wound location, neurological exam, head CT scan findings, surgical management and clinical outcomes. RESULTS: We documented 10 cases of penetrating head trauma caused by the TGC. All victims were males, with a mean age of 16 years (rang = 14- 19 years). The TGCs penetrated the skull in all patients. The mean GCS was 7 (range of 3-10). The neurological examination revealed unilateral hemiplegia/hemiparesis and pupillary defect in 40% (N = 4) and 50% (N = 5) of the patients, respectively. Head CT scans revealed an extensive pattern of brain damage. The TGCs crossed the midline in 40% of the cases (N = 4) and assumed a complete intracranial location in 20% (N = 2). Surgical intervention which included removal of the TGCs, debridement of both brain and skin, and hemostasis was achieved in 70% of the patients (N = 7). The in-hospital mortality rate was 100% (N = 10), with all fatalities occurring within (1-3) days of admission. CONCLUSION: Our findings demonstrate that, when fired directly at the head, tear gas weapons have significant potential to inflict serious injuries and death. For penetrating head injuries related to TGC, the mortality rate can be extremely high. Consequently, strict international guidelines are required before the use of these weapons can be condoned again.

2347. Hoz, S. S., et al. (2020). "Fatal Penetrating Head Injuries Caused by Projectile Tear Gas Canisters." World neurosurgery **138**: e119-e123.

BACKGROUND: Since their advent in the 1920s, tear gas canisters (TGCs) have been frequently used in crowd control. Few reports have documented nonpenetrating injuries attributed directly to TGCs. In this study, we report a case series of fatal penetrating head injuries caused by TGCs., METHODS: We conducted a retrospective chart review of all the patients who were admitted to the Neurosurgery Teaching Hospital in Baghdad, Iraq, since the start of the antigovernment protests (October 2019). All patients who suffered penetrating head trauma caused by TGCs were included in our study. We collected patient demographics, wound location, neurologic examination, computed tomography (CT) scan findings, surgical management, and clinical outcomes., RESULTS: We found 10 cases of penetrating head trauma caused by TGCs. All victims were men, with a mean age of 16 years (range, 14-19 years). The mean Glasgow Coma Scale score was 7 (range, 3-10). The neurologic examination revealed unilateral hemiplegia/hemiparesis and pupillary abnormality in 40% (n = 4) and 50% (n = 5) of the patients, respectively. CT scans revealed an extensive pattern of brain damage. Surgical intervention was done in 80% of cases (n = 8), which included removal of the TGC, wound debridement, and hemostasis. The in-hospital mortality rate was 100% (N = 10), with all fatalities occurring within 1-3 days of admission., CONCLUSIONS: TGCs have the potential to cause lethal penetrating head injuries, calling for a reevaluation of their safety and methods of use in terms of human health.

2348. Hoz, S. S., et al. (2021). "Careening intracranial bullets: An existing entity?" Surgical neurology international **12**.

2349. Hozumi, I., et al. (1990). "GFAP mRNA levels following stab wounds in rat brain." Brain research **534**(1-2): 291-294.

We previously reported that glial fibrillary acidic protein (GFAP) levels increased significantly at 3 days after stab wounds, relative to sham-operated controls, reaching a maximum of 200% of control value at 5-7 days. They then fell to near-normal values by 21 days. To determine whether these protein changes correlated with changes in GFAP mRNA we performed Northern blot analyses. Total RNA, isolated from lesioned, sham-operated and intact rat forebrains, was hybridized with 32P-labeled mouse GFAP cDNA and quantified by densitometry. The maximum increase in total RNA content in lesioned animals was only 20% over controls at 12 h. GFAP mRNA levels increased to 2-fold control values at 6

h and reached 5-fold at 12 h. Thereafter they remained at 3.5- to 6-fold until 5 days and then declined to 1.5-fold by 21 days. The rapid increase of GFAP message at 12 h preceded a significant increase in GFAP by 2 days and the decrease of message after 5 days was more precipitate than the slow decrease in GFAP content. Sham-operated animals showed no significant changes in GFAP mRNA, compared to intact controls, during the period 3 h to 14 days postoperation. GFAP mRNA and GFAP in the stab-wound model reached levels similar to those found in the experimental autoimmune encephalomyelitis (EAE) model, but returned to normal much more rapidly.

2350. Hozumi, I., et al. (1996). "Immunoreactivity of growth inhibitory factor in normal rat brain and after stab wounds--an immunocytochemical study using confocal laser scan microscope." Brain research **741**(1-2): 197-204.

The growth inhibitor factor (GIF) is a new member of the metallothionein family that is downregulated in Alzheimer's disease brain. Using a confocal laser scan microscope with polyclonal and monoclonal antibodies to GIF, and monoclonal antibodies to glial fibrillary acidic protein (GFAP) and MAP-2, we demonstrated that GIF immunoreactivity was expressed primarily in astrocytes and much less in neurons. In astrocytes of normal rat brain GIF immunoreactivity was detected mainly in the cell bodies, while GFAP immunoreactivity was detected mainly in the processes. GIF immunoreactivity was more strongly expressed in reactive astrocytes. These findings were confirmed with both polyclonal and monoclonal antibodies. Following stab wounds, a number of GIF-positive reactive astrocytes were detected around the wounds at 3 days postoperation. After 7 days GIF immunoreactivity was detected in cell bodies and processes of reactive astrocytes. The number of GIF-positive astrocytes and the intensity of the immunoreactivity remained elevated over the control levels at least through 28 days. These immunocytochemical findings correlated well with changes in GIF protein and mRNA levels. Not only changes in GIF protein and mRNA levels but also intracellular localization of GIF in normal rat brain and after stab wounds in rat brain were different from those of GFAP. These results support the concept that GIF plays an important role in the processing of reconstruction after brain damage.

2351. Hsieh, C.-C., et al. (2021). "A Case of Penetrating Head Wound Due to Helicopter Rotor Blade Injury in a 34-Year-Old Naval Helicopter Pilot Who Returned to Active Service 5 Years Later." The American journal of case reports **22**: e933862.

BACKGROUND Head trauma, defined as damage to the brain, skull, or scalp when the head is hit by an external force, is a major cause of mortality in military personnel. Therefore, we report a novel case involving a naval helicopter pilot who sustained a helicopter propeller rotor blade injury. CASE REPORT We describe a case involving a pilot struck on the head by a helicopter rotor blade. He received care from medical staff shortly after the injury and was en route to the nearest trauma center. Cranial computed tomography (CT) scans revealed a comminuted fracture of the right occipital bone, with bone fragment retention in the right cerebral hemispheres. We performed an emergency right occipital craniotomy. The visual field patterns demonstrated right homonymous hemianopia when the patient was discharged. The patient underwent delayed titanium mesh cranioplasty about 3 months after the right occipital craniotomy. From discharge to 5 years, the patient had performed rehabilitation exercise for at least 3 days every week. The patient's continued recovery was confirmed at the 5-year follow-up in 2019. The bilateral visual acuity was 20/20, and the right homonymous hemianopia problem also disappeared. In the same year, after a physical and psychological assessment by an aviation doctor, he was able to resume flying. CONCLUSIONS This report has shown that despite safety regulations for military and civilian helicopter personnel, which include the wearing of helmets, helicopter rotor blade injuries still occur and can have long-term consequences due to the severity of head injury.

2353. Hu, B., et al. (2019). "Brain Abscess with Intracranial Bone Fragment Migration." World neurosurgery **125**: 327-328.

Penetrating brain injury is 1 type of traumatic brain injury. Brain abscess is a common complication after penetrating brain injury, and fragments increase the risk of occurrence of brain abscess. It is uncommon to see the migration of bone fragments in the brain in clinical cases. We report a rare case of brain abscess with migration of bone fragments after traumatic brain injury.

2354. Hu, C.-F., et al. (2013). "Current approaches to the treatment of head injury in children." Pediatrics and neonatology **54**(2): 73-81.

Head trauma is one of the most challenging fields of traumatology and demands immediate attention and intervention by first-line clinicians. Symptoms can vary from victim to victim and according to the victim's age, leading to difficulties in making timely and accurate decisions at the point of care. In children, falls, accidents while playing, sports injuries, and abuse are the major causes of head trauma. Traffic accidents are the main cause of disability and death in adolescents and adults. Injury sites include facial bones, muscles, ligaments, vessels, joints, nerves, and focal or whole-brain injuries. Of particular importance are cranial and intracranial injuries. A closed injury occurs when the head suddenly and violently hits an object but the object does not break through the skull. A penetrating injury occurs when an object pierces the skull and affects the brain tissue. Early diagnosis and proper management are crucial to treat patients with potentially life-threatening head and neck trauma. In this review, we discuss the different cases of traumatic brain injury and summarize the current therapies and neuroprotective strategies as well as the related outcomes for children with traumatic brain injury. 2355. Hu, N., et al. (2020). "Microbiology of acute hematogenous osteomyelitis in hospitalized children." Open forum infectious diseases **7**(SUPPL 1): S693.

Background. Acute hematogenous osteomyelitis affects 1 in 5,000 children in the U.S. and Staphylococcus aureus is the most common bacterial cause. At our institution, clindamycin is used empirically for osteomyelitis, despite increasing clindamycin-resistance over the years. The objective of this study is to describe microbiologic results and antibiotic resistance patterns in children hospitalized with acute hematogenous osteomyelitis. Methods. This was a single-center retrospective cohort study of patients < 21 years of age with acute osteomyelitis hospitalized between 1/1/2010 and 5/31/2019 at Children's National Hospital. We excluded patients with recent orthopedic surgery, hardware infection, penetrating trauma, or with an underlying immunocompromising condition. We performed chart review to collect data on location of infection; blood, synovial fluid, or surgical site cultures; culture results, and susceptibilities. Results. Of the 162 encounters of acute osteomyelitis that met inclusion criteria, the average patient age was 8.3 years. Lower extremity infections were most common (105, 64.8%), followed by upper extremity (31, 19.1%), pelvis (14, 8.6%), spine (7, 4.3%), shoulder (4, 2.5%), rib (1, 0.6%) and mandible (1, 0.6%). Almost half of cases (73, 45%) had no positive cultures, and 89 cases (55%) had at least one positive culture from blood or local source (Figure 1). The most common pathogen was methicillin susceptible S. aureus (MSSA) followed by methicillin resistant S. aureus (MRSA) comprising 60 (67%) and 19 (20%) of culture-positive infections respectively. Other isolated pathogens included S. pyogenes (5, 5.6%) Salmonella species (2, 2.2%), S. pneumoniae (1, 1.1%), S. agalactiae (1, 1.1%), and Kingella kingae (1, 1.1%) (Figure 1). Among S. aureus infections, 69 (87%) were susceptible to clindamycin (85% among MSSA, 95% among MRSA). Categorized Blood and Wound Culture Results Conclusion: Almost half of all children with acute hematogenous osteomyelitis did not have any microbiologic data to guide antibiotic usage. S. aureus was the most common (87%) isolate, with more MSSA (74%) than MRSA (24%). Non-S. aureus isolates were more likely to grow from surgical specimen cultures than from blood cultures. Clindamycin resistance was more commonly seen in MSSA than in MRSA osteomyelitis.

2356. Hu, R., et al. (2018). "Real-time computerised tomography assisted porous tantalum implant in ARCO stage I-II non-traumatic osteonecrosis of the femoral head: minimum five-year follow up." International orthopaedics **42**(7): 1535-1544.

PURPOSES: This study was established to investigate the medium-term clinical effect of real-time CT assisted porous tantalum implant for the treatment of ARCO stage I-II non-traumatic osteonecrosis of the femoral head (ONFH)., METHODS: This study comprised 24 ONFH patients (29 hips) who were treated with intra-operative real-time CT accurate rapid positioning assisted drilling decompression, lesion removal and porous tantalum implant. Harris score, VAS score and imaging in pre-operation and follow-up period were recorded., RESULTS: The average operative time and intra-operative blood loss were 72.6 min and 158.8 ml, respectively. The mean follow-up was 5.4 years. No femoral head penetrating, wound infection, and death occurred. Harris and VAS score improved significantly (73.78 vs. 88.11; 7.13 vs. 2.66) at last follow-up ($P < 0.05$). The functional improvement and pain relief rate was 100% at six months after operation. The effective rate was 86.21% at 12 months after operation and last follow-up. Five pre-operative ARCO stage

I hips had no radiographic progress. Meanwhile, four among the 24 ARCO stage II hips progressed into stage III between eight and 12 months after surgery, among which two progressed into stage IV and two remained in stage III at the last follow-up. The average value of Kerboul combined necrotic angle was 263.24degree. There was no progress in Kerboul combined necrotic angle among the grades 2 and 3 patients. However, among the six cases at grade 4, four cases with post-operative progress, two patients converted to THA., CONCLUSIONS: Our technique is safety and effective in the treatment of ARCO stage I-II non-traumatic ONFH.

2357. Hu, S., et al. (2009). "Trajectory reconstruction through analysis of trace evidence in bullet-intermediate target interaction by SEM/EDX." Journal of forensic sciences **54**(6): 1349-1352.

A young male was shot to death by a police officer with a Chinese Type 64 7.62 mm pistol when he was dealing with an aggravated assault arising from a traffic accident. By using scanning electron microscopy and energy dispersive X-ray spectroscopy (SEM/EDX), trace deposits on the discharged bullet and the intermediate target, i.e., a concrete telegraph pole at the scene, were identified to be from each other. The result demonstrated the bullet causing the death ricocheted from the concrete telegraph pole before striking the victim, thus indicating the incident was accidental. The case report illustrates the evidential value of trace materials derived, respectively, from discharged bullets and intermediate targets in bullet-intermediate target interaction for trajectory reconstruction. In addition, it indicates that the SEM/EDX method with its nondestructive nature, compared to other methods, may be more helpful in certain situations in determining the origins of trace evidentially valuable deposits on substrates.

2358. Hu, Y., et al. (2015). "Acute bilateral mass-occupying lesions in non-penetrating traumatic brain injury: a retrospective study." BMC surgery **15**: 6.

BACKGROUND: Traumatic acute bilateral mass-occupying lesions (TABML) is a common entity in head injury, with high morbidity and mortality. Our aim in this study was to evaluate the benefits of different treatment options and the outcome predictors in patients with TABML., METHODS: From October 2010 to November 2012, a consecutive cohort of patients aged 16-70 years with TABML were retrospectively analyzed based on the clinical and radiological characteristics. Patients with TABML were included if admitted within 24 h after injury and were excluded if they presented with infratentorial lesions, unilateral lesions within the first 24 h after injury, or penetrating head injury. According to their treatment option, patients were divided into three groups: a conservative treatment group, a unilateral surgery group, and a bilateral surgery group. Outcomes were assessed using the Glasgow Outcome Scale (GOS). Binary logistic regression analysis was applied to determine the outcome predictors., RESULTS: Forty-seven patients (58.8%) had severe injuries (Glasgow Coma Scale score (GCS), 3-8) upon admission, and the overall mortality was 31.3% at 6 months post-injury. The mortality was 55.6% in patients who underwent conservative treatment (N = 18), 17.9% in unilateral surgery patients (N = 39), and 34.8% in the bilateral surgery group (N = 23). In the surgical group, the mortality was 53.3% (8 of 15) in those with a GCS of 3-5, which decreased steeply to 14.9% (7 of 47) of those with GCS >= 6. On logistic regression analysis, the absence of pupillary reactivity, disappearances of basal cisterns and conservative treatment were related to higher mortality. A lower initial GCS score was associated with an unfavorable outcome. Midline shift tended to be associated with mortality and an unfavorable outcome, although statistical analysis did not show a significant difference., CONCLUSIONS: TABML is suggestive of severe brain injury. As conservative treatment is always associated with a poorer outcome, surgery is advocated, especially in patients with a GCS score of >= 6. Whereas the prognostic value of midline shift might be limited because of the counter-mass effect in TABML, the GCS score, the pupillary reactivity, and particularly, the compression of basal cisterns should be emphasized.

2359. Hu, Z., et al. (2020). "Human neural stem cell transplant location-dependent neuroprotection and motor deficit amelioration in rats with penetrating traumatic brain injury." The journal of trauma and acute care surgery **88**(4): 477-485.

BACKGROUND: Penetrating traumatic brain injury induces chronic inflammation that drives persistent tissue loss long after injury. Absence of endogenous reparative neurogenesis and effective neuroprotective therapies render injury-induced disability an unmet need. Cell replacement via neural stem cell transplantation could potentially rebuild the tissue and alleviate penetrating traumatic brain injury disability. The optimal transplant location remains to be determined., METHODS: To test if subacute human neural stem cell (hNSC) transplant location influences engraftment, lesion expansion, and motor deficits, rats (n = 10/group) were randomized to the following four groups (uninjured and

three injured): group 1 (Gr1), uninjured with cell transplants (sham+hNSCs), 1-week postunilateral penetrating traumatic brain injury, after establishing motor deficit; group 2 (Gr2), treated with vehicle (media, no cells); group 3 (Gr3), hNSCs transplanted into lesion core (intra); and group 4 (Gr4), hNSCs transplanted into tissue surrounding the lesion (peri). All animals were immunosuppressed for 12 weeks and euthanized following motor assessment., RESULTS: In Gr2, penetrating traumatic brain injury effect manifests as porencephalic cyst, 22.53 +/- 2.87 (% of intact hemisphere), with p value of <0.0001 compared with uninjured Gr1. Group 3 lesion volume at 17.44 +/- 2.11 did not differ significantly from Gr2 ($p = 0.36$), while Gr4 value, 9.17 +/- 1.53, differed significantly ($p = 0.0001$). Engraftment and neuronal differentiation were significantly lower in the uninjured Gr1 ($p < 0.05$), compared with injured groups. However, there were no differences between Gr3 and Gr4. Significant increase in cortical tissue sparing ($p = 0.03$), including motor cortex ($p = 0.005$) was observed in Gr4 but not Gr3. Presence of transplant within lesion or in penumbra attenuated motor deficit development ($p < 0.05$) compared with Gr2., CONCLUSION: In aggregate, injury milieu supports transplanted cell proliferation and differentiation independent of location. Unexpectedly, cortical sparing is transplant location dependent. Thus, apart from cell replacement and transplant mediated deficit amelioration, transplant location-dependent neuroprotection may be key to delaying onset or preventing development of injury-induced disability., LEVEL OF EVIDENCE: Preclinical study evaluation of therapeutic intervention, level VI.

2360. Hu, Z., et al. (2017). "Effect of human neural stem cell grafts on penetrating ballistic-like brain injury (PBBI) induced behavioral deficits." Journal of neurotrauma **34**(13): A20.

We previously reported amelioration of PBBI-induced cognitive deficits following engraftment of NSI-566 human neural stem cells (hNSC). However, the mechanism of such amelioration is unknown. To gain insights we hypothesized that transplant induced behavior modification will depend on transplant location, extent of tissue spared, numbers of cells engrafted derived processes. To test the hypothesis, one million green fluorescent protein (GFP) expressing hNSCs transplanted one week following injury either in the core of injured tissue (intralesional) or in undamaged tissue surrounding the core (perilesional). Same dose of cells were transplanted into an uninjured sham group to uncover hNSCs effects. The animals were tested after 12 weeks (by this time hNSC have been shown to undergo neuronal differentiation) in a standard Morris WaterMaze for acquisition (latency on day 5 after 4 days of training) and performance following spatial reversal (day 12). Linear regression to explore relationship between transplant location, lesion volume, cell numbers and latencies was assessed. Surprisingly there was no relationship between transplant location, extent of engraftment and latency to find platform. Similar analysis on additional parameters such as extent of GFP processes in corpus callosum and internal capsule will be presented to gain insights to the mechanism. These results are similar to those with bone marrow stem cell therapies in stroke patients.

The massive nasopharyngeal bleeding that may accompany complicated comminuted fractures of the craniofacial bones can be controlled by pressure tamponade using an inflatable urinary Foley catheter. However, inadvertent intracranial catheter penetration poses a serious risk in such situations. Management of a relevant case is described, and a simple preventive measure is suggested.

2363. Huang, S.-T., et al. (2020). "Early Application of Bevacizumab After Sclerocorneal Grafting for Patients With Severe Late-Stage Ocular Chemical Burns." Cornea **39**(6): 754-760.

PURPOSE: To investigate whether subconjunctival bevacizumab help prevent corneal graft neovascularization and prolong the graft survival of patients with chemical burns., METHODS: We performed a prospective nonrandomized comparative case series study. Twenty-six eyes received subconjunctival bevacizumab (10 mg/0.4 mL) once and topical immunosuppressive agents after sclerocorneal lamellar keratoplasty as the treatment, and 13 eyes received a topical immunosuppressant alone and served as the control group. The main outcomes were a cumulative probability of graft

survival, development of corneal neovascularization, and complications., RESULTS: The postoperative follow-up time was 14.3 months (range, 2-62 mo). The cumulative graft survival time was significantly longer in the treatment group than that in the control group (42.9 +/- 5.9 vs. 4.8 +/- 0.7 mo; log rank < 0.001). In the treatment group, 19 of the 26 grafts (73.1%) survived as transparent with a mean follow-up of 18.7 +/- 3.0 months. At the end of the follow-up, 4 grafts remained free of neovascularization, 2 developed edema without neovascularization, and 15 remained transparent with a stable ocular surface and some neovascular vessels in the peripheral transplant interface. The other 5 grafts became opaque and neovascularized. In the control group, all grafts became opaque and neovascularized within the follow-up period (5.5 +/- 0.7 mo). During the follow-up, a corneal epithelial defect developed in 9 eyes in the treatment group and 7 in the control group., CONCLUSIONS: Early application of subconjunctival bevacizumab after sclerocorneal lamellar keratoplasty can significantly prevent corneal neovascularization and promote graft survival for severe late-stage ocular chemical burns.

2364. Huang, T., et al. (2020). "Penetrating transorbital injury by a coloring pencil in a 3-year-old child: A case report." The Journal of international medical research **48**(3): 300060519886210.

A transorbital penetrating injury by a foreign body is an extremely rare type of injury, and its severity is often difficult to estimate by examination of the superficial wound alone. Thus, such injuries are challenging for neurosurgeons to investigate and manage. We herein present a peculiar case involving a 3-year-old girl with a penetrating transorbital skull-base injury caused by a coloring pencil and discuss the anatomical location of the foreign body, radiological examination findings, diagnosis, and treatment strategy. The pencil was completely removed by manual extraction. Follow-up investigations confirmed a good outcome. Multidisciplinary cooperation, radiological examination, correct diagnosis, timely treatment, and detailed follow-up studies are necessary to manage penetrating transorbital skull-base injuries caused by foreign bodies. The orbital walls are very thin in children, and the orbital roof and superior orbital fissure are often penetrated by foreign bodies in cases such as that described herein. The anatomical location of the foreign body influences the clinical management strategy.

2365. Huang, Y.-K., et al. (2010). "Traumatic pericardial effusion: impact of diagnostic and surgical approaches." Resuscitation **81**(12): 1682-1686.

INTRODUCTION: In trauma patients with chest injuries, traumatic pericardial effusion is an important scenario to consider because of its close linkage to cardiac injury. Even with advances in imaging, diagnosis remains a challenge and use of which surgical approach is controversial. This study reviews the treatment algorithm, surgical outcomes, and predictors of mortality for traumatic pericardial effusion., PATIENTS AND METHODS: Information on demographics, mechanisms of trauma, injury scores, diagnostic tools, surgical procedures, associated injuries, and hospital events were collected retrospectively from a tertiary trauma center., RESULTS: Between June 2003 and December 2009, 31 patients (23 males and 8 females) with a median age of 31 (range 16-77), who had undergone surgical drainage of pericardial effusion were enrolled in the study. Blunt trauma accounted for 27 (87.1%) insults, and penetrating injury accounted for 4 (12.9%). Patients were diagnosed by Focused Assessment with Sonography for Trauma (FAST) (8 patients), computerized tomography (7 patients), echocardiography (9 patients), and incidentally during surgery (7 patients). Notably, sixteen (51.7%) patients required surgical repair for traumatic cardiac ruptures, including 6 (19.6%) with pericardial defects who presented initially with hemothorax. The surgical approaches were subxiphoid in 8 patients (25.8%), thoracotomy in 7 (22.6%), and sternotomy in 19 (61.2%), including 3 conversions from thoracotomy. The survival to discharge rate was 77.4% (24/31). Concomitant cardiac repair, associated pericardial defects, and initial surgical approach did not affect survival, but the need for massive transfusion, cardiopulmonary cerebral resuscitation (CPCR), trauma score, and incidental discovery at surgery all had a significant impact on the outcome., CONCLUSIONS: Precise diagnoses of traumatic pericardial effusions are still challenging and easily omitted even with FAST, repeat cardiac echo and CT. The number of patients with traumatic pericardial effusion requiring surgical repair is high. Standardized therapeutic protocol, different surgical approaches have not impact on survival. Correct identification, prompt drainage, and preparedness for concomitant cardiac repair seem to be the key to better outcomes.

2367. Huber, A., et al. (1993). "[An unusual case of a blow-out fracture. Entrance of a bone fragment into the frontal lobe after a ski accident]." Ein ungewohnlicher Fall einer Blow-out-Fraktur. Einsprengung eines Knochenfragments ins Frontalhirn nach Skiunfall. **36**(4): 137-139.

Due to a ski accident a 16-year old girl suffered from headache, periorbital hematoma and ptosis of the right eyelid. No penetrating injury could be seen, but in the CT scan a blow-out fracture of the orbital roof and floor was verified. Since there was no evident lesion of the eye muscles, an operative indication could only be a neurosurgical one. Because of the traumatic connection between frontal cerebrum and sinus maxillaris we expected a CSF rhinorrhoea, which could not be confirmed.

2370. Hueck, U., et al. (2020). "Forensic postmortem computed tomography in suspected unnatural adult deaths." European journal of radiology **132**: 109297.

PURPOSE: Our study sought to evaluate validity of forensic postmortem CT in establishing cause of death (COD) in suspected unnatural adult death based on the reference standard of autopsy., METHODS: In our prospective, single-center study, 64 of 94 consecutive corpses (70.7 % male, mean age: 47.4 years) who underwent CT and autopsy between November 2013 and April 2019 were included in the analysis. Primary objective was agreement between CT and autopsy on primary COD using kappa statistics. Secondary objectives were competing COD and specific pathological findings., RESULTS: Agreement on primary COD between forensic CT and autopsy without or in consideration of toxicological and histological findings was strong (85.9 % [55 of 64 corpses]; kappa=0.83 [95 %CI: 0.74 to 0.93] and 95.3 % [61 of 64 corpses]; kappa=0.94 [95 %CI: 0.84-1.04], respectively, McNemar p=0.03). Sensitivity and specificity of CT in identification of acute heart failure, intracranial bleeding, burns and heat shocks, gunshot wounds, polytrauma, cranio-cerebral trauma, and strangulation or hanging was 100 %, each. Acute respiratory failure was detected with a sensitivity and specificity of 100 % and 96.8 %, cuts and stab wounds with 95.2 % and 100 %, and intoxication, pneumonia, or gastrointestinal bleeding with 60.0 % and 100 %, respectively. Agreement on competing COD was moderate (51.6 %, [33 of 64 corpses]; kappa=0.47 [95 %CI: 0.40 to 0.53], p<0.001)., CONCLUSIONS: Forensic postmortem CT, complemented by external, toxicological, and histological examination was sufficiently valid to assess primary COD in the majority of suspected unnatural deaths with few restrictions.

2371. Huet, H., et al. (1996). "Radiological confirmation of brain death: digitised cerebral parenchymography. Preliminary report." Neuroradiology **38 Suppl 1**: S42-46.

Rates of organ procurement from brain dead subjects have fallen substantially in recent years. In France, the legal definition of brain death is based on electroencephalographic criteria in patients with clinical evidence of irreversible coma. However, sedative drugs used in intensive care units usually render the electroencephalogram uninterpretable, and in our medicolegal framework, it is necessary that intracerebral circulatory arrest be demonstrated. We discuss the value of the various available techniques and report our experience with digitised intra-arterial cerebral parenchymography. This simple, fast technique does not alter physiological conditions and provides high-quality images, ensuring prompt diagnosis, which is a prerequisite for optimal organ harvesting.

2372. Huey, E. D., et al. (2016). "Brain Regions Associated With Internalizing and Externalizing Psychiatric Symptoms in Patients With Penetrating Traumatic Brain Injury." The Journal of neuropsychiatry and clinical neurosciences **28**(2): 104-111.

A factor structure underlying DSM-IV diagnoses has been previously reported in neurologically intact patients. The authors determined the brain regions associated with factors underlying DSM-IV diagnoses and compared the ability of DSM-IV diagnoses, factor scores, and self-report measures to account for the neuroanatomical findings in patients with penetrating brain injuries. This prospective cohort study included 254 Vietnam War veterans: 199 with penetrating brain injuries and 55 matched control participants. Measures include DSM-IV diagnoses (from a Structured Clinical Interview for DSM), self-report measures of depression and anxiety, and CT scans. Factors underlying DSM-IV diagnoses were determined using an exploratory factor analysis and correlated with percent of brain regions affected. The ability of the factor scores, DSM-IV diagnoses, and the self-report psychiatric measures to account for the anatomical variance was compared with multiple regressions. Internalizing and externalizing factors were identified in these brain-injured patients. Damage to the left amygdala and bilateral basal ganglia was associated with lower internalizing factor scores, and damage to the left medial orbitofrontal cortex (OFC) with higher, and bilateral hippocampi with lower, externalizing factor scores. Factor scores best predicted left amygdala and bilateral hippocampal involvement, whereas DSM-IV diagnoses best predicted bilateral basal ganglia and left OFC involvement. Damage to the limbic areas involved in the processing of emotional and reward information, including structures involved in the National Institute of Mental Health's Research Domain Criteria Negative Valence Domain, influences the development of internalizing and externalizing psychiatric symptoms. Self-report measures underperformed DSM-IV and factor scores in predicting neuroanatomical findings.

2373. Huggins, A. B., et al. (2016). "Goat horn-induced intracranial emphysema and orbital injury." Orbit (Amsterdam, Netherlands) **35**(6): 355-356.

This is a case description of a male patient found to have orbital and intracranial emphysema, specifically with air in his cavernous sinuses bilaterally following penetrating trauma to the medial orbit from a goat's horn. There were no orbital or skull base fractures. Although the presence of traumatic intracranial emphysema is not uncommon, it is typically the result of direct communication of the cranial vault with the paranasal sinuses in the setting of associated fracture or, alternatively, from direct penetration and inoculation. We present a rare case of orbital emphysema with traumatic intracranial emphysema without these previously described associations and postulate a mech``anism behind its development.

2374. Huggins, R., et al. (2015). "The pattern of head and facial trauma associated with fatal blunt force assault." International journal of oral and maxillofacial surgery **44**: e82.

Violent assault to the head and facial region is a common cause of aesthetic and functional deficits of both temporary and permanent nature. This results in significant and immense pressure being placed on emergency and medical services and is accompanied with traumatic experiences for those involved. The severe cases where injuries are fatal, have widespread repercussions with devastating and prolonged outcomes. Awareness surrounding the increase in prevalence of interpersonal violence has become a major focus around Australia in recent years, especially in relation to alcohol and 'one-punch' deaths. Fatal injury patterns in Motor Vehicle Accidents, sporting incidents and facial trauma requiring in-patient admission, have previously been well described, however, those sustained in fatal assault have yet to be quantified. This study aims to identify the patterns of brain and facial injuries, specific risk factors for fatal outcomes, the mechanism of physical impact and the socio-demographic circumstances of the individuals involved. Between 2006 and 2015, the autopsy and pathology, clinical images, CT radiology and emergency service reports of 126 cases involving fatal blunt trauma assault to the head and facial region have been assessed. Results present in detail, the specific nature and frequency of intracranial bleed and penetrating brain injuries, facial and skull fractures, soft tissue lacerations and contusions and pharmacological agents present during the assault. These outcomes have important implications in identifying fatal injury patterns for medical and emergency personal, the etiology of fatal assault, the behavioral/social interactions that occur prior to fatal assault and to provide adjunct medical information into the circumstances surrounding the death for the medico-legal process.

2375. Hughes, B. D. and J. R. Vender (2006). "Delayed lead pulmonary emboli after a gunshot wound to the head. Case report." Journal of neurosurgery **105**(3 Suppl): 233-234.

Bullet fragment emboli are uncommon, and there have been only a few reports of intracranial-to-extracranial migration of these fragments. The authors present the case of an 11-year-old girl who was struck in the suboccipital

region with a "soft nose" bullet fired at close range. Several months later, the patient was found to have asymptomatic pulmonary emboli. Similar cases are reviewed, and a management strategy is recommended.

2376. Hughes, J. T. and B. Brownell (1968). "Traumatic thrombosis of the internal carotid artery in the neck." Journal of neurology, neurosurgery, and psychiatry **31**(4): 307-314.

2377. Hughes, S. M. (1987). "Sequelae of orbital fractures." Advances in ophthalmic plastic and reconstructive surgery **6**: 313-341.

Many injuries and complications of orbital fractures are instantaneous and unpreventable, some develop over time, and some are a result of surgery. Most complications can either be managed or prevented and are anticipated based on the fracture location and size. A thorough search for probable complications is mandatory, especially ocular injuries and intracranial complications. Most patients are carefully followed for 7-14 days, and the significant residual sequelae are managed. Some complications, however, require urgent care.

2378. Huiszoon, W. B., et al. (2012). "Fatal transorbital penetrating intracranial injury caused by a bicycle hand brake." International journal of emergency medicine **5**(1): 34.

A transorbital penetrating intracranial injury is a rare and severe traumatic brain injury. Patients with this type of injury may present dramatically, but often the injury is subtle and therefore easily overlooked and not recognized in the first place. We present the case of a 45-year-old female admitted to the emergency department after she fell with her bike and the bicycle brake handle penetrated her left eye. A computerized tomography of the cerebrum showed a fracture of the superior orbital roof with multiple bone fragments extending into the brain near the circle of Willis. A pneumocephalus and traumatic frontobasal, intraventricular and subdural hemorrhage was seen. The patient deteriorated suddenly and was transferred to a neurosurgical center where she underwent an emergency craniotomy with evacuation of the intracerebral hematoma and an intraventricular drain was placed. After surgery, the patient's condition deteriorated, and total compression of the brain stem occurred, upon which the patient was declared brain dead. Our case report shows that the Glasgow Coma Scale score at admission is not always a good predictor of the severity of the injury. Even when there is minimal suspicion of a penetrating intracranial injury, a computerized tomography should be performed immediately, independent of the patient's Glasgow Coma Scale score. A direct transfer to a specialized neurosurgical center is recommended because this injury often results in death due to fatal complications such as intracerebral hemorrhage, pneumocephalus and brain stem injury.

2379. Huk, A., et al. (2014). "Skull fracture: Indicator dangerous to life or predictor of intracranial injury?" Journal of neurotrauma **31**(5): A58-A59.

Introduction: In forensic science as well as in the scales (AIS, ISS) of assessment of the severity of injury based on anatomical principles a skull fracture is assessed as a life-threatening injury or a severe injury, which may conflict with clinical observations. The purpose of the work is to identify a skull fracture as an indicator of the severity of traumatic brain injury or as a predictor of intracranial lesions. Materials and methods: A retrospective analysis of cases treated in the institute of neurosurgery (280 patients) and autopsy material (131 autopsies) of patients with traumatic brain injury was conducted. All patients underwent CT and craniography. Statistical processing of the results was done using x2. Results: Analysis of the obtained data showed that the incidence of skull fractures depends on the sample of material being analyzed. Skull fractures were diagnosed in 102 cases (77.9%) at autopsy and in 85 cases (30.4%) in the clinic (x2 - 79.3, P= 0.0000). According to the sample of hospitalized patients, 57.6% of all skull fractures were observed in patients with mild traumatic brain injury. This can be explained by the fact that patients with mild traumatic brain injury outnumbered those with severe traumatic brain injury in the sample (208 vs. 29). Comparison of the incidence of fractures among patients with mild traumatic brain injury and those with severe traumatic brain injury yielded reliable statistical data showing that skull fractureswere predominant in patients with severe traumatic brain injury (x2 - 13.9; ? = 0.0001). Patients with mild traumatic brain injury had skull fractures predominantly in the cranial vault (x2 - 7; p = 0,008) and one bone (x2 - 5.8; p= 0,016) as compared with patients with severe traumatic brain injury. A reliable statistical connection was established between skull fractures and intracranial lesions (x2 - 3.8; p = 0,051) in patients with mild traumatic brain injury. Conclusion: It can be concluded that a linear fracture of the cranial vault is a risk factor

for potential intracranial lesions, but not a predictor of the severity of traumatic brain injury. It is proposed that a skull fracture be regarded as life-threatening only when it directly causes a potentially dangerous injury (open, penetrating TBI, multiple and comminuted fractures of the cranial vault, fractures of the skull base, pneumocephalus, liquorrhea).

2380. Hull, K. L. and R. Denton-Beaumont (2019). "An unsuspected intracranial foreign body on the acute medical unit." BMJ case reports **12**(7).

A 54-year-old man was referred to the acute medical unit with a suspected stroke after presenting to his general practitioner with altered speech, left sided facial droop and confusion. The patient had a new right sided swelling on the lateral aspect of his head but did not report any history of trauma. Imaging revealed a 9.2 cm nail entering via the right parietal bone with associated acute haemorrhage. After further discussion with the patient, he disclosed a suicide attempt with a nail gun 5 days prior to presentation. The nail was successfully removed by the neurosurgical team and the patient received rehabilitation and psychiatric assessment on the brain injury unit before going home.

2381. Humble, S. S., et al. (2018). "Prognosis of diffuse axonal injury with traumatic brain injury." The journal of trauma and acute care surgery **85**(1): 155-159.

BACKGROUND: Determine the prognostic impact of magnetic resonance imaging (MRI)-defined diffuse axonal injury (DAI) after traumatic brain injury (TBI) on functional outcomes, quality of life, and 3-year mortality., METHODS: This retrospective single center cohort included adult trauma patients (age > 17 years) admitted from 2006 to 2012 with TBI. Inclusion criteria were positive head computed tomography with brain MRI within 2 weeks of admission. Exclusion criteria included penetrating TBI or prior neurologic condition. Separate ordinal logistic models assessed DAI's prognostic value for the following scores: (1) hospital-discharge Functional Independence Measure, (2) long-term Glasgow Outcome Scale-Extended, and (3) long-term Quality of Life after Brain Injury-Overall Scale. Cox proportional hazards modeling assessed DAI's prognostic value for 3-year survival. Covariates included age, sex, race, insurance status, Injury Severity Score, admission Glasgow Coma Scale Score, Marshall Head computed tomography Class, clinical DAI on MRI (Y/N), research-level anatomic DAI Grades I-III (I, cortical; II, corpus callosum; III, brainstem), ventilator days, time to follow commands, and time to long-term follow-up (for logistic models)., RESULTS: Eligibility criteria was met by 311 patients, who had a median age of 40 years (interquartile range [IQR], 23-57 years), Injury Severity Score of 29 (IQR, 22-38), intensive care unit stay of 6 days (IQR, 2-11 days), and follow-up of 5 years (IQR, 3-6 years). Clinical DAI was present on 47% of MRIs. Among 300 readable MRIs, 56% of MRIs had anatomic DAI (25% Grade I, 18% Grade II, 13% Grade III). On regression, only clinical (not anatomic) DAI was predictive of a lower Functional Independence Measure score (odds ratio, 2.5; 95% confidence interval, 1.28-4.76], p = 0.007). Neither clinical nor anatomic DAI were related to survival, Glasgow Outcome Scale-Extended, or Quality of Life after Brain Injury-Overall Scale scores., CONCLUSION: In this longitudinal cohort, clinical evidence of DAI on MRI may only be useful for predicting short-term in-hospital functional outcome. Given no association of DAI and long-term TBI outcomes, providers should be cautious in attributing DAI to future neurologic function, quality of life, and/or survival., LEVEL OF EVIDENCE: Epidemiological, level III; Therapeutic, level IV.

2382. Hung, K.-H., et al. (2011). "Management of double-penetrating ocular injury with retained intraorbital metallic foreign body." Journal of the Chinese Medical Association : JCMA **74**(11): 523-526.

The prognosis of double penetrating ocular trauma is usually guarded. We report the good anatomical and functional outcome in a patient with double-penetrating ocular trauma associated with intraorbital foreign body. A 58-year-old man presented at the emergency room complaining of blurred vision of the left eye with stinging pain after he hammered an iron plate. Best-corrected visual acuity was hand movement/30 cm. Subconjunctival hemorrhage with one 1.4-mm laceration wound was noted over the nasal conjunctiva. Fundus examination showed vitreous hemorrhage with one whitish patch over the nasal retina. Orbital computed tomography scan revealed one metallic foreign body at the posterior nasal upper orbit. Double-penetrating globe injury with intraorbital foreign body was impressed, and immediate vitrectomy surgery with endolaser photocoagulation was carried out. One exit wound nasal to the disc was noted during operation. The intraorbital metallic foreign body was left alone. Vision recovered to 6/8.6 without ocular complication after a 20-month follow-up. Prompt, careful preoperative evaluation and meticulous vitrectomy intervention are essential in the successful management of such patients. Posteriorly located intraorbital metallic

foreign body should be managed conservatively. Long-term regular electroretinography evaluation is needed for possible retinal toxicity from intraorbital foreign body. Copyright © 2011. Published by Elsevier B.V.

2384. Hunt, H., et al. (2013). "Thromboelastography (TEG) and thromboelastometry (ROTEM) for trauma-induced coagulopathy in adult trauma patients with bleeding." Cochrane Database of Systematic Reviews **2013**(3).

This is the protocol for a review and there is no abstract. The objectives are as follows: To determine the diagnostic accuracy of global tests of haemostatic function (thromboelastography (TEG) and thromboelastometry (ROTEM)) in adult trauma patients with bleeding.

2385. Hunt, H., et al. "Thromboelastography (TEG) and rotational thromboelastometry (ROTEM) for trauma-induced coagulopathy in adult trauma patients with bleeding." (6).

Background, Trauma-induced coagulopathy (TIC) is a disorder of the blood clotting process that occurs soon after trauma injury. A diagnosis of TIC on admission is associated with increased mortality rates, increased burdens of transfusion, greater risks of complications and longer stays in critical care. Current diagnostic testing follows local hospital processes and normally involves conventional coagulation tests including prothrombin time ratio/international normalized ratio (PTr/INR), activated partial prothrombin time and full blood count. In some centres, thromboelastography (TEG) and rotational thromboelastometry (ROTEM) are standard tests, but in the UK they are more commonly used in research settings., Objectives, The objective was to determine the diagnostic accuracy of thromboelastography (TEG) and rotational thromboelastometry (ROTEM) for TIC in adult trauma patients with bleeding, using a reference standard of prothrombin time ratio and/or the international normalized ratio., Search methods, We ran the search on 4 March 2013. Searches ran from 1970 to current. We searched The Cochrane Library, MEDLINE (OvidSP), EMBASE Classic and EMBASE, eleven other databases, the web, and clinical trials registers. The Cochrane Injuries Group's specialised register was not searched for this review as it does not contain diagnostic test accuracy studies. We also screened reference lists, conducted forward citation searches and contacted authors., Selection criteria, We included all cross-sectional studies investigating the diagnostic test accuracy of TEG and ROTEM in patients with clinically suspected TIC, as well as case-control studies. Participants were adult trauma patients in both military and civilian settings. TIC was defined as a PTr/INR reading of 1.2 or greater, or 1.5 or greater., Data collection and analysis, We piloted and performed all review stages in duplicate, including quality assessment using the QUADAS-2 tool, adhering to guidance in the Cochrane Handbook for Diagnostic Test Accuracy Reviews. We analysed sensitivity and specificity of included studies narratively as there were insufficient studies to perform a meta-analysis., Main results, Three studies were included in the final analysis. All three studies used ROTEM as the test of global haemostatic function, and none of the studies used TEG. Tissue factor-activated assay EXTEM clot amplitude (CA) was the focus of the accuracy measurements in blood samples taken near to the point of admission. These CAs were not taken at a uniform time after the start of the coagulopathic trace; the time varied from five minutes, to ten minutes and fifteen minutes. The three included studies were conducted in the UK, France and Afghanistan in both civilian and military trauma settings. In two studies, median Injury Severity Scores were 12, inter-quartile range (IQR) 4 to 24; and 22, IQR 12 to 34; and in one study the median New Injury Severity Score was 34, IQR 17 to 43., Authors' conclusions, We found no evidence on the accuracy of TEG and very little evidence on the accuracy of ROTEM. The value of accuracy estimates are considerably undermined by the small number of included studies, and concerns about risk of bias relating to the index test and the reference standard. We recognise that the reference standards of PT and INR are imperfect, but in the absence of embedded clinical consensus these are judged to be the best reflection of current clinical practice. We are unable to offer advice on the use of global measures of haemostatic function for trauma based on the evidence on test accuracy identified in this systematic review. This evidence strongly suggests that at present these tests should only be used for research. We consider more thoroughly what this research could be in the Discussion section.

Penetrating head injury by foreign body is relatively uncommon and has been scattered reported in the literature. In this case, a transorbital impalement wound inflicted by bamboo objects was discussed. A 61-year-old alcoholized man died from a transorbital intracranial wound due to penetration of the left orbit after falling from a slope beside the road. Although the facial impalement injury was small and unobtrusive, the penetrating trauma itself could induce lethal consequences, special attention should be paid to such kind of cases. The autopsy and pathological examination revealed subarachnoid hemorrhage, brain contusion and intraparenchymal hematoma. Some pieces of bamboo were also detected in the left anterior cranial fossa. Based on all of the evidence and information, we can draw a conclusion that the bamboo was the instrument causing the injuries and the case was considered as accident.

2389. Hurtado Torres, G. F., et al. (2007). "[Nutritional support in a pregnant woman with brain death. Case report and literature review]." Apoyo nutricio en una mujer embarazada y con muerte cerebral. Informe de un caso y revision de la literatura. **22**(4): 503-506.

The occurence of brain death in pregnancy represents a catastrophic entity although infrequent. The aims of continue medical management are focused in a double purpose: to preserve intrauterine product's life and fetal maturation until delivery and to consider the mother as a potential organ donor. Ethical considerations together with gestational age, fetal well being and relatives' wishes are cardinal for continuing medical support. Modern critical care units allow us to obtain favourable results, supported in scientifical reports that describe successful outcomes. Nutritional aspects plays a cardinal role in the medical management, allowing to preserve the mother's organs' viability and also to preserve fetal intrauterine growth and development.

2390. Husak, S., et al. (2016). "Delayed contralateral presentation of a carotid cavernous fistula following trauma." Canadian Journal of Neurological Sciences **43**: S47.

Background: We present a rare case of a left-sided carotid cavernous fistula (CCF) that presented 15 months post initial trauma with right-sided ophthalmic signs and symptoms. Highlighted is a contralateral endovascular approach to treating this traumatic CCF. Methods: Described is a case of a left-sided CCF caused by a selfinflicted gun shot wound to the head that was initially treated conservatively by neurosurgery and opthomology. The patient presented 15 months later with headache, acute right-sided periorbital swelling, severe right eye and facial pain. Results: Angiography confirmed the presence of a left-sided CCF with preferential drainage into the right cavernous sinus and right superior ophthalmic vein. The left internal carotid artery (ICA) was shown to be narrow and irregular. Multiple attempts to navigate the micro catheter through the vessel were unsuccessful. Instead, the fistula was embolized using a contralateral approach through the right internal carotid artery and across the anterior communicating artery. Imaging post-operatively confirmed successful occlusion of the CCF. Conclusions: This case is a rare example of a left-sided ICA occlusion secondary to trauma presenting 15 months after the initial injury with right-sided ophthalmic signs and symptoms. It is also one of only a few in the literature that describe successful treatment of traumatic CCF through a contralateral approach.

2391. Husseini, M. E., et al. (2019). "Perforating Brain Injury in A One-Year-Old Infant." Journal Medical Libanais **67**(2): 107-112.

Background : Perforating head injuries in children constitute only a small part of the total number of traumatic head injuries seen in the emergency department. Craniocerebral gunshot injuries are increasingly encountered by neurosurgeons in Lebanon, a country with increased gun culture, especially in Bekaa. Traumatic brain injury caused by a gunshot wound is the most devastating injury with a broad spectrum of symptoms and high rates of mortality and

morbidity. Case:We present a case of a 1-yearold male infant with a perforating brain injury. Although this kind of injuries has been previously reported, the present case is special, because the patient showed no neurological deficit after surgery, despite the dangerous trajectory of the bullet. Conclusion : The es-tablishment of management protocol in this kind of injuries is difficult because of the variability of reported cases. Although the current literature predicts poor outcomes in patients with gunshot injuring bi-hemispheres and ventricles, this may not apply equally to the pediatric population. The pediatric population tends to demonstrate more favorable outcomes following intracranial gunshot injury when compared with the adult population.

2392. Hussien, A., et al. (2021). "Incidence of post traumatic epilepsy in Khartoum State, Sudan between the period of December 2018 to January 2020." Journal of the neurological sciences **429**.

Background and aims: Epilepsy is one of the commonest neurological disorders. It has a strong association with trauma to the brain, constituting of 5% of epilepsy cases. To determine the prevalence of post-traumatic epilepsy among Sudanese patients and to demonstrate the relation between traumatic brain injury and occurrence of epilepsy. Methods: A descriptive hospital-based cross-sectional study, conducted in Bashiar, Omdurman, and Ibrahim Malik Teaching Hospitals in Khartoum state, in the period from December 2018 to January 2020. Patients were interviewed by general emergency team. Relevant history was obtained, and both biochemical and neuroimaging investigations were done. Results: 70 patients with history of traumatic brain injury (TBI), 6 (11.3%) developed post traumatic epilepsy (PTE). (82.9%) were males and (17.1%) were females. In the 6 patients who developed PTE, the mode of trauma in two of them was gunshots, two due to fall, one by an automobile accident and one had missing data. Out of them, one had subarachnoid hemorrhage, one had bilateral subdural hematoma and one developed massive epidural hemorrhage. Statistically significant correlation was found between TBI and number of comorbid conditions. Older age was associated with more severe TBI. Significant correlation reported between the etiology of TBI and occurrence of PTE. Significant correlation between higher GCS at the time of trauma and not having PTE. People with TBI and GCS more than 12 had 1.8 less chance to develop PTE. Conclusions: Traumatic brain injury constituting of type of trauma, etiology, formed of brain injury, and GCS at presentation, has a significant implications to occurrence of epilepsy.

2393. Hutchinson, P. J., et al. (2002). "Investigation of the effect of chlormethiazole on cerebral chemistry in neurosurgical patients: a combined study of microdialysis and a neuroprotective agent." British journal of clinical pharmacology **53**(3): 275-283.

AIMS: Promising pre-clinical results from laboratory studies of neuro-protective drugs for the treatment of patients with stroke and head injury have not been translated into benefit during clinical trials. The objective of the study was to assess the feasibility of administrating a potential neuro-protective drug (chlormethiazole) in conjunction with multimodality monitoring (including microdialysis) to patients with severe head injury in order to determine the effect of the agent on surrogate endpoints and penetration into the brain., METHODS: Multimodality monitoring including cerebral and peripheral microdialysis was applied to five head-injured patients on the neuro-intensive care unit. Chlormethiazole (0.8%) was administered as a rapid (10 ml min(-1)) intravenous loading infusion for 5 min followed by a slow (1 ml min(-1)) continuous infusion for 60 min. The following parameters were monitored: heart rate, mean arterial blood pressure, intracranial pressure, cerebral perfusion pressure, peripheral oxygen saturation, continuous arterial oxygen partial pressure, arterial carbon dioxide partial pressure, arterial pH, arterial temperature, cerebral tissue oxygen pressure, cerebral tissue carbon dioxide pressure, cerebral pH, cerebral temperature, electroencephalograph (EEG), bi-spectral index, plasma glucose, plasma chlormethiazole, and cerebral and peripheral microdialysis assay for chlormethiazole, glucose, lactate, pyruvate and amino acids., RESULTS: Despite achieving adequate plasma concentrations, chlormethiazole was not detected in the peripheral or cerebral microdialysis samples. The drug was well tolerated and did not induce hypotension, hyperglycaemia or withdrawal seizures. The drug did not change the values of the physiological or chemical parameters including levels of GABA, lactate/pyruvate ratio and glutamate. The drug did, however, induce EEG changes, including burst suppression in two patients., CONCLUSIONS: Chlormethiazole can be safely given to ventilated patients with severe head injury. There was no evidence of hypotension or withdrawal seizures. Combining a pilot clinical study of a neuro-protective agent with multimodality monitoring is feasible and, despite the lack of effect on physiological and chemical parameters in this study, may be a useful adjunct to the development of neuro-protective drugs in the future. Further investigation of the capability of microdialysis in this setting is required. By investigating the effect of a drug on surrogate end-points, it may be possible to identify promising agents from small pilot clinical studies before embarking on large phase III clinical trials.

2395. Hwang, K. and S. Y. Oh (2020). "Orbital Roof Blowout Fracture With an Intact Orbital Rim: A Case Report." Eplasty **20**: e13.

Background: Fractures of the orbital roof not associated with fractures of the orbital rim are unusual. We describe the case of a blowout fracture of the orbital roof with an intact orbital rim, which was found after craniotomy for removal of epidural hematoma. Case: A 64-year-old man was referred to our emergency department from a local hospital. He fell down from a 3-m stepladder while pruning branches of a tree. Brain computed tomographic scan revealed acute epidural hematoma in both frontal convexities, and he underwent craniotomy at the local hospital. On follow-up brain computed tomography, an orbital roof fracture with a displaced bony fragment and hemorrhage was noticed in the left superior extraconal space. Thereafter, he was transferred to our department. Upon examination, movement of the extraocular muscles was normal. He did not complain of diplopia or decreased sensation of the face. He also did not have nasal stuffiness. Exophthalmometry revealed the same findings for both eyes (18 mm/18 mm). Facial computed tomographic scan before the second operation revealed a displaced orbital roof fracture segment. Under general anesthesia, craniotomy was performed and the epidural hematoma was evacuated. The displaced bony fragment was removed from the left anterior cranial fossa, and the anterior skull base was reconstructed with a titanium mesh plate. Conclusion: Through this case of blowout fracture of the orbital roof with an intact orbital rim, found after craniotomy, we should be aware of the possibility that an orbital roof fracture can be missed on conventional brain computed tomography.

2396. Hwang, Y.-S., et al. (2010). "Iron Foreign Body in the Optic Nerve without Ocular Siderosis." Journal of neuroimaging : official journal of the American Society of Neuroimaging **20**(2): 201-203.

BACKGROUND AND PURPOSE: An intraocular iron foreign body may cause many ocular complications, sometimes even blindness. Therefore, if possible, it should be removed to avoid ocular siderosis. We report a case in which a foreign body was trapped in the optic nerve and could not be removed. After a 2-year follow-up, no ocular siderosis or progressive deterioration in vision was found. This is the first case report of a foreign body in the optic nerve behind the eyeball in the PubMed literature., METHODS: The authors describe the case of a 33-year-old man with an ocular trauma history at work. A metal iron foreign body was trapped in the optic nerve behind the eyeball, which was demonstrated by computed tomography., RESULTS: There was no significant vision change and ocular siderosis by electroretinogram after 2 years of follow-up., CONCLUSIONS: Intra-optic-nerve foreign body may have a better ocular prognosis. Siderosis may not be seen in patients with optic nerve iron foreign body. Intraocular foreign body should be accurately studied before surgical procedures.

2398. Hymel, K. P., et al. (2010). "Head injury depth as an indicator of causes and mechanisms." Pediatrics **125**(4): 712-720.

OBJECTIVE: The goal was to measure differences in the causes, mechanisms, acute clinical presentations, injuries, and outcomes of children <36 months of age with varying "greatest depths" of acute cranial injury., METHODS: Children <36 months of age who were hospitalized with acute head trauma were recruited at multiple sites. Clinical and imaging data were collected, and caregivers underwent scripted interviews. Neurodevelopmental evaluations were completed 6 months after injury. Head trauma causes were categorized independently, and subject groups with varying greatest depths of injury were compared., RESULTS: Fifty-four subjects were enrolled at 9 sites. Twenty-seven subjects underwent follow-up neurodevelopmental assessments 6 months after injury. Greatest depth of visible injury was categorized as scalp, skull, or epidural for 20 subjects, subarachnoid or subdural for 13, cortical for 10, and subcortical for 11. Compared with subjects with more-superficial injuries, subjects with subcortical injuries more frequently had

been abused (odds ratio [OR]: 35.6; P < .001), more frequently demonstrated inertial injuries (P < .001), more frequently manifested acute respiratory (OR: 43.9; P < .001) and/or circulatory (OR: 60.0; P < .001) compromise, acute encephalopathy (OR: 28.5; P = .003), prolonged impairments of consciousness (OR: 8.4; P = .002), interhemispheric subdural hemorrhage (OR: 10.1; P = .019), and bilateral brain hypoxia, ischemia, or swelling (OR: 241.6; P < .001), and had lower Mental Developmental Index (P = .006) and Gross Motor Quotient (P < .001) scores 6 months after injury., CONCLUSION: For children <3 years of age, head injury depth is a useful indicator of injury causes and mechanisms.

2399. Hynes, A. M. (2021). "Finding the missing bullet: A case report of an unusual trajectory from the left scapula into the left orbit." Trauma case reports **35**.

Evaluating a traumatically injured patient requires a systematic evaluation that can rapidly detect life threatening injuries. When there is a discrepancy in the number of expected retained bullets, one must re-evaluate the initial work-up. This case consists of an extremely unusual trajectory course of a scapular wound where the ballistic then traversed off the scapula through the neck entering the para-pharyngeal space, travelling through the facial bones, and coming to rest within the left eye, itself. This case herein reinforces the importance for the evaluating provider to quickly recognize when the work-up is inconsistent with the initial assessment. Failure to recognize this discrepancy may lead to an inappropriate work-up with subsequent devastating life-threatening consequences.

The authors describe rare clinical observations of patients suffering transnasal injuries to the base of the skull. Based on their own experience, they propose practical recommendations for the management of such cases.

2401. Iannelli, A. and G. Lupi (2005). "Penetrating brain injuries from a dog bite in an infant." Pediatric neurosurgery **41**(1): 41-45.

Brain lesions due to dog bites are not frequent and mainly concern infants in the first years of their life because they are short in height, the size of the infant's head is relatively large compared to the body and the skull bones are thin. We report the case of an infant with bilateral skin, skull and brain injuries secondary to a dog bite, and review the relative reports in the literature. We stress the need to consider the possibility of penetration into the intracranial compartment occurring in cases of dog bites of the scalp, because these wounds on the scalp and the skull may appear relatively limited, small in size and slight, in spite of associated potentially dangerous deeper lesions involving the intracranial structures that may be missed on the first observation. Infection is the main possible complication, and may be the cause of permanent and serious neurological deficits. Prompt diagnosis and therapy are mandatory to avoid complications and to achieve good clinical results. Copyright 2005 S. Karger AG, Basel.

2403. Ibayashi, K., et al. (2012). "[A case of a penetrating brain injury due to an explosion of a construction machine]." No shinkei geka. Neurological surgery **40**(5): 421-427.

Penetrating brain injury caused by a high speed projectile is rather rare in Japan, known for its strict gun-control laws. We report a case of a 55-year-old male, who was transferred to our hospital with a foreign body in the brain due to penetrating head injury, which was caused by an explosion of a construction machine. Neurological examination demonstrated severe motor aphagia with no apparent motor paresis. The patient had a scalp laceration on his left forehead with exposed cerebral tissue and CSF leakage. Head CT scan and plain skull X-ray revealed a 20 mmx25 mm bolt which had penetrated due to the explosion of the machine. The anterior wall of the left frontal sinus was fractured resulting in dural laceration, and scattered bone fragments were seen along the trajectory of the bolt. Digital subtraction angiography showed no significant vascular injuries including superior sagittal sinus. We performed open surgery, and successfully removed the bolt along with the damaged frontal lobe. The patient had no infection or seizure after the surgery, and was transferred for further rehabilitation therapy. We performed a cosmetic cranioplasty six months later.

Surgical debridement of the damaged cerebral tissue along the trajectory led to successful removal of the bolt with no further neurological deficit.

2404. Ibebuike, K., et al. (2012). "Spontaneous intracranial bullet migration: A complication of penetrating cranial gunshot wound: Case report and review of the literature." Journal of Neurological Sciences **28**(4): 619-626.

Spontaneous migration of retained bullets in the brain is a recognized rare complication of penetrating cranial gunshot wounds to the brain. The authors report one rare case in a 55-year old male patient who presented with a penetrating cranial gunshot wound and a retained bullet. He had a dense right hemiplegia and expressive aphasia on admission. Skull x-ray confirmed the retained intracranial bullet, which on CT scan was located at the left parietaloccipital region. He was managed conservatively. A repeat CT scan 17 days post injury showed spontaneous migration of the bullet to the left occipital pole adjacent to the superior sagittal sinus and near to the Torcula Herophili. He had a remarkable improvement of his right sided weakness but had severe receptive and expressive language deficits. This case highlights the need to watch out for the occurrence of spontaneous migration of intracranial bullets after a penetrating cranial gunshot wound and when detected management decisions should be individualized.

2405. Icer, M., et al. (2017). "Factors affecting dural penetration and prognosis in patients admitted to emergency department with cranial gunshot wound." European journal of trauma and emergency surgery : official publication of the European Trauma Society **43**(5): 611-615.

PURPOSE: To explore the effect of admission physical examination findings, anamnesis, and computed tomography on dural penetration and prognosis in patients with cranial gunshot wound (CGW)., METHODS: In this study, the medical data of 56 subjects who were admitted to the Emergency Department of Dicle University Hospital with CGWs between January 2011 and December 2013 were retrospectively reviewed. The effects of type of incident (suicidal vs non-suicidal), pupil diameter and light reflex, hemodynamic status, type (bullet or pellet), velocity, trajectory of foreign material, trauma scores, and imaging findings on dural penetration and mortality were explored., RESULTS: The mean age of the study population was 24.8 +/- 13.50 years. Thirty (53.6 %) patients had penetrating injuries and 26 (46.4 %) had non-penetrating injuries; 9 (16.1 %) patients died and 47 (83.9 %) survived. Suicidal injury, pupil diameter and light reflex, bullet as foreign material, and high velocity and lateral trajectory of foreign material significantly affected dural penetration and mortality ($p < 0.05$). In addition, dural penetration, bilobar, multilobar, or bihemispheric involvement of brain parenchyma, presence of intracranial hemorrhage, subarachnoid hemorrhage, ventricular hemorrhage, fracture, shift, edema, and trauma scores significantly affected mortality ($p < 0.05$)., CONCLUSIONS: In CGWs, dural penetration and prognosis can be predicted by physical examination findings and patient characteristics on initial admission.

2406. Ichinose, N., et al. (2009). "[Multiple penetrating head injury by 8 nails: a case report]." No shinkei geka. Neurological surgery **37**(12): 1209-1213.

A case report of penetrating head injury due to 8 nails and a review of multiple penetrating head injury by nails were described. The patient who was a 48-year-old man with a history of for psychiatric care was transferred to our emergency room on May 2007. He had shot his head with 8 nails using a nail-gun in a suicide attempt. His family called an ambulance. His conscious level was 1 on the Japan Coma Scale and 15 on the Glasgow Coma Scale with monoplegia of the right lower extremity and hypoesthesia of the right extremities. X-ray films of his head revealed 8 nails penetrating his cranium. The CT scan showed thin hematoma on the right convexity. Angiography didn't demonstrate any evidence of vascular injury. Under general anesthesia, all nails were removed after craniotomy. His post-operative course was good and he was discharged home with minimal deficits. Penetrating head injury with nail-gun use is sometimes seen, but cases with multiple nails are rare. Operative strategies were discussed in the review. It also suggested the need for the care of mental or background problems.

2407. Iczkiewicz, J., et al. (2007). "Osteopontin expression in activated glial cells following mechanical- or toxin-induced nigral dopaminergic cell loss." Experimental neurology **207**(1): 95-106.

Osteopontin (OPN) is a glycosylated phosphoprotein that regulates both oxidative stress and inflammatory processes. OPN is present in the rat substantia nigra (SN) and both protein and mRNA levels are up-regulated following a

pro-inflammatory insult produced by lipopolysaccharide. We now report on the effects of lesioning the SN using 6-hydroxydopamine (6-OHDA) and mechanical vehicle-induced lesioning on OPN expression. Intranigral administration of 6-OHDA induced a marked time-dependent loss of tyrosine hydroxylase (TH) positive nigral cells. Vehicle administration also produced a loss of TH positive cells. This was small compared to 6-OHDA and due to mechanical damage during surgery. 6-OHDA and mechanical-induced cell loss was accompanied by an increase in OPN protein and mRNA expression. Both 6-OHDA and mechanical lesions resulted in equivalent time-dependent increases in OX-42 positive microglial cells. However, the elevation was far less marked following mechanical damage compared to 6-OHDA-induced cell death. 6-OHDA lesioning induced a slow up-regulation of GFAP positive astroglial cells but this was not present following mechanical damage. Importantly, both 6-OHDA and mechanical lesions resulted in an up-regulation in ED1 positive macrophages of equivalent magnitude and time course. There was co-localisation of OPN with ED1 positive cells but not TH, OX-42 or GFAP cells following both toxin and mechanical lesions. Nigral TH positive cell death of toxin or mechanical origin increases OPN expression in parallel with the up-regulation of ED1 positive macrophages. The increase in OPN/ED1 expression is independent of the extent of cell death. OPN appears to be an important regulator of nigral cell survival through its association with inflammatory events and its manipulation may provide a means of achieving neuroprotection in Parkinson's disease.

2408. Iddrisu, M. D., et al. (2022). "SUCCESSFUL HEART TRANSPLANT WITH A SINGLE LEAFLET MITRAL VALVE DONOR: A CASE REPORT." Journal of the American College of Cardiology **79**(9): 3148.

Background: Single leaflet mitral valve (MV) apparatus are extraordinarily rare congenital defects, previously thought to be incompatible with life beyond the neonatal period. There is no literature about progression of cardiac dysfunction in this structural abnormality Case: 19-year-old male ceased after gunshot wound. Appropriate protocol determined brain dead and family agreed with organs donation. TTE showed large anterior MV leaflet attached to the posteromedial papillary muscle. TEE corroborated findings, with small anterolateral papillary muscle without a chordae. Organ transplantation certified this heart as appropriate for donation. Surgery for organ harvest was performed. Organ donor network reported successful transplantation in similarly aged patient. Recipient recovered uneventfully with total independence and functionality Decision-making: In this case the donor had no previous cardiac history without dysfunction of the native single leaflet MV. It is uncertainty that the recipient will not develop MV disease in the future or how fast the transplanted valve will start to deteriorate, however, the low mortality risk and the good prognosis of a young heart in a young recipient were decisive to pursue transplantation. “True” parachute and parachute-like asymmetric MV were ruled out Conclusion: Inclusion of hearts with asymptomatic single leaflet MV is possible. This measurement may provide a higher volume of donor hearts [Formula presented]

A 48-year-old man died from a transnasal intracranial stab wound caused by an umbrella. The track of the stab passed from the right nostril, through the sphenoid sinus, the left side of the sella turcica and anterior clinoid process, and finally reached the surface of the brain. The stab wound crossed the left internal carotid artery, causing an exsanguination and aspiration of blood into the airway, resulting in death. It is extremely rare that an umbrella tip used during a struggle would stab the nostril of the victim. Transnasal intracranial stab wounds can be overlooked and require sensitive handling.

In forensic pathology, the reactions that occur in the body from somatic death to cell death are commonly termed "supravital reactions". There are many reports of grossly visible and microscopic supravital reactions; however, few papers are available on the supravital reaction concerning gene expression. The aim of this study was to examine the gene expression of immediate early genes (IEGs) including c-fos, fos-B and c-jun in mechanically asphyxiated mouse brain and lung after somatic death and to identify the IEGs expressed at the point of supravital reaction in the brain and lung. Our results confirm that the expression of IEGs changed after death during supravital reaction and that the alterations differed according to the cause of death and the types of organ examined. In addition, IEG expression significantly increased following mechanical asphyxia. These results suggest that there is a specific pattern of gene expression following asphyxia. It is therefore important to identify the specific genes involved, as this may give significant information to aid in the post-mortem diagnosis of strangulation and hanging.

2416. Ildan, F., et al. (1994). "The nonsurgical management of a penetrating orbitocranial injury reaching the brain stem: case report." The Journal of trauma **36**(1): 116-118.

Penetrating and perforating periorbital puncture wounds by lead pencils are not rare, but ones that reach the brain stem are extremely unusual. We recently treated a patient with of this type of injury. A newly sharpened lead pencil was accidentally introduced through the subconjunctiva at the inner canthus of the right eye. It passed along the medial border of the globe transorbitally and went through the superior orbital fissure into the temporal fossa, then continued through the lateral side of the sella and posterior clinoid, reaching the brain stem. The entire pencil was removed inch by inch without incident under CT control. Meanwhile, the operative team remained ready in case of emergency bleeding. The patient's postoperative course was uneventful, but the initial neurologic deficit of the patient remained fixed.

2417. Ilkko, E., et al. (1998). "Spontaneous migration of foreign bodies in the central nervous system." Clinical radiology **53**(3): 221-225.

The authors present four cases where foreign bodies within the central nervous system had spontaneously migrated. Two of these were surgical clips and two were bullets. The clips seemed to pass intradurally into the lumbar region with minor or no symptoms. Possible explanations for the migration are the circulation of CSF and the gravity. A new observation was that an infection may develop at the site where the foreign body had been situated before

migration. From the clinical point of view, the removal of foreign bodies from the intradural space is not indicated, if the patient has no connected symptoms.

2418. Imam, A. M., et al. (2013). "Synergistic effects of fresh frozen plasma and valproic acid treatment in a combined model of traumatic brain injury and hemorrhagic shock." Journal of Surgical Research **179**(2).

Introduction: Traumatic brain injury (TBI) and hemorrhagic shock (HS) are major causes of trauma related deaths, and are especially lethal as a combined insult. Previously we have shown that early administration of fresh frozen plasma (FFP) reduced the size of brain lesion and associated swelling in a swine model of combined TBI+HS. We have also separately shown that the addition of valproic acid (VPA) to the resuscitation protocol attenuates inflammatory markers in the brain and attenuates the degree of TBI. The current study was performed to determine whether a combined FFP+ VPA treatment strategy would exert a synergistic effect in a clinically relevant large animal model of TBI+HS. Methods: Yorkshire swine (42-50 kg) were instrumented to measure hemodynamic parameters, intracranial pressure and brain tissue oxygenation. TBI was created through a 20 mm craniotomy, using a custom-designed, computer-controlled cortical impactor: 15 mm cylindrical tip impactor at 4 m/s velocity, 100 ms dwell time and 12 mm penetration depth. The TBI created was synchronized with the initiation of volume-controlled hemorrhage (40 ± 5% of total blood volume). After a 2 hour period of shock, animals were randomized to one of three resuscitation groups (n=5/gr): 1) normal saline (NS), 2) Fresh Frozen Plasma (FFP), 3) FFP and VPA 300 mg/kg (FFP+VPA). The resuscitative volume for FFP was equivalent to the shed blood, whereas NS was 3X this volume. VPA treatment was started an hour after hemorrhage. Animals were monitored for 6 hours post-resuscitation. At this time the brains were harvested, sectioned into 5mm slices and stained with TTC (2, 3, 5-Triphenyltetrazolium chloride) to quantify the lesion size (mm 3) and brain swelling (% change compared to uninjured side). Results: The combined TBI + HS model resulted in a highly reproducible brain injury. As shown in Figure lesion size and brain swelling in the FFP+VPA group (1459 ± 218 mm3, and 13 ± 1.2% respectively) were significantly smaller than the NS group (3285 ± 130.8 mm 3 $p < 0.001$, and 37 ± 1.6%; $p < 0.001$ respectively). The decrease in lesion size and swelling in the combined treatment group was also significant when compared to the FFP alone group (2160 ± 202.6 mm3; $p < 0.05$ and 22 ± 1 %; $p < 0.001$ respectively). Conclusions: In a large animal model of TBI + HS, treatment with a combination of FFP and VPA leads to a significant reduction in the size of brain lesion as well as swelling, compared to FFP alone or NS. This novel synergistic effect should be explored further to develop effective treatments for these devastating insults (Figure Presented).

2420. Imrie, F. R., et al. (2008). "Surveillance of intraocular foreign bodies in the UK." Eye (London, England) **22**(9): 1141-1147.

AIMS: To estimate the incidence of penetrating injuries with retained intraocular foreign bodies (IOFBs) in the United Kingdom, and to provide epidemiological data on the aetiology, management, and visual outcome of such injuries., METHODS: Cases were identified prospectively by active surveillance through the British Ophthalmological Surveillance Unit reporting card system, for the 12-month period June 2004 to May 2005 inclusive. Questionnaire data were obtained from UK ophthalmologists at presentation and 6 months following presentation., RESULTS: Data were available on 97 patients at presentation and 95 patients at follow-up. The minimum estimated incidence of IOFBs in the United Kingdom identified in this study was 0.16 per 100 000. All patients were male. Hammering was the most common mechanism of injury, occurring in 62% of patients. The IOFB was found in the anterior segment in 24%, the posterior segment in 73%, and involved both segments in 3%. Endophthalmitis was diagnosed in 9% of patients. Best-corrected visual acuity of the injured eye at final follow-up was 6/12 or better in 67%, 6/18 to 6/60 in 11%, and worse than 6/60 in 22%. Prognostic factors for a poor visual outcome included poor visual acuity at presentation, prolapse of intraocular tissue, development of endophthalmitis, development of retinal detachment, and large size of IOFB., CONCLUSIONS: The incidence of IOFB in the United Kingdom appears to have reduced compared to previous studies. The majority of patients (67%) retain good visual acuity in the injured eye; however, a significant minority (22%) sustain long-term severe visual loss.

2421. Imshenetskaia, V. F. (1976). "[Methicillin penetration into the cerebrospinal fluid of patients]." Proniknovenie metiltsillina v spinmomozgovuiu zhidkost' bol' nykh **21**(8): 745-747.

Penetration of methicillin through the blood-liquor barrier in neurosurgical patients was studied. When administered in a dose of 2 gm the drug penetrated through the barrier in 1/3 of all observations within 1 to 3 hours. Increased liquor pressure in the patients resulted in prolongation of the antibiotic effect in the cerebrospinal fluid. The methicillin levels in the liquor were no sufficient for the growth inhibition of most methicillin sensitive staphylococci.

2422. Inamasu, J., et al. (2011). "Fulminant ependymitis following intraventricular rupture of brain abscess." Journal of infection and chemotherapy : official journal of the Japan Society of Chemotherapy **17**(4): 534-537.

A 48-year-old man with a history of a penetrating brain injury was referred with a presumptive diagnosis of bacterial meningitis. Examination revealed a brain abscess in addition to meningitis. Blood and cerebrospinal fluid (CSF) cultures were negative for bacteria, and empirical IV antibiotic therapy with vancomycin (VCM) and meropenem was initiated. Despite initial improvement, however, his condition rapidly deteriorated into coma following intraventricular rupture of the abscess and hydrocephalus. Thereafter, an emergency ventriculostomy was performed and the abscess was evacuated. Bacterial cultures of the pus were negative. To manage the hydrocephalus, 150-200 ml of CSF were drained daily. Intraventricular administration of VCM (20 mg q.d.) was added to the IV antibiotic therapeutic regimen after surgery. Although the primary abscess rapidly decreased in size, ependymitis developed in the fourth ventricle. This new lesion, which resulted from CSF dissemination from the primary abscess, was refractory to treatment, and eventually disappeared after the intraventricular VCM dosage was increased from 20 to 30 mg and continued for 30 days. A possible reason for the development of fulminant ependymitis and why it was refractory to treatment despite the shrinkage of the primary lesion may be that physiological CSF flow from the lateral to the fourth ventricle was lost due to CSF drainage, and the stagnant CSF flow coupled with an insufficient VCM level in the fourth ventricle facilitated the rapid growth of pathogens. Although intraventricular antibiotic administration is efficacious for treating ruptured brain abscesses, it may be associated with the unexpected development of secondary lesions.

2423. Inci, S., et al. (2006). "Unrecognized intracerebral glass particle mimicking cavernoma: case report." Neurosurgery **58**(1): E203-E203.

OBJECTIVE AND IMPORTANCE: Although the presence of a foreign body in the cranium after a head injury is a well-known entity, cases of retained intracranial foreign bodies causing a delayed onset of neurological symptoms are rare. To our knowledge, an unrecognized intracerebral glass particle mimicking a cavernoma has not been previously reported in the literature., CLINICAL PRESENTATION: We report a unique case regarding an intracranial foreign body. A 39-year-old patient presented with new-onset epilepsy. The patient had no history of trauma. According to the magnetic resonance imaging findings and the patient's clinical course, the responsible lesion was considered to be a temporal cavernoma., INTERVENTION: During the operation, surprisingly, a glass particle was found within the temporal lobe. The glass had penetrated the cranium during a minor head injury and had remained undetected for 33 years. The patient was seizure-free without medication during 3 years of follow-up., CONCLUSION: Intracranial small foreign bodies can be difficult to diagnose, especially in patients with no history or a vague history of head trauma. Patients with long-standing retained foreign bodies may remain clinically well until complications arise. Intracranial foreign bodies may mimic other pathologies clinically and radiologically.

2424. Ingle, S. S. and S. Nagpure (2016). "Effectiveness of mannitol therapy in patients of cerebral oedema caused by traumatic brain injury" - a retrospective study." Research Journal of Pharmaceutical, Biological and Chemical Sciences **7**(3): 292-296.

Truamatic Brain Injury: It occurs when sudden trauma causes damage to brain, can result when head suddenly and violently hits objects or when objects pierces the skull. In India estimated 16 lacks persons sustain head injury each year with 2 lacks deaths. Estimated Prevalence in India is 9.7 million, out of which 16% sustain sever TBI. Contributing to leading cause of morbidity, mortality, disability and socioeconomic losses in India and other developing countries. As a result of TBI brain function is temporarily or permanently impaired leading to cerebral oedema in 85% cases. Mannitol: Mannitol, an osmotic diuretic is the mainstay of treatment for cerebral oedema. Rapid iv Mannitol reduces intra-cranial pressure and cerebral edema by reducing brain mass. Considering its cost-effectiveness and rapid action to decrease the

intra-cranial pressure in critical conditions like traumatic brain injury it is fabricated to assess the efficacy of mannitol therapy in trumatic brain injury. To find out optimal duration of mannitol therapy according to grading of severity of TBI. 1 Grading patients according to severity of the brain injury based on Glassglow coma scale 2. Assessing optimal use of mannitol by considering duration of mannitol therapy TYPE OF STUDY: It is a retrospective study. STUDY SETTING: Case records of patients admitted from Aug 2014 to Aug 2015, in AVBRH Hospital sawangi who received Mannitol therapy SAMPLE SIZE: 40 patients. DATA COLLECTION: Data was collected from case papers available at medical report department of AVBRH hospital in structured format STUDY DESIGN: 1. Case records of patients admitted from Aug 2014 to Aug 2015, in AVBRH Hospital sawangi who received Mannitol therapy were assessed at medical report department of AVBRH hospital 2. Depending upon GCS scale written on case paper at time of admission patients were graded as mild, moderate and sever grades of severity 3. With the start of mannitol therapy till the day when GCS scale scored 15/15 was considered to be the total duration of mannitol therapy required to reduce edema effectively. This study suggest stage wise or severity wise treatment regimen of mannitol should be followed to decrease mortality as well as morbidity. Categorization of the patients with TBI is very important as per the severity of TBI with the help of GCS which is a clinical tool designed to assess severity of TBI. This study has certain limitations as it is Retrospective study with less sample size, more Prospective studies with large sample size is required to make this study more evident.

2425. Ingole, P. D., et al. (2014). "Comparison of intermaxillary fixation screw versus eyelet interdental wiring for intermaxillary fixation in minimally displaced mandibular fracture: a randomized clinical study." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **72**(5): 958.e951-957.

PURPOSE: The aim of the present randomized study was to evaluate the efficacy of intermaxillary fixation screw (IMFS) versus eyelet interdental wiring for intermaxillary fixation (IMF) in minimally displaced mandibular fractures., MATERIALS AND METHODS: A total of 50 patients with a minimally displaced mandibular fracture were enrolled, with 25 patients randomly selected for each group. In group I (study group, n = 25), the patients were treated using IMFS, and in group II (control group, n = 25), they received eyelet interdental wiring. Both techniques were assessed for the following parameters: time required for placement and removal of each type of IMF technique, time required for placement of IMF wires, postoperative occlusion, stability of the IMF wire, local anesthesia requirement during removal of each fixation type, oral hygiene status, glove perforation rate, and complications associated with both techniques. The collected data were analyzed using Student's unpaired t test or chi2 test. P < .05 was considered significant and the Statistical Package for Social Sciences software, version 10, was used for analysis., RESULTS: The average time required for placement in groups I and II was 17.56 and 35.08 minutes, respectively (P = .000). The time required for placement of the IMF wire in group I was 2.1 minutes and in group II was 6 minutes. The oral hygiene status was assessed, and the mean plaque index score for groups I and II was 1.44 and 2.12, respectively (P = .00). The glove perforation rate was much less in group I than in group II. Finally, the most common complication in both groups was mucosal growth., CONCLUSIONS: The results established the supremacy of IMFS compared with eyelet interdental wiring. Thus, we have concluded that IMFS, in the present scenario, is a safe and time-saving technique. IMFS is a cost-effective, straightforward, and viable alternative to cumbersome eyelet interdental and other wiring techniques for providing IMF, with satisfactory occlusion during closed reduction or intraoperative open reduction internal fixation of fractures. In addition, oral hygiene can be maintained, and the glove perforation rate was very low using IMFS. The relatively small sample size and limited follow-up period were the study limitations.

2426. Ingvar, M., et al. (1994). "Immunohistochemical markers for neurons and astrocytes show pan-necrosis following infusion of high-dose NMDA into rat cortex." Experimental neurology **128**(2): 249-259.

This study pertains to the transition between selective neuronal necrosis and the development of cerebral infarction (pan-necrosis). We infused the neuron selective excitotoxin N-methyl-D-aspartate (NMDA) at a relatively high concentration (10 microliters of 50 mM NMDA in phosphate buffer, pH 7.4) into the rat cortex. Local injection of lactic acid and a minor stab wound in the cortex were used as a reference. The tissue damage was evaluated with immunohistochemical markers for neurons (MAP2, parvalbumin) and for astrocytes (GFAP and S100 protein). The stab wound and infusion of lactic acid led to a small distinct area of pan-necrosis with a sharp border to the surrounding tissue. The NMDA lesions were characterized by a center of pan-necrosis with loss of all tissue elements that were larger and less distinctly demarcated than the other lesions. This study shows that activation of NMDA receptors per se can

induce pan-necrosis, and we conclude that the transition from selective neuronal necrosis to infarction depends on the intensity of the neuronal damage process.

2427. Inman, J. and Y. Ducic (2012). "Intracranial free tissue transfer for massive cerebrospinal fluid leaks of the anterior cranial fossa." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **70**(5): 1114-1118.

PURPOSE: The management of large skull base defects with refractory cerebrospinal fluid (CSF) leaks treated with intracranially placed free tissue transfers was examined., MATERIALS AND METHODS: A retrospective review of all cases of CSF leak presenting to the senior author from 1997 to 2008 in a private tertiary care referral practice was performed. Patients with intracranially placed free flaps were specifically examined for this review., RESULTS: In total 109 patients with skull base defects larger than 4 cm(2) or intractable CSF leaks were identified. Eighty-eight patients underwent reconstruction with local tissue flaps or free tissue grafts. Persistent massive leaks were repaired with 11 intracranial free tissue transfers. CSF fistulas were successfully closed in each instance, with no cases of flap failure or major complications., CONCLUSIONS: Intracranial placement of nonskin-bearing free tissue is an excellent treatment alternative for massive CSF leaks and refractory CSF fistulas related to large skull base defects.

2428. Inokuchi, S., et al. (2018). "[Frontal Base Penetrating Brain Injury by a Gardening Scissors:A Case Report]." No shinkei geka. Neurological surgery **46**(11): 999-1005.

A 43-year-old woman accidentally fell from a 1.5-m height with gardening scissors, and the cutting edge of the scissors pierced into her skull base through the left nasal cavity. After she pulled the scissors out by herself, her consciousness immediately deteriorated. She was transferred to Juntendo University Shizuoka Hospital by an ambulance helicopter. Intracerebral hematoma in the right frontal lobe caused by the middle cerebral artery injury was detected using brain computed tomography. Emergent hematoma evacuation with decompressive craniectomy was performed. In this procedure, cerebrospinal fluid(CSF)leakage was repaired using a multi-layered flap technique, which placed both the free autologous dura mater and pedicled temporalis muscle flaps into the damaged skull base space. After the surgery, CSF drainage was managed to control both intracranial pressure and CSF leakage. Upon discussion, several clinical issues can be highlighted. First, the gardening scissors were pulled out by the patient herself. Second, the foreign material penetrating the intracranial space might have conferred a high infection risk. Finally, it might be difficult to repair the severe damage inflicted upon the skull base by the large gardening scissors. In conclusion, it was considered that favorable results were obtained by the emergent surgical intervention and by repairing the skull base through forming a multi-layered flap with a combination of free and pedicled tissues.

2429. Iob, I., et al. (1983). "Traumatic cerebral aneurysm in pediatric age. Case report." Journal of neurosurgical sciences **27**(3): 187-190.

Cerebral aneurysm following head trauma in pediatric age is a rare complication particularly in the absence of skull fractures or penetrating brain wounds as in the present case. In the presence of rapid worsening of neurological conditions after head trauma, one may take into consideration this complication among other possible vascular accidents.

2430. Iovieno, A., et al. (2014). "Late-onset peripheral ulcerative sclerokeratitis associated with alkali chemical burn." American journal of ophthalmology **158**(6): 1305-1309.e1304.

PURPOSE: To report delayed-onset peripheral ulcerative keratitis (PUK) following alkali injury., DESIGN: Retrospective case series., METHODS: setting: Single institution (Cornea and External Disease Service, Moorfields Eye Hospital). participants: Six eyes of 5 patients with PUK and associated anterior scleritis that had a history of ocular alkali injury. observationprocedure: Patients were identified among PUK patients seen at Moorfields Eye Hospital over a 20-year period. main outcomes measures: Patients' demographics, clinical features, treatment, and outcomes., RESULTS: Recurrent PUK with scleritis following alkali burns occurred in 5 male patients/6 eyes (median age: 22 years, range 18-38) several years after the chemical trauma (average: 6.4 years; range 3-12). Management of PUK in these patients was similar to PUK arising from other etiologies., CONCLUSIONS: In this series of patients there was no evidence of an

underlying vasculitic cause for the PUK. A localized autoimmune response may, however, be involved in the pathogenesis of these cases, as seen in an animal model of chemical injury or in late mustard gas keratitis. We hope that this case series will bring this newly described condition to the attention of ophthalmologists and that this may assist in their treatment, which, in this series, required systemic immunosuppressive therapy.

2431. Irfan, F. B., et al. (2010). "Craniocerebral gunshot injuries in preschoolers." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **26**(1): 61-66.

INTRODUCTION: Gunshot wounds (GSW) to the head are the most lethal form of trauma; unfortunately, the frequency of children being involved in such form of trauma is increasing at an alarming rate worldwide. We present our experience with four children from 2 to 3 years of age with craniocerebral GSW admitted to the neurosurgery service at a tertiary care hospital., METHODS: For this study, four children, 2 to 3 years old, injured solely from bullet injuries to the head were selected. Their history, arrival Glasgow Coma Scale (GCS), clinical presentation at the time of arrival in ER, radiological findings, management, and follow-up reviewed., RESULTS: Out of four children, only one did not survive. The bullet entrance wound was in the parietal region in robbery-related incidences, and, in three cases, the injury was bihemispheric. The time taken to reach the emergency department was less than 2 h for all patients except one. Of four patients, three presented with GCS between 3 and 5 while 1 presented with GCS well above ten., CONCLUSION: Our results show that even in children presenting with low GCS<5, an early act of aggressive surgical intervention can prove to be a life-saving measure.

2432. Irimia, A. and J. D. Van Horn (2015). "Epileptogenic focus localization in treatment-resistant post-traumatic epilepsy." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **22**(4): 627-631.

Pharmacologically intractable post-traumatic epilepsy (PTE) is a major clinical challenge for patients with penetrating traumatic brain injury, where the risk for this condition remains very high even decades after injury. Although over 20 anti-epileptic drugs (AED) are in common use today, approximately one-third of epilepsy patients have drug-refractory seizures and even more have AED-related adverse effects which compromise life quality. Simultaneously, there have been repeated recommendations by radiologists and neuroimaging experts to incorporate localization based on electroencephalography (EEG) into the process of clinical decision making regarding PTE patients. Nevertheless, thus far, little progress has been accomplished towards the use of EEG as a reliable tool for locating epileptogenic foci prior to surgical resection. In this review, we discuss the epidemiology of pharmacologically resistant PTE, address the need for effective anti-epileptogenic treatments, and highlight recent progress in the development of noninvasive methods for the accurate localization of PTE foci for the purpose of neurosurgical intervention. These trends indicate the current emergence of promising methodologies for the noninvasive study of post-traumatic epileptogenesis and for the improved neurosurgical planning of epileptic foci resection.

2433. Irmak, N. A., et al. (2019). "Analysis of maxillofacial traumas in an emergency clinic." Kuwait Medical Journal **51**(2): 168-171.

Objective: To examine epidemiology, fracture pattern and the relation between fracture pattern and Duke facial trauma severity index in patients admitted for maxillofacial traumas Design: Retrospective study Setting: Emergency Department, Ankara Numune Education and Research Hospital, Turkey Subjects: Four hundred and twenty-eight patients who presented with a diagnosis of maxillofacial trauma Intervention: Medical treatment of patients with maxillofacial trauma Main outcome measure: Epidemiology, fracture pattern and the relation between fracture pattern and Duke facial trauma severity index Results: Of the 428 patients, 185 cases with at least one fracture of the maxillofacial bones were included in the study, 147 (79.5%) males and 38 (20.5%) females. Distribution of gender showed significant difference ($p < 0.001$). Age range was 8 – 90 years and average age was 38.69 ± 14.6 years. The most frequent cause of maxillofacial trauma was violence. The most frequent age range was 21-30 years old (28.6%, n = 53). The most frequent cause of maxillofacial trauma was violence in male cases and traffic accidents in female cases. There was a statistically significant relationship between gender and etiology (chi-square test, $p < 0.003$). There were a total of 268 facial fractures in the cases. Nasal bone fractures (21%) were the most common fractures. Violence was the most common cause of nasal bone, orbital floor and medial wall, zygomatic arch and Le-Fort II fractures. Falling was the most

common cause of frontal sinus, zygomaticomaxillar complex and maxillary sinus fractures. The most detected fracture was isolated upper midface fractures (51.4%). There was a statistically significant relationship between upper midface fractures and violence (Z test, p <0.001). There was also a statistically significant difference between midface fractures and violence and falling (Z test, p <0.002). Conservative treatment was applied to 66.5% of the cases and surgical treatment was applied to 33.5% of the cases. Conclusion: Maxillofacial fractures were significantly more common in males in the third decade of life, in the nasal bone, were caused by violence and treated with conservative treatments.

2434. Irshad, K., et al. (1998). "Unsuspected penetrating maxillo-orbitocranial injury: a case report." Canadian journal of surgery. Journal canadien de chirurgie **41**(5): 393-397.

A healthy 37-year-old man presented to the emergency room, complaining of blunt trauma to his mandible from a tree branch. Plain radiographs and computed tomography demonstrated a penetrating orbitocranial foreign body with the maxillary sinus as the entry site. The foreign body was a chain-saw file. It was extracted successfully through the oral cavity. The patient's recovery was uncomplicated and he suffered no neurologic or opthalmic sequelae.

2435. Isaac, A., et al. (2013). "Penetrating injury to the parapharyngeal space caused by a BB gun in a pediatric patient." Journal of Pediatric Surgery Case Reports **1**(2): 25-27.

Non-powder firearm related trauma to the head and neck has the potential for significant morbidity and mortality. This is especially so in children, whose injuries tend to be particularly under reported and trivialized. We present a case of penetrating trauma in a three-year-old boy caused by a BB gun pellet fired in close range to the face, entering the right side of the head and landing within 3 mm of the carotid bifurcation, fortunately, without major neurovascular injury. Due to potential morbidity related to surgical exploration of the parapharyngeal space, a non-surgical approach was observed. The patient suffered no functional deficit from the injury. This case demonstrates the merits of the non-surgical approach to head and neck trauma. The literature pertaining to the epidemiology of this injury is reviewed, including the advantages and disadvantages of surgical and non-surgical management.

2436. Isaacs, A. M., et al. (2015). "Penetrating intracranial nail-gun injury to the middle cerebral artery: A successful primary repair." Surgical neurology international **6**: 152.

BACKGROUND: Penetrating nail-gun injuries to the head are rare, however, the incidence has been gradually rising over the last decade. While there is a large volume of case reports in the literature, there are only a few incidences of cerebrovascular injury. We present a case of a patient with a nail-gun injury to the brain, which compromised the cerebral vasculature. In this article, we present the case, incidence, pathology, and a brief literature review of penetrating nail-gun injuries to highlight the principles of management pertaining to penetration of cerebrovascular structures., CASE DESCRIPTION: A 26-year-old male presented with a penetrating nail-gun injury to his head. There were no neurological deficits. Initial imaging revealed that the nail had penetrated the cranium and suggested the vasculature to be intact. However, due to the proximity of the nail to the circle of Willis the operative approach was tailored in anticipation of a vascular injury. Intraoperatively removal of the foreign body demonstrated a laceration to the M1 branch of the middle cerebral artery (MCA), which was successfully repaired., CONCLUSION: To our knowledge, this is the first reported case of a vascular arterial injury to the MCA from a nail-gun injury. It is imperative to have a high clinical suspicion for cerebrovascular compromise in penetrating nail-gun injuries even when conventional imaging suggests otherwise.

2437. Isaji, T., et al. (2016). "[Multi-Layered Closure of Transorbital Penetrating Brain Injury without Bone Reconstruction: A Case Report]." No shinkei geka. Neurological surgery **44**(2): 115-119.

A 26-year-old man was injured in a motor vehicle accident. He sustained a compound orbital fracture with brain contusion. The brain tissue protruded through the orbit. Computed tomography showed a long contusion with a moderate amount of hematoma in the right frontal lobe. No foreign body was observed in the cranium. On 3D CTA, the major cerebral vessels were found to be intact. An urgent surgery was first performed by neurosurgeons and subsequently by ophthalmologists. The periosteum was left on the skull. A frontal periosteal, a right temporal fascial, and a right temporal muscular flap were prepared. After debridement and irrigation, the dural tear was closed with the

right periosteal and fascial flaps. Finally, the frontal fascia was used to cover the orbital defect. The patient's clinical course was favorable. The patient was able to walk when discharged 46 days after the surgery. A penetrating brain injury through the orbit is rare, and its treatment is not established. A key to successful management of this injury is immediate assessment. Foreign bodies in the cranium, especially metal, should be checked for immediately. The cerebral vessels should also be evaluated. Usually, a surgical intervention is necessary. Since bone reconstruction can be associated with a risk of infection, a multi-layered closure, as described in this report, could prevent leakage of cerebrospinal fluid and subsequent meningitis.

2440. Ishikawa, E., et al. (2000). "Intracerebellar penetrating injury and abscess due to a wooden foreign body--case report." Neurologia medico-chirurgica **40**(9): 458-462.

A 4-year-old boy presented with chopstick penetration into the cerebellum via the temporal squamosa and tentorium cerebelli, which resulted in a cerebellar abscess 1.5 years after the injury. The neuroimaging appearance of the wooden chopstick were unusual, hyperdense on computed tomography, and isointense on T2-weighted and hypointense on T2-weighted magnetic resonance imaging. Abscess aspiration and continuous drainage was performed with real-time intraoperative ultrasound guidance. The chopstick fragment was surgically removed and the patient discharged with minor neurological deficits. Wooden foreign body may show changes in properties after a long period of intraparenchymal retention. Extra care is required to remove wooden foreign bodies because of the high risk of infection.

2441. Ishisaka, E., et al. (2017). "Radiological findings of transorbital penetrating intracranial injury in a child." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **33**(11): 2061-2064.

In penetrating injuries, woods are known to be difficult to detect with radiological imaging studies, because the wood density are known to be extremely close to the value of air on CT. Adjustment of CT window and reconstruction of a 3D image from CT images allowed us to more accurately distinguish wood from air and to find the fragment of the wooden chopstick. It is particularly useful in transorbital penetrating injury.

2442. IŞik, H. S. and C. Özdemir (2011). "Unusual delayed presentation of celebratory gunshot injury; case report." Journal of Neurological Sciences **28**(1): 120-122.

Celebratory gunshot fire is a common problem all around the world, especially in the undeveloped and developing countries. People shoot into the air for celebration something, such as any kind of sports game, like football, new years, wedding ceremony or special national days. These celebrations generally occur in the crowded places or public housing areas and that can be result undesirable injuries. Here, we present an unusual delayed injury, a 13 years-old boy presented 7 days after an unrecognized celebratory gunshot injury with complaints of headache and vomiting.

2444. Islam, M. R., et al. (2022). "The perplexing postsurgical complication of carotid-jugular fistula: A bitter experience." Surgical neurology international **13**.

Background: Vascular injuries occur in approximately 25% of all penetrating neck traumas, with carotid artery injuries being particularly lethal. Penetrating neck injuries are potentially fatal. Vascular injuries occur in approximately

25% of cases, which can lead to the formation of arteriovenous fistulas. Case Description: The authors present a case of delayed open surgery to repair a carotid-jugular fistula that resulted in an unprecedented complication, as well as a brief review of the condition's diagnosis and treatment options. Conclusion: This case report suggests us that, penetrating neck injuries should be thoroughly evaluated for arteriovenous fistulae. To avoid complications, common carotid-jugular fistulas must be treated as soon as possible. Postoperative complications can be effectively managed with prompt action.

2445. Israr, S., et al. (2016). "Complex vascular sequelae in patients secondary to penetration trauma: An educational perspective from a large level-1 trauma hospital." Emergency radiology **23**(6): 538.

Learning Objectives/Aims: Chicago is a city plagued with violent attacks that lead to traumatic injuries; a trauma center's role is to focus on decreasing the mortality rate when these acute emergencies inevitably present. We aim to educate residents and attending physicians about the classifications and sub-classifications of the occult but deadly complications of penetration injuries. Recognize that prompt use of various radiological techniques, sometimes a multimodality approach is critical in reducing morbidity and mortality in these cases. Background: This is a retrospective case review of gunshot and stab cases presenting to our level 1 trauma center. The primary imaging modalities used for analysis were CT angiogram, CT, and MRI. Complications were categorized as arterial, venous, or uncommon vascular injuries. Arterial injuries were further classified as pseudoaneurysms (most common), dissections, occlusions, extravasations, and AV fistulas Types of venous injuries: cerebral venous occlusions, bullet fragment embolus. Content: Rupture of splenic artery pseudoaneurysms approach a mortality of 100 %, thus early recognition with CT and/or CTA is vital. Pseudoaneurysms are the most common sequela in penetration injuries to the head and neck. AV fistulas and pseudoaneurysms commonly occur simultaneously after trauma.Many of the vascular complications secondary to traumatic injuries are adequately treated with angiographic embolization or surgery. Summary: There are characteristic imaging features of vascular injuries that can help the clinician discern when conservative treatment is not enough. CT venogram is most often used currently to evaluate traumatic head injuries. Early indirect signs that are present in venous occlusion are often subtle, like edema of the gyri. When there is no exit wound and there is no bullet fragment in the expected area on plain film, then a CT scan or angiography should be performed to rule out a bullet embolus.

2446. Itshayek, E., et al. (2010). "Stiletto stabbing: penetrating injury to the hypothalamus with hyperacute diabetes insipidus." Clinical neurology and neurosurgery **112**(10): 924-926.

Diabetes insipidus (DI) is a well documented complication observed after traumatic head injuries. We report a case of hyperacute onset DI in a 19-year-old male who sustained a hypothalamic-pituitary injury when he was stabbed in the head with a 30-cm long thin-bladed knife. At CT, our patient showed significant hemorrhagic contusions of the lower hypothalamus. He developed polydipsia, polyuria, and mild hypernatremia in the Emergency Department. Diagnostic digital subtraction angiography showed a hypervascular congestive pituitary gland with prominent draining veins. On the third day his hypernatremia became severe (183mEq/L). He was managed with parenteral fluids and a regimen of intranasal DDAVP (1-desamino 8-d-arginine vasopressin), leading to improved plasmatic sodium levels, urine output, and urinary specific gravity. In patients presenting with hyperacute posttraumatic DI, emergency room physicians and neurosurgeons should rule out direct injury to the hypothalamus and/or the posterior lobe of the pituitary, and initiate early pharmacological treatment.

2450. Iwakura, M., et al. (2005). "Knife blade penetrating stab wound to the brain--case report." Neurologia medico-chirurgica **45**(3): 172-175.

A 28-year-old man attempted to kill himself with a knife stab into the parietal area. Neuroimaging showed no vascular impairment except slow venous flow around the knife due to tamponading. After obtaining informed consent, the knife was removed through a craniotomy without new brain injury. Postoperative neurological findings showed no deficit. Follow-up angiography revealed no vascular impairment. No infection occurred. Brain stab wounds cause numerous complications, such as intracranial hemorrhage, injury of important vessels, and infections. Minimal blade movement during removal and precautions to prevent massive hemorrhage are essential.

2451. Izci, Y., et al. (2005). "Comparison of clinical outcomes between anteroposterior and lateral penetrating craniocerebral gunshot wounds." Emergency medicine journal : EMJ **22**(6): 409-410.

OBJECTIVE: To investigate and compare, using a retrospective clinical study, the clinical outcomes of penetrating craniocerebral gunshot wounds (PCGW) with respect to the trajectory of penetration in the axial plane., METHODS: In total, 22 patients with PCGW caused by conflict, suicide attempt, or accidental firing were included in this study. They were divided into two groups: anteroposterior and lateral. All patients underwent surgical treatment following emergency intervention., RESULTS: Of the 22 patients, 16 had anteroposterior and 6 had lateral penetrating injury. Four patients with anteroposterior and five patients with lateral injury died despite surgical treatment. Mortality rate was 25% in the anteroposterior and 83% in the lateral injury group., CONCLUSION: We found that lateral PCGW is the most devastating type of missile injury to the head.

2452. Izci, Y., et al. (2003). "The clinical, radiological and surgical characteristics of supratentorial penetrating craniocerebral injuries: a retrospective clinical study." The Tohoku journal of experimental medicine **201**(1): 39-46.

Penetrating craniocerebral injuries (PCIs) are the most fatal injuries of the head that usually have a poor outcome. From the parenchymal destructions to ventricular lacerations, a wide variety of damages occurs during the injury. Surgical treatment is still the mainstay of the management in these patients. Twenty-two consecutive patients with supratentorial PCIs were retrospectively evaluated. Conflicts were the main causes of such injuries followed by suicide attempts and accidental gunfires. Shrapnel and bullet were the most wounding agents. All of the patients underwent surgical treatment following clinical and radiological evaluations. Nine of them were died and 7 were rehabilitated because of severe neurological deficits.

2455. Jabbari, B., et al. (1987). "Clinical and radiological correlates of somatosensory evoked potentials in the late phase of head injury: a study of 500 Vietnam veterans." Electroencephalography and clinical neurophysiology **67**(4): 289-297.

Somatosensory evoked potentials were obtained after median nerve stimulation in 500 Vietnam veterans surviving penetrating head wounds 12-16 years earlier and 76 age-matched, uninjured controls. The results were studied in relation to neurologic history and findings, anatomical data provided by CT scan, and information derived from electroencephalograms. Thirty-five percent of head-injured individuals had abnormal SEPs and 76% of SEP abnormalities consisted of absence of N20 or N20/P25 complex. SEP abnormality correlated (P greater than 0.001) with the extent of total brain volume loss, sensory deficits (especially position and cortical discriminatory modalities), hemiparesis, organic mental disorder, CT evidence of parietal or thalamic injury, and centro-parietal EEG abnormalities. Recovery from hemiparesis was correlative with patients who subsequently had normal SEPs.

2456. Jabbari, B., et al. (1986). "Clinical and radiological correlates of EEG in the late phase of head injury: a study of 515 Vietnam veterans." Electroencephalography and clinical neurophysiology **64**(4): 285-293.

Electroencephalograms were obtained in 515 Vietnam veterans 12-16 years after penetrating head injury, and the results were correlated with a variety of clinical and radiological parameters. Forty-two percent of EEGs were abnormal; 9% disclosed epileptiform findings (EF). EF correlated highly (P = 0.0001) with the extent of brain volume loss (defined by CT), posttraumatic epilepsy, and organic mental disorder. 'Seizure persistence' was higher and duration of posttraumatic epilepsy was longer in patients with 'prominent EF.' All patients with anterior temporal or central spike foci experienced posttraumatic seizures. Focal slowing correlated significantly with focal neurologic deficits such as hemisensory deficit or hemiparesis and Broca's aphasia as well as with seizures and residual organic mental disorder. Total or near total recovery from original hemiparesis was noted in 70% of the patients with normal EEG and 32% of the patients with focally slow tracings.

2457. Jabbarinejad, R., et al. (2021). "Determinants of caregiver burden in male patients with epilepsy following penetrating traumatic brain injury." Epilepsy & behavior : E&B **116**: 107768.

PURPOSE: We determined burden of caring for patients with post-traumatic epilepsy (PTE) following penetrating traumatic brain injury (TBI) and identified factors predicting higher burden., METHOD: We assessed 331 caregiver-veteran dyads in Phase 2 (136 PTE, 136 non-PTE, and 59 HC dyads), 133 in Phase 4 (47 PTE, 56 non-PTE, and 30 HC dyads) - 30years later, and 46 dyads in the follow-up study (18 PTE, 19 non-PTE, and 9 HC). Caregiver's burden was measured by Zarit Burden Index and a questionnaire. Veterans completed demographic, mental and physical well-being, quality-of-life, and medical-related information. Caregivers provided information about burden and their assessments of cognitive decline and neuropsychiatric status of the veterans., RESULTS: PTE caregivers perceived significantly more burden than comparison groups at all phases. Bivariate analyses revealed that caregiver distress due to the veteran's neuropsychiatric state including cognitive decline, apathy, and disinhibition and the veteran's characteristics including older age at epilepsy onset and role limitation due to physical problems were associated with higher burden. Finally, we revealed disinhibition distress, and role imitation due to physical problems as the predictors in a model of caregiver burden., CONCLUSION: Elevated PTE caregiver burden is persistent across the life span suggesting that caregivers could benefit from counseling and targeted psychosocial interventions to reduce their burden.

2458. Jablonska, A., et al. (2013). "Different methods of immunosuppresion do not prolong the survival of human cord blood-derived neural stem cells transplanted into focal brain-injured immunocompetent rats." Acta neurobiologiae experimentalis **73**(1): 88-101.

Cerebrovascular diseases are the leading cause of severe disability worldwide, with an enormous financial burden for society. There is growing evidence that stem cell-based therapy may positively influence recovery from stroke. Cord blood is an attractive source of ontogenetically young, yet safe, stem cells. Conceptually, preclinical studies in which donor cells were of human origin have been the most valuable, and thus, it is likely that these cells will be used in clinical trials. Unfortunately, immunological barriers impede discordant xenotransplantations. We have previously observed acute rejection of cord blood derived neural stem cells (HUCB-NSC) after transplantation to the brains of intact animals. Since it was reported recently that a brain lesion may actually improve the chances of graft survival, in this study, we used infarcted animals as graft recipients. In ongoing studies, we tested three immunosuppressive regimes: group I received cyclosporine A (CsA: 10 mg per kg i.p.); group II received a triple-drug therapy (CsA: 10 mg per kg i.p., azathioprine: 5 mg per kg i.p., and methylprednisolone: 1.5 mg per kg i.m.); group III included rats that were formerly desensitized with HUCB, group IV had not undergone immunosuppression. Animals were sacrificed at five time-points: 1, 3, 7, 14, and 21 days post-transplantation to evaluate graft survival and the time-course of immunological response. We observed a gradual decrease in the number of transplanted cells, with complete disappearance by day 14, surprisingly, with no difference among the experimental groups. The involvement of the innate immune system in the process of graft rejection dominated over an adaptive immunoresponse, with the highest activity on day 3, and subsequent fading of immune cell infiltration. In this work, we have shown that none of our immunosuppressive strategies proved adequate to prevent rejection of human stem cell grafts after transplantation into immunocompetent animals.

2459. Jackowski, C., et al. (2004). "Visualization and quantification of air embolism structure by processing postmortem MSCT data." Journal of forensic sciences **49**(6): 1339-1342.

Venous air embolism (VAE) is an often occurring forensic finding in cases of injury to the head and neck. Whenever found, it has to be appraised in its relation to the cause of death. While visualization and quantification is difficult at traditional autopsy, Magnetic Resonance Imaging (MRI) and Computed Tomography (CT) offer a new potential in the diagnosis of VAE. This paper reports the findings of VAE in four cases of massive head injury examined postmortem by Multislice Computed Tomography (MSCT) prior to autopsy. MSCT data of the thorax were processed using 3D air structure reconstruction software to visualize air embolism within the vascular system. Quantification of VAE was done by multiplying air containing areas on axial 2D images by their reconstruction intervals and then by summarizing the air volumes. Excellent 3D visualization of the air within the vascular system was obtained in all cases, and the intravascular gas volume was quantified.

2460. Jackson, A. M., et al. (2008). "Answer to last month's radiology case and image: Keyhole Fracture of the Skull (Case # 31 appears at the end of this article)." Military medicine **173**(12): xix-xx.

2461. Jackson, C., et al. (2012). "Perfluorocarbon emulsion improves cerebral tissue oxygenation after penetrating ballisticlike brain injury in rat." Journal of neurotrauma **29**(10): A214.

Introduction Cerebral ischemia is a common secondary sequela of traumatic brain injury (TBI). The aim of this study is to analyze the pharmacological effect of the normobaric perfluorocarbon (PFC) emulsion (PerftecTM) in the rat penetrating ballistic-like brain injury (PBBI) on cerebral oxygenation using continuous brain oxygen tension (PbtO2, LICOX) monitoring. Methods Adult SD rats received unilateral PBBI and were assigned into one of three groups (n = 7/group). Under anesthesia and controlled ventilation, a small burr hole was made at the right parietal skull and a PbtO2 monitor was inserted into the parietal brain tissue. Another burr hole was made at the right frontal skull for PBBI. After stabilization of the PbtO2 monitor (> 20min), the PBBI probe was inserted and rapidly inflated to induce injury. (1) PFC group: Fifteen minutes post-injury, PFC emulsion (10ml/kg) was infused at a rate of 0.5ml/min through the femoral vein catheter. (2) Vehicle group: An equivalent volume of saline was infused at a rate of 0.5ml/min. (3) Sham control group: Received craniotomy and equivalent saline infusion without PBBI. PbtO2, MAP, and arterial blood gases were compared among the three groups. Data was expressed as percentage change from baseline. Results There were no significant differences in MAP and arterial blood gas data among the three groups. Compared to the sham control group, cerebral oxygen tension was significantly decreased in the PBBI vehicle group. Tissue oxygenation was significantly improved in the PFC group ($p < 0.05$) but not in the vehicle group. At the end of the recording, PbtO2 in the PFC group was significantly higher than in the vehicle group (last 10 minutes; 23.54 - 0.65 vs 20.05 - 0.38 mmHg). Conclusions This study suggests the efficacy of PFC as a therapeutic strategy targeted to abolish/reduce the hypoxia observed in PBBI. Further, volumetric histopathology and cell count studies are under way.

2462. Jackson, F. E., et al. (1965). "Utilization of pulsed sonic beams (echoencephalogram) for detection of fragments of bone indriven into the brain." Military medicine **130**(11): 1107-1109.

2463. Jacob, B., et al. (1989). "Multiple suicidal gunshots to the head." The American journal of forensic medicine and pathology **10**(4): 289-294.

We report two cases of suicide by multiple gunshots to the head. The first victim (of two shots) fired the first shot, which was observed, into his mouth, leading to damage to the left optic nerve and frontal lobe. The man still was able to drive his car home, where he shot himself in his right temple. He died 2 days later. The second victim (of three shots) was a 58-year-old man who was found dead on his bed. Reconstruction of the case disclosed that the first shot had passed through his tongue and slightly damaged the second cervical vertebral body. He then shot himself in his right temple, leading to damage of the temporal lobe. Finally, he shot himself in his left temple, resulting in destruction of the pons. In the first case, an amateurishly modified 8-mm blank revolver firing 6.35-mm- (.25)-caliber ammunition was used; in the second case, a rifle firing 5.6-mm (.22)-caliber ammunition with a reduced charge was used. In both cases, low-energy transfer to brain tissue by the initial bullets was due to low bullet energy or due to the bullets' missing the brain or vital centers.

2464. Jacob, J. T., et al. (2005). "Transorbital penetrating brainstem injury in a child: case report." Journal of neurosurgery **102**(3 Suppl): 350-352.

The authors present the unusual case of a 9-year-old girl who sustained injury to her brainstem as a result of the orbital penetration of a metal projectile (nail) into the juxtamedullary region. This case and others reported in the literature associate this type of injury with relatively minor complications. Thorough imaging of the intracranial contents and surgical removal of the projectile is recommended.

2465. Jacob, O. J., et al. (1999). "Late complications of arrow and spear wounds to the head and neck." The Journal of trauma **47**(4): 768-773.

2466. Jacobi, G. (1992). "[Post-traumatic epilepsy]." Posttraumatische Epilepsien. **140**(9): 619-623.

There might be 3 different forms of epilepsy following head injury: earliest seizures with occasional characteristics, early seizures prompting considerations of differential diagnosis, and, late seizures which might have a chronic course = posttraumatic epilepsy proper. The risks to have posttraumatic epilepsy for a child suffering from head injury are: penetrating cranial trauma, early seizures, intracranial hemorrhage, unconsciousness > 24 hours, depressed fracture with dural laceration and unconsciousness > 24 hours, fractures on the base of the skull, focal synchronous activity in the EEG which is related to the site of brain injury. If a or > or = 2 of b-g are given we recommend prophylactic antiepileptic therapy: in the younger (< 5 years) with a low dose of phenobarbital and in the elder (> 5 years) carbamazepine for at least 2 years of treatment.

2467. Jacobi, K. W. (1975). "[Early keratoplasty after perforating injury of the cornea (author's transl)]." Fruhe Keratoplastik nach perforierenden Hornhautverletzungen **167**(3): 427-434.

A report is given of experiences with early penetrating keratoplasty after perforating injury of the cornea, lens, and vitreous. 10x0-nylon through- and through sutures were used. The technique of operation and the results of treated cases are demonstrated with photos.

2468. Jacobs, B., et al. (2012). "Sucessful treatment with temsirolimus in a patient with cutane and retinal relapse of mantle cell lymphoma." Onkologie **35**: 45.

Introduction: Mantle cell lymphoma frequently presents with extranodal involvement as cutaneous manifestations or cerebral lesions. The mTOR inhibitor temsirolimus, which was recently approved for treatment of relapsed or refractory mantle cell lymphoma, penetrates the blood-brain barrier and may be therefore suitable for treatment of CNS-involvement. Methods: We report here a patient with cutaneous and retinal manifestations of a relapsed mantle cell lymphoma, responding to treatment with temsirolimus. Results: A 71-year old patient presented with blastoid mantle cell lymphoma stage IV (bone marrow, cervical/ abdominal lymph nodes). He was treated with 3 cycles of R-CHOP and R-DHAP respectively and was consolidated with radiotherapy. High dose chemotherapy was not feasible because of significant comorbidities and complications during initial treatment. A good partial remission was achieved. 1 month later, suspected cutaneous recurrence was successfully treated with local steroids. After nearly one year, the patient relapsed with retroperitoneal lymphomas, splenomegaly and ascites. Second line therapy with Rituximab-Bendamustine was started. After 6 cycles, a complete response was achieved. Three weeks later, the patient presented with several new cutaneous lesions on his left arm, impaired peripheral vision of his left eye and new pararenal lymphoma. Ophthalmologic examination was consistent with retinal and vitreous body involvement. Biopsy of the cutaneous nodules confirmed infiltration of blastoid mantle cell lymphoma. Therapy with temsirolimus was started and led to rapid improvement of the peripheral vision, complete response of the cutaneous lesions and partial response of the abdominal lymph nodes. Ophthalmologic examination revealed only small residual lesions in the retina, consistent with cicatrices, and no residual vitreous body infiltration. Therapy was well tolerated. The patient remained stable without any signs of progression up to now for at least 5 months under continuous therapy. Conclusion: We report here for the first time a patient with retinal and vitreous body involvement of relapsed mantle cell lymphoma, successfully

treated with temsirolimus. This case suggests that temsirolimus could be a useful agent for treatment of cerebral manifestations of mantle cell lymphoma.

2469. Jacobs, D. G., et al. (1995). "Transcranial gunshot wounds: cost and consequences." The American surgeon **61**(8): 647-644.

Poor outcomes following transcranial gunshot wounds (TC-GSW) and the perception of significant financial loss have led some institutions to adopt a fatalistic attitude towards these patients. This study was undertaken to define those factors predictive of mortality following TC-GSW as well as to determine the costs and benefits associated with providing care to these individuals. We reviewed the medical records of 57 TC-GSW patients seen at our Level I Trauma Center between January 1990 and December 1992. Overall mortality was 75 percent, and was statistically associated with an admission Glasgow Coma Score of 4 or less, a respiratory rate of less than 10, and self-inflicted wounds. Complete financial information was available for 37 of the 57 patients. Reimbursements for this group were $306,156 and exceeded costs by $62,257. Organ donation efforts were successful in 44.2 per cent of the nonsurvivors (19/43), yielding 60 organs and 29 tissues for transplantation. Nonsurvivors who became organ donors were clinically and demographically indistinguishable from those in whom organs/tissues could not be retrieved. Despite the poor outcome following TC-GSW, vigorous resuscitation and stabilization is justified in all patients, in that nearly one half of nonsurvivors will become organ and/or tissue donors. Concerns regarding excessive monetary looses by treating facilities are unfounded.

2472. Jacobs, J. B. and M. S. Persky (1980). "Traumatic pneumocephalus." The Laryngoscope **90**(3): 515-521.

2473. Jacobs, L. M., et al. (1985). "Crowbar impalement of the brain." The Journal of trauma **25**(4): 359-361.

The management of impaled foreign objects is always a challenge. Stabilization of the object, control of hemorrhage, and adherence to the basic principles of airway and breathing control are hallmarks of prehospital management. Once the patient is in the hospital, a careful assessment of the involved vital structures is essential before removal is attempted. A penetrating injury to the left hemisphere of the brain with a crowbar is presented. This case demonstrates the characteristics of these injuries in terms of extrication, assessment, management of complications, and neurologic sequelae.

2474. Jacobs, N. A. and L. H. Morgan (1988). "On the management of retained airgun pellets: a survey of 11 orbital cases." The British journal of ophthalmology **72**(2): 97-100.

Relevant factors determining the management of inaccessible retained lead airgun pellets are discussed in relation to 11 orbital cases. Although the injuries were of between one month's and 26 years' standing, serum lead levels were normal at under 350 micrograms/l in all instances. This is attributable to the modern alloy composition of the ammunition in question. It is concluded that surgical intervention may be indicated only where there is a mechanical disturbance of ocular motility allied with good visual function.

2475. Jacobson, A. S., et al. (2009). "Asymptomatic lower extremity deep venous thrombosis resulting in fibula free flap failure." The Laryngoscope **119**(6): 1085-1087.

OBJECTIVES/HYPOTHESIS: The successful harvest and transplant of a fibular flap depends on many factors, including healthy inflow and outflow systems. A contraindication to harvesting a fibular flap is disease of the lower

extremity arterial system; therefore, preoperative evaluation of the arterial system is routine. Preoperative evaluation of the venous system is not routine, unless there is clinical suspicion of venous disease., METHODS: Retrospective chart review., RESULTS: Two cases of occult deep venous thrombosis (DVT) were encountered intraoperatively resulting in nontransplantable flaps., CONCLUSIONS: This finding represents a serious concern, and we believe that venous imaging should be considered in patients with significant risk factors for harboring an occult DVT. Laryngoscope, 2009.

2476. Jadhao, S., et al. (2021). "Study of shirogat (head region) avedhyasira and marma with special reference to adhipati and shankha as avedhyasira and sadhyapranharmarma." European Journal of Molecular and Clinical Medicine **8**(1): 214-221.

Ayurved is science of healthy life, which has its unique and useful basic concepts. Out of these concepts, Avedhyasira and Marma-Vigyan are important structural concepts which are described by AcharyaSushrutin SushrutaSamhitaSharirsthan and by AcharyaVagbhat in AstangHridayaSharirsthan. Without studying Avedhyasira and Marma, Surgeon cannot perform skilled and perfect surgery as well as for physician it will be definitely difficult to treat the patients without knowing the perfect location of these structures. In our present study we emphasized on Avedhyasira and Marmain the head region. Specially Adhipati and Shankhathese two structures which are studying in the text as Marma and Avedhyasira are the same, which in the modern texts are given as vital parts. With the help of correlation with modern anatomy, here we try to explain exact anatomicalstructure mentioned as Adhipati and ShankhaAvedhyasiraand sadhyapranharMarma. In ancient time AcharyaSushrut and Vagbhat have clearly mentioned these structures from which incision should not be taken and more care should be taken as they are vital parts and fatal of life. Injury to these structures may cause death also.

2477. Jafari, A. A., et al. (2022). "Paroxysmal sympathetic hyperactivity during traumatic brain injury." Clinical neurology and neurosurgery **212**: 107081.

Traumatic brain injury (TBI) is one of the leading causes of disability, morbidity, and mortality worldwide. Some of the more common etiologies of TBI include closed head injury, penetrating head injury, or an explosive blast head injury. Neuronal damage in TBI is related to both primary injury (caused by mechanical forces), and secondary injury (caused by the subsequent tissue and cellular damages). Recently, it has been well established that Paroxysmal Sympathetic Hyperactivity (PSH), also known as "Sympathetic Storm", is one of the main causes of secondary neuronal injury in TBI patients. The clinical manifestations of PSH include recurrent episodes of sympathetic hyperactivity characterized by tachycardia, systolic hypertension, hyperthermia, tachypnea with hyperpnea, and frank diaphoresis. Given the diverse manifestations of PSH and its notable impact on the outcome of TBI patients, we have comprehensively reviewed the current evidence and discussed the pathophysiology, clinical manifestations, time of onset and duration of PSH during TBI. This article reviews the different types of head injuries that most commonly lead to PSH, possible approaches to manage and minimize PSH complications in TBI and the current prognosis and outcomes of PSH in TBI patients.

2478. Jaja, B. N. R. and P. O. Eghwrudjakpor (2014). "Effect of demographic and injury etiologic factors on intensive care unit mortality after severe head injury in a low middle income country." Annals of African medicine **13**(4): 204-209.

BACKGROUND: Low- and middle-income countries bear the mortality burden of head injury compared with high-income countries. Not much has been studied about predictors of poor outcome after head injury in these countries. This study describes and quantifies the effect of demographics and injury causative factors on mortality in a cohort managed in a Nigerian tertiary hospital intensive care., MATERIALS AND METHODS: A retrospective study was undertaken of all patients admitted into intensive care with severe head injury at the University of Port Harcourt Teaching Hospital, Nigeria between 1 st January, 1997 and 31 st December, 2006. Logistic regression analysis was performed to examine the effect of age, gender and injury etiology on risk of intensive care unit (ICU) mortality., RESULTS: The number of ICU admission for severe head injury was 231 patients with a male to female ratio of 2.8:1. Patients' mean age and standard deviation was 31.2 +/- 15.5 years. The mortality rate was 52.8%. Road traffic injury was the most common etiologic factor (84%). Logistic regression analysis indicated a 56% increase in the risk of ICU mortality between the ages of 21 and 40 years. The effect of age was found to be nonlinear (likelihood ratio P = 0.033). On multivariable analysis, patient's gender (odds ratio 1.07; 95% confidence interval: 0.56-1.97) and etiology of injury were not significantly associated with risk of mortality. Gender was not a modifier of the effect of age (P = 0.218).,

CONCLUSION: The study indicated a strong prognostic effect of age. Gender and etiology of injury had no effect on ICU mortality among study cohort.

2479. Jakobsen, L. K., et al. (2018). "[Insufficient CT scan in visualizing an intracerebral parenchymal damage in a six-month-old boy]." Ugeskrift for laeger **180**(7).

A six-month-old boy fell over, and a crochet hook penetrated his skin underneath his left eye. The hook was removed, and an emergency physician found a Glasgow Coma Scale score of 6-7. A CT scan showed no cerebral or ophthalmic injury. However, the patient was persistently apathic with head- and gaze direction towards the left and a facial nerve palsy. An MRI showed a linear intracerebral lesion stretching through pons into the cerebellar vermis. The patient had neuropaediatric rehabilitation and recovered fully within months. The case is an example of CT scan being insufficient in visualizing intracerebral parenchymal damage.

2480. Jamal, Z., et al. (2021). "Head injury predominance of fire arm injury with temporal bone fracture." Pakistan Journal of Medical and Health Sciences **15**(2): 604-605.

Objective: To identify in patients the causes of head injury and fractured bone in the head. Study Design: Retrospective study Place and Duration of Study: Department of Radiology and Department of Forensic Medicine, Peoples Medical College/Hospital, Nawabshah, Shaheed Benazirabad, Sindh, Pakistan from 1stJanuary 2018 to 31stDecember 2018. Methodology:Six hundred and twenty one cases of fire arm injuries were evaluated. Results:Majority of patients come from rural dwellers, 89 (54.6%) compared to 74 (45.4%) proportionately from urban dwellers. Firearm injury is the leading cause of injury in 61 (36.1%) of cases. Temporal bone 96 (56.8 %) is the most head injured as shown in Conclusion: Most of the patients are from rural areas and among them is the most common cause of head injury is fire arm injury, and temporal bone is also harmed by cranial bone injury.

2481. Jamali, M., et al. (2021). "Multiple Brain Abscesses by an Air Gun Shot: A Case Report." Brazilian Neurosurgery **40**(4): E404-E407.

Introduction Low-velocity penetrating brain injury is not prevalent. In some conditions such as childhood, and with the penetration of a pellet in weak spots of skull, low-velocity penetrating brain injury is expected; however, high-velocity projectiles have also been reported as the cause of severe brain injuries. One of the complications of penetrating brain injury is infection, in which different types of microorganisms play a role. The Streptococcus genus is the leading cause of abscess formation in non-traumatic patients. Multiple brain abscesses are not common. Case Presentation A 10-year-old boy with penetrating brain injury caused by an air gun pellet, who developed signs and symptoms of high intracranial pressure 18 days after the trauma. After the imaging scans and the detection of multiple brain abscesses and severe brain edema, prompt surgical intervention was performed for all three lesions in a single operation. The culture of a pus specimen was positive for Streptococcus species, and, with adequate antibiotic therapy, the patient was discharged from the hospital in good condition. Conclusion Brain injury with air gun shot is not prevalent. The penetration of a low-velocity air gun pellet in weak points of the skull (such as the orbit, the squamous portion of the temporal bone, and the cranial suture), specially in children, can cause significant brain injuries.

2482. James, C. A. (1997). "Magnetic resonance angiography in trauma." Clinical neuroscience (New York, N.Y.) **4**(3): 137-145.

Following blunt or penetrating trauma to the head and neck, a variety of traumatic vascular injuries may occur. Often the clinical presentation of a craniocervical arterial injury is delayed and neuroimaging studies are necessary to evaluate for delayed findings of intracranial infarction or hemorrhage. In this setting, magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) may allow a prompt noninvasive diagnosis of craniocervical vascular injury. MRA may be helpful in selecting those patients requiring conventional angiography and allows a noninvasive follow-up evaluation of arterial injury following institution of therapy.

2483. James, G., et al. (2006). "A case of self-inflicted craniocerebral penetrating injury." Emergency medicine journal : EMJ **23**(5): e32.

2484. Jamjoom, A. B., et al. (1989). "Airgun injuries of the brain." Injury **20**(6): 344-346.

Brain injuries caused by airguns are serious. The optimal management is wound exploration, excision of contaminated tissues and removal of loose bone fragments. In addition, careful monitoring, prophylactic antibiotics and anticonvulsants are required. The outcome is dictated by the importance of the intracranial structures which the pellet transects and the development of complications. Removal of the pellet is desirable only if easily accessible. We report five cases, of which four survived without deficits and one remained severely handicapped.

2485. Jamous, M. A. (2019). "Outcome of Craniocerebral Penetrating Injuries: Experience from the Syrian War." Journal of neurological surgery. Part A, Central European neurosurgery **80**(5): 345-352.

OBJECTIVES: Gunshot wounds to the brain are the most fatal of all firearm injuries. The aim of this study was to evaluate mortality and morbidity in patients with penetrating craniocerebral gunshot injuries and to identify risk factors that affect the outcome., PATIENTS AND METHODS: A retrospective review from June 2012 to November 2013 of 44 Syrian patients with gunshot wound to the head was performed. A thorough physical examination and computed tomography (CT) of the brain was obtained for all patients at the time of admission. Associated systemic injuries were found in 19 patients (43%). Surgical intervention was performed in 25 patients (57%); the remaining patients were managed conservatively. The patients were followed for a period of 1 to 15 months (range: 6 +/- 2 months). Univariate analysis of patient age, sex, type of penetrating object, Glasgow Coma Scale (GCS) score and pupil size on admission, brain CT findings, presence of systemic injuries, and surgical intervention on the patient outcome was performed., RESULTS: Eleven patients (25%) had a bullet injury; the remaining 33 (75%) patients had blast injuries. Initial brain CT revealed different types of skull fractures, intracerebral hemorrhage, and brain edema in all patients. The mortality rate during the follow-up period was 25%. Of the survivors, 25 patients (76%) had a good recovery, eight patients (24%) had a mild disability, and none had a severe disability. The significant factors determining outcome in this series were GCS on admission ($p < 0.005$) and positive pupil reaction to light ($p < 0.05$). The patient age, sex, CT findings, systemic injuries, neurosurgical intervention, and hospital length of stay were not significant prognostic factors ($p > 0.05$)., CONCLUSIONS: Among various variables, GCS and pupil reactivity were the outcome predictors in patients with penetrating craniocerebral injuries. Age, sex, type of penetrating object, CT findings, and surgical intervention did not have a significant effect on survival for these kinds of injuries.

2486. Janas, A., et al. (2019). "Higher DAI grade correlates with worse short term outcome in pediatric traumatic brain injury." Neurocritical care **31**(1): S300.

Introduction Traumatic brain injury (TBI) is the leading cause of disability in children. Neuroimaging is essential for the acute evaluation of moderate-severe TBI, although its prognostic utility is unclear. Magnetic resonance imaging (MRI) allows for detailed characterization of diffuse axonal injury (DAI), the hallmark pathology described in non-penetrating TBI. Higher DAI grade in adults correlates with worse outcome, but this association has not been rigorously tested in children. We hypothesize that acute Rotterdam Score and DAI grade predict short-term functional outcome in children with acute TBI. Methods Patients admitted to Stanford Children's Hospital for acute TBI were identified via retrospective chart review based on ICD9 and ICD10 codes for TBI. Inclusion criteria were age >1mo and <19yrs with blunt, closed head trauma and MRI brain obtained during hospitalization. Exclusion criteria included history of epilepsy, prior TBI, developmental delay, and penetrating or non-accidental trauma. The first head CT and brain MRI obtained during hospitalization were used for analysis of Rotterdam Score and DAI grade, respectively. Discharge destination (home versus facility) was used as a marker of short-term functional outcome. Results Multiple logistic regression analysis on cohort of 44 children revealed that lower GCS and ventriculostomy were independent predictors for discharge to acute rehabilitation (OR 1.6 and 27, respectively) versus discharge home. Neuroimaging analysis revealed that more severe DAI significantly correlated with discharge to a rehabilitation facility ($p=0.011$), while Rotterdam CT score did not correlate with discharge destination ($p=0.106$). Conclusions Our study demonstrates that higher DAI grade is associated with worse short-term outcome in pediatric patients with closed head trauma, similar to findings in adults. Further studies are needed to better understand the short-and long-term prognostic value of acute neuroimaging in pediatric TBI.

2487. Janatpour, Z. C., et al. (2019). "Inadequate Decompressive Craniectomy Following a Wartime Traumatic Brain Injury - An Illustrative Case of Why Size Matters." Military medicine **184**(11-12): 929-933.

Traumatic brain injury has been called the "signature injury" of the wars in Iraq and Afghanistan, and the management of severe and penetrating brain injury has evolved considerably based on the experiences of military neurosurgeons. Current guidelines recommend that decompressive hemicraniectomy be performed with large, frontotemporoparietal bone flaps, but practice patterns vary markedly. The following case is illustrative of potential clinical courses, complications, and efforts to salvage inadequately-sized decompressive craniectomies performed for combat-related severe and penetrating brain injury. The authors follow this with a review of the current literature pertaining to decompressive craniectomy, and finally provide their recommendations for some of the technical nuances of performing decompressive hemicraniectomy after severe or penetrating brain injury.

2488. Janeke, J. B. (1984). "An unusual craniofacial injury. A case report." South African medical journal = Suid-Afrikaanse tydskrif vir geneeskunde **66**(5): 190.

A 13-year-old White boy was operated on for a penetrating craniofacial injury caused by a speargun fishing harpoon. The missile penetrated the left nasal ala, traversed the maxillary sinus and the postero-medial wall of the latter and penetrated the posterior nasopharyngeal soft tissue and mucous membrane, almost abutting the anterior surface of the atlas. At an emergency procedure the missile was retrieved via a combined lateral rhinotomy/Caldwell-Luc approach. In spite of the horrific appearance of the accident there was no neurological deficit and vascular findings were minimal.

2489. Janez-Garcia, L., et al. (2018). "Occult Orbital Injury with Dagger Fragment with Resulting Pneumocephalus." Case reports in ophthalmological medicine **2018**: 5093417.

Penetrating injuries of the cranium are relatively uncommon, only 0.4% of all head injuries. In patients with disturbed conscious level, an extensive examination should be performed in the emergency unit to rule out transorbital penetrating brain injury. A 25-year-old male was attacked with a dagger. He presented with ethylic intoxication and the physical examination demonstrated a small skin injury on the lateral canthus of the left eye with a large periocular hematoma which prevented eyelid opening. Cranial CT scan showed a metallic intraorbital foreign body consisting of a fragment of a dagger which perforated the eyeball, and penetrated through the superomedial wall of the orbit into the anterior cranial fossa. Reconstruction of the eyeball was performed and the fragment was removed. Orbital injuries with a knife in situ are very unusual. Early identification and removal of retained foreign bodies are essential.

2490. Jankovic, S., et al. (2000). "Craniocerebral war missile injuries: clinical and radiological study." Acta neurochirurgica **142**(1): 101-102.

In this study we reviewed the initial clinical and radiological management and early outcomes of 176 consecutive patients from the war in Croatia.

2491. Jankovic, S., et al. (1997). "Early intracranial infections after brain missile injuries--the role of computer tomography in diagnosis and treatment." Acta medica Croatica : casopis Hravatske akademije medicinskih znanosti **51**(4-5): 233-237.

During the war in Croatia, from August 1991 until December 1994, 138 soldiers were treated at the Split University Hospital for different brain injuries inflicted by missiles. Nine of these 138 patients developed intracranial infection. This retrospective study reports on the outcome of these 9 intracranial infections caused by penetrating missile head injuries. In case of clinically suspected infection, computerized tomography scan was obtained at two time points during the course of infection in the same patient. Scans were obtained with and without contrast media, 7 to 14 days after the injury and the 4 weeks later. The role of computerized tomography in the detection and follow-up of various intracranial infections and long-term consequences were evaluated.

2492. Jankovic, S., et al. (1998). "Orbitocranial war injuries: report of 14 cases." Military medicine **163**(7): 490-493.

OBJECTIVE: In this study, we review the initial clinical and radiological management and early outcomes of 14 patients with orbitocranial war injuries treated at the University Hospital Split between 1991 and 1995., METHODS: This investigation involves 14 patients (13 soldiers and 1 civilian) with orbitocranial war injuries. The mean patient age was 31 years (range, 23-54 years). The penetrating object was a metal shrapnel fragment in 8 patients and a bullet in 6 patients. The results of clinical and radiological management were retrospectively analyzed., RESULTS: The mean time from the moment of wounding to hospital admission was 6 hours (range, 1-30 hours). The mean Glasgow Coma Scale score was 8 (range, 3-14). Craniotomy was the basic neurosurgical procedure, and three patients were treated with simple scalp wound debridement and closure. Osteoplastic operations of the orbital bones were performed in 13 patients. Enucleation/evisceration was performed in 6 patients (42.8%). At discharge, the mean Glasgow Outcome Scale score was 13, and 1 patient died in the hospital. Blindness (including amaurosis and anophthalmus) was present in nine eyes (8 patients), light-perception positivity and projection positivity were present in four eyes, and visual acuity was at 0.1 in 1 patient., CONCLUSION: An early multidisciplinary therapeutic approach and computed tomography as a diagnostic procedure are necessary for a good result in the treatment of orbitocranial war injuries.

2493. Jankovic, S., et al. (1998). "Clinical and radiological management of wartime eye and orbit injuries." Military medicine **163**(6): 423-426.

OBJECTIVE: The purpose of this study is to present our experience in treating 191 patients with eye and orbit injuries that occurred during the war in Croatia and Bosnia and Herzegovina., METHODS: The authors retrospectively reviewed the clinical and radiological management of wartime eye and orbit injuries in patients hospitalized at Clinical Hospital Split., RESULTS: Seventy-nine percent of the war eye and orbit injuries were caused by fragments of explosive devices, 9.9% by high-velocity missiles, and 8.4% by other objects. Most of the patients were admitted to the hospital within 24 hours of injury. The total number of injured globes was 222; 48.2% of globes had intrabulbar (mostly magnetic) foreign bodies, and 13% had extrabulbar intraorbital foreign bodies. Extensive wounds (perforation, double perforation, rupture, and evisceration/ enucleation) were encountered in 74% of patients, and 26% of patients had slight trauma. There was a statistically significant correlation between admission within the first 12 hours and postoperative visual acuity (Chi 2 = 3.93; p = 0.0474)., CONCLUSION: Along with clinical examination, computed tomography is the most important diagnostic procedure in preoperative evaluation of various forms of globe and orbit injuries. The admission time is the most important factor in determining postoperative visual acuity.

2494. Januário, J. G. d. O. M. S., et al. (2021). "Non-fatal Bihemispheric Penetrating Brain Injury from a Crossbow Arrow with Good Clinical Outcome: Case Report." Brazilian Neurosurgery **40**(2): e179-e182.

Crossbow injuries to the head have seldom been reported in the literature, and they represent a unique type of penetrating brain injury (PBI) in which a low-velocity arrow results in an intracranial fragment larger than most high-velocity projectiles, usually with a lethal outcome. We present the case of a 34-year-old man who attempted suicide with a self-inflicted cranial injury from a crossbow arrow, with a right parietal point of entry and a palpable subcutaneous tip in the left parietal region. The emergency team reported a Glasgow coma scale (GCS) score of 15, and the patient was brought sedated and intubated. Computed tomography (CT) imaging scans showed that the arrow crossed both parietal lobes, with mild subarachnoid hemorrhage and small cerebral contusions adjacent to its intracranial path. Careful retrograde removal of the penetrating arrow was performed in the CT suite, followed by an immediate CT scan, which excluded procedure-related complications. The patient woke up easily and was discharged 3 days later with mild left hand apraxia and no other neurologic deficits. To the best of our knowledge, there are no similar case reports describing both good clinical outcome and rapid discharge after a bihemispheric PBI. Individualizing the management of each patient is therefore crucial to achieve the best possible outcome as PBI cases still represent a major challenge to practicing neurosurgeons worldwide.

2495. Jaquins-Gerstl, A. and A. C. Michael (2009). "Comparison of the brain penetration injury associated with microdialysis and voltammetry." Journal of neuroscience methods **183**(2): 127-135.

Emerging evidence suggests that differences between microdialysis- and voltammetry-based estimates of extracellular dopamine in the brain might originate in the different penetration injury associated with each technique. To address this issue in a direct fashion, microdialysis probes and voltammetric microelectrodes were implanted in the

rat striatum for 1, 4, or 24 h. Tissues were perfused with a suspension of fluorescently labeled nanobeads to assess blood vessels near the implant. Tissue sections (30 microm) were labeled with antibodies for PECAM, an endothelial cell marker, or GFAP, a glial marker. In non-implanted control tissue, blood vessels were reliably double-labeled with nanobeads and antiPECAM. Tissue near microdialysis probe tracks exhibited ischemia in the form of PECAM immunoreactive blood vessels devoid of nanobeads. Ischemia was most apparent after the 4-h implants. Probe tracks were surrounded by endothelial cell debris, which appeared as a diffuse halo of PECAM immunoreactivity. The halo intensity decreased with implant duration, indicative of an active wound-healing process. Consistent with this, after 24-h implants, the probe tracks were surrounded by hyperplasic and hypertrophic glia and glial processes were extending towards, and engulfing, the track. Carbon fiber microelectrodes produced a diffuse disruption of nanobead labeling but no focal disruption of blood vessels, no PECAM immunoreactive halo, and no glial activation. These findings illuminate the differences between the extent and nature of the penetration injuries associated with microdialysis and voltammetry.

2496. Jaquins-Gerstl, A., et al. (2011). "Effect of dexamethasone on gliosis, ischemia, and dopamine extraction during microdialysis sampling in brain tissue." Analytical chemistry **83**(20): 7662-7667.

Microdialysis sampling of the brain is an analytical technique with numerous applications in neuroscience and the neurointensive care of brain-injured human patients. Even so, implanting microdialysis probes into brain tissue causes a penetration injury that triggers gliosis (the activation and proliferation of glial cells) and ischemia (the interruption of blood flow). Thus, the probe samples injured tissue. Mitigating the effects of the penetration injury might refine the technique. The synthetic glucocorticoid dexamethasone is a potent anti-inflammatory and immunosuppressant substance. We performed microdialysis in the rat brain for 5 days, with and without dexamethasone in the perfusion fluid (10 muM for the first 24 h and 2 muM thereafter). On the first and fourth day of the perfusion, we performed dopamine no-net-flux measurements. On the fifth day, we sectioned and stained the brain tissue and examined it by fluorescence microscopy. Although dexamethasone profoundly inhibited gliosis and ischemia around the probe tracks it had only modest effects on dopamine no-net-flux results. These findings show that dexamethasone is highly effective at suppressing gliosis and ischemia but is limited in its neuroprotective activity.

2497. Jardeleza, C., et al. (2021). "A chopstick snapped in two: A serious pediatric transoral impalement injury requiring external approach (open neck) operative intervention." Otolaryngology Case Reports **21**.

This case report presents a 27-month old child with an oral cavity impalement injury with a retained foreign body and potential great vessel injury. Whilst these oropharyngeal injuries are not uncommon in these subset of patients, most are managed conservatively with minimal injury of the puncture site. This unusual case describes a patient with a retained snapped wooden chopstick through the oral cavity into the parapharyngeal space and adjacent to skull base. Potential external carotid artery and internal jugular vein injury were also identified on imaging. A management algorithm for these potentially catastrophic injuries has been provided.

2498. Jardim, E. C. G., et al. (2011). "Foreign body in preauricular region." The Journal of craniofacial surgery **22**(4): 1531-1533.

Foreign bodies, although they are often found throughout the body, to a lesser degree in the face, still constitute a diagnostic challenge for the trauma surgeon. Its removal means danger of damaging important facial anatomic structures, even if its exact position from the image data was known. So, the objective is to describe a clinical report of a patient (42 years of age, male sex) who experienced falling to the ground, attended by the Department of Surgery and Traumatology Bucco-Maxillo-Facial Surgery, Faculty of Dentistry of Aracatuba, Sao Paulo State University, and 2 days after the trauma, he reported difficulty in mouth opening and pain. After clinical evaluation, we observed the presence of injury in the left preauricular region already in the process of healing. During the intraoral physical examination, a limitation of the mouth opening was noted. Radiographic posteroanterior and profile of the face showed 2 radiopaque foreign bodies in the left side, lying apparently at the region of the mandibular condylar process. Under local anesthesia, foreign body removal was carried from there with access to it through the preexisting facial injury. Further clinical examinations showed an improvement in mouth opening, absence of pain complaints, and/or functional complaints.

2499. Jarho, L. (1973). "Korsakoff-like amnesic syndrome in penetrating brain injury. A study of Finnish war veterans." Acta neurologica Scandinavica. Supplementum **54**: 3-156.

2500. Jarrahy, R., et al. (2001). "Retained foreign body in the orbit and cavernous sinus with delayed presentation of superior orbital fissure syndrome: case report." The Journal of craniofacial surgery **12**(1): 82-86.

Reports of delayed onset of neurological symptoms after penetrating intracranial trauma are rare. We present the case of a patient who presented with superior orbital fissure syndrome 72 hours after reported trauma to the right eye. Subsequent workup revealed a foreign body located within the orbit, passing through the superior orbital fissure and into cavernous sinus, impinging on the right cavernous carotid artery. Evidence of an intraorbital abscess was also present. Surgical management consisted of a combination of frontopterional and orbital approaches to fully expose both the cavernous sinus and the orbital contents. The foreign body was removed and the abscess was drained. The carotid artery was found to be intact. At 10-month follow-up examination, a slight ptosis and medial gaze of the right eye persist. All other symptoms have resolved.

2501. Javadi, S. A. H., et al. (2021). "Long-Term Outcome Following Decompressive Craniectomy in Pediatric Penetrating Blast Brain Injury; a Prospective Study." Archives of Neuroscience **8**(4).

Background: Brain penetrating blast injury is a leading cause of early death due to excessively elevated intracranial pressure (ICP), culminating in trans-tentorial herniation. The role of craniectomy to decrease ICP and secondary injuries has been controversial particularly in pediatric patients. Three cases of pediatric penetrating blast injuries undergoing decompressive craniectomy are reported in Methods: The current study was a prospective series, including fifteen cases of pediatric blast-related brain injury referred to the emergency ward during a period of two years. Three survived patients had a Glasgow Coma Scale (GCS) of four along with anisocoric pupillary light reflex (PLR). Decompressive craniectomy and ventriculostomy (EVD) were performed. The patients underwent ICP monitoring for two weeks. Results: Early postoperative GCS (5 days) was 7/15 in all three patients. Two weeks and one month's GCS were 9 and 14, respectively. After three months, cranioplasty was performed. Long-term follow-up detected no major motor deficits after one year and was associated with excellent school performance. Neuroplasticity resulted in contralateral dominancy and handedness in one case. Conclusions: Survivors of pediatric blast brain injury had a favorable outcome after decompressive craniectomy in the current paper. However, there was a limited number of patients, and the results could not be generalized. Further research in this regard with larger sample size is recommended.

2502. Javeed, F., et al. (2020). "Outcome of cranial firearm injuries in civilian population based on a novel classification system." Surgical neurology international **11**.

Background: Cranial firearm injuries (CFAIs) are expected to be frequent during warfare; however, it is becoming increasingly common among civilian population in our part of the world. these injuries are associated with significant morbidity and mortality in addition to financial loss. the objective of our study is to evaluate the pattern of gunshot injuries to cranium and their outcome. Methods: the study was conducted on 114 patients presenting with CFAIs to Jinnah Postgraduate Medical Centre, Karachi, Pakistan, between June 2015 and January 2019. Patients were evaluated with respect to age, gender, pattern of injury, Glasgow coma scale on arrival, radiological and clinical assessment, surgical intervention, and Glasgow outcome score measured at 6 months follow-up. Results: Among patients with cranial gunshot, injuries most were males (76.3%). More than 50% patients aged between 18 and 35 years. About 46.5% of patients presented with moderate traumatic brain injury commonly involving the temporal lobe (36.8%). Of total 114 patients, 84.2% were managed conservatively but wound debridement was done in all patients. At 6 months, the overall mortality in our patients was 33.3%. Patients with good outcome (GOS 4 and 5) were 30.7% and 35.9% patients had bad outcome (GOS 2 and 3). Complication rate was 14.9% and the most common complication was disseminated intravascular coagulation in 5.2%. Conclusion: Surgical intervention has no significant benefit over conservative management on long-term mortality and should be limited to patients with large intracranial hematomas and intraventricular hematomas causing hydrocephalus.

2503. Jaworski, D. M., et al. (1999). "Intracranial injury acutely induces the expression of the secreted isoform of the CNS-specific hyaluronan-binding protein BEHAB/brevican." Experimental neurology **157**(2): 327-337.

Hyaluronan (HA) plays an important role in tissue reorganization in response to injury. The mechanisms by which HA participates in these processes are likely to include HA-binding proteins. Previously, we reported the cloning and initial characterization of a central nervous system (CNS)-specific HA-binding protein, BEHAB (brain enriched hyaluronan binding), which was independently cloned in another laboratory and named brevican. BEHAB/brevican mRNA is expressed in the ventricular zone coincident with the initial proliferation and migration of glial cells and in surgical samples of human glioma, where glial-derived cells proliferate and migrate. To determine whether BEHAB/brevican is also expressed during the cellular proliferation and migration associated with CNS injury, we have examined BEHAB/brevican expression during reactive gliosis. BEHAB/brevican occurs as secreted and cell-surface, glycosylphosphatidylinositol (GPI)-anchored, isoforms. The secreted, but not the GPI-anchored, isoform is up-regulated in response to a stab wound to the adult rat brain. The temporal regulation and spatial distribution of BEHAB/brevican expression parallel the gliotic response and the expression of the intermediate filament protein nestin. The up-regulation of BEHAB/brevican in response to CNS injury suggests a role for this extracellular matrix molecule in reactive gliosis. Glial process extension, a central element in the glial response to injury, may require the reexpression of both cytoskeletal and matrix elements that are normally expressed during the glial motility seen in the immature brain.

2504. Jayadevan, R., et al. (2014). "A case of penetrating glass foreign body within the renal cortex." Urology **83**(6): e13.

A 32-year-old patient sustained a penetrating injury to the left flank and kidney after a fall backward onto a glass table. On computed tomography imaging, a 12x10x4 cm glass shard was identified penetrating the renal cortex. The patient was taken to the operating room to remove the foreign object. A rubber-shodded clamp was used to successfully remove the glass shard without complication. Although we commonly encounter stab wounds at our trauma center, the penetrating object is rarely present. The presence of the glass object resulted in a technically challenging and rare case.

2505. Jayamanne, D. G. and R. W. Bell (1994). "Non-penetrating corneal foreign body injuries: factors affecting delay in rehabilitation of patients." Journal of accident & emergency medicine **11**(3): 195-197.

A review of 783 patients with non-penetrating, superficial corneal foreign bodies (FBs), indicated that delay in rehabilitation was related to two factors: (1) the size of the abrasion following removal of the FB, larger abrasions requiring longer duration of antibiotic ointment, and (2) inadequate removal of corneal rust. Allergy to chloramphenicol 1% ointment (5.5 in 1000), commonly used in the management of corneal abrasions, is unpredictable and can also impair rapid rehabilitation.

2506. Jazayeri, M. A., et al. (2017). "Management of impacted intramyocardial shrapnel due to gunshot wound." Journal of the American College of Cardiology **69**(11): 2481.

Background: Intramyocardial shrapnel due to gunshot wound (GSW) poses a unique management challenge due to a paucity of data for optimal therapy, particularly with respect to embolization and stroke. Case: A 32-year-old male veteran with a history of alcohol abuse and depression was admitted after a self-inflected GSW to the left chest. There was concern for direct cardiac injury from bullet fragments. Electrocardiogram demonstrated diffuse inferolateral ST-segment elevation, and cardiac troponin I was 8.8 ng/mL. Transthoracic echocardiogram showed preserved ejection fraction, apical dyskinesis, and several 7-mm apical-inferior echodense masses. Non-operative management was pursued due to hemodynamic stability. On day 7 a facial droop was noted. Head CT showed evolving bilateral subcortical infarcts without hemorrhage. Transesophageal echocardiogram demonstrated prior dyskinesis but no intracardiac thrombus or shunt. CT coronary angiogram confirmed the presence of multiple bullet fragments in the left ventricular (LV) myocardium and pericardial space without cavitary filling defect. Decision-Making: His course was complicated by ischemic stroke in bilateral middle cerebral artery territories with a possible cardioembolic mechanism in the context of LV apical dyskinesis. Without compelling indication to remove the shrapnel due to overall clinical stability, and with a general lack of understanding regarding the long term evolution of intramyocardial shrapnel vis-à-vis potential migration, myocardial rupture, and pericardial tamponade, a clinical decision was made following discussions with

Neurology and Surgery colleagues that the potential risks of systemic anticoagulation likely outweighed any conferred benefit in the absence of intracardiac thrombus. The patient was discharged to a rehabilitation facility on day 21 with no further complication 12 months later. Conclusions: Management of intramyocardial shrapnel presents a complex clinical conundrum due to high potential for morbidity with invasive and conservative approaches. Multimodal cardiac imaging and a Heart Team approach may inform decision-making in an otherwise challenging risk-benefit analysis.

2507. Jaźwiec, A. M. and E. D. Komorowska Timek (2022). "The importance of a lifeboat-median artery forearm flap in Goldenhar Syndrome." European Journal of Plastic Surgery **45**(1): 197-201.

We present a case of a 32-year-old male with left-sided Goldenhar Syndrome and delta phalanx of the thumb, who was offered free tissue transfer from the forearm to address an intra-oral soft tissue deficiency. Despite the presence of appropriately developed right radial artery, used in previous facial reconstruction, the left radial artery occurred to be hypoplastic. He ultimately underwent free flap transfer based on the anomalous persistent left median artery. We suggest that in face of an unusual hand anatomy, flexible flap creation techniques that allow a lifeboat strategy of adjusting flap design should be considered preoperatively. Level of evidence: Level V, therapeutic study.

2509. Jedrzejewski, B., et al. (2018). "Pseudoaneurysm of the Superficial Temporal Artery--Two Case Reports of a Rare Entity." Craniomaxillofacial Trauma and Reconstruction Open **2**(1): E70-E75.

In this paper, the authors present two case reports with patients who presented at different institutions for traumatic aneurysmal dilation of temporal vessels. The first case is a 18-year-old male who presented to plastic surgery following attempted excision by an outside provider after a fist fight. The second case is a 22-year-old male who presented to plastic surgery while inpatient after gunshot wound to the face. The differences in the cases are highlighted by the different approaches to the management of the lesions with direct incision and embolization respectively.

2510. Jelača, B., et al. (2022). "Minimally invasive treatment of transorbital penetrating injury of skull base and cavernous sinus - A case report." Vojnosanitetski pregled **79**(3): 301-304.

Introduction. A transorbital intracranial injury with a foreign body can be a very complex and controversial therapeutic problem. The orbit's content is susceptible to penetrating trauma, and neurovascular skull base structures are at high risk from injury. There are some traditional cranial surgical approaches and more recently reported different endoscopic approaches for treating this kind of injury. Case report. We presented a case of a 30-year-old male who had an accident at work when a piece of wood hit him in his head and entered through the medial aspect of his left orbit with skull base and cavernous sinus injury. Rapid and complete radiological and clinical assessments were performed, and the patient was treated in a minimally invasive manner. The foreign body was manually extracted with an endoscopic and endovascular team ready to treat adverse events. No postoperative complications were reported, and visual acuity increased at the one-month follow-up. Conclusion. Penetrating wounds of the orbit represent a challenge that requires a multidisciplinary assessment and well-organized management. Combined endoscopic minimally invasive approaches should be considered during the treatment of this kind of injury.

2511. Jeng, T. C., et al. (2008). "Delayed traumatic intracranial haemorrhage and progressive traumatic brain injury in a major referral centre based in a developing country." The Malaysian journal of medical sciences : MJMS **15**(4): 56-67.

A repeat Computer Tomographic (CT) brain after 24-48 hours from the 1(st) scanning is usually practiced in most hospitals in South East Asia where intracranial pressure monitoring (ICP) is routinely not done. This interval for repeat CT would be shortened if there was a deterioration in Glasgow Coma Scale (GCS). Most of the time the prognosis of any intervention may be too late especially in hospitals with high patient-to-doctor ratio causing high mortality and morbidity. The purpose of this study was to determine the important predictors for early detection of Delayed Traumatic Intracranial Haemorrhage (DTICH) and Progressive Traumatic Brain Injury (PTBI) before deterioration of GCS

occurred, as well as the most ideal timing of repeated CT brain for patients admitted in Malaysian hospitals. A total of 81 patients were included in this study over a period of six months. The CT scan brain was studied by comparing the first and second CT brain to diagnose the presence of DTICH/PTBI. The predictors tested were categorised into patient factors, CT brain findings and laboratory investigations. The mean age was 33.1 +/- 15.7 years with a male preponderance of 6.36:1. Among them, 81.5% were patients from road traffic accidents with Glasgow Coma Scale ranging from 4 - 15 (median of 12) upon admission. The mean time interval delay between trauma and first CT brain was 179.8 +/- 121.3 minutes for the PTBI group. The DTICH group, 9.9% of the patients were found to have new intracranial clots. Significant predictors detected were different referral hospitals (p=0.02), total GCS status (p=0.026), motor component of GCS (p=0.043), haemoglobin level (p<0.001), platelet count (p=0.011) and time interval between trauma and first CT brain (p=0.022). In the PTBI group, 42.0% of the patients were found to have new changes (new clot occurrence, old clot expansion and oedema) in the repeat CT brain. Univariate statistical analysis revealed that age (p=0.03), race (p=0.035), types of admission (p=0.024), GCS status (p=0.02), pupillary changes (p=0.014), number of intracranial lesion (p=0.004), haemoglobin level (p=0.038), prothrombin time (p=0.016) as the best predictors of early detection of changes. Multiple logistics regression analysis indicated that age, severity, GCS status (motor component) and GCS during admission were significantly associated with second CT scan with changes. This study showed that 9.9% of the total patients seen in the period of study had DTICH and 42% had PTBI. In the early period after traumatic head injury, the initial CT brain did not reveal the full extent of haemorrhagic injury and associated cerebral oedema. Different referral hospitals of different trauma level, GCS status, motor component of the GCS, haemoglobin level, platelet count and time interval between trauma and the first CT brain were the significant predictors for DTICH. Whereas the key determinants of PTBI were age, race, types of admission, GCS status, pupillary changes, number of intracranial bleed, haemoglobin level, prothrombin time and of course time interval between trauma and first CT brain. Any patients who had traumatic head injury in hospitals with no protocol of repeat CT scan or intracranial pressure monitoring especially in developing countries are advised to have to repeat CT brain at the appropriate quickest time .

Whereas the key determinants of PTBI were age, race, types of admission, GCS status, pupillary changes, number of intracranial bleed, haemoglobin level, prothrombin time and of course time interval between trauma and first CT brain. Any patients who had traumatic

head injury in hospitals with no protocol of repeat CT scan or intracranial pressure monitoring especially in developing countries are advised to have to repeat CT brain at the appropriate quickest time.

2513. Jenkins, M. T. (1978). "At Parkland Hospital, tragic memories remain. Interview by Brenda Stone." American medical news **21**(46): 1-6.

2514. Jenkins, R., et al. (2017). "Inpatient factors are more strongly associated with tracheostomy than admission characteristics in traumatic brain injury." Neurocritical care **27**(2): S82.

Introduction Recent studies suggest benefits for early tracheostomy in patients with traumatic brain injury (TBI), yet data regarding who will require tracheostomy is lacking. Methods We performed a retrospective analysis of adult TBI patients requiring ICU admission for > 72 hours and mechanical ventilation for > 24 hours between January 2014 and December 2014. Patients who had lifesustaining measures withdrawn were excluded. Admission and inpatient variables were compared. Multivariable logistic regression analyses were used to assess admission and inpatient factors associated with receiving a tracheostomy and to develop models predictive of tracheostomy. Results There were 209 patients (78% men, mean 48 years-old, median GCS 8) meeting study criteria with tracheostomy performed in 94 (45%). Admission predictors of tracheostomy included GCS, Marshall score, injury mechanism, PaO2/FiO2 ratio, and number of quadrants on chest x-ray with consolidation. Inpatient factors associated with tracheostomy included the requirement for an external ventricular drain (EVD), number of operations, pneumothorax, inpatient dialysis, aspiration, reintubation, and the presence of hospital acquired infections. Multiple logistic regression analysis demonstrated that the development of hospital acquired infection (adjusted odds ratio [AOR], 4.78; 95% confidence interval [CI], 2.18-10.48; p < .001), number of operations (AOR, 1.47; 95% CI, 1.2-1.78; p < .001), pneumothorax (AOR, 2.64; 95% CI, 1.08-6.48; p = .034), reintubation (AOR, 7.18; 95% CI, 2.50- 20.54; < .001), penetrating TBI (AOR, 0.14; 95% CI, 0.03- 0.60; p=0.008) and placement of EVD (AOR, 6.73; 95% CI, 3.03- 14.95; < .001) were independently associated with patients undergoing tracheostomy. A model of inpatient variables only was more strongly associated with tracheostomy than one with admission variables only (ROC AUC 0.90 vs. 0.72, P<0.001) and did not benefit from addition of admission variables (ROC AUC 0.91 vs 0.90, P=0.76). Conclusions Potentially modifiable inpatient factors have a stronger association with tracheostomy than do admission characteristics.

2515. Jennett, B. (1975). "The donor doctor's dilemma: observations on the recognition and management of brain death." Journal of medical ethics **1**(2): 63-66.

2516. Jennett, B. and C. Hessett (1981). "Brain death in Britain as reflected in renal donors." British medical journal (Clinical research ed.) **283**(6287): 359-362.

The diagnostic mix of 1228 brain-dead renal donors in Britain was similar to that of 479 cases of brain death recently reported from three neurosurgical units. About half the donors came from non-teaching hospitals without a neurosurgical unit, many of them small and distant from the centre. The different circumstances that preceded brain deaths were examined--namely, diagnosis and whether the fatal ictus of brain damage occurred when the patient was already in hospital--to explain why donors spend varying times on the ventilator. Head injuries accounted for half the donors, and intracranial haemorrhage for almost a third. While many potential donors are not made available, the size of the pool has been overestimated, particularly in regard to head injury. Reduction in organ donation since "Panorama" has been very uneven, with some places increasing their yield; this suggests reluctance of doctors to initiate donation rather than relatives withholding permission.

2517. Jensen, K. O., et al. (2020). "Is there any difference in the outcome of geriatric and non-geriatric severely injured patients?—a seven-year, retrospective, observational cohort study with matched-pair analysis." Journal of Clinical Medicine **9**(11): 1-10.

Geriatric trauma is expected to increase due to the lifestyle and activity of the aging population and will be among the major future challenges in health care. Therefore, the aim of this study was to investigate differences between polytraumatized geriatric and non-geriatric patients regarding mortality, length-of-stay and complications with

a matched pair analysis. We included patients older than 17 years with an Injury Severity Score (ISS) of 16 or more admitted to our level 1 trauma center between January 2008 and December 2015. The cohort was stratified into two groups (age < 70 and ≥ 70 years). One-to-one matching was performed based on gender, ISS, mechanism of injury (penetrating/blunt), Glasgow coma scale (GCS), base excess, and the presence of coagulopathy (international normalized ratio (INR) ≥ 1.4). Outcome was compared using the paired t-test and McNemar-test. A total of 1457 patients were identified. There were 1022 male (70%) and 435 female patients. Three hundred and sixty-four patients (24%) were older than 70 years. Matching resulted in 57 pairs. Mortality as well as length-of-stay were comparable between geriatric and non-geriatric polytraumatized patients. Complication rate (34% vs. 56%, p = 0.031) was significantly higher in geriatric patients. This indicates the possibility of similar outcomes in geriatric polytraumatized patients receiving optimal care.

2518. Jenzer, A. C., et al. (2020). "Traumatic Facial Tattoo Injuries From Gunpowder and Ammunition: A Case Series." Craniomaxillofacial Trauma and Reconstruction **13**(4): 133-137.

Background and Overview: Gunpowder inclusion injuries are rare occurrences in the civilian sector but are more frequently encountered in the military setting. The authors report a case series of 3 active duty military service members treated by an Army hospital's Oral & Maxillofacial Surgery service for the removal of embedded gunpowder particles so as to avoid traumatic tattooing. Case Description: Three otherwise healthy active duty military service members were treated for gunpowder inclusion injuries incurred while conducting live fire training exercises at a state-side military installation between 2018 and 2019. All 3 males presented with injuries of the same etiology: Their weapons malfunctioned, and while visually inspecting the action, a round exploded close to the face. This peppered the face with gunpowder particles that were both superficially and deeply embedded. Treatment focused on individual removal using fine forceps. The patients were followed up and healed quickly without any complications, specifically without traumatic tattooing from the gunpowder injuries. Conclusion and Practical Implications: Gunpowder inclusion injuries should be addressed quickly to remove the particles before epidermal healing occurs, thus avoiding the complication of traumatic tattooing. This surgical team recommends meticulous fine forceps removal as the treatment of choice for larger particles.

2519. Jeon, Y. H., et al. (2014). "Serious penetrating craniocerebral injury caused by a nail gun." Journal of Korean Neurosurgical Society **56**(6): 537-539.

Penetrating cerebral injuries caused by foreign bodies occur rarely due to the substantial mechanical protection offered by the skull. Throughout most of history, the brain, residing in a "closed box" of bone, has not been vulnerable to external aggression. Recently, we encountered a serious penetrat-ing craniocerebral injury caused by a nail gun. Total excision of the offending nail via emergency craniotomy was performed, but the patient's neurologic status was not improved in spite of aggressive rehabilitative treatment. Here, we report on this troublesome case in light of a review of the relevant literature.

2520. Jernigan, S., et al. (2013). "Penetrating intracranial injury treated with fluoroscopically-guided noninvasive removal." Journal of neurointerventional surgery **5**: A66-A67.

Background Spear-like penetrating injuries with retained intracranial foreign bodies have been previously managed with craniotomy and removal in the OR. In this case, with the foreign body traversing both hemispheres, with potential haemorrhage from a large region, we opted for extraction in the angiography suite, with haemorrhage to be managed using endovascular means. Case Report This 20 month-old fell directly onto a pencil, which penetrated her right superomedial orbital wall. She was grossly neurologically intact, other than right eye movements on arrival to the emergency department. A CTA was performed, showing that 14 cm of the pencil were intracranial, traversing the right orbitofrontal region and much of the left hemisphere. The left MCA was narrowed, but there was no intracranial haemorrhage. The right globe appeared intact. The patient was brought to the angiography suite and the pencil was slowly extracted under flouroscopic-guidance and repeated angiography, first in the left hemisphere, and then in the right, once the tip had crossed the midline. Pre- and post-pull angiography demonstrated near normalisation of the caliber of the left MCA after the pencil was removed. The patient initially had mild rightsided hemiparesis, with near complete resolution on follow-up. Vision and extraocular movements are intact. Discussion Due to a potentially wide field of sites of haemorrhage in both hemispheres, we opted to extract this foreign object in the angiography suite

rather than the OR. The patient remarkably tolerated the initial injury with minimal deficits and there was no morbidity related to the extraction. (Figure presented).

2521. Jeromel, M., et al. (2014). "Endovascular embolization of posttraumatic orbital arteriovenous fistula using percutaneous and surgically exposed approach." Journal of Vascular and Interventional Radiology **25**(5): 811.e827-811.e828.

Purpose: Orbital arteriovenous fistula (AVF) is a rare condition that can appear spontaneously or posttraumatically. Endovascular embolization represents effective treatment; however, the approach to the fistula could be challenging. A case of a patient with posttraumatic orbital AVF, treated with combined percutaneous and surgically exposed approach, is presented (Figure 1). Material and Methods: A 52-year-old patient was admitted to an emergency department after a gunshot wound to the right orbitotemporal region. Surgical treatment with enucleation of the affected eye was performed, while retro-orbital intracranial injuries were treated conservatively. A postoperative imaging revealed a posttraumatic AVF in the posterior aspect of the affected orbit. Angiographic study confirmed lowflow communication between small feeders (originating from facial and superficial temporal artery) and the superior ophthalmic vein (Figure 2). The patent achieved a very good clinical recovery with minor neurological deficit. However, due to a progressive variceal enlargement of draining veins, the decision about endovascular treatment was made. The endovascular treatment was performed as a 2-stage procedure. A transarterial approach through a femoral artery was used first. The liquid embolization agent (ethylene vinyl alcohol copolymer) was applied through a selectively catheterized facial artery, resulting in partial reduction of flow to the fistula. An additional transvenous approach through a femoral vein was made with attempt to catheterize an angular vein, which proved to be technically impossible. A second stage endovascular procedure was performed with direct placement of a cannula in the angular vein under surgical exposure (Figure 3). The approach was used as an alternative to transorbital puncture, which in our case was not possible due to previous enucleation. A catheterization of the superior ophthalmic vein and additional transarterial supraselective catheterization of the superficial temporal artery enabled embolization of the fistula. Results: Angiography at the end of the procedure showed almost complete cessation of flow through the fistula, with a tendency to further spontaneous closure (Figure 4). Magnetic resonance imaging after 1 month revealed complete obliteration of the fistula. Conclusions: Endovascular treatment of posttraumatic fistulas could be challenging. A multidisciplinary approach using all possible vascular accesses (percutaneous and surgically exposed) is mandatory. (Figure Presented).

2523. Jewsbury, H. and D. O'Duffy (2011). "The best treatment can be no treatment: retained retro-orbital air gun pellet following attempted suicide." BMJ case reports **2011**.

2524. Jha, R. M., et al. (2021). "Glibenclamide Treatment in Traumatic Brain Injury: Operation Brain Trauma Therapy." Journal of neurotrauma **38**(5): 628-645.

Glibenclamide (GLY) is the sixth drug tested by the Operation Brain Trauma Therapy (OBTT) consortium based on substantial pre-clinical evidence of benefit in traumatic brain injury (TBI). Adult Sprague-Dawley rats underwent fluid percussion injury (FPI; n = 45), controlled cortical impact (CCI; n = 30), or penetrating ballistic-like brain injury (PBBI; n = 36). Efficacy of GLY treatment (10-mug/kg intraperitoneal loading dose at 10 min post-injury, followed by a continuous 7-day subcutaneous infusion [0.2 mug/h]) on motor, cognitive, neuropathological, and biomarker outcomes was assessed across models. GLY improved motor outcome versus vehicle in FPI (cylinder task, $p < 0.05$) and CCI (beam balance, $p < 0.05$; beam walk, $p < 0.05$). In FPI, GLY did not benefit any other outcome, whereas in CCI, it reduced 21-day lesion volume versus vehicle ($p < 0.05$). On Morris water maze testing in CCI, GLY worsened performance on hidden platform latency testing versus sham ($p < 0.05$), but not versus TBI vehicle. In PBBI, GLY did not improve any outcome. Blood levels of glial fibrillary acidic protein and ubiquitin carboxyl terminal hydrolase-1 at 24 h did not show significant treatment-induced changes. In summary, GLY showed the greatest benefit in CCI, with positive effects on motor and neuropathological outcomes. GLY is the second-highest-scoring agent overall tested by OBTT and the only drug to

reduce lesion volume after CCI. Our findings suggest that leveraging the use of a TBI model-based phenotype to guide treatment (i.e., GLY in contusion) might represent a strategic choice to accelerate drug development in clinical trials and, ultimately, achieve precision medicine in TBI.

2525. Ji, K. S., et al. (2019). "Endoscopic endonasal reconstruction of extensive anterior skull base defect from gunshot wound." Journal of Neurological Surgery, Part B: Skull Base **80**.

Introduction: Ballistic injuries involving the skull base can be challenging to manage. Significant bone and soft tissue loss in addition to tissue ischemia, infection, and necrosis can complicate reconstruction. Thorough debridement with transfer of vascularized tissue is an important aspect of management. We describe a case of a patient who presented with a gunshot wound (GSW) to the face causing extensive damage to the anterior skull base and surrounding structures. Method: Case report. Results: A 34-year-old male presented with a GSW to the right face. On arrival, he had a Glasgow coma scale score of 6. The bullet had entered through the right nasal bridge, traversing the right nasal cavity and orbit, and shattering the anterior skull base to penetrate the frontal and parietal lobes. Computed tomography demonstrated acute intracranial hemorrhage in addition to middle cerebral artery dissection, right globe rupture, and destruction of the cribriform and orbital roof with herniation of brain tissue through the anterior skull base defect ([Fig. 11). After emergent bilateral decompressive frontotemporal craniectomy, endoscopic endonasal debridement and reconstruction of the skull base were performed six days later. Intraoperatively, necrotic brain matter was seen protruding from the right nostril ([Fig. 21). Necrotic brain tissue mixed with bony partitions in the nasal cavity was debrided, leaving a defect of the entire right anterior skull base including the orbital roof. An abdominal fat graft was used to fill the large intracranial dead space, and duraplasty using collagen matrix was performed. A nasoseptal flap was then draped over the ethmoid roof and the medial orbit. The patient made an extensive recovery, sustaining mildly diminished cognitive capacity and left hemiparesis. The patient returned 5 months after surgery, and the reconstruction was found to be fully healed on endoscopy ([Fig. 3]). Conclusion: This case demonstrates the utility of the endoscopic endonasal approach to debride and reconstruct an extensive anterior skull base defect resulting from GSW (Figure Presented) .

2526. Ji, T. F., et al. (2017). "[Huge glass foreign body penetrating into the infratemporal fossa through the maxillary sinus:a case report]." Lin chuang er bi yan hou tou jing wai ke za zhi = Journal of clinical otorhinolaryngology, head, and neck surgery **31**(17): 1372-1373.

We report a rare case of glass foreign body penetrating into the infratemporal fossa through the maxillary sinus. The patient felt a little difficulty to open mouth. Both CT and DSA are helpful in diagnosis and treatment. It was important to keep the foreign body stability and integrity, through the modified Weber incision around the original traumatic wound and removal of anterior wall of the maxillary sinus around the foreign body. 2527. Jia, H. and T. Sun (2004). "Extranodal NK/T-cell lymphoma mimicking cellulitis." Leukemia & lymphoma **45**(7): 1467-1470.

NK/T-cell lymphoma is difficult to diagnose because there is no characteristic cytology to help the diagnosis in tissue sections, particularly when there is polymorphic cellular infiltration in the early stage of the disease. However, the nasal type of extranodal NK/T-cell lymphoma has a characteristic histologic pattern, which is angiocentric, angioinvasive and angiodestructive. Therefore, many cases of this tumor may show extensive necrosis that mimics infectious process. Furthermore, because the immunosuppressive status of these patients, they may, in fact, have superimposed infections. We are reporting a case that presented as cellulitis and only after careful examination with immunohistochemistry that a correct diagnosis of extranodal NK/T-cell lymphoma, nasal type, was established. Since this lymphoma is incurable and immunophenotyping is instrumental for the diagnosis and prediction of the prognosis, a high index of suspicion for this tumor is needed when an angiocentric lesion is found in the midline of the head and neck region, and a thorough immunohistological study should always be conducted in these cases.

2528. Jiang, C. and S. Bavishi (2018). "Use of olanzapine for central vestibular dysfunction in a traumatic brain injury patient: A case report." PM and R **10**(9): S98.

Description: The patient sustained a gunshot wound to the head. Initial Glasgow Coma Scale was 14, with unknown duration of loss of consciousness. The bullet entered the left ear, traversed the inferior portion of the left cerebellar hemisphere, and terminated in the midline occipital region. Other significant findings included a subdural hematoma along the posterior foramen magnum. He underwent a left suboccipital craniotomy for posterior fossa decompression. Otolaryngology performed a left mastoid wound exploration with no significant findings. He also developed anxiety and nightmares which was briefly treated with olanzapine. He was eventually admitted to inpatient rehabilitation and at that time was having symptoms of dizziness that did not interfere with his function. His anxiety and nightmares had resolved so olanzapine was discontinued. Within two days of this medication change, his dizziness worsened. On further evaluation the symptoms he described were consistent with vertigo. Physical therapy performed vestibular testing and confirmed that this was a central vestibular dysfunction. His symptoms developed into intractable nausea and vomiting, which did not respond to ondansetron, prochlorperazine, scopolamine patch, or meclizine. He could not tolerate therapies or even a clear liquid diet. Setting: Inpatient rehabilitation facility Results: After more than a week of trialing different medications, olanzapine 2.5mg daily was started, given its off-use label for nausea in cancer patients. The patient's vertigo, nausea, and vomiting improved after one day of treatment. After three days, his symptoms were nearly completely resolved. Discussion: While olanzapine was initially started for anxiety in this case, it is likely that it was also helping with his vertigo. To our knowledge, this is the first case demonstrating that the use of olanzapine can improve vertigo related to central vestibular dysfunction. Conclusions: Olanzapine may be an option to treat central vestibular dysfunction in traumatic brain injury patients.

2529. Jian-Wei, L., et al. (2015). "The clinical characteristics of alcohol-related ocular rupture." Graefe's archive for clinical and experimental ophthalmology = Albrecht von Graefes Archiv fur klinische und experimentelle Ophthalmologie **253**(8): 1307-1311.

PURPOSE: To evaluate the characteristics and outcomes of drunken patients treated for ocular rupture, and to compare these results to patients injured without alcohol consumption., DESIGN AND METHODS: The medical records of 182 patients with or without alcohol consumption before injury who were treated and followed up because of ocular rupture at the Affiliated Hospital of Weifang Medical University from October 2007 to October 2011 were evaluated retrospectively. The characteristics and outcomes of 45 alcohol-related injury patients were compared with the rest in the cohort. The clinical data included in this study were: anatomic sites and length of the wound, involvement of ocular adnexa injuries, evisceration rate, and final mean visual acuity., RESULTS: Wound locations were significantly different between the alcohol-related group and the non-alcohol-related one. Compared with the non-alcohol-related ocular rupture population, the anatomic sites of the drunken patients were more likely to be located at zone I and zone II (60.0 vs 40.1 %; chi2 = 5.39,P < 0.05). The difference of wound length between the alcohol-related group and the non-alcohol-related one was significant. The alcohol-related patients had a longer wound length (Z = -8.590,P < 0.05). Compared with the non-alcohol population, the alcohol-consuming patients were more likely to suffer adnexa injuries (84.4 vs 59.8 %; chi2 = 5.86,P < 0.05), and had worse final visual acuities (Z = -7.195,P < 0.05). The evisceration rate of the alcohol-related patients was significantly higher than the non-alcohol patients (24.4 vs 9.4 %; chi2 = 6.62,P < 0.05)., CONCLUSIONS: Drinking more easily leads to injury of the front part of eyes. Moreover, the drunken patients had a worse visual acuity outcome, longer wound length, higher evisceration rate, and were more prone to endure adnexa injuries. The importance of prevention and education to recognize the hazards of drinking cannot be overemphasized.

2530. Jimenez, C. M., et al. (2013). "Risk factors for intracranial infection secondary to penetrating craniocerebral gunshot wounds in civilian practice." World neurosurgery **79**(5-6): 749-755.

OBJECTIVE: To determine risk factors for intracranial infection secondary to penetrating craniocerebral gunshot wounds (PCGWs) in civilian practice, in patients who underwent surgery with removal of bullet fragments, wound debridement, and watertight dural closure., METHODS: An observational, analytical, prospective, cohort-type study was conducted with follow-up in a group of patients with PCGWs caused by a low-velocity projectile admitted between January 2000 and November 2010. There were 160 patients, 59 of whom were administered prophylactic antibiotics based on the decision of the treating neurosurgeon. Average follow-up time was 39 months (range, 3-92 months)., RESULTS: Infection occurred in 40 patients (25%); 20 patients received antibiotics (20 of 59 [33.9%]), and 20 patients did not receive antibiotics (20 of 101 [19.8%]). Three variables were independent risk factors for infection: (i) persistence of parenchymal osseous or metallic fragments after surgery (P < 0.0001, relative risk [RR] 7.45); (ii) projectile trajectory through a natural cavity with contaminating flora (P = 0.03, RR 2.84); and (iii) prolonged hospitalization time (P < 0.0001,

RR 3.695)., CONCLUSIONS: Administration of prophylactic antibiotics was not associated with the incidence of intracranial infection secondary to PCGWs. Projectile trajectory through potentially contaminating cavities, persistence of intraparenchymal osseous or metallic fragments after surgery, and prolonged hospital stay were independent risk factors for intracranial infection.

2531. Jimenez, I. A., et al. (2021). "Surgical stabilization of traumatic elbow joint luxation and proximal ulnar fracture in a silvery langur (Trachypithecus cristatus)." Journal of the American Veterinary Medical Association **259**(12): 1466-1470.

CASE DESCRIPTION: A 3-year-old 5-kg sexually intact female silvery langur housed in a single-species group at a zoological institution was presented because of acute trauma to the left forelimb., CLINICAL FINDINGS: Radiography of the left forelimb revealed a type II Monteggia fracture (proximal ulnar fracture with cranial displacement and caudal luxation of the radial head). During surgery, disruption of the annular ligament and rupture of the lateral collateral ligament were noted., TREATMENT AND OUTCOME: The langur underwent open reduction and internal fixation of the ulnar fracture and placement of a radioulnar positional screw, a prosthetic lateral collateral ligament, and a temporary hinged type 1A external skeletal fixator. The langur was returned to group housing, underwent behavioral training, and was periodically anesthetized for physical therapy sessions to improve range of motion of the left elbow joint. The external skeletal fixator was removed 4 weeks after surgery, and the radioulnar positional screw was removed 6 weeks after surgery. Three months after surgery, the range of motion of the langur's left elbow joint was considered normal, and the animal returned to normal activity., CLINICAL RELEVANCE: For the captive silvery langur of the present report, surgical stabilization and postoperative management of a type II Monteggia fracture of the left forelimb were successful with recovery of elbow joint function. These techniques may be applied to other captive nonhuman primates, including those that brachiate or are members of social species that must be housed with conspecifics in the postoperative period to maintain group dynamics.

2532. Jinkins, J. R., et al. (1992). "Value of acute-phase angiography in the detection of vascular injuries caused by gunshot wounds to the head: analysis of 12 cases." AJR. American journal of roentgenology **159**(2): 365-368.

A study of the angiographic findings in consecutive civilian patients with cranial gunshot wounds examined in the acute stage has not been done. Most prior clinical studies have evaluated the findings in survivors in the subacute or chronic stages and have often been of war-time casualties. We determined the clinicoradiologic features of six cases of posttraumatic intracranial aneurysm, vascular occlusion, or arteriovenous fistula caused by penetrating missiles among 12 civilian patients who were examined in the acute posttraumatic stage (within 48 hr of injury) during a 1-year period. Three internal carotid/vertebral artery aneurysms, one external carotid artery aneurysm, one combined aneurysm/arteriovenous fistula of the vertebrobasilar circulation, and one cerebral venous occlusion were identified. The 50% overall prevalence of major vascular lesions in this series of civilian patients with penetrating missile injuries examined in the acute stage suggests these injuries are more common than previously suspected. It may indicate that selective cerebral angiography should be considered in the evaluation of the cranial vascular system of such persons.

Transient unilateral forebrain hypoxia-ischaemia (HI) in 14-day-old rats produces infarction and delayed neuronal death in the frontal cortex. Cell death can also be observed in regions distant from the primary injury, a phenomenon known as diaschisis. While apoptosis is involved in selective neuronal death, its role in infarction and diaschisis remains poorly understood. Here, we have investigated the proteolytic cleavage of poly(ADP ribose)

polymerase (PARP) and the occurrence of apoptosis in the hippocampus and the cerebellum following either HI or traumatic brain injury. We demonstrate that: (i) in vitro, PARP is cleaved during apoptosis but not necrosis in cultured neuronal (N1E) cells and Swiss 3T3 fibroblasts; (ii) following HI, apoptotic cells can be detected by 4 h after injury in the hippocampus; (iii) in the ipsilateral hippocampus the appearance of cells with apoptotic morphology is preceded by a dramatic increase in PARP cleavage in the same region, starting immediately following HI and persisting for 24 h; (iv) HI also induces apoptosis in the cerebellum and, as in the hippocampus, the appearance of cells with apoptotic morphology is preceded by PARP cleavage that is greater on the side ipsilateral to forebrain injury; and (v) similarly, traumatic brain injury to the forebrain leads to PARP cleavage and apoptosis in the cerebellum. We conclude that HI injury or traumatic injury to the developing rat forebrain leads to PARP cleavage in directly affected areas and in sites distant from the primary injury that precedes the appearance of cells with apoptotic morphology. Our results are consistent with a role for apoptotic cell death in infarction and in diaschisis resulting from forebrain injury to the developing brain.

2536. John, S. S., et al. (2008). "Missed diagnosis of a wooden intra-orbital foreign body." Indian journal of ophthalmology **56**(4): 322-324.

Intraorbital foreign bodies often present a confusing clinical picture. Wooden foreign bodies are notorious for remaining quiescent for a long time, before presenting with a variety of complications. The wound of entry may often be small and self-sealing. Wooden foreign bodies also show a propensity to break during attempted removal. Intraorbital wood is often not detected by standard diagnostic tests like the computed tomography scan, adding to the diagnostic dilemma. The presence of an intraorbital mass with a discharging sinus should evoke suspicion of a retained organic foreign body, regardless of the time interval between the trauma and current presentation. It is imperative to maintain a high index of suspicion in such cases to avoid misdiagnosis. We report an unusual case of a missed wooden intraorbital foreign body, which spontaneously extruded after five years.

2537. Johnson, B. W., et al. (2015). "Combat-related facial burns: analysis of strategic pitfalls." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **73**(1): 106-111.

PURPOSE: Burns constitute approximately 10% of all combat-related injuries to the head and neck region. We postulated that the combat environment presents unique challenges not commonly encountered among civilian injuries. The purpose of the present study was to determine the features commonly seen among combat facial burns that will result in therapeutic challenges and might contribute to undesired outcomes., MATERIALS AND METHODS: The present study was a retrospective study performed using a query of the Burn Registry at the US Army Institute of Surgical Research Burn Center for all active duty facial burn admissions from October 2001 to February 2011. The demographic data, total body surface area of the burn, facial region body surface area involvement, and dates of injury, first operation, and first facial operation were tabulated and compared. A subset analysis of severe facial burns, defined by a greater than 7% facial region body surface area, was performed with a thorough medical record review to determine the presence of associated injuries., RESULTS: Of all the military burn injuries, 67.1% (n = 558) involved the face. Of these, 81.3% (n = 454) were combat related. The combat facial burns had a mean total body surface area of 21.4% and a mean facial region body surface area of 3.2%. The interval from the date of the injury to the first operative encounter was 6.6 +/- 0.8 days and was 19.8 +/- 2.0 days to the first facial operation. A subset analysis of the severe facial burns revealed that the first facial operation and the definitive coverage operation was performed at 13.45 +/- 2.6 days and 31.9 +/- 4.1 days after the injury, respectively. The mortality rate for this subset of patients was 32% (n = 10), with a high rate of associated inhalational injuries (61%, n = 19), limb amputations (29%, n = 9), and facial allograft usage (48%, n = 15) and a mean facial autograft thickness of 10.5/1,000th in., CONCLUSIONS: Combat-related facial burns present multiple challenges, which can contribute to suboptimal long-term outcomes. These challenges include prolonged transport to the burn center, delayed initial intervention and definitive coverage, and a lack of available high-quality color-matched donor skin. These gaps all highlight the need for novel anti-inflammatory and skin replacement strategies to more adequately address these unique combat-related obstacles.

2538. Johnson, D., et al. (2017). "Acute and subacute microRNA dysregulation is associated with cytokine responses in the rodent model of penetrating ballistic-like brain injury." The journal of trauma and acute care surgery **83**(1 Suppl 1): S145-S149.

BACKGROUND: MicroRNAs (miRNAs) are small stable RNAs that regulate translational degradation or repression of genes involved in brain trauma-mediated inflammation. More recently, miRNAs have emerged as potential novel TBI biomarkers. The aim of this study was to determine if a select set of miRNAs (miR-21, Let-7i, miR-124a, miR-146a, miR-107) that were previously associated with TBI models and clinical studies would be dysregulated and correlated to inflammatory cytokine abundance in the rat penetrating ballistic-like brain injury (PBBI) model., METHODS: Adult male Sprague-Dawley rats received a unilateral frontal 10% PBBI, which produces a temporary cavity. Sham animals received a craniotomy only. Ipsilateral brain tissue and serum were collected 4 hours to 7 days post-injury. Quantitation of miR-21, Let-7i, miR-124a, miR-146a, or miR-107 levels was conducted using Taqman PCR assays normalized to the endogenous reference, U6 snRNA. Brain tissue derived from matching cohorts was used to determine 1L-1beta and IL-6 levels by enzyme-linked immunosorbent assay., RESULTS: Brain tissue Let-7i and miR-21 increased at 4 hours and 1 day, whereas miR-124a and miR-107 were enhanced only 1 day post-injury. MiR-146a displayed a biphasic response and increased 1 day and 7 days, whereas elevation of miR-21 was sustained 1 day to 7 days after PBBI. Pathway analysis indicated that miRNAs were linked to inflammatory proteins, IL-6 and IL-1beta. Confirmation by enzyme-linked immunosorbent assay indicated that both cytokines were increased and peaked at 1 day, but fell at 3 days through 7 days after PBBI, indicating an inverse relationship with miRNA abundance. Serum Let-7i, alone, was differentially abundant 7 days after PBBI., CONCLUSION: Brain tissue-derived miRNAs linked to increased cytokine levels demonstrates a plausible therapeutic target of TBI-induced inflammation. Suppression of serum derived Let-7i may have utility as a biomarker of subacute injury progression or therapeutic responses.

2539. Johnson, D., et al. (2013). "Altered microrna expression at acute time points following penetrating ballistic-like brain injury (PBBI) in rats." Journal of neurotrauma **30**(15): A67.

Introduction Biomarkers of traumatic brain injury (TBI) are being evaluated to aid in diagnosis, track prognosis and demonstrate a therapeutic response to treatment. Recently, microRNAs (miRNAs) have emerged as possible stable TBI biomarkers. Therefore we examined changes in specific miRNAs in our rodent model of penetrating ballistic-like brain injury (PBBI). Methods As a proof-of-concept study, we used the penetrating ballistic-like brain injury (PBBI) model to examine the expression of six specific miRNAs demonstrated previously to change in response to severe brain injury. PBBI injury was caused by the rapid inflation/deflation (i.e. < 40 msec) of an elastic balloon attached to the end of the custom probe, injuring 10% of total brain volume. Sham (control) animals received only a craniotomy. Ipsilateral coronal brain tissue sections 6mm from bregma, were collected 4h, 24h and 72h post injury. Total RNA was isolated from brain tissue sections and cDNA was created via reverse transcription. Real-time PCR was performed using Taqman assays specific to each miRNA of interest. The relative quantities of the miRNAs were normalized to U6 endogenous control. Results Of the six miRNAs studied the relative quantities of miR-21and Let-7i were significantly upregulated in brain tissue at 4 hours post injury compared to sham controls (80% and 60% respectively, $p < 0.05$). Three miRNAs, miR-107, miR-146a and miR-124a, were unchanged 4 hours post injury compared to sham controls. Additionally, miR- 292-5p was undetectable in both injured and sham (control) animals. Investigation of these six miRNAs at 24 and 72 hours post injury are in progress. Conclusions Previous studies in other TBI rodent models have demonstrated an increase in brain miR-21 (FPI) and serum Let-7i (Blast) from 3 hours to at least 24 hours post injury. Here we demonstrate similar increases in brain tissue following PBBI as early as 4 hr post injury. These two specific miRNAs are postulated to be involved in the regulation of apoptotic and neuroinflammatory processes, respectively, both of which are prominent following PBBI. Thus, this study provides proofof- concept that miRNA dysregulation indicative of specific types of secondary injury can be measured in brain following PBBI. Future studies will 1) examine the associated change in these markers in serum and 2) the full genomic arrays to determine if changes occur in other novel miRNAs over the course of PBBI, and 3) establish study the potential utility of miRNAs as biomarkers to aid in the diagnosis, prognosis and tracking of TBI treatments.

2540. Johnson, D., et al. (2014). "Microrna dysregulation occurs at acute time points after penetrating ballistic-like brain injury." Journal of neurotrauma **31**(12): A91.

ecent studies have shown that microRNAs (miRNAs), small RNAs that regulate cellular processes, may serve as novel markers of brain injury. Therefore five miRNAs, previously reported to change in the first 24 hours in other brain injury models, were examined as a proofof-concept study in our severe TBI model. MicroRNAs were measured following penetrating ballistic-like brain injury (PBBI) where a temporary cavity was generated in rats disrupting 10% of brain volume. Sham animals received a craniotomy. Ipsilateral brain tissue was collected 4 h, 24 h, 72 h and 7 d post injury.

Total RNA was isolated, reverse transcribed into cDNA and examined using real-time PCR with Taqman assays. The relative quantities of miRNAs were normalized to U6 endogenous reference gene. Similar to changes described in other TBI models, all miRNAs tested (miR-21, Let-7i, miR-124a, miR-146a, miR-107) were altered at 24 hours post PBBI. Let-7i demonstrated the most acute profile with a 1.6-fold increase at 4 h and a 2.7-fold increase at 24 h after injury. However, changes in Let-7i returned to normal by 72 h. MiR-146a demonstrated both an initial and delayed response to injury with a 2.4-fold increase 24 h after injury which resolved by 72 h but rebounded with a 3.9-fold increase at 7 days after injury. Most notably, miR-21 demonstrated an acute response with a 1.8-fold increase at 4 h that continued to increase over time where a 6.9-fold increase was measured by 7 days post injury. Initial pathway analysis indicated that these specific miRNAs are involved in regulating inflammation, cell migration and cell differentiation at 24 h, sterol metabolism at 72 h and matrix polymerization at 7 days. This study demonstrated that, similar to other TBI models, miRNAs are also altered by PBBI and exhibit temporal signatures of injury. Of interest, miR-21 showed sustained elevation for 7 days suggesting potential value as a therapy biomarker, and potentially aiding in our understanding of the chronic pathology following severe TBI.

2541. Johnson, D. J., et al. (2014). "A molecular method to correlate bloodstains with wound site for crime scene reconstruction." Journal of forensic sciences **59**(3): 735-742.

Bloodstain pattern analysis to determine the wound-of-origin of bloodstains is problematic with nonspecific patterns. In this proof-of-concept study, the authors examined a molecular approach to correlate bloodstains with injuries using the rat as a model. Specifically, investigations were conducted on the rat brain marker, rno-miR-124-3p, with the QIAGEN miScript System and real-time PCR analysis. Rno-miR-124-3p was detected in brain homogenates diluted 100,000 times; in 3-week-old, room temperature stored, simulated brain-blood stains; and in bloodstains from head gunshot wounds collected with swabs and subsequently frozen for 9-18 months; however, rno-miR-124-3p was not detected in whole blood. Proof-of-principle was demonstrated by the ability to distinguish bloodstains from a gunshot wound to the head versus bloodstains from a gunshot wound to the chest, by the testing of otherwise identical bloodstains from the two patterns for the presence of the marker. The results suggest a viable approach to a longstanding problem in casework. Copyright © 2014 American Academy of Forensic Sciences.

2542. Johnson, I. (1984). "Intra-operative ultrasound." Journal of neurosurgical nursing **16**(4): 208-210.

Real time intraoperative ultrasound can provide instant evaluation of the operative field. One can expect high quality images of intracranial anatomy. With such information, the neurosurgeon can make determinations of direction and position as well as depth of the lesion. The procedure is safe and easy to perform. There are no radiation hazards present. It may be advantageous to keep the ultrasound available as one operates to visualize the progress of tumor removal; it can also be utilized after closure of the dura for bleeding or other complications. Biopsy procedures and localization of lesions in the brain can be extremely problematic. The neurosurgeon does not have the luxury of exploring a brain during a craniotomy as a general surgeon does in exploring an abdomen during laparotomy. Despite the fact that modern day technology with angiography and CT scanning may provide excellent preoperative localization information, the neurosurgeon must translate the information into his own perspective when operating and lesions may be missed by a millimeter. Once the transducer visualizes the brain substance, the neurosurgeon can actually observe the progress of the craniotomy.

2543. Johnson, J., et al. (2012). "Gun orientation in self-inflicted craniomaxillofacial gunshot wounds: risk factors associated with fatality." International journal of oral and maxillofacial surgery **41**(8): 895-901.

The purpose of this study was to evaluate whether orientation of a firearm predicts survival, and to identify risk factors associated with fatality in subjects with self-inflicted craniomaxillofacial gunshot wounds. A retrospective cohort study design was used. The primary predictor variable was orientation of the weapon, defined as in the coronal (lateral) or sagittal (anterior-posterior) trajectory pattern. The primary outcome variable was death for subjects on arrival or during their hospital stay. Other covariates measured include demographic, firearm-related, and psychosocial variables. Risk factors for fatality were identified using multivariate logistic regression. Of the 92 subjects that met study inclusion criteria, 47 (67.2) held the firearm in the coronal position. In the full multivariate model, coronal gun orientation (OR=7.7, 95% CI: 2.0, 30.1, p=0.003) and the absence of a psychiatric diagnosis were associated with an increased risk of fatality (OR=0.1, 95% CI: 0.04, 0.5, p=0.002). Coronal firearm orientation was associated with an increased risk of fatality

following self-inflicted craniomaxillofacial gunshot injuries. A patient with a documented psychiatric disorder was not found to be more likely to succumb to this type of injury.

2544. Johnson, L. W. (1986). "A case for organ donation." Journal of emergency nursing **12**(4): 196-198.

2545. Johnson, M., et al. (2018). "A level I trauma center's five-year experience with aggressive management of civilian cranial gunshot wounds." Journal of neurotrauma **35**(16): A142-A143.

Introduction: Civilian cranial gunshot wounds (cGSW) require resource intensive management. Limited data exist to determine which clinical factors should be assessed to direct patient management. At our institution it has been practice to provide aggressive management to all traumatic brain injury patients in accordance with the Brain Trauma Foundation guidelines and the Surgical Management of Traumatic Brain Injury recommendations. Here we present 5-year outcomes from our Level I trauma center with a Tri-State catchment area. Methods: We compiled prospective data from our trauma registry at the University of Cincinnati Medical Center over a five-year period (2012-2017). All patients over 16 years of age with cGSW were included. Records were analyzed for demographic and injury factors that could affect the primary endpoint of mortality during admission. Multivariable regression analysis using age, race, sex, injury motive, transfer status, initial hospital GCS, and Injury Severity score (ISS) was conducted. Results: Of the 251 patients identified, 85.7% were male and the mean age was 33.2 years old (SD 15.2). There were 203 (80.9%) Ohio, 39 (15.5%) Kentucky, and 7 (2.8%) Indiana residents. Thirtyone patients (12.4%) were transferred from an outside hospital. One hundred and thirty-eight (55.0%) patients were alive at discharge, while 113 (45.0%) patients died during admission. Among nonsurvivors, injury motive was more often self-inflicted (53.1% versus 17.4%), and 83.2% had hospital length of stay of one day or less. For survivors, the average total ICU length of stay was 3.77 days (SD 6.0). Multivariable regression analysis showed that age, race, sex, transfer status, and injury motive did not contribute to mortality during admission, while initial hospital GCS (OR 0.67; CI 0.59-0.76) and ISS (OR 1.12; CI 1.05 -1.20) were significantly associated with hospital death. Conclusions: In a large single-center cohort of cGSW, a lower presenting GCS and significant extracranial injury were associated with hospital mortality; the majority of deaths occurred within the first 24 hours. We thus support aggressive management of cGSW patients, with continued treatment for those that survive the critical first day. Ongoing analysis will help identify additional variables important for cGSW survival.

2546. Johnson, M., et al. (2011). "Imaging assessment of traumatic ocular injury in the emergency room." Emergency radiology **18**(6): 465.

Purpose/Aim: 1-To assess the clinical indications for imaging assessment of ocular injuries 2- To review the use of ultrasound, CTandMRI in the setting of traumatic globe injury 3- To demonstrate common and uncommon findings of globe injury 4- To recognize post surgical changes that make mimic foreign body or other globe injury. Background: In the United States, it is estimated that 3% of all emergency room visits are secondary to eye injury, with many seen in combination with other orbital injuries. These often result from motor vehicle accidents and sports-related injuries. Clinical ophthalmologic examination is the key to rapid and accurate diagnosis of most ocular injuries. Imaging, in combination with the ophthalmologic examination, can be a powerful tool in the evaluation of traumatic injury to the globe. Content Organization: Systematic imaging assessment should include the position and density of the lens, the contour and volume of the globe, the density within the globe, the contours of the retina and sclera, the volume within the anterior chamber, and the presence of foreign bodies. It is also important to identify the imaging findings of globe or orbital surgery or remote traumatic injury. We present a representative retrospective series of cases to illustrate a variety of traumatic globe injurues including blunt and penetrating trauma, retinal and choroidal detachment and hyphema among others. We review the roles of CT ultrasound and MR in the assessment of these patients. The post surgical globe may manifest findings that mimic acute pathology. common post surgical appearances are demonstrated. Summary/Conclusion: Traumatic globe injury is an important cause of vision loss. Although clinical ophthalmologic examination is the mainstay of diagnosis, many types of globe injuries have characteristic imaging findings that are useful in treatment planning. Imaging evaluation of the globe should include the density and position of the lens, evaluation of the vitreous and aqueous humor, the shape and contour of the globe, the volume of the globe and the anterior chamber, assessment for retinaland/or choroidal detachments, and the presence of potential foreign bodies. By taking a logical, systematic approach to interpretation of globe imaging, most of these injuries can be elucidated.

2547. Johnson, M. D., et al. (2021). "Single-center experience with antibiotic prophylaxis and infectious complications in civilian cranial gunshot wounds." Neurosurgery Open **2**(1).

BACKGROUND: Despite the widespread adoption of systemic antibiotic prophylaxis in civilian cranial gunshot wounds (cGSWs), there remains a lack of consensus on microbial coverage and duration of therapy. OBJECTIVE: To analyze a 6-yr experience with prophylactic antibiotics in civilian cGSWs with a focus on infectious complications. METHODS: Records were reviewed for demographic and injury characteristics that could influence the risk of intracranial infection. Patients over 16 yr of age with cGSWs who survived more than 48 h were included. Antimicrobial prophylaxis was initiated at the discretion of the treating neurosurgeon, with eligible patients divided into 3 groups: no prophylaxis, single agent, and multiagent. Univariate analysis and multivariable logistic regression were performed to determine variables contributing to the development of intracranial infection. RESULTS: Of 75 eligible patients, prophylactic antibiotics were utilized in 61 (81.3%) with a 5 d median duration. Injury Severity Score (ISS) was significantly higher and Glasgow Coma Scale (GCS) was significantly lower in those who received prophylaxis. Eight intracranial infections were documented (10.7%) over a range of 1 wk to 3 yr from injury. Antibiotic prophylaxis did not contribute to infection, but the presence of cerebrospinal fluid (CSF) leak was associated with intracranial infection risk in multivariable regression (odds ratio [OR] = 11.8, P = .013). CONCLUSION: In a cohort of cGSW patients, those with a more severe injury profile were more likely to receive multiagent antimicrobial prophylaxis. However, we found that multiagent antimicrobial prophylaxis did not confer an advantage, and that the presence of CSF leak may be a more important contributing variable to the development of intracranial infection.

2548. Johnson, M. D., et al. (2020). "An external validation of the surviving penetrating injury to the brain (SPIN) score." Journal of neurosurgery **132**(4): 82.

Introduction: The Surviving Penetrating Injury to the Brain (SPIN) score utilizes clinical variables to estimate in-hospital and six-month mortality following civilian cranial gunshot wounds (cGSW). The initial SPIN score had excellent discrimination (area under the ROC curve (AUC) = 0.968), with good discrimination (AUC = 0.880) in a validation study. The goal of our study was to provide an independent, external validation of the SPIN score for in-hospital mortality. Methods: We retrospectively reviewed six years of data from our institutional trauma registry. SPIN score variables were collected including; gender, transfer status, injury motive, pupillary reactivity, motor Glasgow Coma Score (mGCS) subscore, Injury Severity Score (ISS), and admission international normalized ratio (INR). Multivariable logistic regression identified variables associated with in-hospital mortality. We compared the AUC between models using a non-parametric test for equality. Results: Of the 282 patients identified, 101 had all SPIN score components available. Our SPIN model had an AUC of 0.962. Continuous mGCS alone had an AUC of 0.932 and the addition of all SPIN score components, did not result in a significant increase in AUC (0.957, p=0.26). Using only mGCS resulted in fewer exclusions due to missing data. The AUC for continuous mGCS (0.932) was significantly higher compared to categorical mGCS (0.891, p=0.005). No additional variable included in the predictive model with continuous mGCS was both a significant predictor of inpatient mortality and increased model discrimination. Conclusion: The excellent discrimination of the SPIN score, when applied to our cohort, was due to a single variable. The continuous 6-point mGCS may be sufficient as a generalizable predictor of inpatient mortality in patients with cGSW with excellent discrimination and reduced bias due to missing data. Future prospective studies are needed to assess whether our cohort supports use of SPIN score variables for prediction of 6-month mortality.

2549. Johnson, M. D., et al. (2022). "An independent, external validation and component analysis of the Surviving Penetrating Injury to the Brain score for civilian cranial gunshot injuries." Journal of neurosurgery: 1-8.

OBJECTIVE: The Surviving Penetrating Injury to the Brain (SPIN) score utilizes clinical variables to estimate in-hospital and 6-month mortality for patients with civilian cranial gunshot wounds (cGSWs) and demonstrated good discrimination (area under the receiver operating characteristic curve [AUC] 0.880) in an initial validation study. The goal of this study was to provide an external, independent validation of the SPIN score for in-hospital and 6-month mortality., METHODS: To accomplish this, the authors retrospectively reviewed 6 years of data from their institutional trauma registry. Variables used to determine SPIN score were collected, including sex, transfer status, injury motive, pupillary reactivity, motor component of the Glasgow Coma Scale (mGCS), Injury Severity Score (ISS), and international normalized ratio (INR) at admission. Multivariable logistic regression analysis identified variables associated with

mortality. The authors compared AUC between models by using a nonparametric test for equality., RESULTS: Of the 108 patients who met the inclusion criteria, 101 had all SPIN score components available. The SPIN model had an AUC of 0.962. The AUC for continuous mGCS score alone (0.932) did not differ significantly from the AUC for the full SPIN model (p = 0.26). The AUC for continuous mGCS score (0.932) was significantly higher compared to categorical mGCS score (0.891, p = 0.005). Use of only mGCS score resulted in fewer exclusions due to missing data. No additional variable included in the predictive model alongside continuous mGCS score was a significant predictor of inpatient mortality, 6-month mortality, or increased model discrimination., CONCLUSIONS: Given these findings, continuous 6-point mGCS score may be sufficient as a generalizable predictor of inpatient and 6-month mortality in patients with cGSW, demonstrating excellent discrimination and reduced bias due to missing data.

2550. Johnson, N. A. (1997). "Penetrating BB shot head wound in an asymptomatic 9-year-old girl: the ultimate teaching moment." The Journal of the American Board of Family Practice **10**(2): 125-130.

BACKGROUND: Air rifle BB injuries represent a common type of childhood accident. The purpose of this case report is to encourage all providers of pediatric care to include nonpowder firearm safety education with standard well-child anticipatory guidance., METHODS: A case report is described and experience with similar injuries is discussed from cases found in a literature review using the key words "air rifle," "patient education," "pediatric," "ballistics," and "trauma.", RESULTS: A 9-year-old girl came to the emergency department after having been accidentally shot in the head by her 7-year-old brother with a toy air rifle. The BB shot entered through the left cheek and traversed up into the soft tissue above the mandible, just medial to the internal carotid artery, and posterior to the facial nerve. Other than local pain, she was entirely asymptomatic. The cheek was repaired without complication. Conservative therapy was recommended. She and her family were given anticipatory guidance, and her course thereafter was uneventful., CONCLUSION: Firearm education is not a standard part of every well-child encounter. Injuries by all types of firearms are increasing at epidemic rates. Questioning about the accessibility of both powder- and non-powder-based weapons (ie, air rifle) and providing routine safety education should become the standard of care at all well-child encounters.

2552. Johnson, W. B., et al. (1995). "Indicator expression directed by regulatory sequences of the glial fibrillary acidic protein (GFAP) gene: in vivo comparison of distinct GFAP-lacZ transgenes." Glia **13**(3): 174-184.

An increase in the expression of the glial fibrillary acidic protein (GFAP) gene by astrocytes appears to constitute a crucial component of the brain's response to injury because it is seen in many different species and features prominently in diverse neurological diseases. Previously, we have used a modified GFAP gene (C-339) to target the expression of beta-galactosidase (beta-gal) to astrocytes in transgenic mice (Mucke et al.; New Biol 3:465-474 1991). To determine to what extent the in vivo expression of GFAP-driven fusion genes is influenced by intragenic GFAP sequences, the E. coli lacZ reporter gene was either placed downstream of approximately 2 kb of murine GFAP 5' flanking region (C-259) or ligated into exon 1 of the entire murine GFAP gene (C-445). Transgenic mice expressing C-259 versus C-445 showed similar levels and distributions of beta-gal activity in their brains. Exclusion of intragenic GFAP sequences from the GFAP-lacZ fusion gene did not diminish injury-induced upmodulation of astroglial beta-gal expression or increase beta-gal expression in non-astrocytic brain cells. These results demonstrate that 2 kb of murine GFAP 5' flanking region is sufficient to restrict transgene expression primarily to astrocytes and to mediate injury-responsiveness in vivo. This sequence therefore constitutes a critical target for mediators of reactive astrocytosis. While acute penetrating brain injuries induced focal increases in beta-gal expression around the lesion sites in C-259, C-445, and C-339 transgenic mice, infection of C-339 transgenic mice with scrapie led to a widespread upmodulation of astroglial beta-gal expression. Hence, GFAP-lacZ transgenic mice can be used to monitor differential patterns of astroglial activation in vivo. These and related models should facilitate the assessment of strategies aimed at the in vivo manipulation of GFAP expression and astroglial activation.

2553. Johnstone, D. J., et al. (1993). "The Victoria bomb: a report from the Westminster Hospital." Injury **24**(1): 5-9.

On 18 February 1991 a bomb exploded on Victoria station, London. A total of 51 people were injured including one fatally. Of the most seriously wounded, 30 were treated at The Westminster Hospital. The majority of injuries were

to the lower limbs, but serious wounds were also sustained to the chest, abdomen, forearm, orbit and cranium. Almost all injuries were caused by shrapnel. The low incidence of infection was attributed to thorough early surgical debridement. The administration of antibiotics was varied and uncoordinated, reflecting a lack of a common policy. The exhaustion of common external fixators necessitated the use of equipment unfamiliar to the surgeons and underlined the need for the rapid transfer of equipment between hospitals at the time of major incidents.

2554. Jonas, J. B., et al. (2000). "Prognostic factors in ocular injuries caused by intraocular or retrobulbar foreign bodies." Ophthalmology **107**(5): 823-828.

OBJECTIVE: To evaluate prognostic factors associated with final visual outcome, development of posttraumatic infectious endophthalmitis, and occurrence of proliferative vitreoretinopathy in patients with penetrating ocular injuries caused by intraocular or retrobulbar foreign bodies (FBs)., DESIGN: Clinic-based cross-sectional study., PARTICIPANTS: One hundred thirty patients presenting with penetrating ocular injuries caused by lacerations from FBs were operated on by one of two surgeons between 1989 and 1997. Follow-up time was an average of 20.84 +/- 20.76 months (median: 17.0 months). All FBs were located posterior to the lens., INTERVENTIONS: Pars plana vitrectomy; foreign body removal; additional surgical procedures according to the clinical situation., MAIN OUTCOME MEASURES: Postoperative visual acuity; posttraumatic infectious endophthalmitis; proliferative vitreoretinopathy., RESULTS: Occurrence of posttraumatic infectious endophthalmitis developing in seven patients (7/130 = 5.4%) was significantly (P = 0.026) associated with removal of the FB later than 24 hours after the accident and with the type of the FB (P < 0.01). Size (P = 0.37) of the FB, preoperative visual acuity (P = 0.62), presence of traumatic cataract (P = 0.75) or a retinal lesion by the FB (P = 0.16), age (P = 0.39), and gender (P = 0.46) did not show a statistically significant influence on the occurrence of endophthalmitis. Statistically significant risk factors for the development of proliferative vitreoretinopathy occurring in 27 patients (27 of 99 [27.6%] patients with a minimal follow-up of 3 months) were size of the FB (P < 0.001), preoperative visual acuity (P = 0.02), presence of a retinal lesion (P = 0.002), and traumatic cataract (P = 0.03). The time between FB removal and the accident was statistically marginally associated with the development of proliferative vitreoretinopathy (P = 0.07). Postoperative visual acuity depended significantly on size of the FB (P = 0.002), preoperative visual acuity (P < 0.001), presence of a retinal lesion (P = 0.049), and location of the retinal lesion (P < 0.001). Three eyes had to be enucleated because of endophthalmitis or phthisis bulbi., CONCLUSIONS: Prognosis in open-globe injuries with intraocular or retrobulbar foreign bodies depends on the size and type of the foreign body, presence and location of retinal lacerations, additional involvement of other intraocular structures, preoperative visual acuity, and timing of surgery. These factors may be important in preoperative counseling of the patient and for planning surgery.

2555. Jones, A. M., et al. (1987). "Suicidal contact gunshot wounds to the head with .38 Special Glaser Safety Slug ammunition." Journal of forensic sciences **32**(6): 1604-1621.

Glaser Safety Slug TM ammunition is a uniquely designed, essentially prefragmented ammunition. Tests performed by the U.S. Justice Department demonstrated that the ammunition possesses high kinetic energy, high relative incapacitation index (RII) and poses a very low risk to bystanders because of its total loss of kinetic energy in the target. Despite having been manufactured since 1974, no deaths from this ammunition have been previously reported. The authors herein describe the first three reported human deaths.

2558. Jong, C. N., et al. (1999). "The effect of cocaine on traumatic brain injury outcome: a preliminary evaluation." Brain injury **13**(12): 1017-1023.

The effect of acute cocaine use on the functional and neuropsychological outcome of persons with traumatic brain injury, (TBI) was examined by comparing persons with TBI who tested positive for cocaine at the time of admission with persons with negative drug and alcohol screens. Subjects were matched for age, admission GCS score, level of education, and aetiology of injury (closed vs penetrating head injury). Dependent measures were: the Disability Rating Scale, the Functional Independence Measure, and selected neuropsychological tests. No group differences were found in DRS, FIM, FIM subsets, or FIM change. However, the cocaine group scored significantly lower than the no-drug group on the Rey Auditory Verbal Learning Test, but did not differ on any of the other neuropsychological tests.

2559. Jooma, R., et al. (1984). "Computed tomography in penetrating cranial injury by a wooden foreign body." Surgical neurology **21**(3): 236-238.

We present a case in which the skull and brain were pierced by a piece of wood, the low attenuation value of which, in a CT scan, simulated an intracerebral pneumatocoele. The risk of misinterpreting the CT appearance of intracranial wood is discussed, and the importance of thorough exploration of a penetrating cranial injury is stressed.

2561. Jopp-van Well, E., et al. (2016). "[Reconstructive investigations and identification measures in unknown soldiers of the Second World War]." Rekonstruktive Untersuchungen und Identifikationsmassnahmen bei unbekannten Soldaten aus dem Zweiten Weltkrieg. **237**(5-6): 153-171.

The article reports on the exhumation and identification of unknown soldiers from the Second World War. With the help of medicolegal investigation and reconstruction methods an American pilot presumably murdered by a shot to the head (lynch law) and an interned Italian soldier could be identified after about 70 years and brought back home.

2562. Jordana, F., et al. (2013). "Diagnosis of skull fractures according to postmortem interval: an experimental approach in a porcine model." Journal of forensic sciences **58 Suppl 1**: S156-162.

Most studies on fracture morphology of fresh or dry bones, specifically skull bones, have a limited focus, and they are often based on observations rather than experimental tests. This study characterized pig cranial fractures sustained under known impact conditions. An impact machine (mobile carriage guided by columns) was used to perform a fracture on each skull. Impacts were performed at the same energy level on fresh and dry bones, with two types of impactor: a sharp striker (n = 50) and a blunt striker (n = 50). We found distinct features under different conditions, including osseous flakes on fresh bones, 90degree fracture angles on dry bones, and more fractures with greater fragmentation on dry bones. These features highlighted the effects of time on perimortem fracture characteristics and the importance of bone storage conditions in the study of fracture genesis.

2563. Jorgensen, J. J., et al. (2016). "Injuries caused by fragmenting rifle ammunition." Injury **47**(9): 1951-1954.

INTRODUCTION: Although penetrating injuries are encountered on a regular basis in high volume trauma centres, most civilian trauma teams will be unfamiliar with the treatment of patients with injuries caused by fragmenting ammunition. The terrorist attacks in Norway on July 22, 2011 included a shooting spree causing 69 deaths and 60 injured. One of the weapons used was a semi-automatic rifle, calibre 5.56mm, with soft tip, short stop ammunition. The aim of the present study was to describe the characteristic injury patterns and lessons learned from the treatment of multiple patients admitted at the regional trauma centre with injuries from this type of ammunition., METHODS: We undertook an observational study of patients admitted at Oslo University Hospital, Ulleval after the shooting spree at Utoya on July 22, 2011. Data on demographics, injuries, injury severity, surgical procedures and outcome were collected prospectively., RESULTS: Of the 21 patients admitted after the shooting incident, 18 were identified with injuries caused by fragmenting ammunition and included in the study. Median age was 17 years (IQR 16, 19), median ISS 21 (IQR 12, 30) and 12 patients were female. They had been hit by a total of 38 projectiles, of which 32 were fragmenting bullets. Of the seven patients who sustained injuries to the head, neck and face, one patient required a craniotomy and one patient

had a non-survivable head injury. Of the 11 patients with torso injuries, six of the eight patients with chest injuries had intra-thoracic injuries that could be treated with chest tubes only. One patient had cardiac tamponade, requiring thoracotomy. Six patients underwent laparotomy, four of them more than one. Of the 10 patients with extremity injuries, two had nerve injuries and six patients had fractures. Five amputations were performed within the first nine days. A total of 101 operations were required within the first four weeks. The majority of these were repeated soft tissue debridements due to progressive necrosis., CONCLUSION: Knowledge about the specific challenges created by the progressive soft tissue necrosis caused by fragmenting ammunition should lead to planned, repeated debridements to reduce total tissue loss and complications.

2564. Jorgensen, O. S., et al. (1997). "Synaptic remodeling and free radical formation after brain contusion injury in the rat." Experimental neurology **144**(2): 326-338.

The purpose of this study was to explore whether bilateral frontal cortex contusion in rats would demonstrate changes relevant for understanding the pathology of frontal lobe injury in humans. Rats were allowed to survive for 3, 7, or 18 days postinjury (dpi). In the contused rats, albumin was trapped in frontal cortices, as well as in other brain areas, showing that neurons were exposed to plasma components. In the sham-operated rats, which had only craniotomy but no penetration of dura, the level of trapped albumin was also increased compared to intact controls, suggesting a partial lesion-like condition. Choline acetyltransferase activity was severely decreased in the frontal cortices of contused rats, compared to the sham-operated controls. The decrease was most pronounced at 3 dpi and less pronounced 18 dpi, suggesting that after the initial damage, regeneration of the cholinergic terminals occurred. The concentration of the mature presynaptic membrane protein D3(SNAP-25) was also decreased in the frontal cortices of contused rats at 3 and 7 dpi, whereas it was normalized at 18 dpi. Previously, we have evaluated changes in the rate of synaptic remodeling in brain injury by calculating the ratio of the neural cell adhesion molecule (NCAM) to D3(SNAP-25). The NCAM/D3(SNAP-25) ratio at 3 dpi was elevated by more than 60% in the frontal cortices of contused rats, suggesting a high initial rate of synaptic remodeling. The ratios were smaller at 7 and 18 dpi, suggesting that after the initial burst, the rate of remodeling leveled off. In contrast, astrocyte activation was less pronounced at 3 dpi than at 7 and 18 dpi, as measured by the levels of glial fibrillary acidic protein and glutamine synthetase immunoactivities. The immunoreactivity of glutamine synthetase more than doubled in the contused brains but its enzymatic activity increased less than 50%, suggesting that many enzymatic centers had been inactivated by free radicals. Calculated as the difference between the relative immunoreactivity and the relative enzymatic activity the "lost glutamine synthetase activity" increased continuously in frontal cortex and striatum from 3 to 18 dpi, indicating the production of free radicals long after the initial contusion event. In conclusion, following frontal cortical contusions the early synaptic damage was partly compensated by synaptic remodeling. We suggest that the continuous production of free radicals may have contributed to the declining remodeling rate and impair functional recovery.

2565. Jose, A., et al. (2019). "Management of Life-Threatening Hemorrhage from Maxillofacial Firearm Injuries Using Foley Catheter Balloon Tamponade." Craniomaxillofacial Trauma and Reconstruction **12**(4): 301-304.

The aim of this study is to evaluate the efficacy of Foley catheter in the management of hemorrhage from penetrating maxillofacial injuries in austere environment. This retrospective cohort study evaluated all penetrating head and neck trauma caused by firearm injuries reported to a military hospital at a forward aid location during 2015-2017. Foley catheter was used in the emergency management of bleeding in 11 cases. The effectiveness of this technique in controlling hemorrhage, its indication, contraindications, and complications has been explained. Out of 26 penetrating injuries received during the time period, 11 patients underwent Foley catheter balloon tamponade for the control of hemorrhage. Ten out of 11 patients responded adequately to balloon tamponade. One patient with a bullet lodged inside the neck underwent immediate surgical exploration for its removal and repair of internal jugular vein. No neurological deficits or complications were noted in any of the patients. Foley catheter balloon tamponade is very effective in managing hemorrhage from head and neck penetrating injuries. It significantly reduces the mortality by controlling bleeding from the major vessels especially in a combat environment.

2566. Joseph, A. P., et al. (2021). "An unusual case of a penetrating neck injury (PNI) illustrating the use of a “no zone” approach for the management of this injury and a review of the literature." Trauma case reports **32**.

We present an unusual case of a young male with a penetrating neck injury (PNI) due to a work-related injury. A metallic foreign body traversed from entry at surgical Zone 2 to Zone 1 in the neck and resulted in a transection of the left thyrocervical trunk at the origin with the left subclavian artery. Computed Tomographic Angiography (CTA) of the aortic arch and major branch vessels demonstrated haemorrhage anterior to the left subclavian artery and left thyrocervical trunk. We describe some of the diagnostic and operative challenges which may occur in these rare and life-threatening injuries. We have also reviewed some of the recent key literature on this topic and have collated the recommendations of the review. In recent years, there has been a movement away from selective “zone-based” mandatory surgical exploration for Zone 2 injuries, as well as invasive and time-consuming investigations (such as digital subtraction angiography, contrast oesophageal swallow and bronchoscopy) for Zone 1 and 3 injuries due to the high number of negative surgical procedures and investigations. We demonstrate there is now an evidence-based algorithm which demonstrates that a “no zone” approach to the management of these patients is safe and effective. This requires an initial physical examination looking for the presence or absence of “hard”, “soft” or “no” physical signs in these patients, and then deciding on subsequent management which would include immediate surgery, CTA of the aortic arch and branches (and subsequent surgical or other management) or observation only. Our aim in describing this case it to highlight that there is now good evidence-based guidance for the safe and effective management of patients with this infrequent but potentially fatal injury.

2567. Joseph, B., et al. (2014). "Improving survival rates after civilian gunshot wounds to the brain." Journal of the American College of Surgeons **218**(1): 58-65.

BACKGROUND: Gunshot wounds to the brain are the most lethal of all firearm injuries, with reported survival rates of 10% to 15%. The aim of this study was to determine outcomes in patients with gunshot wounds to the brain, presenting to our institution over time. We hypothesized that aggressive management can increase survival and the rate of organ donation in patients with gunshot wounds to the brain., STUDY DESIGN: We analyzed all patients with gunshot wounds to the brain presenting to our level 1 trauma center over a 5-year period. Aggressive management was defined as resuscitation with blood products, hyperosmolar therapy, and/or prothrombin complex concentrate (PCC). The primary outcome was survival and the secondary outcome was organ donation., RESULTS: There were 132 patients with gunshot wounds to the brain, and the survival rates increased incrementally every year, from 10% in 2008 to 46% in 2011, with the adoption of aggressive management. Among survivors, 40% (16 of 40) of the patients had bi-hemispheric injuries. Aggressive management with blood products ($p = 0.02$) and hyperosmolar therapy ($p = 0.01$) was independently associated with survival. Of the survivors, 20% had a Glasgow Coma Scale score >= 13 at hospital discharge. In patients who died (n = 92), 56% patients were eligible for organ donation, and they donated 60 organs., CONCLUSIONS: Aggressive management is associated with significant improvement in survival and organ procurement in patients with gunshot wounds to the brain. The bias of resource use can no longer be used to preclude trauma surgeons from abandoning aggressive attempts to save patients with gunshot wound to the brain. Copyright Published by Elsevier Inc.

2568. Joseph, B., et al. (2015). "Mild traumatic brain injury defined by Glasgow Coma Scale: Is it really mild?" Brain injury **29**(1): 11-16.

INTRODUCTION: Conventionally, a Glasgow Coma Scale (GCS) score of 13-15 defines mild traumatic brain injury (mTBI). The aim of this study was to identify the factors that predict progression on repeat head computed tomography (RHCT) and neurosurgical intervention (NSI) in patients categorized as mild TBI with intracranial injury (intracranial haemorrhage and/or skull fracture)., METHODS: This study performed a retrospective chart review of all patients with traumatic brain injury who presented to a level 1 trauma centre. Patients with blunt TBI, an intracranial injury and admission GCS of 13-15 without anti-platelet and anti-coagulation therapy were included. The outcome measures were: progression on RHCT and need for neurosurgical intervention (craniotomy and/or craniectomy)., RESULTS: A total of 1800 patients were reviewed, of which 876 patients were included. One hundred and fifteen (13.1%) patients had progression on RHCT scan. Progression on RHCT was 8-times more likely in patients with subdural haemorrhage >=10 mm, 5-times more likely with epidural haemorrhage >=10 mm and 3-times more likely with base deficit >=4. Forty-seven patients underwent a neurosurgical intervention. Patients with displaced skull fracture were 10-times more likely and patients with base deficit >4 were 21-times more likely to have a neurosurgical intervention., CONCLUSION: In patients with intracranial injury, a mild GCS score (GCS 13-15) in patients with an intracranial injury does not preclude progression on repeat head CT and the need for a neurosurgical intervention. Base deficit greater than four and

displaced skull fracture are the greatest predictors for neurosurgical intervention in patients with mild TBI and an intracranial injury.

2569. Joseph, C. (2017). "Characteristics and outcomes of gunshot-acquired spinal cord injury in South Africa." South African Medical Journal **107**(6): 518-522.

Background. Spinal cord injuries (SCIs) caused by assault present a unique challenge facing the healthcare system, in that very little is known about how these injuries manifest compared with other causes of injury. Understanding the nuances of gunshot SCIs could contribute towards better care provision. Objective. To determine the characteristics of gunshot SCI and compare both injury characteristics and outcomes between gunshot SCI and all other traumatic causes taken together. Methods. The gunshot SCI sub-cohort was derived from a 1-year prospective, population-based study, including both tertiary-level hospitals providing SCI care in the Cape Metropolitan area of South Africa (SA). All consenting 145 survivors, after a window period of 7 days, were included, and their demographic and injury characteristics were captured according to the International SCI Core Basic Data Set. Further, selected secondary medical complications (outcomes) were prospectively and routinely assessed throughout acute care. Both descriptive and inferential statistics were used to describe and compare characteristics and outcomes, respectively. Results. Of the 145 survivors of traumatic SCIs, 45 (31%) injuries were caused by gunshots. The gunshot SCI group consisted mainly of males (n=43; 96%), and the average age of injury onset was 26 years. Most survivors of the gunshot SCI group were paraplegic (69%), had complete lesions (69%) and vertebral injuries (96%), and presented with significant associated injuries (84%). When comparing gunshot SCI with all other traumatic causes, significant differences were found in relation to demographic and injury characteristics and adverse outcomes, indicating that those survivors with gunshot SCI were typically younger males with complete paraplegia, had more frequent secondary medical complications, and a longer hospital stay. Conclusion. This study contributes to the knowledge base of survivors with gunshot SCIs in a region of SA. Efforts should be made to reduce the occurrence of all gunshot SCIs, since those injuries impact survivors negatively in terms of injury characteristics and adverse outcomes.

2570. Joseph, G., et al. (2005). "Delayed hydrocephalus as an unusual complication of a stab injury to the spine." Spinal cord **43**(1): 56-58.

STUDY DESIGN: Case report., OBJECTIVE: To report a rare complication following a stab injury to the upper cervical spine and cord., SETTING: National spinal injury unit in a Scottish university teaching hospital., CASE REPORT: A 19-year-old male sustained a stab injury to his upper cervical spine, with a partial cord transection. After 5 months of rehabilitation, his condition deteriorated. CT scans showed hydrocephalus, which was treated by shunting. After shunting, the patient's condition improved but he remained tetraplegic requiring ventilatory support at night., CONCLUSION: Hydrocephalus as a late complication of a cervical spine injury is rare but should be considered if the condition of the patient with an upper cervical spine injury deteriorates. The likely mechanism of the hydrocephalus development is also discussed.

2571. Joubert, C., et al. (2019). "Vacuum-assisted closure (VAC) for craniocerebral wounds in severely injured patients: technical note of a damage control procedure." Journal of the Royal Army Medical Corps **165**(6): e1.

The management of a craniocerebral wound (CCW) remains challenging, particularly in a severely injured patient. Considering the complexity of the multilayer insult and damage control care in an unstable patient, every procedure performed should promptly benefit the patient. We report an illustrative case of a patient with a gunshot wound to the head that resulted in a CCW for which we applied vacuum-assisted closure (VAC) therapy according to damage control principles. We describe the technical approach and discuss the indications, results and technique by considering the literature available. VAC can be used for CCWs, particularly for large defects in selected patients according to clinical and CT evaluations following immediate resuscitation. In severely injured and unstable patients, VAC aims to delay definitive reconstructive and time-consuming treatment. Interestingly, it appears to be a safe treatment based on the previously described-but not exclusively trauma-cases with no secondary cerebrospinal fluid leakage encountered.

2572. Joud, A., et al. (2015). "Foreign body of the brainstem by penetrating injury: Conservative treatment." Neuro-Chirurgie **61**(6): 401-403.

Traumatic brainstem injuries usually lead to severe lesions and unfavourable outcome. In the literature, the few cases with favourable outcome all benefited from surgical removal of the foreign body. We report a very unusual case of a penetrating brainstem injury with a crossbow arrow with conservative treatment and favourable clinical course despite an infectious complication (brainstem abscess). This case illustrates an important gap between a good clinical status and the severity of the lesion highlighted by CT scan. In addition, a collegial decision was made not to treat the lesion surgically, but only the complication, the abscess, by stereotactic puncture. The treatment must thus be tailored in this type of lesion.

2573. Jourdan, C., et al. (1993). "[Cranio-cerebral gunshot wounds in civilian practice in children]." Plaies cranio-cerebrales par balle en pratique civile chez l'enfant. **48**(5): 389-396.

The circumstances and the prognosis of six gunshot craniocerebral wounds in civilian children are presented. The cause is a suicide in two cases and an accident in four cases. In three out of these four cases, another person is responsible for this accident, an adult two times, a child in one case. When the accident is due to a child, it is always by play and one time the accident is the autofact of a 2-year-old boy. In all cases, the fire arm was loaded and an adult's imprudence is present. The mortality is important (4/6). More than the initial clinical state, the seriousness of which is not a pejorative indice, the prognosis is subordinated to the CT scan aspect about the missile tract, and to the initial value of the intracranial pressure.

2574. Jousset, N., et al. (2010). "Suicide by skull stab wounds: a case of drug-induced psychosis." The American journal of forensic medicine and pathology **31**(4): 378-381.

Suicide by stabbing to the head and/or driving sharp objects into the skull is of extreme rarity. This article reports the case of a 27-year-old man, who committed suicide by multiple knife stabs and cuts to the head, the torso, one shoulder and the forearms. Autopsy showed a perforating wound of the skull and the 10-cm long broken blade of the knife being still embedded in the right temporal lobe of the brain. The deceased had no history of psychiatric illness but was currently treated by mefloquine, a quinine derivative associated with a high rate of psychiatric adverse effects. Toxicological examination confirmed a recent intake of mefloquine together with chloroquine, another antimalarial drug. To our knowledge, this is the first report of a completed suicide with very strong evidence of mefloquine implication. Discussion focuses upon mefloquine-induced psychiatric disorders and highlights the importance of performing toxicological investigations in cases of unusual suicides.

2575. Jovanovic, M., et al. (2002). "[Problems in diagnosis and extraction of foreign bodies from the orbit associated with pain]." Problem dijagnostike i ekstrakcije stranog tela u orbiti pracenog bolovima. **130**(11-12): 412-415.

The aim of this study was to present the troubles and significance of a proper diagnosis of a foreign body which caused a double perforation of the eyeball and was retained in the orbit. Another reason for this case report was the intensive pain associated with the existing foreign body in the orbit. A male, 54 years old, had a perforating wound of the eyeball caused by a metal foreign body, which stayed in the orbit close to the scleral wall. X-ray and echographic examinations of the orbit were not conclusive regarding the question whether this foreign body was situated within or outside the eyeball. Only CT imaging showed that foreign body produced a double perforation of the eyeball and was externally close to the sclera. Foreign body was extracted by transconjunctival anterior orbitotomy through the inferior fornix, using the electromagnetic probe. Since the first day of injury and up to the eighth day, the patient had intensive deep orbital pain, which was alleviated only partially by analgetics. It could not be explained by secondary glaucoma because IOP was normal or by an inflammatory process, or in any other way. Only the extraction of foreign body from the orbit led to the complete relief of pain. We believe that the pain was caused by compression of foreign body to some of scleral sensory nerves. X-ray and echographic examinations of the orbit are not always a reliable proof in the proper evaluation whether foreign body is within or outside the eyeball in the orbit. Precise diagnosis can be made only by CT imaging. The pain in the orbit may be caused by compression of foreign body to sensory nerves.

2576. Judd, O. and J. P. Wyatt (2007). "Circular saw suicide." Journal of forensic and legal medicine **14**(4): 235-237.

A case of an individual who died as a result of a self-inflicted circular saw injury to the head is presented. Death appeared to result from massive haemorrhage from injury to the superior sagittal sinus. The described mechanism of injury appears to be very unusual and may have reflected underlying issues. In particular, potential background factors resulting in the self-infliction of an injury to the head are discussed.

2578. Jurda, M., et al. (2019). "Digital restoration of fragmentary human skeletal remains: Testing the feasibility of virtual reality." Journal of forensic and legal medicine **66**: 50-57.

Experts in forensic anthropology and medicine have become gradually accustomed to examining components of the human body in the virtual workspace. While the computer-assisted approach offers numerous benefits, the interactions with digital three-dimensional biological objects are often problematic, particularly if conducted with mouse, keyboard and flat-panel screen. The study focusses on feasibility of a virtual reality (VR) system for virtual restoration of fragmentary skeletal remains. The VR system was confronted with three cases of fragmentary remains. The cases were reassembled manually by twenty participants using a HTC Vive headset combined with an in-house application A.R.T. The same task was performed using a CloudCompare software in conjunction with a desktop peripheral. The two systems were compared in terms of time efficiency, the geometric properties of the resulting restorations, and convenience of use. Restoration using the VR system took approximately half the time the desktop set-up did. The VR system also yielded a lower error rate when a severely fragmented skull was reassembled. Ultimately, although the efficiency of the reassembling was shown to be strongly dependent on the operator's experience, the use of the VR system balanced out the uneven levels of proficiency in computer graphics. The current generation of virtual reality headsets has a strong potential to facilitate and improve tasks relating to the virtual restoration of fragmented skeletal remains. A VR system offers an intuitive digital working environment which is less affected by an operator's computer skills and practical understanding of the technology than the desktop systems are.

2579. Jurgens, C., et al. (2008). "[Use of high-frequency ultrasound for foreign body imaging in chronic conjunctivitis due to microtrauma]." Fremdkorpernachweis mittels Hochfrequenzsonografie bei chronischer Konjunktivitis durch Mikrotrauma. **225**(7): 660-662.

Conjunctivitis is a frequent disease mostly caused by infections. In the case of a single-sided manifestation and additional resistance to anti-infective therapy a widespread differential diagnosis has to be considered. The case report of a 41-year-old patient suffering from unilateral persistent conjunctivitis is presented. Initially, there was no biomicroscopic evidence for a penetrated ocular foreign body. The unilateral, chronic and sectoral conjunctivitis was resistant to topical application of antibiotics and steroids. After repeated in-depth anamnesis the patient recalled an inconsiderable trauma while he was working on a building site. High-frequency ultrasound was used to locate an intrascleral foreign body 3 mm behind the limbus corneae while slit lamp biomicroscopy and ophthalmoscopy failed to detect the foreign material. The precise localisation provided by the 20-MHz sector scanner optimised the management of operative intervention and consequently led to an uncomplicated extraction of the bulbar foreign body.

2580. Juricek, L., et al. (2011). "[The real firing wound of type of skull perforation and head penetration compared with the mathematical model of behaviour of FMJ pistol projectile of calibre of 6.35 mm Browning (25 Auto)]." Realne strelne poraneni typu prustrel lebky a zastrel hlavy ve srovnani s matematickym modelem chovani FMJ strely pistoloveho naboje raze 6,35 mm Browning (25 Auto). **56**(4): 50-52.

Searching for the answer whether the bullet cal. 6.35 mm Browning (25 Auto) could entrance the human skull and stay inside without resting the head against the solid barrier inside the vehicle, forensic experts in the field of ammunition and wound ballistics used mathematical model of the monoogival pistol bullet's velocity decrease through the penetration of the several type of human tissue due to physical and mechanical properties. The result of the expert's terminal ballistics task was the mathematical prediction of wound track length at the moment of bullet's stop in the

tissue. The results has been compared with the cases where the similar weapon system with the resembling energetic output has been used.

2581. Just, T., et al. (2000). "[Danger from exploding fireworks and blank firearms]." Gefahrdung durch explodierende Feuerwerkskorper oder Schreckschusswaffen. **48**(12): 943-948.

Explosive amusement and deterrent articles such as New Year's Eve cannons and rockets, toy pistols, and blank guns are not at all harmless items. Their potential dangerousness is often extremely underestimated. Two damaging mechanisms are important: during explosions, high pressures and temperatures develop and a considerable sound pressure level can be measured. If the explosion happens near the human body (intentionally or inadvertently), not only superficial lesions can occur, but also (mainly due to contact shots) serious, deep-seated tissue damage, especially in the head and neck region with its endangered sense organs such as eye and ear, the vessels and nerves supplying the brain, the speech- and voice-forming apparatus, and in particular the face, can be the consequence. Their mutilation can lead to serious and extensive interpersonalchanges. Accidents are published in the relevant otological and forensic medical papers, but nevertheless it seems important to us to point out the dangerousness of these readily available items.

2583. Jusue-Torres, I., et al. (2016). "Wooden Foreign Body in the Skull Base: How Did We Miss It?" World neurosurgery **92**: 580.e585-580.e589.

BACKGROUND: Timely detection of intraorbital and skull base wooden foreign bodies is crucial. Wooden foreign bodies are difficult to detect on imaging. The radiologist may fail to identify wooden foreign bodies on two thirds of initial scans and can miss them in almost one third of total cases., CASE DESCRIPTION: A 66-year-old woman sustained a penetrating injury through the left upper eyelid with a small tree branch. The branch was immediately removed in the field, and she was provided with prompt medical care at a local hospital. Initial computed tomography (CT) scan diagnosis was "posttraumatic sinusitis," and this was treated empirically with vancomycin and piperacillin/tazobactam. On the eighth day after injury, she developed progressive swelling and pain of her eyelid with left trigeminal/supraorbital numbness and complete left ophthalmoplegia. A new CT scan showed an open "track" from the region of the left upper orbit/superior rectus to the contralateral sphenoid sinus, which raised suspicion for a retained foreign body. Further imaging confirmed the suspicion. Endoscopic sinus surgery was performed with extraction of the wooden object and evacuation of the left orbital infection., CONCLUSIONS: This case indicates that intraorbital and skull base wooden foreign bodies are elusive, demanding a high index of suspicion from both clinicians and radiologists to identify retained material in the setting of ocular or sinus trauma. For better identification of wooden foreign bodies, bone windows on CT should have a width of -1000 Hounsfield units with a soft tissue window level of -500 Hounsfield units. 2584. Kabugi, J. G. and S. Okelo (2011). "Awake nasotracheal fiber-optic intubation in a patient with severe gunshot injury to the face: Case Report." Annals of African Surgery **7**: 66-67.

Facial trauma significantly increases the difficulty in airway management in the emergency department or during the provision of anesthesia for surgery. We present airway management in a patient with severe facial trauma that necessitated awake nasotracheal fiber-optic intubation for safe induction of anesthesia.

2585. Kacheris, B. N., et al. (2019). "Penetrating intracranial trauma of two minors treated with endovascular technique with the use of temporary balloon occlusion for proximal arterial control." BMJ case reports **12**(4).

We present two children treated with endovascular techniques to gain proximal arterial control of the internal carotid and vertebral artery prior to removal of penetrating objects from the skull base. Both siblings (8-month-old and 22-month-old boys) were injured by different sharp objects (knife and scissor) by a guardian. They were transported to the emergency room where vascular control, including coil embolisation and internal carotid balloon occlusion, was

performed in the neuroendovascular suite for safe removal of penetrating objects. Both minors recovered and were discharged home without any focal neurological deficits. In two children with scissor and knife stab with intracranial penetration, endovascular technique allowed safe removal of objects and ensured proximal arterial control was maintained to control for possible extravasation of blood on removal from the skull base.

2586. Kadhim, A. H. K., et al. (2020). "Cranial falling bullet injuries, a series of 30 cases in Iraq." British journal of neurosurgery **34**(2): 135-141.

Purpose: The purpose of this study is to highlight the importance of cranial falling bullet injuries and raise awareness about them. We studied the clinical and radiological findings, and their relation to the treatment and outcome. There are limited studies in this field. Materials and methods: Thirty patients, (aged 8-55 years) with cranial falling bullet injury were included in this study. They were followed during their hospitalization and up to 6 months thereafter. Post-resuscitation clinical findings, unenhanced brain CT scan findings, treatment and outcome (Glasgow Outcome Scale) were studied. Results: Male to female ratio was (1.73:1). Median age of all patients was: 17.5 years. 20(66.7%) patients had a GCS of 13-15, 3(10%) had 9-12, 2(6.7%) had 6-8, and 5(16.6%) had 3-5 at presentation. 23(76.7%) patients had normal pupillary reaction and symmetry whereas 7(23.3%) had poor reaction and/or asymmetry. On CT scan, 13 had a unilobar injury, six had multilobar or bihemispheric injuries, 10 had a bullet through the deep midline structures of the brain, seven had transventricular with IVH, four had SAH, none had large intracranial hematomas. All patients received medical treatment. Local wound care and/or extraction of extracranial subgaleal bullets were performed in 24 patients (80%). More extensive surgery was performed in six patients (20%). There was significant correlation (using Correlation Coefficient) between GCS, pupillary reaction/symmetry and CT imaging findings with the patient outcome. Low GCS, poor pupillary reaction and/or asymmetry, CT findings of central area injury, transventricular, IVH, or multilobar injury were associated with poor outcome. Conclusions: Cranial falling bullet injuries are uncommon, but they can cause significant morbidity and mortality. More studies are needed to document the impact of these injuries and to raise awareness among the society to support the efforts aiming at controlling the irrational use of guns in different countries of the world.

2588. Kadri, H. (2013). "Ballistic trauma in Pediatrics Population." Child's Nervous System **29**(9): 1780.

Independent sources reported that more than 4000 kids were killed while 13000 were injured between 2011 and early 2013 in Syria. 42 patients aged between 2 months and 16 years were seen in critical conditions suffering frombrain injuries by gunshot. 11 cases the bullet was present in the skull space (no exit site) while in 31 the bullet left the head. All those patients were managed in primary battlefield hospital set up in secrets by some doctors. The aim was: stopping the bleeding by local homeostasis, decompression the brain and in few cases removing the projectile. Glasgow scale score was evaluated for all patients it varied between 4 and 13. 18 patients who arrived alive to medical unit, had an initial GS at 4 they died shortly after admission while 6 kids had GSS <11 needed artificial ventilation died later on because of lake or maladapted artificial ventilation. 18 kids underwent a surgical repair for their lesions. In those 18 patients who were evaluated as (in good condition), 10 of them had an outlet hole no XR was performed for them. While 8 out of the have no outlet hole, they had either an XR or CT scan in peripheral hospital. Transportation was itself an issue. The surgical repair varies between skin repair to prevent CSF leak, decompression by removal of bone fragments which were compressing the brain and local homeostasis. 8 patients died later from other complications a 10 stayed alive 3 of them have severe handicaps. Conclusion: Unfortunately the penetrating head injury by a gunshot have a bad prognosisi when it is managed in poorly equipped medical unit.

2589. Kaech, D. L. and D. Wyler (2016). "Delayed death one week following a gunshot injury due to air embolism." Swiss Medical Weekly **146**: 154S.

Introduction Gunshot injuries can be fatal or may be survived with neurological and neuropsychological deficits. At KSGR they are rare with one patient every 4-7 years. We report an exceptional case with a survival during one week

followed by death due to air embolism. Case report This 39 years old man was admitted following a right frontal to left parietal parasagittal gunshot injury after having being found comatose with CGS 4, but still breathing and coughing, with reacting and symmetrical pupils. He was intubated and brought to our hospital. (see Figs. 1-4). After stabilization of the hemodynamic situation, he underwent a neurosurgical wound revision with hemostasis, removal of some epidural blood, some bony fragments and protruding necrotic brain tissue, leaving some epidural blood layer “padding” the injured parieral midline. The wounds were adapted without achieving a watertight closure. He remained stable and was transferred on day 7 to the medical ward for further care. On day 8 he suddenly died after an attempt to mobilize him, i.e., to put him in an upright position. Result of the medico-legal examination Gas accumulation in the right sided heart chambers. Gunshot induced bi-parietal hemorrhagic lesions with 1 cm epidural hematoma extending to the frontal region, torn superior sagittal sinus (see Fig.5) with elevated about 4 cm large fragments of the parietal bone. Discussion This patient didn't die during the first days, but after one week, following what is routinely done in head injured patients: a progressive mobilization with verticalization. Autopsy revealed air embolism as cause of death. Some air has probabely entered through a not watertight closure of the skin, and the blood left on the dura didn't occlude enough the way to the torn superior sagittal sinus. Conclusion The risk of air embolism is well known, but the awareness of this risk is not present in daily routine especially in the very rare case of a gunshot injury to the brain. The upright position is known to be a trigger for air aspiration in patients with open head injuries or operations performed in sitting position because of negative pressure in the superior vena cava and the right atrium. The risk is comparable to the one during removal a central venous catheter, which should be performed in horizontal to Trendelburg position. This knowledge should be implemented into the checklists and guidelines, as recommendations to doctors, physiotherapists and nursing staff.

2590. Kafih, M., et al. (2009). "[Intra-uterine fetal death by knife: case report]." Mort foetale intra-uterine par arme blanche (a propos d'un cas). **38**(2): 182-185.

INTRODUCTION: Opened injuries by knife are rare in pregnant women and are responsible of foetal death in most cases., OBSERVATION AND COMMENTARY: We report a case of a 27-years woman, in her 8th months of pregnancy, victim of three knife punchs in her right iliac fossa. An emmergent laparotomy revealed deep wounds in the uterus and its right vascular pedicles, and a right external iliac artery lesion. Hysterectomy was performed and the extracted fetus was dead. He had two wounds in skull and back. Foetal death is common in opened knife injuries especially at the end of pregnancy. On one hand, the fetus has an abdominal situation that expose him to penetrating lesions. On the other hand, the uterus is richly vascularized during this period of pregnancy, thus any uterine or pedicular wound could result in a maternal hemorrhagic shock and hence a poor foetal and maternal prognosis., CONCLUSION: Knife injuries in pregnant women could compromise the foetal prognosis. Managmanent should be early and requires a close collaboration between resuscitators, obstetricians and vascular surgeons.

2591. Kahler, R. J., et al. (1998). "Orbitocranial penetration by a fern: case report." Neurosurgery **42**(6): 1370-1373.

OBJECTIVE AND IMPORTANCE: Cranial and orbitocranial penetration by organic foreign material is not infrequent. It is important to identify whether penetration has occurred and to localize and remove the organic foreign material., CLINICAL PRESENTATION: We report a 15-month-old patient who suffered orbitocranial penetration with the stem of a fern. The stem passed through the orbit, exiting via the superior orbital fissure. It continued through the middle cranial fossa to end in the posterior cranial fossa., INTERVENTION: The patient underwent surgery, and a modified Dolenc procedure was performed. The foreign body was identified in the prepontine cistern and was removed. An extradural approach was performed to the cavernous sinus and superior orbital fissure, and the remaining foreign body was removed., CONCLUSION: Retained intracranial wood should be removed. The radiological diagnosis can be difficult, and magnetic resonance imaging is the investigation of choice. Magnetic resonance imaging may not detect some cases of organic foreign material penetration.

2592. Kahugu, E. (2013). "Management of severe orbital trauma: A local experience." International journal of oral and maxillofacial surgery **42**(10): 1323.

Trauma from road traffic accidents and interpersonal violence provide for at least 50% of any maxillofacial Surgeons in Kenya. High speed motor vehicle accidents are common due to the recently developed 'super highways' and gunshot injuries are also common due to conflict in neighbouring nations. The management of these injuries in a

developing nation is presented with an emphasis on the application of new techniques and older techniques in a challenging environment to achieve desirable outcomes. The use of and adaptation of modern technology in this developing environment is presented.

2593. Kairinos, N., et al. (2009). "Pneumocephalus following gunshot injury to the thoracic vertebral column: a case report." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES **15**(6): 614-616.

Subarachnoid pleural fistula (SPF) following injury to the vertebral column is an extremely rare complication and is usually described after blunt trauma. We report the first case of SPF with pneumocephalus due to a gunshot wound to the spine.

2594. Kaiser, G. M., et al. (2010). "[Process of organ donation at a maximum care hospital]." Organspendeprozess an einem Krankenhaus mit Maximalversorgung. **135**(42): 2065-2070.

BACKGROUND: A chronic shortage of organs for transplantation has developed due to the disparity between the demand for solid organs and the current supply. Improved processes for identifying potential donors could expand the pool of available organs., PATIENTS AND METHODS: All patients who died between January 1, 2006 and December 31, 2008 in the University hospital of Essen suffering from a primary or secondary cerebral injury were assessed retrospectively. Age, date of death, duration of stay in the intensive care unit, main and additional diagnoses and diagnostic test for assessing brain death as well as discussions with relatives were recorded anonymously., RESULTS: 424 deaths with primary or secondary cerebral injury (group A) were identified during the study period. 267 deaths (62.9 %) (group B) were further evaluated for organ donation after excluding absolute medical contraindications, e. g. malignancies, multiple organ failure. In 68 cases (16.0 %), diagnostic test of brain death had been completed (group C). Despite a high refusal rate, 36 (8.5 %) organ procurements were realized (group D) resulting in 140 transplanted organs (3.9 per organ donor)., CONCLUSION: The first crucial step to improve the rate of organ donation is to identify any potential donor. In 8.5 % of intensive care unit deaths with primary or secondary cerebral damage, organ procurement was realized. In addition, education regarding transplant medicine and a positive attitude to organ donation among the general public as well as medical personnel is necessary to minimize the high refusal rates.

2595. Kaiser, G. M., et al. (2014). "In-house coordination for organ donation--single-center experience in a pilot project in Germany (2006 to 2013)." Transplantation proceedings **46**(6): 2066-2069.

A challenge for solid organ transplantation in Germany is the shortage of organs. In an effort to increase donation rates, some federal states mandated hospitals to install transplantation officers to coordinate, evaluate, and enhance the donation and transplantation processes. In 2009 the German Foundation for Organ Transplantation (DSO) implemented the In-House Coordination Project, which includes retrospective, quarterly, information technology-based case analyses of all deceased patients with primary or secondary brain injury in regard to the organ donation process in maximum care hospitals. From 2006 to 2008 an analysis of potential organ donors was performed in our hospital using a time-consuming, complex method using questionnaires, hand-written patient files, and the hospital IT documentation system (standard method). Analyses in the In-House Coordination Project are instead carried out by a proprietary semiautomated IT tool called Transplant Check, which uses easily accessible standard data records of the hospital controlling and accounting unit. The aim of our study was to compare the results of the standard method and Transplant Check in detecting and evaluating potential donors. To do so, the same period of time (2006 to 2008) was re-evaluated using the IT tool. Transplant Check was able to record significantly more patients who fulfilled the criteria for inclusion than the standard method (641 vs 424). The methods displayed a wide overlap, apart from 22 patients who were only recorded by the standard method. In these cases, the accompanying brain injury diagnosis was not recorded in the controlling and accounting unit data records due to little relative clinical significance. None of the 22 patients fulfilled the criteria for brain death. In summary, Transplant Check is an easy-to-use, reliable, and valid tool for evaluating donor potential in a maximum care hospital. Therefore from 2010 on, analyses were performed exclusively with Transplant Check at our university hospital.

2596. Kaiser, M. C., et al. (1983). "CT in a case of intracranial penetration of a pencil. A case report." Neuroradiology **24**(4): 229-231.

A case is reported of an unusual foreign body, a pencil, penetrating the right temporal lobe through the squamous temporal bone in a fall. Wood has low attenuation coefficients, so that the appropriate CT examination includes multiple window settings to permit accurate assessment of bone fragment displacement as well as recognition of detached wood splinters. CT scanning and early surgery are important steps in the management of these injuries to reduce significantly the overall mortality as well as immediate and long term complications. The necessity for meticulous surgical technique when removing the foreign body is stressed as retained wood can not easily be visualized against the hypodense background due to postoperative changes.

2597. Kalani, M. Y. S., et al. (2013). "Cerebral herniation as a complication of chest tube drainage of cerebrospinal fluid after injury to the spine." World neurosurgery **79**(5-6): 798.E717-799.

BACKGROUND: Patients with concomitant injuries to the thorax and thecal sac requiring chest tube drainage are at risk for cerebral herniation caused by overdrainage of cerebrospinal fluid (CSF)., CASE DESCRIPTION: A 40-year-old man presented to the trauma service awake, alert, and oriented with an isolated gunshot wound to the midaxillary line through the tenth intercostal space and a complete spinal cord injury at T12. The patient was stabilized and intubated. A chest tube was placed, and he was transferred to the neurologic intensive care unit. The patient was found to be comatose with complete absence of brainstem reflexes 3 hours after admission., RESULTS: Magnetic resonance imaging (MRI) and autopsy revealed diffuse cerebral edema, occlusion of the bilateral posterior cerebral arteries, and tonsillar herniation extending several centimeters below the foramen magnum, with petechial hemorrhages and absence of gliosis., CONCLUSIONS: To the authors' knowledge, this case represents the first report of cerebral herniation secondary to chest tube drainage of a CSF leak caused by traumatic injury to the thecal sac.

2598. Kalavrezos, N., et al. (2005). "Reconstruction of through-and-through osteocutaneous defects of the mouth and face with subscapular system flaps." Annals of the Royal College of Surgeons of England **87**(1): 45-52.

BACKGROUND: Major ablative surgery in the head and neck region may create composite defects involving the oral mucosa, bone and the overlying facial skin. The large surface area and the three-dimensional nature of these defects pose a difficult reconstructive challenge requiring adequate bone and large, positionally versatile skin flaps., PATIENTS AND METHODS: From September 1993 to May 2000, 19 patients with through-and-through osteocutaneous defects of the mouth and face were reconstructed with composite subscapular artery system flaps. The evaluated parameters included: (i) site and dimensions of the tissue defect; (ii) specific flap properties; and (iii) review of the recipient and donor site morbidity., RESULTS: 10 variants of scapular osteocutaneous flaps, eight latissimus dorsi with serratus anterior and rib osteo-myocutaneous flaps, and one combination of an osteocutaneous scapular and myocutaneous latissimus dorsi flap were used to reconstruct composite facial defects with mean dimensions of: skin 54.4 cm(2), mucosa 56.2 cm(2) and bone of 8.2 cm. Ischaemic complications occurred in three patients including one total flap failure and one failure of the bony component in previously irradiated patients. The third flap was successfully salvaged. No significant long-term donor site morbidity was noted., CONCLUSION: Composite flaps based on the subscapular artery system are a versatile reconstructive modality for large through-and-through defects of the mouth and face.

2599. Kaliszan, M., et al. (2021). "Fake gunshot wounds in the skull-post-mortem artifact caused by steel probe during police search for a missing body." International journal of legal medicine **135**(3): 879-883.

The paper presents a case of a forensic autopsy of a young woman who was murdered and her dismembered body was hidden in soil and water. In the skull of the deceased, in the temporal and occipital regions, the autopsy revealed 3 round, almost identical holes, which looked like small caliber gunshot wounds. Doubts about the cause of these injuries were raised by the fact that despite the decomposition of the body, the continuity of the dura at the site of these holes remained undamaged and the absence of any trace of a bullet's wound track in the brain, the absence of a foreign body in the cranial cavity, as well as the absence of wounds on the opposite side of the skull that could be exit wounds. A thorough analysis of the investigation and the activities carried out during the search for the missing body allowed to adopt and finally confirm the hypothesis that the above mentioned skull damage occurred during the search

for the cut-off head of the deceased in shallow water by means of special tapered conical steel probes used by the rescue/search teams. Due to the structure of such a spike, i.e., a sharp end and then a wide cone, only a superficial puncture of the steel probe tip three times into the skull had taken place, which caused regular, rounded bone damage without damaging the dura and brain. The presented case indicates that sometimes post-mortem artifacts may suggest a completely different origin of wounds, which emphasizes the need for a comprehensive analysis of all possible causes of their occurrence, particularly data concerning the handling of the corpse before it is delivered to the morgue, so as not to make a diagnostic error during autopsy.

2600. Kalman, M., et al. (2000). "Characteristics of glial reaction in the perinatal rat cortex: effect of lesion size in the 'critical period'." Neural plasticity **7**(3): 147-165.

In this study we investigate the capability of lesions, performed between embryonic day E18 and postnatal day P6, to provoke glial reaction. Two different lesion types were applied: 'severe' lesion (tissue defect) and 'light' lesion (stab wound). The glial reaction was detected with immunostaining against glial fibrillary acidic protein. When performed as early as P0, severe lesions could result in reactive gliosis, which persisted even after a month. The glial reaction was detected at P6/P7 and became strong by P8, regardless of the age when the animals were lesioned between P0 and P5. Namely, a strict limit could be estimated for the age when reactive glia were already found rather than for the age when glial reaction-provoking lesions could occur. After prenatal lesions, no glial reaction developed, but the usual glia limitans covered the deformed brain surface. Light lesions provoked glial reactions when performed at P6. In conclusion, three scenarios were found, depending on the age of the animal at injury: (i) healing without glial reaction, regardless of the remaining deformation; (ii) depending on the size of the lesion, either healing without residuum or with remaining tissue defect plus reactive gliosis; and (iii) healing always with reactive gliosis. The age limits between them were at P0 and P5. The glial reactivity seemingly appears after the end of the neuronal migration and just precedes the massive transformation of the radial glia into astrocytes. Estimating the position of the appearance of glial reactivity among the events of cortical maturation can help to adapt the experimental results to humans.

2601. Kalousek, M., et al. (1993). "Computed Tomography Analysis of Head and Spinal Cord Injuries Inflicted by Missiles and Explosives." Journal of Neuroimaging **3**(3): 178-183.

Cerebral and spinal column computed tomography (CT) was performed in 53 patients wounded during war in the Republic of Croatia from June through December 1992. Of these, 36 (67%) suffered craniocerebral injuries; 10 (18%) sustained facial, neck, and paranasal sinus wounds; and 7 (13%) had vertebral andjor paravertebral lesions. Twenty-five (70%) of the patients with craniocerebral injuries had penetrating wounds with diffuse and multiple, predominantly hemorrhagic lesions of cortical and subcortical structures, with basal ganglia lesions in 15 (43%) and brainstem lesions in 6 (20%). Of the 7 vertebral studies. 4 showed paravertebral tissue damage to the spinal column and cord.

2602. Kamal, S. R., et al. (2022). "Spatial and temporal dynamics of HDACs class IIa following mild traumatic brain injury in adult rats." Molecular psychiatry **27**(3): 1683-1693.

The fundamental role of epigenetic regulatory mechanisms involved in neuroplasticity and adaptive responses to traumatic brain injury (TBI) is gaining increased recognition. TBI-induced neurodegeneration is associated with several changes in the expression-activity of various epigenetic regulatory enzymes, including histone deacetylases (HDACs). In this study, PET/CT with 6-([18F]trifluoroacetamido)-1- hexanoicanilide ([18F]TFAHA) to image spatial and temporal dynamics of HDACs class IIa expression-activity in brains of adult rats subjected to a weight drop model of diffuse, non-penetrating, mild traumatic brain injury (mTBI). The mTBI model was validated by histopathological and immunohistochemical analyses of brain tissue sections for localization and magnitude of expression of heat-shock protein-70 kDa (HSP70), amyloid precursor protein (APP), cannabinoid receptor-2 (CB2), ionized calcium-binding adapter protein-1 (IBA1), histone deacetylase-4 and -5 (HDAC4 and HDAC5). In comparison to baseline, the expression-activities of HDAC4 and HDAC5 were downregulated in the hippocampus, nucleus accumbens, peri-3rd ventricular part of the thalamus, and substantia nigra at 1-3 days post mTBI, and remained low at 7-8 days post mTBI. Reduced levels of HDAC4 and HDAC5 expression observed in neurons of these brain regions post mTBI were associated with the reduced nuclear and neuropil levels of HDAC4 and HDAC5 with the shift to perinuclear localization of these enzymes. These results support the rationale for the development of therapeutic strategies to upregulate expression-activity of HDACs class IIa post-TBI. PET/CT (MRI) with [18F]TFAHA can facilitate the development and clinical translation of unique therapeutic

approaches to upregulate the expression and activity of HDACs class IIa enzymes in the brain after TBI. Copyright © 2021. The Author(s), under exclusive licence to Springer Nature Limited.

2603. Kamat, A. A., et al. (2007). "Brain sag as a cause of postoperative neurological deterioration following anterior cranial fossa floor repair for post traumatic cerebrospinal fluid rhinorrhoea." British journal of neurosurgery **21**(3): 303-306.

A patient with posttraumatic CSF rhinorrhoea underwent a transcranial anterior skull base repair, with a lumbar drain being inserted at induction of anaesthesia. Postoperative neurological deterioration occurred due to brain sag. Following treatment, there was significant recovery albeit in a slow and steady fashion. Patients with brain sag as a result of lumbar drain insertion can make a good recovery, despite an initial presentation with signs of severe brainstem compression, which could easily be misinterpreted as having a poor prognosis. Absence of an initial dramatic response to treatment does not necessarily imply poor outcome in the long term.

2604. Kamel, H., et al. (2010). "Delayed adverse reactions to blood donation." Transfusion **50**(3): 556-565.

BACKGROUND: Blood donation is safe, but a small proportion of donors have delayed and/or off-site reactions that have the potential to lead to serious injury. This retrospective study sought to identify risk factors for delayed reactions (DRs)., STUDY DESIGN AND METHODS: The records of 793,293 allogeneic whole blood and apheresis donations in 2007 were assessed for vasovagal reactions. Donor demographic, biometric, and clinical measurements were captured. Incidents related to needle insertion and mild reactions were excluded. Based on the reaction onset time relative to the procedure end time, reactions were classified as delayed (>15 min) or immediate (<or=15 min). Reactions were analyzed by multivariable logistic regression comparing donors with immediate reactions (IRs) or DRs to donors without reactions and comparing donors with DRs to IRs. The clinical consequences of off-site and on-site reactions are reported., RESULTS: The prevalence of reactions classified as moderate or severe was 41 in 10,000 donations; 24% of these reactions were delayed and 12% occurred off-site. DRs were associated with female sex (odds ratio [OR], 2.96; 95% confidence interval [CI], 2.21-3.96) and with low estimated blood volume (EBV; OR, 3.91; 96% CI, 2.84-5.51). Off-site reactions, particularly in female donors, were more likely to be associated with a fall, with head trauma, with other injury, and with the use of outside medical care., CONCLUSION: Low EBV, youth, and first-time donor status are major risk factors for IRs and DRs. Women are more likely than men to report DRs. Delayed and off-site reactions lead to potentially preventable morbidity. Understanding the physiologic basis of DRs may lead to the development of appropriate interventions to reduce their likelihood.

2605. Kamenski, R. S., et al. (2008). "Short interval spontaneous migration of an intracranial bullet fragment." The Journal of trauma **65**(2): E13-15.

2606. Kamiyama, H., et al. (2008). "A case of penetrating craniofacial injury caused by chopstick performed surgical repair of the CSF fistula 48 years later." Japanese Journal of Neurosurgery **17**(2): 150-155.

We report a rare case of delayed cerebrospinal fluid rhinorrhea after penetrating craniofacial injury caused by chopstick. A 50-year-old male had a transmaxillar penetrating injury with a chopstick when the patient was 2 years old. The patient had suffered from recurrent meningitis 3 times after trauma. Forty-eight years after a penetrating craniofacial injury, the patient experienced rhinorrhea of cerebrospinal fluid (CSF), and surgical repair of the CSF fistula at the anterior skull base was performed. Previous penetrating craniofacial injury should be considered in patients with recurrent CSF rhinorrhea and meningitis.

2607. Kammal, M., et al. (2007). "[Suicidal gunshot to the head while driving a car]." Suizidaler Kopfschuss im fahrenden Pkw. **219**(3-4): 124-130.

A severe traffic accident occurred on the German autobahn. According to eye witnesses, the car had changed from the left to the right lane at 160 km/h before crashing into a thicket at full speed. In the car, a sports pistol was found in the footwell of the driver's side. The emergency doctor who performed the external examination of the victim's body found a gunshot wound in the region of the driver's right lower jaw. As the prosecutor released the body without

further examination, the family of the suicide asked for an autopsy, which demonstrated a lethal suicidal gunshot to the head; toxicological tests proved a previous consumption of cocaine.

2608. Kamphausen, T., et al. (2019). "Wounding potential of 4.4-mm (.173) caliber steel ball projectiles." International journal of legal medicine **133**(1): 143-150.

From time to time, severe or fatal injuries caused by small caliber air rifle projectiles are seen. In forensic sciences, the theoretical wounding potential of these weapons and projectiles is widely known. Usually, shots against the skull were reported and, in these cases, penetrating the eyes or thin bone layers of the temporal region. Amongst a huge number of different projectiles available for air guns, sub-caliber 4.4-mm (.173) caliber steel ball projectiles were used in an unusual suicide case. This case led to fundamental questions concerning wound ballistics. An 82-year-old man shot once against his right temporal region and twice into his mouth with a 4.5-mm (.177) caliber air rifle. Because of the exceptionally deep penetration of the base of the skull and the use of spherical-shaped sub-caliber air rifle projectiles, terminal ballistic features were analyzed and compared to results published in forensic literature. Test shots using the same weapon and similar projectiles were fired into ballistic gelatin to measure and calculate basic wound ballistic variables of cal. 4.4-mm (.173) steel balls. In comparison, further test shots with cal. 4.5-mm (.177) steel balls BB (ball bearing), flat-headed and pointed air rifle pellets ("diabolos") were carried out. The theoretical penetration depth in solid bone was calculated with 36.4 mm, and test shots in gelatin from hard contact produced an on-average wound track of 120 mm underlining the potential wounding effect. Furthermore, spherical projectiles could roll back and forth within the barrel, and an air cushion between projectile and breechblock can reduce muzzle velocity by more than half, explaining the retained missile in the temporal region.

2609. Kamphausen, T., et al. (2017). "Suicide by air rifle-a case report under consideration of ballistic particularities." Rechtsmedizin **27**(4): 315.

Background. Suicidal shooting injuries are very common in legal medicine. In those cases the distinction between self-inflicted injuries and third party fault is the main purpose of medicolegal examinations. Material and methods. The 82 year old male body was found in a forest with an air rifle lying at his feet. Medicolegal autopsy was performed and three gunshot entry wounds could be found: a 0.5 mm measuring skin defect on the right temporal region with a 4.5 mm measuring projectile lying in the M. temporalis and causing a superficial defect on the outer bone table without penetrating the scull. Two further 0.5 mm measuring gunshot entry wounds were found in the mouth, penetrating the mucosa of the palate. Here one projectile stuck in the ethmoid sinus after penetration of the palatial bone. The third projectile perforated the soft tissue of the palate and entered the scull cavity through the sphenoidal os in front of the hypophyseal fossa. It travelled through the left hemisphere penetrating the left putamen and caused bleeding into the arachnoidea as well as general cerebral edema and a blood-aspiration. Subsequently ballistic investigations and experiments were performed to evaluate the potential effectiveness by means of projectile's velocity and energy. Results. 2178 autopsies were performed in a three year period at the Institute of Legal Medicine Cologne from 2014 to 2016 including 46 gunshot injuries. In 28 cases out of 46 a suicide could be confirmed (60.9%). Usually firearm ammunition, at least .22 cal. were used. In Germany air rifles, not allowed to exceeding kinetic energy at the muzzle of 7.5 Joule, can be purchased by adults without further permit, because they seem to be most likely harmless. It is widely known, but rarely seen, that air rifles cause severe or deadly injuries. Usually deadly injuries occur in children penetrating the temporal bone by shots from point blank range or nearly close contact. Discussion and conclusions. The results of our ballistic tests and a review of the literature will be presented and discussed.

2610. Kan, S. and K. Hayakawa (2009). "Usefulness of scout view of head CT." Neuroradiology **51**: S125.

PURPOSE Scout view is usually used as an aid to locating the scan level. However, scout view can contribute to the reading of brain CT. The purpose of this exhibit is to illustrate the usefulness of scout view of head CT. MATERIALS & METHODS When reading the brain CT scans, scout view is also viewed and evaluated. RESULTS Following conditions are visualized on scout view and useful information are also obtained. 1. Post operative state Several types of operation such as burr hole, burr hole button, cranioplasty, aneurysm clipping, deep brain stimulation, VP shunt. craniectomy, craniotomy, coiling for aneurysm 2. Bone defect Metastasis, diploic vein, vascular groove 3. Bone sclerosis Metastasis, osteopetrosis, hyperostosis frontalis interna Fibrous dysplasia 4. Skull fracture 5. Calcification Cranipharyngioma, AVM, meningioma, petroclinoid ligament 6. Skull size change 7. Paranasal lesion Sinusitis, tumor, pneumosinus dilatance 8.

Sellar enlargement 9. Craniovertebral junction lesions Atlantoaxial vertical subluxation CONCLUSION We found that a careful study of CT scout view can contributes significantly to the diagnosis of brain CT. Scout view imaging must be displaced with axial head CT slice and carefully evaluated.

2611. Kanagarajan, A. and S. Sgouros (2007). "Unusual penetrating cranio-cerebral injuries in children from mains plugs." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **23**(10): 1181-1183.

INTRODUCTION: Domestic accidents resulting in head injury are not uncommon. They mostly involve falls from high beds, tables or window seals. Rarely, children suffer penetrating skull injuries, often from unlikely objects., MATERIALS: We present two children, 2.5- and 1.5-year-old boys, respectively, who suffered penetrating wounds and compound depressed skull fractures when they fell from moderate height and landed on nearby electric mains plugs, which were driven into their heads. None of them lost consciousness or developed epilepsy. The first patient was brought with one plug pin firmly driven into the skull in the right frontal region. Parents had disassembled and removed the rest of the plug. The second patient was brought in with the whole plug attached and one pin embedded in the left parietal region. On plain radiographs and computed tomography (CT) scan, there was complete skull perforation, a compound depressed skull fracture, and the plug pin was embedded in the brain parenchyma in both patients. In the second patient, the injury site was near the motor cortex. In both cases, the plug was surgically removed, and the skull fracture was repaired., DISCUSSION: This type of injury from the protruding ends of mains plugs is uncommon and has to be borne in mind by parents, carers and any person dealing with childhood trauma because the plug could be removed at home and the child brought to the Emergency Department with only a small wound in the scalp, hiding a potentially serious underlying brain injury.

2615. Kaneko-Ohtaki, A., et al. (2011). "Ophthalmoplegia associated with transorbital penetrating brainstem injury by broken fishing pole." Clinical ophthalmology (Auckland, N.Z.) **5**: 927-929.

We report our findings in a case of ophthalmoplegia caused by a transorbital penetrating brainstem injury. An 8-year-old boy was accidentally injured by a broken fishing fiberglass pole which penetrated through the right orbit and entered the brainstem. Magnetic resonance imaging showed a linear wound that entered and passed through the pons obliquely and reached the fourth cerebral ventricle and cerebellar vermis. He had a left-sided hemiplegia and left facial nerve palsy and was diagnosed with "one-and-a-half syndrome". His hemiplegia and left facial nerve palsy resolved in 2 weeks leaving only a left abducens nerve palsy. The eye position and eye movements fully recovered within 3 months. These findings suggest a good prognosis for this type of trauma unless life-threatening changes develop.

2617. Kanoff, R. B., et al. (1990). "Cranial gunshot wounds." The Journal of the American Osteopathic Association **90**(6): 515-518.

Cranial gunshot wounds frequently produce devastating injuries to central nervous system structures. This article reviews pertinent principles of ballistics to explain several mechanisms of injury to the brain. A series of 21 consecutive cases of cranial gunshot wounds is presented outlining a protocol for management and identifying factors of prognostic significance.

2618. Kantarci, M., et al. (2007). "Detection of a giant wooden foreign body with multidetector computed tomography and multiplanar reconstruction imaging." The American journal of emergency medicine **25**(2): 211-213.

We describe the case of an unusual (unbelievable) giant wooden foreign body traversing the neck via the glabella. The relationship between the giant wooden foreign body and the nasopharynx air column was demonstrated through multidetector computed tomography (CT). The wooden foreign body mimicking air on a standard CT window setting was distinguished from air with the use of a higher CT window setting. Cases of accidental penetration injury of the head and neck by foreign bodies are not rare, but the entry of giant wooden foreign bodies into the neck via the glabella has never been reported in the literature. In our case patient, such a giant wooden foreign body was detected neither in the emergency department nor during radiologic investigations (conventional radiograms and standard CT) until the patient underwent multidetector CT 8 days after the related accident.

2619. Kanu, L. N., et al. (2019). "Self-insertion of foreign bodies into the orbit and periocular tissue." Orbit (Amsterdam, Netherlands) **38**(6): 486-491.

We describe six patients with 12 separate episodes of self-inflicted periocular foreign body injuries, which presented to our institution recently. All patients were male, relatively young (mean 28.5 years old), incarcerated, and had significant underlying psychiatric conditions. The subjects had inserted staples (6), paperclips (2), or other small metallic wire segments (4) into the periocular region. Most cases (9/12) involved concurrent self-inflicted injury to other body parts. Ten cases involved foreign bodies inserted through the palpebral conjunctiva into the upper eyelid, while two cases involved insertion into the orbit. Identification and surgical retrieval of foreign bodies was successful in most cases (9/11) but was not attempted in one case. Self-inflicted periocular injuries, while rare, are challenging cases for which the ophthalmologist should be prepared. A multidisciplinary approach, including psychiatric assessment and treatment, is important for optimal care.

2620. Kao, P.-T., et al. (2003). "Brain abscess: clinical analysis of 53 cases." Journal of microbiology, immunology, and infection = Wei mian yu gan ran za zhi **36**(2): 129-136.

Fifty-three cases of brain abscess were treated at Mackay Memorial Hospital from January 1991 through December 2001. The ages ranged from 2 weeks to 84 years, with a peak at 40 to 50 years (11/53, 21%). The male to female ratio was 1.8:1 (34 males, 19 females). The most common presenting symptoms were fever (30/53, 57%), headache (29/53, 55%), and changed mental status (24/53, 45%). The duration of symptoms before hospitalization ranged from several hours to 2 months. A shorter duration of symptoms was associated with poor outcome. The common predisposing factors were otic infection (10/53, 19%), penetrating head trauma and neurosurgery (10/53, 19%), and bacterial endocarditis (5/53, 9%). The leading underlying diseases were diabetes mellitus (12/53, 23%) and/or liver cirrhosis (6/53, 11%), and both were independently associated with increased risk of mortality. Computed tomographic scanning and magnetic resonance imaging facilitated early diagnosis and proper management. Surgical intervention was used together with antibiotics in 33 (62%) of 53 patients in whom the average abscesses diameter was 3.75 cm (range, 2-6 cm). The remaining 20 (38%) patients whose average abscesses diameter was 2.3 cm (range, 1-3.5 cm) were treated with antibiotics only. Culture of material drained from abscesses isolated 27 microorganisms from 19 (58%) of the 33 patients, 81% (22/27) of which were aerobic and 19% (5/27) anaerobic bacteria. The most common pathogen was alpha-hemolytic Streptococcus spp. (6/27, 22%). Most of the patients with Klebsiella pneumoniae isolated from brain abscess, cerebrospinal fluid, and blood cultures were diabetic. A high mortality rate (9/20, 45%) was found in patients with medical treatment. A high index of suspicion is needed for the early diagnosis of brain abscess, particularly in patients with predisposing factors. In this series, early diagnosis using computed tomography and/or magnetic resonance scanning, optimal timing of surgery, and appropriate use of antibiotics were associated with improved outcome.

2621. Kapoor, A. G., et al. (2020). "Retained intraorbital wooden foreign body presenting with combined anterior and posterior scleritis." BMJ case reports **13**(2).

Penetrating injury of the orbit with a wooden stick is not an uncommon finding in ocular emergencies. A 36-year-old man presented with redness, pain in the left eye following fall from a motorcycle 3 days ago. Ocular examination showed features of combined anterior and posterior scleritis in the form of an anterior scleral nodule, retinal folds and T sign on ultrasonography. There was worsening of symptoms along with new onset diplopia following scleral deroofing which led to the suspicion of an intraorbital wooden foreign body (IOWFB). CT scan of orbit showed a well-defined hypodensity between the medial rectus and optic nerve resembling a pocket of air surrounded by a rim of hyperdensity. IOWFB was removed under direct visualisation via transconjunctival orbitotomy. This is the case of a missed retained IOWFB presenting with features of combined anterior and posterior scleritis.

2622. Kapoor, R. and B. Rastogi (2021). "Diagnostic and prognostic significance of CSFCPK in meningitis." Neurology **96**(15 SUPPL 1).

Objective: To measure the CSF and serum CPK values in pyogenic, tubercular and viral meningitis and ascertain its association with severity of disease. Background: Creatinine phosphokinase (CPK), an enzyme involved in the phosphorylation of the creatinine with ATP from ADP and creatinine phosphate is markedly elevated in meningitis of varied etiology. Out of CPK isoenzymes, CPK-BB (Brain type) was found to be more specifically raised in infections of central nervous system. The liberation of CPK-BB from the brain tissue and its penetration into the intercellular fluid and then into the CSF was related to the functional structural changes in the cellular membranes of the brain in meningitis. Design/Methods: A cross section study with a sample size of 40 patients was carried out, 20 of which were controls. For the study group, clinically evident cases were selected, lumbar puncture was done and CSF was sent for cytology/biochemical analysis including CPK. Serum CPK samples were sent simultaneously. Asymtomatic patients who were posted for surgery under spinal anaesthesia were taken as controls. Their CSF and serum CPK samples were sent in a similar fashion. Results: Serum CPK values in all the three groups of meningitis were not elevated corresponding to CSF-CPK. CSF-CPK values were elevated more in cases of pyogenic meningitis than tubercular and viral meningitis. The CSF-CPK had a direct relationship with the deteriorating level of consciousness and mortality. Conclusions: It can be concluded that the CSF-CPK is elevated in all cases of meningitis. It was not possible to differentiate the type of meningitis on the basis of enzymatic activity in any of them. However it was possible to assess the degree of brain damage and to predict prognosis because higher basal activity of the enzyme was associated with poor prognosis. It also had a direct relationship with the level of consciousness of the patient and mortality.

2623. Kapp, J. P. and I. Gielchinsky (1972). "Management of combat wounds of the dural venous sinuses." Surgery **71**(6): 913-917.

2624. Kaptigau, W. M., et al. (2007). "Open depressed and penetrating skull fractures in Port Moresby General Hospital from 2003 to 2005." Papua and New Guinea medical journal **50**(1-2): 58-63.

BACKGROUND: Open wounds to the head with skull bone depression pose the potential for serious injuries to the brain parenchyma and an increased risk of infection. The treatment of these injuries aims to repair the breached dura as well as remove any nidus for infection. Open wounds to the head due to bullets pose special problems and have a high fatality rate., AIM: To review the presentation, management and outcome of depressed and penetrating open fractures of the skull in Port Moresby., METHOD: All cases seen from 2003 to 2005 were included. All were managed without a CT (computed tomography) scan. Their Glasgow Outcome Scale (GOS) was documented on discharge., RESULTS: There were 340 traumatic brain injury (TBI) cases over a period of 3 years between 2003 and 2005 managed by the Neurosurgery Unit of Port Moresby General Hospital. The open depressed and penetrating skull fractures seen in these cases numbered 46 (14%), of which 42 were males and 4 females. The weapons most commonly used were blunt objects (16), knives (11), guns (6) and axes (4). Gunshots contributed to 4 of the 7 deaths. 4 out of the 7 deaths were due to primary brain injury and 3 were due to infection., CONCLUSION: Open depressed fractures and penetrating injuries form a small but significant group in the management of head injuries. The use of blunt objects, firearms and arrows coupled with increasing urban violence is responsible for most of these injuries. The outcome of patients admitted who are fully conscious is expected to be good. They can be managed by prompt debridement of the wound, elevation of the

fracture and removal of fragments as appropriate. However, the mortality rate is high in those with a Glasgow Coma Score of 8 or less on admission, a finding indicative of the severity of brain injury beneath the wound.

2625. Kara, H., et al. (2022). "Unusual Transorbital-Penetrating Intracranial Injury by A Metal Bar: A Case Report." Akademik Acil Tip Olgu Sunumlari Dergisi **13**(1): 4-7.

The orbit has a fine bony structure and represents the most vulnerable structure in the cranium. Therefore, penetrating orbital injuries are often associated with traumatic brain injury. Although transorbital-penetrating intracranial injury is not commonly encountered in emergency medicine practice, this occurrence has the potential to cause severe and fatal brain injury. In this study, we report the case of a 21-year-old male patient presented with an injury to his left orbit, caused by falling while holding a metal bar. A local examination revealed a perforating injury at the entry location of a metallic bar (S-shaped) that penetrated his left orbit. CT imaging showed the appearance of a metallic foreign body that entered anterior superior to the left orbit, passed into the left half of the frontal sinus, and extended into the intracranial area. The metallic bar was removed by craniotomy. The patient fully recovered and was discharged on postoperative 9th day. The penetration of foreign bodies through the orbitofrontal region is rare but potentially life-threatening. An emergent surgical initiative is necessary to save the life of the patient. When managed in a timely and efficient manner, the associated mortality and morbidity can be reduced.

2626. Karabagli, H. (2005). "Spontaneous movement of bullets in the interhemispheric region." Pediatric neurosurgery **41**(3): 148-150.

Gunshot wounds to the head are usually mortal injuries. Their frequency has been increasing in the last years because of increasing crime and war rates. Penetrating craniocerebral injury in children and adolescents at the age of 17 or under is an increasing cause of emergent neurosurgical admissions to major metropolitan medical centers. I report a patient in whom a bullet in the brain moved from the interhemispheric region to 1 cm to the left of the inner occipital protuberance and midline. The patient recovered from surgery uneventfully. He was followed up for 4 years without neurodeficits. Spontaneous movement of bullets within the brain has been reported sporadically. The removal of intracerebral bullets is obviously warranted in patients undergoing craniotomy or craniectomy for debridement or evacuation of intracerebral clots or bone fragments if the metallic fragment is in proximity to the operative site. Before surgical removal of any intracerebral bullet, it is recommended that an intraoperative plain skull X-ray be obtained after final positioning of the head.

2627. Karabatsou, K., et al. (2005). "Self-inflicted penetrating head injury in a patient with manic-depressive disorder." The American journal of forensic medicine and pathology **26**(2): 174-176.

A 32-year-old Caucasian male with a history of repeated self-injury drilled a hole in his skull using a power tool and subsequently introduced intracerebrally a binding wire from a sketch pad. An emergency craniotomy was performed around the site of cranial injury, and the foreign body was carefully extracted. The wire was located partially in the subdural space and partially in the right hemisphere of the brain. The patient made an excellent recovery and was referred to a psychiatrist for further treatment. This is a rare case of unusual and complex repetitive self-destructive behavior without apparent suicidal intent. The pertinent literature is reviewed and the surgical and psychiatric implications of such injuries are discussed.

2628. Karaca, M. A., et al. (2015). "Evaluation of gunshot wounds in the emergency department." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES **21**(4): 248-255.

BACKGROUND: This study aimed to evaluate injury patterns of patients admitted to the emergency department with gunshot wounds, results of imaging studies, treatment modalities, outcomes, mortality ratios, and complications., METHODS: A retrospective descriptive study was carried out including a total number of one hundred and forty-two patients admitted to Hacettepe University Emergency Department with gunshot injuries between January 1, 1999 and December 31, 2013. The Glasgow Coma Scale (GCS), Revised Trauma Score (RTS), Injury Severity Score (ISS), and the Trauma and Injury Severity Score (TRISS) probability of survival for penetrating trauma were calculated for all patients., RESULTS: Among the one hundred and forty-two patients in the study, one hundred and twenty-eight (90.1%) were male. Mean age was 36 years. On admission, the average GCS score was 13, mean RTS was 6.64, median ISS was 5 and

median TRISS probability for survival was 99.4% for penetrating trauma. Fluid was detected in three (13%) patients in FAST, whereas intra-abdominal solid organ injury and bowel injury were detected in 11 (58%) patients in abdominal CT. The pneumothorax, hemothorax and lung injuries were detected in 10 (40%) patients, whereas hemothorax was detected only in one patient with thoracic injury by chest X-ray. Twenty four (16.9%) patients died; eighteen patients (75%) had isolated severe intracranial injuries, two (8.3%) had thoracic injuries with head and neck injuries, and four (16.7%) patients had intra-abdominal organ injuries (one with concomitant head injury). Ten patients were brought to the ED in cardiopulmonary arrest. In dead patients, GCS, RTS and TRISS were significantly lower, and ISS were significantly higher than in surviving patients. Twenty three (95.8%) patients were in critical injury level (ISS 25-75, actually ISS >50) in the exitus group., CONCLUSION: Mortality rates in gunshot wound patients with cranial injuries are very high. Spontaneous return is not seen in patients brought to the ED in arrest state. Bullets can cause internal organ injuries which can be greater than expected. In thoracoabdominal gunshot wound injuries, conventional X-ray and bedside FAST can be ineffective in detecting the whole extent of intrathoracic and intra-abdominal injuries. Thus, thoracic and abdominal CT should be planned early for hemodynamically stable patients in order to eliminate causes of fatality and make a timely and correct diagnosis. ISS, RTS and GCS are useful in predicting prognosis and mortality. Especially in patients with ISS scores >50, the mortality rate can be as high as 96%.

2629. Karadas, S., et al. (2014). "Treatment of intracranial foreign body." JPMA. The Journal of the Pakistan Medical Association **64**(7): 828-829.

Craniospinal penetrating foreign body (FB) injuries are interesting, but rarely observed, cases. They are important in terms of the complications that they may cause. The etiologies of craniospinal penetrating injuries and intracranial FB are also different. Though a sewing needle is more rarely seen in an intracranial FB, it may occur as atttempted infanticide or as a result of an accident especially in early childhood before the closure of fontanels. We detected an intracranial sewing needle in the head radiograph of a case admitted to the emergency department for another reason. We present this case since this is a rare injury and the etiologies of craniospinal penetrating foreign body have different characteristics.

2630. Karaman, E., et al. (2009). "Carotid-cavernous fistula after functional endoscopic sinus surgery." The Journal of craniofacial surgery **20**(2): 556-558.

Carotid-cavernous fistulas (CCFs) are anomalous communications between the carotid arterial system and the venous cavernous sinus. They can arise because of spontaneous or trauma causes. Most caroticocavernous fistulas are of spontaneous origin and unknown etiology. Spontaneous CCF may also be associated with cavernous sinus pathology such as arteriosclerotic changes of the arterial wall, fibromuscular dysplasia, or Ehler-Danlos syndrome. Traumatic CCFs may occur after either blunt or penetrating head trauma. Their clinical presentation is related to their size and to the type of venous drainage, which can lead to a variety of symptoms, such as visual loss, proptosis, bruit, chemosis, cranial nerve impairment, intracranial hemorrhage (rare), and so on. Treatment by endovascular transarterial embolization with electrolytically detachable coils is a very effective method for CCF with good outcomes. Carotid-cavernous fistulas have been rarely reported after craniofacial surgery and are uncommon pathologies in otolaryngology practice. In this study, we report a 40-year-old woman with CCF secondary to blunt trauma of functional endoscopic sinus surgery.

2631. Karaman, E., et al. (2011). "Encephalomalacia in the frontal lobe: complication of the endoscopic sinus surgery." The Journal of craniofacial surgery **22**(6): 2374-2375.

Encephalomalacia is the softening or loss of brain tissue after cerebral infarction, cerebral ischemia, infection, craniocerebral trauma, or other injury. The term is usually used during gross pathologic inspection to describe blurred cortical margins and decreased consistency of brain tissue after infarction. Multicystic encephalomalacia refers to the formation of multiple cystic cavities of various sizes in the cerebral cortex of neonates and infants after injury, most notably perinatal hypoxic-ischemic events. Chronic sinusitis has become one of the most common diseases in otolaryngology practice. Many of these patients can be managed successfully with medical therapy. Those who fail intensive medical therapy may be candidates for functional endoscopic sinus surgery (ESS). This procedure has variable complication rates and can have some serious consequences. Serious complications of functional ESS are very rare, but cerebrospinal fluid leak, meningitis, hemorrhage, infection, or vision loss has been reported in a few cases. In this study, we present a 57-year-old man with encephalomalacia after a penetrating brain injury incurred during ESS.

2632. Karamarkovic, A.-R., et al. (2007). "Hepatic abscess secondary to a rosemary twig migrating from the stomach into the liver." World journal of gastroenterology **13**(41): 5530-5532.

The ingestion of a foreign body that penetrates the gastric wall and migrates to the liver, where it causes an abscess is uncommon. A case of an ingested rosemary twig perforating the gastric antrum, then migrating to the liver, complicated by hepatic abscess and Staphylococcus aureus sepsis is reported. A 59-year-old man without a history of foreign body ingestion was admitted to our hospital because of sepsis and epigastralgia, which had progressively worsened. No foreign body was identified at preoperative imaging, but a rosemary twig was discovered during laparotomy. The liver abscess and sepsis were controlled successfully with surgery and antibiotics. This unusual condition should be kept in mind when dealing with cases of hepatic abscess, or even sepsis of unknown origin. Despite the improvement of non-surgical techniques such as percutaneous drainage and interventional endoscopy, surgery still remains important in the treatment of hepatic abscess caused by an ingested foreign body.

2633. Karamlou, T., et al. (2005). "Decreased recipient survival following orthotopic heart transplantation with use of hearts from donors with projectile brain injury." The Journal of heart and lung transplantation : the official publication of the International Society for Heart Transplantation **24**(1): 29-33.

BACKGROUND: Fatal gunshot injury to the brain can cause significant alterations in the neuroendocrine state and myocardial dysfunction. Therefore heart allografts from these donors may result in graft failure following orthotopic heart transplantation (OHTx). We evaluated whether receiving a heart from a donor who died from fatal gunshot wound to the brain independently affected the outcome of transplantation., METHODS: A retrospective review of 113 consecutive patients undergoing OHTx at a university hospital from 1996 to 2002 was performed. Group 1 received hearts from donors with fatal gun shot brain injury (n = 17), and Group 2 received hearts from donors who died from other causes (n = 96)., RESULTS: Recipient age, gender, United Network for Organ Sharing (UNOS) status, indication for transplantation, and other co-morbid conditions were similar in both groups. Young male donors pre-dominated in Group 1, but other donor characteristics were not significantly different. The incidence of Grade 3A rejection was higher in Group 1 than Group 2 (35% vs 6.3%, p = 0.003), as was the incidence of post-operative infection (35% vs 7.2%, p = 0.004). Actuarial survival at 1 and 5 years was significantly lower in Group 1 than in Group 2 (81% and 74% vs 97% and 94%, respectively, p = 0.005). Multivariate logistic regression analysis also demonstrated that fatal gunshot brain injury, as cause of donor death, was a risk factor for recipient mortality (p = 0.01)., CONCLUSION: Receiving a heart from a donor with fatal gunshot brain injury is a significant risk factor for recipient mortality following OHTx. Cautious use of heart allograft from these donors, especially in low-risk recipients, may lead to improved outcome following heart transplantation.

2634. Karampatakis, V., et al. (1998). "The risk of optic nerve injury in retrobulbar anesthesia: a comparative study of 35 and 40 mm retrobulbar needles in 12 cadavers." European journal of ophthalmology **8**(3): 184-187.

PURPOSE: This study was designed to demonstrate the increased risk of optic nerve injury by the 40 mm needle when fully inserted into the orbit., METHODS: Retrobulbar anesthesia needles 35 and 40 mm long were inserted into the orbits of 12 well-embalmed cadavers, as for typical retrobulbar anesthesia. The needle was seen directly through a fenestration of the orbital roof and by dissection of the orbital structures overlying the optic nerve., RESULTS: In all orbits the 40 mm needle reached and in seven cases significantly pushed against the optic nerve and could obviously penetrate its sheaths. The 35 mm needle could just slightly touch the outer optic nerve sheath only in two cases., CONCLUSIONS: We conclude that the 40 mm retrobulbar needle should not be fully inserted into the orbit and the 35 mm retrobulbar needle must be used with caution.

2635. Karasu, A., et al. (2008). "[Craniocerebral civilian gunshot wounds: one hospital's experience]." Kranyoserebral atesli silah yaralanmalari: bir hastanenin deneyimi. **14**(1): 59-64.

BACKGROUND: In this study we have discussed the factors that affect our surgical results according to our experience on patients who were admitted to our hospital's Emergency Surgery Department for civilian craniocerebral gunshot wounds between 1997 and 2006., METHODS: The clinical and radiological findings of 82 patients (74 males, 8 females) who were treated for civilian craniocerebral gunshot wounds were retrospectively recorded. Neurological and

physical examination, cranial computerized tomography (CCT) findings, trauma types, treatment modalities, prognosis, complications, morbidity and mortality rates were analyzed., RESULTS: Seventy-four (90%) of the patients were male, the mean age was 29.2 year. The Glasgow Coma Scores (GCS) during admission were as following respectively: 3-5 in 35 patients, 6-8 in 9 patients, 9-12 in 19 patients and 13-15 in 19 patients. According to their radiological findings, most commonly subdural hematoma, intracerebral hematoma, multiple contusion, depressed fracture and subarachnoidal hematoma were encountered. Operation or debridement was performed in 51 patients totally. Forty-one patients died and the mortality rate of 82 patients was calculated as 50%., CONCLUSION: The mortality rate of craniocerebral gunshot wound is high. The patients with GCS higher than 8 and with unihemispheric lesions during admission have better prognosis. We concluded that all patients must undergo debridement and the patients that have mass effect must be operated as soon as possible.

2636. Karasu, A., et al. (2009). "[Epidemiological study in head injury patients]." Kafa travmali hastalarda epidemiyolojik calisma. **15**(2): 159-163.

BACKGROUND: The aim of this study was to determine the hospital-based epidemiological data of the head injury patients who admitted to our Emergency Surgery Department., METHODS: The records of the patients (284 males [66%], 146 females [34%]; mean age 30+/-19) with head injury who admitted to our Emergency Surgery Department between 01.01.2006 - 31.12.2006 were analyzed retrospectively., RESULTS: Among the age groups, most head injuries occurred in children (22%) and young adults (30%). The most common trauma types were due to falls (40%) and motor vehicle accidents (37%). The mortality rate in head injury patients was 11%, serious morbidity was 2%, and the rate of deaths from head injury among all deaths in 2006 was 30%., CONCLUSION: According to these data, the most common causes of death in head-injured patients are falls (0-16 years of age) and outside vehicle traffic accidents and cranial gunshot wounds (16-35 years of age), especially for males. Admission Glasgow Coma Score is an important prognostic factor in head-injured patients. Primary precautions for head injury must be taken according to each age group. Further development of the diagnosis and treatment options will help to lower the mortality and morbidity of patients with traumatic brain injury.

2637. Karatela, M., et al. (2022). "Vertebral artery transection with pseudoaneurysm and arteriovenous fistula requiring antegrade and retrograde embolization." Journal of Vascular Surgery Cases, Innovations and Techniques **8**(2): 183-186.

Traumatic vertebral artery injury is a rare, life-threatening injury that has been increasingly managed with endovascular intervention. However, an antegrade endovascular approach alone can fail to occlude traumatic pseudoaneurysms (PSAs) and arteriovenous fistulas (AVFs), requiring high-risk surgical reoperation. We have presented the case of a 27-year-old man with traumatic right vertebral artery PSA and AVF. Despite successful ipsilateral coil embolization, the PSA and AVF persisted via retrograde filling from the contralateral vertebral artery. Distal coil embolization was achieved through the contralateral vertebral artery in a novel “up and over” approach through the basilar artery. The findings from our case report have broadened the endovascular options for complicated traumatic injuries.

2638. Karatoprak, S., et al. (2021). "Percutaneous radiological biliary interventions after failed endoscopic treatment in living liver donors: experience of a high-volume transplantation center." Transplant international : official journal of the European Society for Organ Transplantation **34**(12): 2846-2855.

This study aimed to evaluate the role of percutaneous radiological treatments for biliary complications (BCs) in donors after living donor liver transplantation (LDLT). We retrospectively evaluated BCs in donors involved in 1839 LDLTs between May 2009 and January 2019 at our centre. BCs were classified according to the modified Clavien-Dindo classification (MCDC). Patients treated with percutaneous transhepatic biliary intervention (PTBI) were identified. Complications requiring endoscopic, interventional or surgical treatment (MCDC grades III-IV) involved 123 (6.6%) donors. Complications comprised leakage, n = 73 (60%); stricture, n = 36 (29%); and both leakage and stricture, n = 14 (11%). Percutaneous drainage of biloma formations under ultrasound guidance was performed in 57 donors, endoscopic treatment in 83 and PTBI in 14. Of 83 patients who received endoscopic treatment, 13 were referred for PTBI due to failure or uncannulation. Eight of 14 patients were successfully treated with PTBI. Six patients were treated with a rendezvous procedure combining percutaneous and surgical treatments. In 13 patients, no BCs were developed after catheter or stent removal. In donors with BCs, the treatment should progress from the least invasive method to surgery.

In some patients, percutaneous radiological treatments eliminate the need for surgery or can guide surgical treatment.

2639. Karavaev, V. M. (2014). "[A case of suicide committed with a crossbow]." Sudebno-meditsinskaia ekspertiza **57**(1): 45-46.

The paper reports the results of forensic medical expertise of the corpse of a young man who committed suicide by two arrow shots to the head with a MK-80-A4AL crossbow. Both wounds are penetrating brain injuries.

2640. Karcioglu, Z. A. and A. M. Nasr (1998). "Diagnosis and management of orbital inflammation and infections secondary to foreign bodies: A clinical review." Orbit **17**(4): 247-269.

Orbital inflammation and secondary infections may be caused by many types of foreign bodies, including organic and inorganic matter, non- autogenous surgical implants and allografts, and surgical hardware and materials utilized in reconstructive surgery. In penetrating injury patients, the nature of the foreign body determines the clinical behavior; inert objects such as steel and glass may not cause significant inflammation to warrant their removal. Removal of organic foreign bodies, however, is mandatory since these objects usually lead to secondary infection with abscess and fistula formation. This paper reviews salient points related to history-taking and physical examination, diagnostic workup, and medical and surgical treatment in foreign body-induced orbital inflammation and infections. It is emphasized that practically every case of orbital trauma should be approached with a high index of suspicion for penetrating injury with possible intraorbital foreign body. The investigational tools to detect orbital foreign bodies, including ultrasonography, computed tomography and magnetic resonance imaging, are reviewed. The principles of the management, including antimicrobial therapy, surgical indications and techniques, are also discussed.

2641. Karger, B., et al. (1997). "[Retained capacity for action in brain gunshot injury. Case report and systematic examination]." Erhaltene Handlungsfahigkeit bei Gehirnschussverletzung. Kasuistik und systematische Untersuchung. **199**(5-6): 159-166.

A case of physical activity following a suicidal gunshot to the head including perforation of the left frontal lobe from a .22 rimfire rifle is reported. Subsequently, the man was able to walk a distance of more than 100 m and to reload manually. The special wound ballistic features of the head leading to increased intracranial projectile effects are discussed and the morphological changes such as cortical contusion zones, intracerebral hemorrhages or indirect skull fractures are explained. The analysis of 38 cases of head shots followed by physical activity reveals that injury to certain CNS-areas or the use of centre fire rifles and large handguns usually excludes a potential for subsequent physical activity. But physical activity is possible if the trajectory is restricted to the frontal brain or one temporal lobe only and if a projectile of low wounding potential has been used for this gunshot.

2642. Karger, B. and B. Brinkmann (1997). "Multiple gunshot suicides: potential for physical activity and medico-legal aspects." International journal of legal medicine **110**(4): 188-192.

Out of 138 clearly defined gunshot suicides which were autopsied, 11 persons (8%) fired two or more gunshots to the body. From these 11, 5 cases involved 2 gunshots to the head where the bullets fired first had missed the brain. The trajectories were restricted to the chest in three cases and a combination of gunshots to the head and chest including two perforating heart wounds without immediate incapacitation occurred in three more cases. Reliable incapacitation is based on physiological effects (tissue disruption) and can only be achieved by decreasing the functioning capability of the CNS. This can be accomplished by direct disruption of brain tissue or indirectly by cerebral hypoxemia from massive bleeding. Targets of immediate incapacitation are restricted to certain CNS areas and targets of rapid incapacitation include the heart, the (thoracic) aorta and the pulmonary artery. Other major blood vessels and major organs (lungs, kidneys, liver, spleen) constitute targets of delayed incapacitation. This general classification can be derived from the literature and is illustrated by the cases presented. A thorough post mortem can exclude or quantify the potential for physical activity. Typical features of single gunshot suicides such as contact shots, classical entrance wound sites and soot/backspatter on a hand also occur in multiple gunshot suicides.

2643. Karger, B., et al. (2001). "Proof of a gunshot wound and its delayed effects 54 years post injury." International journal of legal medicine **115**(3): 173-175.

In 1945 a 6-year-old girl received a tangential gunshot injury to the left posterior inferior skull. After hospitalisation because of septicemia she was unable to walk for several months. Since 1967 she had been repeatedly applying for compensation because of pseudoneurasthenia and residual ataxia and many medical examinations were performed including X-ray, CT and MRI. Although certain objective findings (e. g. cerebellar atrophy) could be verified, a causal connection between the gunshot injury and the clinical findings could not be established. Therefore previous investigators concluded on a vascular origin of the disease. During the present re-examination of the patient, the authors found patch-like scars at the left posterior inferior skull base and behind the left ear, a cord-like scar formation in the subcutaneous tissue, connecting both skin scars, a gutter-like defect in the left occipital base of the skull and an indention of the left mastoid process, both again in line between the skin scars and a large defect of the left cerebellar hemisphere. It could be concluded with certainty that the anatomical findings and the clicinal symptoms were the direct result of a gunshot injury. Previous investigations had failed because of deficient investigations and techniques. In addition to an anatomical reconstruction, three dimensional reconstructions from CT scans proved most helpful.

2644. Karger, B., et al. (2002). "Backspatter on the firearm and hand in experimental close-range gunshots to the head." The American journal of forensic medicine and pathology **23**(3): 211-213.

The deposition of backspatter on the firearm or person shooting can greatly assist the reconstruction of shooting incidents. Backspatter was investigated in experimental transverse gunshots (9-mm Luger) to the heads of calves (n = 9) from shooting distances of 0 to 10 cm. The firearms were examined with a magnifying glass; the surgical gloves and the right sleeve worn by the person shooting were examined with a stereomicroscope. On the firearms, backspatter of blood was found in five of the nine cases, and one or both gloves showed bloodspatter deposits in six and the right sleeves in four cases. Most droplets were 1 to 3 mm and circular or elongated. In addition, a fine spray of tiny blood deposits was present on the firearm and textiles in four cases. The distribution of the droplets on the firearms varied: the areas included regions shielded by prominent parts, and the droplets were predominantly located on the extensor side of the fingers and the radial aspect of the hands and sleeves. Backspatter of tiny bone fragments was recovered from the firearm and sleeve in only one case, but tissue (bone, fat, muscle, skin) was present on the ground in front of the entrance wound in seven cases. A careful investigation, including appropriate lightning and magnification, is necessary for reliable statements concerning the absence of backspatter or the extent of backspatter present.

2645. Karger, B., et al. (1998). "Morphological findings in the brain after experimental gunshots using radiology, pathology and histology." International journal of legal medicine **111**(6): 314-319.

The tissue disruption inside the brain after experimental gunshots to the head was investigated with special reference to secondary bone missiles and intracranial pressure effects such as cortical contusion and deep intracerebral haemorrhages. The evidential value of various examination methods is compared. 9 mm Parabellum ammunition was fired to the temporal region of calves (n = 10) from a distance of 0-10 cm. Plain film radiography, CT, MRI, visual inspection and histology were performed on every brain. The tissue disruption of the permanent tract is delineated best by artefact-free MRI. Cortical contusions and deep intracerebral haemorrhages were detected infrequently by visual inspection and imaging techniques although they were present in every brain as verified by histology. These injuries remote from the tract increase cerebral wounding compared to non-confined tissue. In particular, the brain stem and central areas were frequent sites of haemorrhages, which can be expected to have serious and immediate consequences. Ectopic bone fragments were found in all brains using CT scans. Bone fragments were located inside clearly enlarged permanent tracts or were driven into brain tissue. In the latter cases, secondary shot channels up to 4 cm in length could be verified by histology. Cortical contusions and intracerebral haemorrhages can only be detected reliably by histology. The localization of bone fragments requires CT scans. Therefore, a detailed examination is accomplished best by a combination of the methods applied in this study.

2646. Karimi, A., et al. (2016). "Dynamic finite element simulation of the gunshot injury to the human forehead protected by polyvinyl alcohol sponge." Journal of materials science. Materials in medicine **27**(4): 74.

Although there are some traditional models of the gunshot wounds, there is still a need for more modeling analyses due to the difficulties related to the gunshot wounds to the forehead region of the human skull. In this study,

the degree of damage as a consequence of penetrating head injuries due to gunshot wounds was determined using a preliminary finite element (FE) model of the human skull. In addition, the role of polyvinyl alcohol (PVA) sponge, which can be used as an alternative to reinforce the kinetic energy absorption capacity of bulletproof vest and helmet materials, to minimize the amount of skull injury due to penetrating processes was investigated through the FE model. Digital computed tomography along with magnetic resonance imaging data of the human head were employed to launch a three-dimensional (3D) FE model of the skull. Two geometrical shapes of projectiles (steel ball and bullet) were simulated for penetrating with an initial impact velocity of 734 m/s using nonlinear dynamic modeling code, namely LS-DYNA. The role of the damaged/distorted elements were removed during computation when the stress or strain reached their thresholds. The stress distributions in various parts of the forehead and sponge after injury were also computed. The results revealed the same amount of stress for both the steel ball and bullet after hitting the skull. The modeling results also indicated the time that steel ball takes to penetrate into the skull is lower than that of the bullet. In addition, more than 21% of the steel ball's kinetic energy was absorbed by the PVA sponge and, subsequently, injury sternness of the forehead was considerably minimized. The findings advise the application of the PVA sponge as a substitute strengthening material to be able to diminish the energy of impact as well as the load transmitted to the object.

2647. Karras, C. L., et al. (2022). "Outcomes Following Penetrating Brain Injuries in Military Settings: A Systematic Review and Meta-Analysis." World neurosurgery **166**: 39-48.

OBJECTIVE: While neurosurgeons are experienced in treating penetrating brain injuries (PBIs) in civilian settings, much less is known about management and outcomes of PBIs in military settings., METHODS: A systematic review was performed according to Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA) guidelines. Data extracted included surgical management, age, gender, location/type of injury, initial Glasgow Coma Scale (GCS) score, and outcomes. The primary outcomes were last reported Glasgow Outcome Score (GOS) and mortality. The secondary outcomes included central nervous system infections, seizures, and cerebrospinal fluid leak/fistula. Odds ratios (ORs) with corresponding 95% confidence intervals (CIs) were used for outcome analysis., RESULTS: Twelve studies with 1738 patients treated for PBIs in military settings were included. The weighted mean age was 27.8 years, 86.7% were male, and 64.3% underwent neurosurgical intervention. Most patients (64.3%) presented with a GCS score >8, while 31.0% presented in a coma (GCS score <8). Over a median last follow-up time of 9 months, 68.6% achieved a favorable (GOS = 4-5) outcome and 34.2% achieved a poor (GCS score = 1-3) outcome. The overall mortality was 18.0%. A meta-analysis was performed using 5 of 12 studies to evaluate the effect of the presenting GCS score on primary outcomes. Patients with an initial GCS score <8 had statistically significant lower odds of a favorable (GOS = 4-5) outcome (OR: 0.03; 95% CI: 0.00-0.19; P: 0.000) and higher odds of mortality (OR: 28.46; 95% CI: 8.62-94; P: 0.000) than patients with an initial GCS score >8. The pooled rates of central nervous system infection, seizures, and cerebrospinal fluid leak/fistula were 13.8%, 13.2%, and 5.4%, respectively., CONCLUSIONS: In this first systematic review and meta-analysis of outcomes following combat-related PBIs, a GCS score >8 at presentation was found to be an important predictor of a favorable GOS and decreased mortality.

2648. Karvonen, K. L., et al. (2020). "Ed utilization varies by race/ethnicity in premature infants." Journal of Investigative Medicine **68**(1): A169.

Purpose of study While racial/ethnic disparities in preterm birth are well-documented, less is known about differences in postdischarge health outcomes. We sought to investigate emergency department (ED) use by race/ethnicity in very preterm infants (<32 weeks gestational age [GA]), late and moderate preterm infants ([LMPT] 32-36 weeks GA), and all preterm infants (<37 weeks GA). Methods used Cohorts were derived from a California database of infants born between 2007-2011 maintained by the California Office of Statewide Health Planning and Development. A Kaplan-Meier table illustrating time to ED visit by race/ethnicity was constructed. Logistic regressions were used to predict outcomes by race/ethnicity among cohorts compared to white infants controlling for: Model 1-none; Model 2-GA, birthweight, and sex; Model 3-additionally adjusting for maternal BMI, smoking, drug/alcohol use, hypertension, diabetes, mental health disorders, and prenatal care; and Model 4-addi-tionally adjusting for maternal education, insurance status, and WIC use. Summary of results Racial/ethnic differences in time to ED visit are shown in figure 1. Hispanic and Black very preterm infants were more likely to visit the ED (model 4 OR 1.4 95% confidence interval [CI] 1.3-1.5, model 4 OR 1.4 CI 1.3-1.6). Hispanic and Black LMPT infants and all premature infants were more likely to visit the ED (model 4 OR 1.3 CI 1.3-1.4, model 4 OR 1.4 CI 1.3-1.5). Very premature and LMPT Asian infants were less likely to

visit the ED (model 4 OR 0.8 CI 0.7-1.0, model 4 OR 0.8 CI 0.7-0.8). Conclusions There are racial/ethnic disparities in ED utilization among preterm infants over the first year of life, with Black and Hispanic infants more likely to visit the emergency room compared to White non-Hispanic infants.

2649. Kasamo, S., et al. (1992). "[Transorbital penetrating brain injury]." No shinkei geka. Neurological surgery **20**(4): 433-438.

Transorbital penetrating brain injury is rare during this time of peace. In our paper, we reported seven cases of these injuries and discussed the mechanism and treatment of intracranial complications. Transorbital penetrating brain injuries were caused by thin, long and relative hard objects such as chop-stick (case 3), pencil (case 6), bamboo stick (case 1, 2, 7) and a piece of metal (case 4, 5). CT scan, MRI and angiography demonstrated a large variety of intracranial complications. For instance, intracerebral hematoma, cerebral contusion, intraventricular hemorrhage, pneumocephalus, brain stem injury and carotid cavernous sinus fistula. We had no case of infectious complications such as meningitis and brain abscess. If the direction of the injuring object runs parallel to the orbital roof, it penetrates the cranial cavity commonly via the superior orbital fissure or the optic canal, which routes provide direct access without bone fracture. This direction will cause critical intracranial complications such as CCF or brain stem injury. If the injuring object runs upward and across the orbital roof which has thin bone and therefore offers little resistance, the frontal lobe will be easily damaged, and it will cause intracerebral hematoma. But the prognosis for this type of injury is not so poor because we can easily remove the hematoma and the foreign body. With our treatment policy of "pull and see", all our cases but one recovered well. The one exception was a case in which a large intracerebral hematoma was over-looked in an ophthalmological clinic. This patient died. Nowadays, CT scan and MRI give clear information about the anatomical location of injuring objects and intracranial complications.(ABSTRACT TRUNCATED AT 250 WORDS)

2650. Kasmann-Kellner, B., et al. (2022). "[Optical rehabilitation and pediatric ophthalmological care following keratoplasty for childhood corneal opacities]." Optische Rehabilitation und kinderophthalmologische Betreuung nach Keratoplastik bei kindlichen Hornhauttrubungen. **119**(5): 462-470.

BACKGROUND: The younger the children are at the time of corneal transplantation, the worse the survival prognosis of the graft., PREOPERATIVE CONSIDERATIONS: Preoperative considerations are significant in terms of accurate parental education, ensuring adherence to treatment and choosing the appropriate surgical time frame (amblyopia versus graft failure, compliance of the patient). Parental education must include the reduced visual prognosis in young children, exceptions being later acquired corneal pathologies such as inflammatory corneal scars (herpes) and keratoconus., POSTOPERATIVE CARE: A distinction must be made between morphological care after transplantation and refractive correction as well as treatment of amblyopia. The younger the children, the less favorable the prognosis for the transplant and the more often multiple examinations with anesthesia are necessary in order to detect complications, such as infiltrates or suture loosening at an early stage. Especially unilateral congenital pathologies often do not lead to a sufficient improvement of amblyopia (refractory amblyopia, poor compliance)., CONCLUSION: The prognosis after keratoplasty in childhood is already partly decided by the careful evaluation of indications (no surgery of a sclerocornea) and the detailed and realistic clarification for the parents (cooperation with long-term ocular and systemic treatment even if the child has poor compliance, frequent check-ups, reduced chances of amblyopia treatment). The younger the child is at the time of transplantation, the more frequent are graft failure and the development of complications. Later manifesting diseases in older children (herpetic corneal scars, keratoconus) have a better prognosis.

2651. Kasparov, A. A. and I. V. Aladinskaia (2002). "[Possibilities of immunosuppressive therapy in reconstructive keratoplasty (experience gained in the use of cyclosporin)]." O vozmozhnostiakh immunosupressivnoi terapii pri rekonstruktivnoi keratoplastike (opyt primeneniia preparata tsiklosporin). **118**(4): 16-18.

Cyclosporin was used for preventing the graft rejection reaction after reconstructive operations on the anterior segment of the eye. Analysis of the results of surgical treatment of patients with vascularized corneal leukomas of different etiology in 23 patients (25 eyes) who received postoperative oral cyclosporin therapy and in 25 patients to whom this drug was instilled showed that cyclosporin promoted transparent healing of the keratotransplant and its use was not associated with serious side effects.

2652. Kasper, E. M., et al. (2010). "Retained transorbital foreign body with intracranial extension after pipe bomb explosion." Surgical neurology international **1**: 94.

BACKGROUND: Penetrating brain injuries caused by explosions are survived in extremely rare cases only. However, potential casualties of such cases may be encountered by regular physicians even outside a war zone, e.g., due to an assault or terror blast. There is very limited literature to this end; therefore, we report the successful neurosurgical management of a penetrating head injury due to a pipe bomb explosion., CASE DESCRIPTION: A 19-year-old man was brought to the ER with a swollen, bleeding right orbit, and a severely injured left hand after having sustained an unwitnessed explosion from a self-made pipe bomb. He presented with a GCS (Glasgow Coma Scale) of 15 at time of admission, work-up revealed an intracranial retained metal fragment measuring 5 x 1 x 0.2 cm lodged retro-orbitally and in the skull base. The patient underwent emergent right temporal craniotomy and temporal lobectomy and simultaneous right enucleation before the petrous bone and sphenoid wing lodged metal fragment was successfully removed., CONCLUSION: This case underscores the importance of having a high suspicion for the presence of an intracranial injury and a retained foreign body in the setting of a penetrating head injury. Aggressive and timely workup as well as expeditious surgical management are crucial in these settings and can generate exceptionally good outcomes despite a major trauma.

2653. Kassan, A. H., et al. (2000). "A retrospective analysis of gunshot injuries to the maxillo-facial region." SADJ : journal of the South African Dental Association = tydskrif van die Suid-Afrikaanse Tandheelkundige Vereniging **55**(7): 359-363.

This study analysed the prevalence, demography, soft- and hard-tissue injury patterns, management and complications of gunshot injuries to the maxillo-facial region in 301 patients treated at Groote Schuur Hospital, Cape Town. The number of patients presenting with maxillo-facial injuries caused by gunshot increased over the 15-year study period. The majority were caused by civilian type low-velocity hand-guns and were purposefully and intentionally inflicted by others. Males in their third decade of life and of low socioeconomic status were most often the victims. The wounding effects of these low-velocity injuries were characteristic--small rounded entrance wounds, causing fragmentation of teeth and comminution of the underlying bone, usually without any exit wounds. A comminuted displaced type of fracture pattern was most frequently observed. Special investigations included plain film radiographs with more sophisticated investigations being requested where indicated. Definitive surgical management was initiated by early soft-tissue debridement. Both the mandibular and maxillary fractures had more open than closed reductions. Bone continuity defects as a result of the initial injury were usually reconstructed secondarily using free autogenous bone grafts. All the patients received anti-tetanus toxoid on admission and the majority received antibiotic treatment. The most common complications were sepsis, ocular and neurological complications and limitation of mouth opening. The postoperative sepsis rate was high (19%). The wounding effects of these low-velocity missile injuries are devastating and pose a treatment challenge to the maxillo-facial surgeon.

2654. Kassel, E. E. and P. W. Cooper (1983). "Radiologic studies of facial trauma associated with a regional trauma centre." Journal of the Canadian Association of Radiologists **34**(3): 178-188.

The study of severe facial trauma has been altered by the development of computed tomography (CT). As a regional trauma unit we have gained increasing experience with complex fractures of the face. In those patients most severely injured, high resolution CT has become the imaging modality relied upon to offer the safest and most accurate information. Conventional films still have a role, especially in the less severely traumatized patient. We describe our methods and observations, based upon experience at a trauma unit, in the radiologic investigation of facial injuries.

2655. Kassi, A. A. Y., et al. (2018). "Enduring Neuroprotective Effect of Subacute Neural Stem Cell Transplantation After Penetrating TBI." Frontiers in neurology **9**: 1097.

Traumatic brain injury (TBI) is the largest cause of death and disability of persons under 45 years old, worldwide. Independent of the distribution, outcomes such as disability are associated with huge societal costs. The heterogeneity of TBI and its complicated biological response have helped clarify the limitations of current pharmacological approaches to TBI management. Five decades of effort have made some strides in reducing TBI mortality but little progress has been made to mitigate TBI-induced disability. Lessons learned from the failure of numerous randomized clinical trials and the

inability to scale up results from single center clinical trials with neuroprotective agents led to the formation of organizations such as the Neurological Emergencies Treatment Trials (NETT) Network, and international collaborative comparative effectiveness research (CER) to re-orient TBI clinical research. With initiatives such as TRACK-TBI, generating rich and comprehensive human datasets with demographic, clinical, genomic, proteomic, imaging, and detailed outcome data across multiple time points has become the focus of the field in the United States (US). In addition, government institutions such as the US Department of Defense are investing in groups such as Operation Brain Trauma Therapy (OBTT), a multicenter, pre-clinical drug-screening consortium to address the barriers in translation. The consensus from such efforts including "The Lancet Neurology Commission" and current literature is that unmitigated cell death processes, incomplete debris clearance, aberrant neurotoxic immune, and glia cell response induce progressive tissue loss and spatiotemporal magnification of primary TBI. Our analysis suggests that the focus of neuroprotection research needs to shift from protecting dying and injured neurons at acute time points to modulating the aberrant glial response in sub-acute and chronic time points. One unexpected agent with neuroprotective properties that shows promise is transplantation of neural stem cells. In this review we present (i) a short survey of TBI epidemiology and summary of current care, (ii) findings of past neuroprotective clinical trials and possible reasons for failure based upon insights from human and preclinical TBI pathophysiology studies, including our group's inflammation-centered approach, (iii) the unmet need of TBI and unproven treatments and lastly, (iv) present evidence to support the rationale for sub-acute neural stem cell therapy to mediate enduring neuroprotection.

2656. Kastanaki, A. E., et al. (2009). "An unusual suicide inside a grave with two gunshot wounds to the head--the psychological approach." Journal of forensic sciences **54**(2): 404-407.

In this report, the authors present a case of suicide committed by a 66-year-old man, inside a grave at the local cemetery, with two gunshot wounds to the head. A multiple-paged, handwritten suicide note was found in an army type bag inside the victim's car, while a second one was found in his house. Medicolegal examination of the body revealed two typical contact gunshot entrance wounds and one exit wound to the head. Toxicological analysis of the femoral blood was negative for alcohol and drugs. The history, scene and autopsy findings, along with further police investigation, indicated an obvious case of suicide. The literature is reviewed and discussed. We report this case as the place of suicide is extremely uncommon and as there is no mention of a gunshot suicide inside a grave in the current literature.

2657. Kataria, R., et al. (2011). "Low velocity penetrating head injury with impacted foreign bodies in situ." Asian journal of neurosurgery **6**(1): 39-44.

Penetrating head injury is a potentially life-threatening condition. Penetrating head injuries with impacted object (weapon) are rare. The mechanism of low velocity injury is different from high velocity missile injury. Impacted object (weapon) in situ poses some technical difficulties in the investigation and management of the victims, and if the anticipated problems are not managed properly, they may give rise to serious consequences. The management practice of eight patients with impacted object in situ in context of earlier reported similar cases in literature is presented.

2658. Katayama, K., et al. (2013). "Translucent three-dimensional CT is useful in considering the treatment strategy for the penetrating skull base injury with a metal rod: case report." Neurologia medico-chirurgica **53**(9): 613-615.

An 18-year-old male suffered a penetrating skull base injury caused by a metal rod. We made translucent three-dimensional (3D) computed tomography (CT) for clearing the injury site. This method has revealed that right carotid artery was compressed directly by the foreign body, and internal carotid artery trapping was carried out based on hemodynamics as revealed by angiography. This patient achieved modified Rankin scale score of 1 at discharge. Cases of trauma involve a variety of circumstances and therefore require a case-by-case evaluation that depends on the patient's condition. Translucent 3D CT was useful in considering the treatment strategy of the penetrating skull base injury.

2660. Kaufman, E. J., et al. (2017). "Patient Characteristics and Temporal Trends in Police Transport of Blunt Trauma Patients: A Multicenter Retrospective Cohort Study." Prehospital emergency care : official journal of the National Association of EMS Physicians and the National Association of State EMS Directors **21**(6): 715-721.

BACKGROUND: Police transport (PT) of penetrating trauma patients has the potential to decrease prehospital times for patients with life-threatening hemorrhage and is part of official policy in Philadelphia, Pennsylvania. We hypothesized that rates of PT of bluntly injured patients have increased over the past decade., METHODS: We used Pennsylvania Trauma Outcomes Study registry data from 2006-15 to identify bluntly injured adult patients transported to all 8 trauma centers in Philadelphia. PT was compared to ambulance transport, excluding transfers, burn patients, and private transport. We compared demographics, mechanism, and injury outcomes between PT and ambulance transport patients and used multivariable logistic regression to identify independent predictors of PT. We also identified physiological indicators and injury patterns that might have benefitted from prehospital intervention by EMS., RESULTS: Of 28 897 bluntly injured patients, 339 (1.2%) were transported by police and 28 558 (98.8%) by ambulance. Blunt trauma accounted for 11% of PT and penetrating trauma for 89%. PT patients were younger, more likely to be male, and more likely to be African American or Asian and were more often injured by assault or motor vehicle crash. There were no significant differences presenting physiology between PT and EMS patients. In multivariable logistic regression analysis, male sex (OR 1.89, 95%CI 1.40-2.55), African American race (OR 1.71 95%CI 1.34-2.18), and Asian race (OR 2.25, 95%CI 1.22-4.14) were independently associated with PT. Controlling for injury severity and physiology, there was no significant difference in mortality between PT and EMS. Overall, 64% of PT patients had a condition that might have benefited from prehospital intervention such as supplemental oxygen for brain injury or spine stabilization for vertebral fractures., CONCLUSIONS: PT affects a small minority of blunt trauma patients, and did not appear associated with higher mortality. However, PT patients included many who might have benefited from proven, prehospital intervention. Clinicians, EMS providers, and law enforcement should collaborate to optimize use of PT within the trauma system.

2661. Kaufman, H. H., et al. (1985). "Neurobehavioral outcome after gunshot wounds to the head in adult civilians and children." Neurosurgery **16**(6): 754-758.

To assess the quality of long term outcome of civilian gunshot wounds to the head after intensive neurosurgical management, particularly with regard to the possibility of subtle problems due to diffuse injury, we administered neuropsychological tests to six survivors (four adults and two children) at about 1 year after injury. Five patients were moderately disabled, and one patient achieved a good recovery. Residual neurobehavioral sequelae were present in all cases. Defects in long term memory for new information were the most common sequelae, whereas the persistence of linguistic and visuospatial deficits was related to the hemispheric lateralization of injury. In comparison with the outcome reported for patients with closed head injuries who had similar Glasgow coma scale scores, our patients exhibited more severe impairment due to significant focal brain injuries and less evidence of diffuse damage.

2662. Kaufman, H. H., et al. (1995). "Patients with Glasgow Coma Scale scores 3, 4, 5 after gunshot wounds to the brain." Neurosurgery clinics of North America **6**(4): 701-714.

Even this information is only partial. To study fully the effects of treatment would require optimal care at all points from time of injury, including rapid prehospital resuscitation, rapid transport to an optimally equipped and staffed hospital, immediate evaluation and treatment of the initial injury and all complications, rapid and comprehensive rehabilitation, and supportive and flexible home and work settings for the patient on discharge. Patients would need to be stratified for premorbid characteristics, including intelligence, personal traits, and training. Prolonged follow-up, possibly for several years, would be required to determine true outcome. No current study contains sufficient numbers of patients treated optimally and studied for prolonged periods, but this should be done. One way of looking at such patients is to decide that many should be treated to salvage a few. The other way of looking at them is that so many must receive care, at great emotional and economic cost to themselves and others, that such treatment is inappropriate for any of them. Treating all such patients would be a major undertaking. If most of these patients were treated vigorously, a great proportion of them would still die but probably not for a number of days. During this period, their families would be under extreme stress. Once stabilized and receiving ongoing care, some patients would enter a permanent vegetative state and survive for prolonged periods until their prognosis was clear and care was withdrawn, again causing family stress as well as high cost. Some would likely survive although impaired. The charges and real costs of care for all these patients would be tremendous. The question therefore arises as to how to decide what to do about caring for a large group of patients whose maximal care would be costly in emotional and financial terms, particularly at

a time when it is recognized that resources for medical care are going to be limited. When discussing such patients as a group with a view toward developing practice guidelines, many considerations must be brought to bear. One consideration is the certainty of the prognosis in both a quantitative and a qualitative sense in an individual case. It is not clear that one can be certain in patients except when there are overwhelmingly unfavorable features. As has been noted, even patients who have been shot through the geographic center of the brain and are posturing can make excellent recoveries. This would push toward aggressive treatment for many patients. Decision making must therefore be considered in terms of bioethics. The major principle-based systems of bioethics are deontologic, arising from accepted principles, and utilitarian, arising from effect on outcome. A virtue-based ethic for physicians arising from "the caring bond and the public trust" is being revived as a balance to analytical ethics. A similar orientation from the point of view of patients is communitarian ethics, that is asking for only what is reasonable and not so much as might harm others. Some of the issues to be considered include the sanctity of life while taking into account the criteria for life--vegetative function versus some level of mental function. One must also review each decision from the viewpoints of all the parties involved--patients, family and friends, physicians, and society--in the context of a heterogeneous society in which individual rights and tolerance enforced by law are primary features. In the patients' terms, there is a desire and right to medical care to maintain a healthy productive life. Even if impaired to some extent, patients may still have an interest in living. Balancing benefits and burdens of life is a complex problem. There is also the right, based on patients' values, to refuse care if there is the wish not to take a chance of having a significantly compromised existence. Such declaration before injury should be honored...

2663. Kaufman, H. H., et al. (1983). "Civilian gunshot wounds: the limits of salvageability." Acta neurochirurgica **67**(1-2): 115-125.

Patients who have suffered gunshot wounds in civilian settings, who present with posturing and in whom the bullet has passed through the geographical centre of the brain have generally not been felt to be salvageable. However, surprisingly favourable outcomes in two such patients have led us to believe that some such patients may deserve aggressive treatment.

2664. Kaufman, H. H., et al. (1986). "Gunshot wounds to the head: a perspective." Neurosurgery **18**(6): 689-695.

Craniocerebral gunshot wounds are a significant cause of injury and death in the United States. However, despite reports of occasional unexpectedly favorable outcome in surgically treated patients, these injuries have been viewed pessimistically and indeed have generally been excluded from modern studies of head injuries, which have concentrated on closed head injuries. A review of 143 victims of craniocerebral gunshot wounds admitted to Hermann Hospital, Houston, Texas, during a recent 30-month period confirmed that a few apparently neurologically devastated patients can be saved. A detailed analysis of these patients, including demographic details, general and neurological condition, anatomic injuries, laboratory findings, surgical care, neurological course, and neurological and functional outcome follows. The helpfulness of early resuscitation and appropriate criteria for surgery need to be studied using historic or randomized controls.

2665. Kaufman, H. H., et al. (1980). "Delayed intracerebral hematoma due to traumatic aneurysm caused by a shotgun wound: a problem in prophylaxis." Neurosurgery **6**(2): 181-184.

A delayed traumatic intracerebral hematoma was seen in a patient after a shotgun wound to the brain. The cause of the hemorrhage seemed to be a traumatic aneurysm. Both complications are reviewed, and it is suggested that clinical and intracranial pressure monitoring should lead to early diagnosis and may minimize the effects of this problem and that angiography may be appropriate early in the course of patients who have had fragments pass near intracranial vessels.

2666. Kaufman, H. H., et al. (1991). "A national survey of neurosurgical care for penetrating head injury." Surgical neurology **36**(5): 370-377.

We report results of a survey on the management patterns of penetrating head injury (PHI). American neurosurgeons (N = 2969) were asked to participate in a mail survey. One thousand one hundred twenty-eight responded, providing detailed information about their practices, their opinions concerning diagnostic testing,

nonoperative therapy, and surgical debridement for PHI. Although there was agreement on some areas of management and care, including the use of computed tomography scanning, antibiotics, anticonvulsants, and a few surgical indications/contraindications, there was wide variation on a significant number of points. These included testing for coagulopathy; use of corticosteroids, intracranial pressure monitoring, and barbiturate coma; and surgical indications including debridement of contusions, removal of fragments, location of injury, and Glasgow Coma Score 5-8. Many nonoperative decisions were influenced by the presence of neurosurgical residents, whereas the decision to operate was based primarily on judgment of patient salvageability. This survey uncovered disagreement on several crucial issues in the care of patients with penetrating head injury and the need for continued research in this area of patient care.

2667. Kaufman, K., et al. (2010). "Hypersexuality following traumatic brain injury (TBI) and neurosurgery: Case analysis with literature review." European Psychiatry **25**.

Introduction: Hypersexuality is an uncommon behavioral complication associated with traumatic brain injury (TBI) involving lesions to frontal basal, temporal, or diencephalic structures. Experimental brain injury in animals has produced hypersexual behaviors; however, there is comparative paucity of knowledge in humans. TBI with hypersexuality offers insights into neurological basis of aberrant sexual behaviors as well as potential treatments. This case report describes social/sexual disinhibition in a patient following neurosurgery for self-inflicted TBI. Method: Case analysis with literature review. Results: 32-year-old male was admitted with TBI following an unsuccessful suicide attempt, self-inflicted nail gun injury to the occiput. CT scan revealed 6.5cm nail that had entered the skull in right occiput, right parasagittal location with nail head right of vein of Galen, coursing through splenium of corpus callosum, right thalamus-hypothalamus-midbrain, with its tip at the suprasellar cistern. Occipital craniotomy with retrieval of foreign body was performed eleven days after admission. From post-operative day eight through twenty-seven, patient made inappropriate sexual comments to female medical student: asking her out repetitively, describing her physical appearance, enquiring about her suitors, and requesting her to call him upon his discharge. Prior psychiatric history was pertinent for major depression and social anxiety (especially women) with psychotropic noncompliance. During admission, patient was diagnosed with recurrent major depression, social anxiety by history, and impulse control disorder nos. On sertraline titrated to 100mg qhs, depression resolved with increased control over newly acquired sexual/social disinhibition noted. Conclusion: TBI can lead to social disinhibition and hypersexuality. Sertraline may be a beneficial treatment.

2670. Kaufman, Y., et al. (2008). "Contemporary issues in facial gunshot wound management." The Journal of craniofacial surgery **19**(2): 421-427.

Facial gunshot wounds pose a significant challenge for reconstructive surgeons, particularly when composed of significant soft and bone tissue defects. Often the result of assault, accident, or suicide attempt, facial defects must be thoroughly evaluated to devise an appropriate tissue repair and replacement with the likely prospect of secondary revision. In the acute setting after injury, the primary concern is patient stabilization centered on advanced trauma life support. Thorough examination along with appropriate imaging is critical for identifying any existing defects. As opposed to past surgical management that advocated delayed definitive treatment using serial debridement, today's management favors the use of more immediate reconstruction. Recent improvements in microsurgical technique have shifted favor from local tissue advancement to distant free-flap transfers, which improve cosmesis and function. This has reduced the number of surgeries necessary to achieve reconstruction. Given the diversity and complexity of facial gunshot injuries, a systematic algorithm is essential to help manage the different stages of healing and to ensure that the best outcome is ultimately achieved.

2671. Kaukinen, S., et al. (1995). "Significance of electrical brain activity in brain-stem death." Intensive care medicine **21**(1): 76-78.

A 46-year-old man was diagnosed clinically brain dead after sustaining head trauma. The patient was in deep coma, brain nerves were unresponsive and spontaneous breathing was absent. However, EEG showed well preserved activity, but no reactivity to external stimuli. EEG activity disappeared within 40 h. BAEP were highly abnormal, flash-VEP as recorded 3 h after the diagnosis of brain stem death was of high amplitude but of simplified form. The neurophysiological findings revealed that the main reason for deep coma was brain stem damage while cortical activity was still present. This condition raises ethical questions when brain death is diagnosed clinically prior to removal of organs for transplantation.

2672. Kaups, K. L. (2011). "Editorial comment." Journal of Trauma - Injury, Infection and Critical Care **71**(3): 769-770.

2673. Kawamura, S., et al. (1997). "Penetrating head injury caused by chopstick--case report." Neurologia medico-chirurgica **37**(4): 332-335.

A 4-year-old boy suffered a transorbital penetrating head injury caused by falling on a wooden chopstick while walking. The chopstick was removed completely, but full diagnosis was delayed for 3 years because the entry wound had not appeared to be serious. The patient later experienced rhinorrhea of cerebrospinal fluid (CSF), and recurrent bacterial meningitis. Surgical repair of the CSF fistula at the anterior skull base was performed when the patient was 7 years old. Previous penetrating head injury should be considered in patients with recurrent CSF fistula and meningitis.

2674. Kawanishi, M., et al. (2000). "Penetrating brain injury at the occipital midline region by a nail-gun: A case report." Japanese Journal of Neurosurgery **9**(2): 81-85.

A case of penetrating brain injury by a nail-gun at the site of the occipital midline region is reported. A 57-year-old male was urgently transported to our hospital due to a penetrating head injury due to a nail- gun accident. On admission the nail-head was seen at the occipital midline region. The patient was conscious and alert and he showed no focal neurological signs. Plain craniography, CT and 3 dimensional-CT revealed that the nail penetrated the skull at the sagittal suture in the occipital midline. Cerebral angiography did not show any particular findings strongly suggesting an injured superior sagittal sinus. As the possibility of injuries to this sinus could not be ruled out the nail was carefully extracted by craniotomy. The prognosis of penetrating brain injury by nail is mainly dependent on major vascular injury, infection and traumatic aneurysm, so meticulous preoperative examination and surgical exploration prior to the removal of the nail are mandatory.

2675. Kawashima, M., et al. (2009). "Characteristics of traumatic globe rupture after keratoplasty." Ophthalmology **116**(11): 2072-2076.

OBJECTIVE: To analyze risk factors of traumatic wound rupture after penetrating keratoplasty (PKP) or deep anterior lamellar keratoplasty (DALK)., DESIGN: Retrospective case series., PARTICIPANTS: A total of 1962 consecutive cases were included., METHODS: A review of consecutive patients undergoing either PKP (1776 eyes) or DALK (186 eyes) at 1 regional center between 1998 and 2006 was carried out to determine the incidence of traumatic globe rupture after keratoplasty. Ophthalmic and demographic factors were analyzed. A comparison with previous literature was performed., MAIN OUTCOME AND MEASURES: Incidence, causes, and final visual acuity., RESULTS: Of 43 eyes with globe rupture during this period, 36 received keratoplasty during this study period. The incidence of globe rupture after keratoplasty was 1.8% (36/1962). These 36 cases consisted of 35 of the 1776 eyes receiving PKP (2.0%) and 1 of the 186 eyes receiving DALK (0.5%). Globe rupture occurred 61.6+/-50.0 months (mean +/- standard deviation) after keratoplasty in 43 cases. The major cause of trauma was a fall in elderly patients (73.2+/-8.4 years, 17 eyes), with lens damage occurring in all such cases. Although 15 eyes (34.9%) had a visual acuity of 20/200 or better at final follow-up, eyes showing lens damage were associated with poorer visual acuity than eyes with no lens damage ($P<0.01$)., CONCLUSIONS: Wound weakness persisted for a long period after keratoplasty. A fall was observed frequently in elderly patients and resulted in poor visual outcome. Globe rupture associated with lens injury could be the predictor for future visual outcome.

2676. Kawasumi, Y., et al. (2012). "Postmortem computed tomography images of a broken piece of a weapon in the skull." Japanese journal of radiology **30**(2): 167-170.

The use of post-mortem radiological imaging is becoming increasing widespread in forensic medicine. These images can help improve the quality and safety of autopsy. We report two cases of homicide victims that had broken pieces of a weapon in their skull. Postmortem multislice computed tomography (MSCT) demonstrated metal artifacts in the skull of two homicide cases. Autopsy showed that both artifacts were pieces broken off of a sharp instrument. Some possible benefits of postmortem MSCT include the ability to reconstruct visual images of weapons and the possible prevention of injury to autopsy personnel.

2677. Kawecki, Z. and L. Konieczny (1972). "Cranio-cerebral injuries in adults." Polish medical journal **11**(2): 447-453.

2678. Kawu, A. A., et al. (2011). "Complications and causes of death in spinal cord injury patients in Nigeria." West African journal of medicine **30**(4): 301-304.

BACKGROUND: There have been many reports on the problems of spinal cord injury (SCI) in Nigeria but few have reported on the complications and causes of death in spinal cord injured patients. OBJECTIVE: The objective of this study was to determine the complications, causes of death and associated risk factors in patients with SCI within six months post injury. METHODS: Patients were retrospectively identified from the hospital trauma database from January 1997 to December 2007. Complications and cause of death within the first six months of SCI were determined along with associated risk factors. RESULTS: Five hundred and eighty-two patients were eligible for analyses and data were obtained for 422 (72.5%) patients with a mean age of 37.2 (±14.2) years at six months follow-up. Muscle spasms 417 (98.8%) and neurogenic pain 382 (94.5%) were the main complications noted. The mortality during the review period was 144 (34.1%). Respiratory failure (44.4%) was the commonest cause of death. The independent predictors of mortality were mainly age, GCS<9, Frankel Type A at presentation and cervical spine injury (CSI) and while CSI and Frankel Type A injury were the main predictors of complications. CONCLUSION: Most common complication and cause of death following SCI are muscle spasm and respiratory failure respectively. The risk factors associated with mortality are age, GCS<9, cervical spinal injury, and complete neurologic injury and those for complications were cervical spinal injury and Frankel Type A injury.

2679. Kayhanian, S. and R. J. Machado (2020). "Head Injuries in Homer's Iliad." World neurosurgery **143**: 33-37.

The Iliad is an epic poem chronicling the journey of Achilles in the Trojan War. The poem is one of the earliest sources of written literature in the Western canon. It is not a medical text, but the many and varied descriptions of injuries and their consequences mean that it is an important source for examining the earliest notions of anatomy and knowledge of the pathologies that result from trauma. Head injuries feature prominently in the text and represent written accounts of neurotrauma from nearly 3000 years ago. Previous work on the poem has suggested an awareness of neurological concepts such as nystagmus, syncope, and pupillary dilatation after trauma. In this paper, we identify and categorize all of the head injuries detailed in the text and examine these to identify concepts of functional neuroanatomy that are revealed by the descriptions. We identify and discuss 2 detailed descriptions of head injury, suggesting an awareness of decerebrate posturing after brainstem injury and cerebrospinal fluid leakage following a basal skull fracture.

2680. Kaylor, J. P., et al. (2012). "Electronic medical records and compliance with goal-directed therapy in traumatic brain injury." Annals of emergency medicine **60**(4): S50.

Study Objectives: Traumatic brain injury (TBI) is a devastating public health crisis. There are 1.5-2 million annual incident cases in the United States; the sequelae of which comprise 295,000 hospitalizations, 1/3 of all injury-related mortality, and severe disability. Goal-directed therapy (GDT) has been shown to mitigate secondary brain injury in TBI. GDT is dependent upon timely review of the patient's physiological profile, radiographs, and response to clinical intervention. Electronic medical record systems allow providers across specialties to access the essential components of a patient's treatment simultaneously. This study assesses emergency department (ED) compliance with physiological

monitoring and GDT (ex: early intubation, blood pressure management, neurosurgical intervention) in the treatment of TBI, before and after implementation of an electronic medical record system. Methods: An observational multi-phase before/after cohort study was conducted to assess TBI care at 2 points in time. The study was completed at an urban Level I Trauma Center (annual census >100,000). Patients with a diagnosis of blunt head trauma and initial GCS 3-12 were identified via retrospective review of the on-site trauma registry. Exclusion criteria included: penetrating trauma, GCS >12, and age <18y. 169 subjects met inclusion criteria at Time 1, prior to electronic medical record (1/1/2008-1/1/2010). 137 subjects met inclusion criteria at Time 2, after implementation of electronic medical record (1/3/11-12/31/11). Data on demographics, history, physical exam, clinical care, and disposition were collected. Univariate analyses were completed using SPSS v19, 2010. Results: Distribution of mechanism of injury did not differ significantly between groups. In the post- electronic medical record group, patients had higher initial GCS scores (5.93/6.68, p = 0.04). Despite this difference, time to neurosurgical intervention significantly improved at Time 2 (344/151 minutes, p = .002). At Time 2, patients were also more likely to receive ED placement of an external ventricular drain (p = .01). No statistically significant differences were noted in compliance with parameters for: blood pressure goals, endotracheal intubation, use of antiseizure medicine, or mortality Conclusion: After implementation of electronic medical record there was a significant decrease in time to neurosurgical interventions, such as surgical decompression of hemorrhage and/or placement of external ventricular drain. Future research is needed to assess the relationship between electronic medical record, critical care, and early identification of surgical emergencies, essential components of GDT in TBI.

2681. Kazan, S., et al. (1997). "Intracranial glass." Turkish neurosurgery **7**(3-4): 100-102.

A case of intracranial glass following an orbitocranial trauma is presented. During a car crash, glass fragments from shattered windshield passed through the orbital plate and penetrated into the ventral portion of the frontal lobe. No injury to the globe was observed and the patient did not show any demonstrable signs of neurological deficit. Intracranial glass was surgically removed.

2682. Kazanci, A., et al. (2012). "Intracranial sewing needles in an adult patient." Turkish neurosurgery **22**(6): 775-776.

A 37-year-old patient is reported with intracranial sewing needles, which were located in the right frontal lobe. Both clinical and radiological findings suggested that these needles must have been introduced in infancy before the closure of anterior fontanelle during an unsuccessful homicide. Usually intracranial foreign objects are placed due to penetrating trauma or surgical procedures. Child abuse has been known for centuries. Many types of physical traumas have been reported, especially in Western countries. In Iran, insertion of sewing needles into the brain aiming to kill the infant have been seen in a lot of cases. This situation takes part in a lot of Persian stories. We reported a 37-year-old man who had 2 intracranial sewing needles with unknown etiology.

2683. Kazanis, E., et al. (2001). "Molecular mechanisms involved in the response of brain tissue to trauma molecular mechanisms involved in the response of brain tissue to trauma." Archives of Hellenic Medicine **18**(4): 363-374.

OBJECTIVE: Brain trauma is a major medical problem. It is a primary cause of death, and in the event of survival it leads to long-term ill-health, as well as social and economic problems. The elucidation of the molecular mechanisms involved in the destruction of brain tissue after trauma and in the induction of permanent changes in brain function is necessary for the development of rational therapeutic approaches. METHOD: A model of focal, mechanical, penetrating injury was employed in adult rats. In this model the expression of certain proteins was studied in order to investigate the response of the brain tissue to trauma. The expression of Heat-shock protein-70 (Hsp-70), Brain-Derived Neurotrophic Factor (BDNF), Neurotrophin-3 (NT-3), the astrocytic marker Glial Fibrillary Acidic Protein (GFAP) and Insulin-like Growth Factor-I (IGF-I) were studied immunohistochemically. The occurrence of apoptotic cell death was investigated by the TUNEL reaction. In addition, IGF-I was administered to the injured rats and its neuroprotective properties were determined. RESULTS: 4 and 12 hours after the injury, an increase in Hsp-70 expression, limited induction of IGF-I and activation of astroglia around the core of the injury were observed. Neurotrophin expression was severely reduced in a restricted peritraumatic zone and scattered apoptotic cells were detected, mainly in the injured hemisphere but to a lesser degree in the contralateral hemisphere. One week later, an astroglial scar had been formed at the site of the injury and Hsp-70 expression was limited. BDNF levels remained low, while the reduction in NT-3 was no longer visible. IGF-I expression as well as the number of apoptotic cells were further increased. The local administration of IGF-I following the injury restored the normal tissue patterns to a significant degree, as evidenced by the maintenance of

normal neurotrophin expression and the reduction of the apoptosis in the injured hemisphere. CONCLUSIONS: Focal mechanical injury of the brain induces significant local changes in BDNF, NT-3 and IGF-I expression, which remain detectable at least one week after the injury. With time, degenerative cellular phenomena, as reflected by Hsp-70 expression and apoptotic cell death, spread beyond the site of tissue damage. Administration of IGF-I after the injury reverses some of these phenomena and is able to help maintain homeostasis of the brain tissue.

2684. Kazanis, I., et al. (2003). "Neuroprotective effects of insulin-like growth factor-I (IGF-I) following a penetrating brain injury in rats." Brain research **991**(1-2): 34-45.

The elucidation of the molecular mechanisms involved in the response of brain tissue to trauma and the recognition of substances with neuroprotective properties is a prerequisite for the development of rational therapeutic approaches. In this study, we used a model of, unilateral, penetrating stab-like brain injury and examined the possible beneficial effects of post-injury administration of insulin-like growth factor-I (IGF-I) both at the cellular level, 4 and 12 h post-injury, and on the physical condition of the animals up to 1 week following the trauma. The consequences of injury were assessed by immunohistochemically observing the expression of heat-shock protein 70 (Hsp70), which is thought to be a marker of cell stress and injury, and by staining the tissue with the TUNEL reaction, in order to detect apoptotic cell death. Injury resulted in an increase in the number of Hsp70 and TUNEL positive cells in the peritraumatic area. The physical condition of the rats was followed by measuring body weight changes, food and water intake and by estimating their "motor activity". IGF-I administration resulted in a significant decrease in the number of Hsp70 and TUNEL positive cells in the peritraumatic area. Additionally, it improved the total "motor activity" of injured rats, increased food intake and attenuated the post-injury body weight loss. IGF-I thus emerges as a factor acting both at the cellular level as a neuroprotectant and at the systemic level as an anabolic agent.

2685. Kazanis, I., et al. (2004). "Alterations in IGF-I, BDNF and NT-3 levels following experimental brain trauma and the effect of IGF-I administration." Experimental neurology **186**(2): 221-234.

The effects of a unilateral, penetrating brain trauma on IGF-I, BDNF and NT-3 were studied immunocytochemically in the rat. BDNF and NT-3 were decreased in the peritraumatic area, but increased in the adjacent region, 4 and 12 h post-injury. One week following the trauma, BDNF remained low in the peritraumatic area, but was restored to normal levels in the adjacent, while no effect of injury on NT-3 levels was detected in either area. Injury resulted in an increase in IGF-I levels in the peritraumatic area, which was most pronounced 1 week following the trauma, indicating that IGF-I could participate in endogenous repair processes. We thus administered IGF-I immediately following the trauma and investigated its effects on injury-induced changes in neurotrophin levels. Administration of IGF-I partially reversed the injury-induced decrease in BDNF and NT-3 in the peritraumatic area observed 4 and 12 h post-injury, while at the same time-points, it completely cancelled the effects of injury in the adjacent region. One week after the trauma, BDNF levels were dramatically increased in both the peritraumatic and adjacent area, reaching levels even higher than those of the sham-operated animals, following IGF-I administration. Our results showing that IGF-I not only counteracts injury-induced changes in neurotrophins, but can also further increase their levels, indicate that this growth factor could mediate repair and/or protective processes, following brain trauma.

2686. Kazemi, H., et al. (2012). "Intractable epilepsy and craniocerebral trauma: analysis of 163 patients with blunt and penetrating head injuries sustained in war." Injury **43**(12): 2132-2135.

Post-traumatic epileptic seizure is a common complication of brain trauma including military injuries. We present clinical characteristics and correlates of post-traumatic epilepsy in 163 head-injured veterans suffering from intractable epilepsy due to blunt or penetrating head injuries sustained during the Iraq-Iran war. The medical records of 163 war veterans who were admitted by the Epilepsy Department of the Shefa Neuroscience Center between 2005 and 2009 were retrospectively reviewed. The mean follow-up period after developing epilepsy was 17.2 years. The time interval between the trauma and the first seizure was shorter and the seizure frequency was higher in epileptic patients suffering from penetrating head trauma. There was no difference in seizure type between epileptic patients traumatised by blunt or penetrating injury. Patients with seizure frequency of more than 30 per month mostly had simple partial seizure. Frontal and parietal semiologies were observed more frequently in patients with penetrating trauma, whereas patients with blunt trauma showed a higher temporal semiology. The most common brain lesion observed by CT scan was encephalomalacia followed by porencephaly and focal atrophy. There was no association between intracerebral

retained fragments and different characteristic features of epilepsy. Patients with military brain injury carry a high risk of intractable post-traumatic epilepsy decades after their injury, and thus require a long-term medical follow-up.

2687. Kazemi, H., et al. (2014). "Intractable epilepsy and craniocerebral trauma: Analysis of 163 patients with blunt and penetrating head injuries sustained in war." Brain injury **28**(5-6): 620.

Objectives: Post-traumatic epileptic seizure is one of the common neurological disorders after military injuries. This study evaluated clinical characteristics of post-traumatic epilepsy in 163 patients injured during the Iraq-Iran war. Methods: The medical records of patients who were admitted by the Epilepsy Department of the Shefa Neuroscience Center between 2005-2009 were retrospectively reviewed. The mean follow-up period after developing epilepsy was 17.2 years. Results: The time interval between the trauma and the first seizure was shorter and the seizure frequency was higher in epileptic patients suffering from penetrating head trauma while there was no difference in seizure type between patients injured by blunt or penetrating trauma. Patients with seizure frequency of more than 30 per month mostly had simple partial seizure. Frontal and parietal semiologies were observed more frequently in patients with penetrating trauma, whereas patients with blunt trauma showed a higher temporal semiology. The most common brain lesion observed by CT scan was encephalomalacia followed by porencephaly and focal atrophy. There was no association between intracerebral retained fragments and different characteristic features of epilepsy. Conclusions: There is a high risk of intractable post-traumatic epilepsy in patients suffering from military brain injury. Consequently, these patients require a long-term medical follow-up.

2688. Kazim, S. F., et al. (2011). "Management of penetrating brain injury." Journal of emergencies, trauma, and shock **4**(3): 395-402.

Penetrating brain injury (PBI), though less prevalent than closed head trauma, carries a worse prognosis. The publication of Guidelines for the Management of Penetrating Brain Injury in 2001, attempted to standardize the management of PBI. This paper provides a precise and updated account of the medical and surgical management of these unique injuries which still present a significant challenge to practicing neurosurgeons worldwide. The management algorithms presented in this document are based on Guidelines for the Management of Penetrating Brain Injury and the recommendations are from literature published after 2001. Optimum management of PBI requires adequate comprehension of mechanism and pathophysiology of injury. Based on current evidence, we recommend computed tomography scanning as the neuroradiologic modality of choice for PBI patients. Cerebral angiography is recommended in patients with PBI, where there is a high suspicion of vascular injury. It is still debatable whether craniectomy or craniotomy is the best approach in PBI patients. The recent trend is toward a less aggressive debridement of deep-seated bone and missile fragments and a more aggressive antibiotic prophylaxis in an effort to improve outcomes. Cerebrospinal fluid (CSF) leaks are common in PBI patients and surgical correction is recommended for those which do not close spontaneously or are refractory to CSF diversion through a ventricular or lumbar drain. The risk of post-traumatic epilepsy after PBI is high, and therefore, the use of prophylactic anticonvulsants is recommended. Advanced age, suicide attempts, associated coagulopathy, Glasgow coma scale score of 3 with bilaterally fixed and dilated pupils, and high initial intracranial pressure have been correlated with worse outcomes in PBI patients.

2689. Kazmi, S. A. M., et al. (2001). "Missile injuries of the brain." Journal of the College of Physicians and Surgeons Pakistan **11**(1): 4-7.

Data was analyzed relating to a consecutive series of 16 patients of penetrating brain injuries received at forward defence lines. Characteristics studied were the cause of injury, level of consciousness and various neurological deficits presented on initial examination, CT scan findings, the surgical procedures performed and the final outcome after one year of follow-up. One, out of 16 patients, died due to severe associated injuries to abdominal viscera and major vessels. Meningitis occurred in one patient during the immediate postoperative period. All patients with motor weakness, speech deficits and incontinence showed significant improvement. Hearing loss of one ear persisted in one patient. Two patients developed delayed onset seizures. It is concluded that, patients with penetrating brain injuries should be evacuated to the tertiary care neurosurgical centres as soon as possible. In operation only obviously necrotic brain and easily accessible metal and bone pieces should be removed. There is no need to explore the normal brain as it

would only result in increased neurological deficits. The patients with such injuries should receive broad-spectrum antibiotics to prevent the infective complications.

2690. Kc, K. M., et al. (2022). "Frontal Bone Osteomyelitis in Adult." Journal of Nepal Health Research Council **20**(1): 257-259.

Frontal bone osteomyelitis is a rare clinical disease which occurs as a result of frontal sinusitis, penetrating injury on head, post-operative complication after sinus surgery and hematogenous spread from distant site. Early diagnosis, appropriate surgical debridement and antibiotic are keys to prevent from life threatening intracranial complications. We report a 63 years old male patient with osteomyelitis of outer cortex of frontal bone. The wound was thoroughly debrided after computer tomography scan showed an osteolytic lesion on outer table of fontal bone and antibiotic was continued for 2 months until inflammatory markers become normal. Keywords: Frontal bone; Intracranial complications; osteomyelitis; pott's puffy tumour.

2692. Kedous, M. A., et al. (2018). "Unusual circumstances to diagnose cervical Pott's disease." Skeletal radiology **47**(5): 723-727.

Tuberculous spondylodiscitis usually affects the dorso-lumbar spine, and its cervical location is a rare condition that can mimic other diseases and consequently cause treatment delays. We report a case of tuberculous spondylodiscitis of the lower cervical spine discovered under unusual circumstances in a patient with severe polytrauma involving a cranio-cerebral trauma, a non-displaced fracture of the two laminae and the spinous process of the C6 vertebrae as well as fibular and tibial shaft fractures. The patient underwent static tibial nailing, and a collar with occipital and chin supports was applied. At 2-month follow-up, the patient presented with severe neck pain without neurologic deficits. Plain and dynamic cervical radiographs showed a stable C6-C7 subluxation and C7 superior endplate collapse. The CT scan also outlined prevertebral soft tissue swelling. The MRI showed a C6-C7 spondylodiscitis associated with a prevertebral abscess with am 8-cm major axis. The diagnosis of C6-C7 Pott's disease was confirmed by a CT-guided biopsy. The patient received 12 months of antituberculous chemotherapy, after which the paravertebral abscess completely disappeared, and the patient has had no functional sequelae. The diagnosis of cervical spine tuberculosis is difficult and requires a high level of attention. Delays in establishing the diagnosis and starting the appropriate treatment result in severe complications such as spinal cord compression and spinal deformity, which are difficult to manage.

2693. Keel, M., et al. (2005). "The role of surgical hip dislocation in the treatment of acetabular and femoral head fractures." European Journal of Trauma **31**(2): 138-147.

Background and Purpose: Surgical hip dislocation by trochanteric flip osteotomy facilitates access to acetabular and femoral head fractures. Furthermore, it allows evaluation of cartilage damage and vascularity of the femoral head. In this study the potential benefits of this procedure for improved fracture management and for prognostic assessment were investigated. Patients and Methods: From July 1997 to October 1999, 20 selected patients with displaced acetabular fractures (n = 12), femoral head fractures (n = 7), or combined injuries (n = 1) were included. Inclusion criteria for acetabular fractures were either displaced posterior wall fragments with cranial extension or complex acetabular fractures involving a displaced transverse fracture line. Open reduction and fixation of either complex acetabular fractures or femoral head fractures were carried out through Kocher-Langenbeck approach, trochanteric flip osteotomy, and complete surgical hip dislocation. Additionally, the extent of cartilage destruction and femoral head perfusion were assessed. Results: Anatomic reduction (≤ 1 mm displacement) of acetabular fractures was achieved in 69% of patients and good reduction (< 3 mm) in 31%. In patients with acetabular fractures, severe cartilage destruction of the acetabulum was found in 38% and of the femoral head in 15%, while patients with isolated femoral head fractures revealed severe cartilage damage of the femoral head in 57%. Arterial bleeding from the femoral head, tested by drilling, was observed in all patients. Secondary dislocation of the trochanteric osteotomy occurred in one patient and made refixation necessary. Patients were reexamined at least 2 years after intervention. 77% of patients with acetabular

fractures and all patients with femoral head fractures showed good or excellent results after 32.6 ± 6.1 months according to the functional score of D'Aubigné & Postel. Conclusion: Surgical hip dislocation allows adequate reconstruction of complex acetabular and femoral head fractures and intraoperative evaluation of local cartilage damage and femoral head perfusion. © Urban & Vogel.

2695. Kelishadi, S. S., et al. (2019). "Facial Fracture Patterns Associated with Traumatic Optic Neuropathy." Craniomaxillofacial Trauma and Reconstruction **12**(1): 39-44.

Traumatic optic neuropathy (TON) is rare. The heterogeneity of injury patterns and patient condition on presentation makes diagnosis difficult. Fracture patterns associated with TON have never been evaluated. Retrospective review of 42 patients diagnosed with TON at the R. Adams Cowley Shock Trauma Center from May 1998 to August 2010 was performed. Thirty-three patients met criteria for study inclusion of fracture patterns. Additional variables measured included patient demographics and mechanism. Cluster analysis was used to form homogenous groups of patients based on different fracture patterns. Fracture frequency was analyzed by group and study population. Visual depiction of fracture patterns was created for each group. Cluster analysis of fracture patterns yielded five common groups or fracture patterns among the study population. Group 1 (n = 3, 9%) revealed contralateral lateral orbital wall (100%), zygoma (67%), and nasal bone (67%) fractures. Group 2 (n = 7, 21%) demonstrated fractures of the frontal bone (86%), nasal bones (71%), and ipsilateral orbital roof (57%). Group 3 (n = 14, 43%) involved fractures of the ipsilateral zygoma (100%), lateral orbital wall (29%), as well as frontal and nasal bones (21% each). Group 4 (n = 5, 15%) consisted of mid- and upper-face fractures; 100% fractured the ipsilateral orbital floor, medial and lateral walls, maxilla, and zygoma; 80% fractured the orbital roof and bilateral zygoma. Group 5 (n = 4, 12%) was characterized by fractures of the ipsilateral orbital floor, medial and lateral orbital walls (75% each), and orbital roof (50%). A notably high 15 of 33 patients (45%) sustained penetrating trauma. Our study demonstrates five fracture pattern groups associated with TON. Zygomatic, frontal, nasal, and orbital fractures were the most common. Fractures with a combination of frontal, nasal, and orbital fractures are particularly concerning and warrant close attention to the eye.

2697. Kell, H. M., et al. (1993). "Traumatic optic neuropathy complicated by thyroid eye disease." Journal of the American Optometric Association **64**(6): 432-439.

BACKGROUND: Thyroid eye disease is the most common orbital disorder found in adults. Ocular changes may occur with or without systemic hyperthyroidism. Blunt orbital trauma can affect the eye in many ways and can confound and alter the natural course of thyroid eye disease., METHODS: A 76-year-old patient with a number of ophthalmic findings and associated symptoms which could have been related to previous blunt ocular trauma. Careful optometric evaluation, systemic laboratory testing, and review of the ocular and medical findings demonstrated the onset of thyroid dysfunction., RESULTS: Thyroid disease was diagnosed on the basis of the presence of enlarged extraocular muscles by CT scan and elevated tensions on attempted upgaze. The patient demonstrated an elevated T3 uptake and low TSH levels for which he was treated with propylthiouracil. The occurrence of thyroid disease and damage from blunt trauma confounded the diagnosis because forced duction testing and optic atrophy could well have been the result of previous blunt trauma., CONCLUSIONS: This case elucidates the many differential diagnoses and complications that result from the combination of previous blunt trauma and the occurrence of new thyroid disease with ophthalmic findings.

2701. Kelly, P. and C. J. Drago (2009). "Surgical and prosthodontic treatment of a patient with significant trauma to the middle and lower face secondary to a gunshot wound: a clinical report." Journal of prosthodontics : official journal of the American College of Prosthodontists **18**(7): 626-637.

Large defects of dentofacial structures may result from trauma, disease (including neoplasms), and congenital anomalies. The location and size of the defects are related to difficulties that patients report relative to speech, mastication, swallowing, facial esthetics, and self-image. This article reports on the evaluation and treatment of a patient who suffered significant trauma to the lower and mid-face secondary to a gunshot injury. It describes the initial presentation, life-saving procedures, and subsequent bone grafts, implant placement, and prosthetic treatments required to rehabilitate the patient to a condition that closely approximated his preoperative condition. This clinical report confirms that no matter the degree of complexity involved in treating the results of significant facial trauma, successful treatment is dependent on thorough physical and radiographic examinations, development of the appropriate diagnoses, and treatment based on sound prosthodontic and surgical principles.

2702. Kelly, P. D., et al. (2021). "Incorporating conditional survival into prognostication for gunshot wounds to the head." Journal of neurosurgery: 1-10.

OBJECTIVE: Several scores estimate the prognosis for gunshot wounds to the head (GSWH) at the point of hospital admission. However, prognosis may change over the course of the hospital stay. This study measures the accuracy of the Baylor score among patients who have already survived the acute phase of hospitalization and generates conditional outcome curves for the duration of hospital stay for patients with GSWH., METHODS: Patients in whom GSWH with dural penetration occurred between January 2009 and June 2019 were identified from a trauma registry at a level I trauma center in the southeastern US. The Baylor score was calculated using component variables. Conditional overall survival and good functional outcome (Glasgow Outcome Scale score of 4 or 5) curves were generated. The accuracy of the Baylor score in predicting mortality and functional outcome among acute-phase survivors (survival > 48 hours) was assessed using receiver operating characteristic curves and the area under the curve (AUC)., RESULTS: A total of 297 patients were included (mean age 38.0 [SD 15.7] years, 73.4% White, 85.2% male), and 129 patients survived the initial 48 hours of admission. These acute-phase survivors had a decreased mortality rate of 32.6% (n = 42) compared to 68.4% (n = 203) for all patients, and an increased rate of good functional outcome (48.1%; n = 62) compared to the rate for all patients (23.2%; n = 69). Among acute-phase survivors, the Baylor score accurately predicted mortality (AUC = 0.807) and functional outcome (AUC = 0.837). However, the Baylor score generally overestimated true mortality rates and underestimated good functional outcome. Additionally, hospital day 18 represented an inflection point of decreasing probability of good functional outcome., CONCLUSIONS: During admission for GSWH, surviving beyond the acute phase of 48 hours doubles the rates of survival and good functional outcome. The Baylor score maintains reasonable accuracy in predicting these outcomes for acute-phase survivors, but generally overestimates mortality and underestimates good functional outcome. Future prognostic models should incorporate conditional survival to improve the accuracy of prognostication after the acute phase.

2703. Kendirli, M. T., et al. (2012). "A more realistic animal model of post-traumatic epilepsy." Epilepsy Currents **12**(1).

Rationale: Epilepsy is a common consequence following traumatic brain injury, with the highest incidence following penetrating injuries such as gun shot wounds. There are many models of traumatic brain injury, but they do not replicate all of the features of penetrating injuries, including retained foreign materials such as metal. To create a

model that was closer to the clinical situation, we examined if placing metal fragments into a penetrating injury increased the risk for subsequent epilepsy. Methods: Under isoflurane anesthesia adult male Sprague-Dawley (250-350 g) rats had penetrating injuries induced with a small bore (approximately 1mm tip diameter) , at one or two different frontal and/or limbic sites from the dorsal to ventral surface. In two thirds of the animals immediately after the penetrating lesion we put several lead or copper metal fragments into the lesion areas. At a minimum of 3 months following the lesion, recording electrodes were placed around the site of the lesion and over the frontal cortex, and the electrodes were secured with dental acrylic. Following the surgery the animals were recorded intermittently to determine the presence of spontaneous seizures for until 6 months following the injury. Results: Six rats died from complications of the lesion, and 4 rats lost headsets before recordings were completed. Of the rats that were tested until 6 months post lesion, 0/4 of the lesion only, 10/10 of the lesion plus copper and 3/4 of the lesion plus lead rats showed spontaneous seizures ($p<0.01$). The incidence of epilepsy increased over the 3 months of observation. The mean seizure number per day was 6.8±1.5 and the mean seizure duration was 73±9 second. Many of the seizures were convulsions, but there were also many nonconvulsive seizures. Frontal lesions were as likely to result in seizures as limbic lesions. Initial pathological examination suggested that the presence of copper and lead resulted in larger lesions. Conclusions: Retained metal fragments significantly increase the risk of epilepsy and may cause additional brain damage. The long term presence of these toxic metals may cause additional changes that lead to epilepsy. This model may more closely replicate the epilepsy that follows gun shot wounds and may also provide a useful model of neocortical epilepsy.

2704. Kendirli, M. T., et al. (2014). "A model of posttraumatic epilepsy after penetrating brain injuries: effect of lesion size and metal fragments." Epilepsia **55**(12): 1969-1977.

OBJECTIVE: Penetrating brain injury (PBI) has the highest risk for inducing posttraumatic epilepsy, and those PBIs with retained foreign materials such as bullet fragments carry the greatest risk. This study examines the potential contribution of copper, a major component of bullets, to the development of epilepsy following PBI., METHODS: Anesthetized adult male rats received a penetrating injury from the dorsal cortex to the ventral hippocampus from a high speed small bit drill. In one group of animals, copper wire was inserted into the lesion. Control animals had only the lesion or the lesion plus stainless steel wire (biologically inert foreign body). From 6 to up to 11 months following the injury the rats were monitored intermittently for the development of epilepsy with video-electroencephalography (EEG). A separate set of animals was examined for possible acute seizures in the week following the injury., RESULTS: Twenty-two of the 23 animals with copper wire developed chronic epilepsy, compared to three of the 20 control rats (lesion and lesion with stainless steel). Copper was associated with more extensive injury. The control rats with epilepsy had larger lesions. In the acute injury group, there was no difference in the incidence of seizures (83% lesion plus stainless steel, 70% lesion plus copper)., SIGNIFICANCE: Copper increases the risk for epilepsy and may increase damage over time, but there were no differences between the groups in the incidence of acute postinjury seizures. Lesion size may contribute to epilepsy development in lesion-only animals. Copper may be an independent risk factor for the development of epilepsy and possible secondary injury, but lesion size also contributes to the development of epilepsy. The consequences of prolonged exposure of the brain to copper observed in these animals may have clinical implications that require further evaluation.

2705. Kennedy, F., et al. (1993). "The Glasgow Coma Scale and prognosis in gunshot wounds to the brain." The Journal of trauma **35**(1): 75-77.

To determine which factors predict survival in patients with gunshot wounds to the brain, 192 patients who had intracranial injury demonstrated on computed tomographic (CT) scanning were retrospectively reviewed. Glasgow Coma Scale (GCS) scores on admission seemed to be the most important factor in predicting survival. Age, the presence of extruded brain, and use of a shotgun could not be shown to be factors independent of admission GCS score. Findings on CT scans (single lobe vs. multilobe involvement) helped to predict survival only in patients with GCS scores 5-13. The mortality rate was 35%. Among survivors 18% had brain-related long-term disability, and an additional 27% had long-term disability related to associated eye injury.

2706. Kennedy, F. R., et al. (1994). "Incidence of cervical spine injury in patients with gunshot wounds to the head." Southern medical journal **87**(6): 621-623.

Cervical spine immobilization is standard during the early stages of prehospital and hospital care of patients with blunt head injury. However, the need for cervical spine immobilization in patients with gunshot wounds to the head has not been addressed. To determine the incidence and types of cervical spine injury in this group, we retrospectively examined the records of 308 consecutive patients who had computed tomographic (CT) scans of the head to evaluate brain injury after gunshot wounds. Of the 266 patients with data adequate for review, 157 (59%) had a complete lateral x-ray film of the cervical spine. Of these 157, 105 had wounds limited to the calvaria, and none had cervical spine injury. Of 52 patients with complete lateral x-ray films and wounds not limited to the calvaria, 5 (10%) had cervical spine or spinal cord injury. Of the 192 patients who had CT-proven intracranial injury, 86 (45%) required immediate intubation before x-ray films were obtained, and 67 (35%) died. We conclude that cervical spine immobilization may not be required during endotracheal intubation of brain-injured gunshot victims with wounds limited to the calvaria.

2707. Kennedy, M. C., et al. (1996). "Drugs and brain death." The Medical journal of Australia **165**(7): 394-398.

IN THE EARLY HOURS of the morning, a fit young man leaves a party, where drugs are reported to have been consumed, to walk home. A short time later he is found unconscious by the roadside, with severe head injuries. En route to hospital by ambulance, he suffers a cardiac arrest and is successfully resuscitated. On arrival at the Emergency Department he has obvious head injuries and is deeply unconscious, but shows spontaneous ventilatory movements. Available history is that he is a 20-year-old student with well-controlled epilepsy for which he takes phenytoin. It is not known how he sustained his injuries. Pupils are equal, small and react sluggishly to light. There is generalised flaccidity and an extensor-plantar response to painful stimuli. Skull x-rays show no fractures and computed tomography shows early cerebral oedema and scattered cerebral contusions with evidence of subarachnoid haemorrhage. He is transferred to the intensive care unit and measures to inhibit cerebral oedema, including mannitol, are commenced. An N-methyl-D-aspartate (NMDA) inhibitor is administered for neuroprotection and ventilatory support is commenced. Over the next 24 hours haemodynamic support is needed with fluid loading and vasopressors. A urine drug screen by Toxilab (Toxilab Incorporated, Irvine, Calif.) shortly after arrival shows the presence of phenytoin and morphine. The report states that the presence of benzodiazepines is suspected. Plasma phenytoin concentration at the time of arrival was 78 mumol/L (optimal range, 40-80 mumol/L). Forty hours after admission his condition has deteriorated. His pupils are at midposition, no longer reactive to light and his lower limbs exhibit only spinal reflexes. His relatives begin to prepare themselves for the fact he may not survive and raise the issue that he would have been keen to donate organs under such circumstances. What is the opinion regarding withdrawal of life support at this time?

2708. Kennedy, M. S., et al. (2019). "Epidemiology of ocular trauma in the Indigenous vs non-Indigenous population in the Top End." Clinical & experimental ophthalmology **47**(8): 995-999.

IMPORTANCE: Epidemiological data on visually significant ocular trauma in the Top End of the Northern Territory., BACKGROUND: Our main objective is to determine whether Indigenous patients are disproportionately affected by visually significant ocular trauma as compared to non-Indigenous patients., DESIGN: This was a retrospective audit at the Royal Darwin Hospital in the Top End of the Northern Territory during January 2013 to June 2015., PARTICIPANTS: A total of 104 ocular trauma patients were included; 43 were Indigenous and 61 were non-Indigenous., METHODS: Medical records of patients with ocular trauma between January 2013 and June 2015 (except simple, non-penetrating corneal foreign bodies and abrasions) were reviewed. Vision loss was defined by visual acuity: mild >=6/18, moderate 6/18-6/60, severe <=6/60 following World Health Organization standards., MAIN OUTCOME MEASURES: The study included the incidence of ocular trauma patients by ethnicity (Indigenous vs non-Indigenous). Our secondary outcome included vision loss, mechanism of injury, open vs closed injury, age, remoteness and alcohol involvement., RESULTS: A total of 104 patient charts were reviewed; 43 (41%) were Indigenous and 61 (59%) were non-Indigenous. Alleged assault was the greatest contributor to ocular trauma in both groups (74% in Indigenous vs 39% non-Indigenous). Severe vision loss was more prevalent in the Indigenous vs non-Indigenous patients (30% vs 16%)., CONCLUSIONS AND RELEVANCE: Indigenous patients were disproportionately affected by visually significant ocular trauma compared to non-Indigenous patients. This research provides important data on ocular trauma in the Northern Territory. Further prevention strategies are needed to reduce vision loss in this population.

2709. Kennedy, U. M., et al. (2007). "Intracranial stab wound: a case report." European journal of emergency medicine : official journal of the European Society for Emergency Medicine **14**(2): 72-74.

OBJECTIVE: Intracranial stab wounds are relatively uncommon, as the adult skull usually provides an effective barrier to penetration. We present an interesting case of a penetrating intracranial stab wound with several important teaching points., CLINICAL PRESENTATION: A 44-year-old man presented to the emergency department with a 1.2-cm stab wound to the left temporal area. His initial Glasgow Coma Score was 14/15. Computerized tomography of his brain revealed a left temporal lobe haemorrhage and contusion. Magnetic resonance images of his brain revealed a linear haematoma extending from his left temporal lobe into the left middle cerebellar peduncle, consistent with a penetrating injury. He was managed conservatively with intravenous antibiotics and made an excellent recovery. Three weeks after injury, he had mild residual problems with recall and attention., CONCLUSION: Several leaning points exist in this case. Firstly, as stab wounds to the brain frequently present as apparently innocuous facial or scalp lacerations, a high index of suspicion is needed to prevent these injuries presenting with serious late infective complications. Secondly, reports of similar cases in the literature suggest that stab wounds to the temporal region are associated with a high morbidity and mortality. This case demonstrates that a patient with an injury such as this can occasionally make a good functional recovery. Finally, this case highlights the advantage of magnetic resonance imaging over computerized tomography in patients with these injuries once it has been established that there is no residual intracranial metal fragment prior to magnetic resonance imaging. In this case, the entire wound tract was only evident on magnetic resonance imaging and not on the initial computerized tomography scans.

2710. Keong, N. C. H., et al. (2006). "Neurosurgical history: Comparing the management of penetrating head injury in 1969 with 2005." British journal of neurosurgery **20**(4): 227-232.

Penetrating head trauma may present challenging problems in the acute phase (removal of foreign bodies, control of haemorrhage, prevention of infection) and in the management of long-term sequelae (neurological deficit, cognitive impairment, seizures). Two unusual cases demonstrate the progress made in emergency medicine, radiology neurointensive care, and neurosurgical head injury management over 36 years.

2711. Ker, K. and K. Blackhall "Bradykinin beta-2 receptor antagonists for acute traumatic brain injury." (7).

Background, Traumatic brain injury (TBI) is a leading cause of death and disability worldwide. Cerebral oedema, the accumulation of fluid within the brain, is believed to be an important contributor to the secondary brain damage that occurs following injury. The release of kinins is thought to be an important factor in the development of cerebral vasogenic oedema and the use of bradykinin beta-2 receptor antagonists, which prevent the release of these kinins, has been proposed as a potential therapeutic intervention., Objectives, The objective was to assess the safety and effectiveness of bradykinin beta-2 receptor antagonists for TBI., Search methods, We searched the Cochrane Injuries Group Specialised Register, Cochrane Central Register of Controlled Trials (The Cochrane Library 2010 Issue 2), MEDLINE (Ovid SP), EMBASE (Ovid SP), ISI Web of Science: Science Citation Index Expanded (SCI-EXPANDED), ISI Web of Science: Conference Proceedings Citation Index-Science (CPCI-S), Zetoc: British Library's table of contents of journal articles and conference proceedings, PubMed, and Current Controlled Trials covering all available years up to 20th May 2010. We also searched the Internet and checked the reference lists of relevant papers and other reviews to identify any further studies., Selection criteria, Randomised controlled trials of beta-2 receptor antagonists versus placebo for TBI., Data collection and analysis, Two authors independently screened search results and assessed the full texts of potentially relevant studies for inclusion. Data were extracted and the risks of bias assessed. Relative risks (RR) and 95% confidence intervals (CIs) were calculated and data were pooled using a fixed-effect model., Main results, Four studies involving 406 participants were included. All four studies reported the effects of beta-2 receptor antagonists on mortality. The pooled RR for mortality was 0.84 (95% CI 0.55 to 1.29). Two studies measured disability and the RR of death or severe disability with beta-2 receptor antagonists was 0.81 (95% CI 0.59 to 1.09). One trial reported data on adverse events, the RR of at least one serious adverse event was 1.37 (95% CI 0.76 to 2.46) and the RR of local skin reactions was 13.79 (95% CI 0.85 to 224.81). Two studies measured the effect on intracranial pressure (ICP), only in one study did this finding reach statistical significance. There was no evidence for the presence of heterogeneity., Authors' conclusions, There is no reliable evidence that bradykinin beta-2 receptor antagonists are safe or effective for use in TBI patients, and they should not be used outside the context of well conducted trials. Further adequately powered and well conducted randomised controlled trials are required.

2712. Kerbler, S., et al. (1990). "[Traumatic embolization of the middle cerebral artery]." Traumatische Embolisierung der Arteria cerebri media. **45**(5): 301-303.

A 3 mm metallic particle, which had blasted during grinding operation, shot into the neck of a nine year old boy, penetrated into the common carotid artery and embolized the right middle cerebral artery. There had been no neurological symptoms until four days after the injury. Suddenly, a mild left side hemiparesis occurred with accentuation of the arm. The case illustrates an unusual penetration and intravascular migration of a foreign body. After the injury, penetration and subsequent peripheric embolisation can happen immediately, or as in our case within a short time after. Hence, the small particle may not be detected by a local radiogram, or may not be found on surgical exploration. Therefore, in all cases of neck wounds caused by low velocity injection of foreign bodies, radiological evaluation with skull-x-rays and a neurological examination should be done. If further special scans are required, these should be accomplished by axial computer tomography, because the metallic nature of the foreign bodies would prohibit the examination by magnetic resonance.

2713. Kerr, M. L. and J. A. Prahlow (2014). "Seizure disorder secondary to remote gunshot wound of the head: a case of sudden unexpected death in epilepsy." Forensic science, medicine, and pathology **10**(4): 643-646.

2714. Kerr, N. A., et al. (2019). "Human lung cell pyroptosis following traumatic brain injury." Cells **8**(1).

Approximately 30% of traumatic brain injured patients suffer from acute lung injury or acute respiratory distress syndrome. Our previous work revealed that extracellular vesicle (EV)-mediated inflammasome signaling plays a crucial role in the pathophysiology of traumatic brain injury (TBI)-induced lung injury. Here, serum-derived EVs from severe TBI patients were analyzed for particle size, concentration, origin, and levels of the inflammasome component, an apoptosis-associated speck-like protein containing a caspase-recruiting domain (ASC). Serum ASC levels were analyzed from EV obtained from patients that presented lung injury after TBI and compared them to EV obtained from patients that did not show any signs of lung injury. EVs were co-cultured with lung human microvascular endothelial cells (HMVEC-L) to evaluate inflammasome activation and endothelial cell pyroptosis. TBI patients had a significant increase in the number of serum-derived EVs and levels of ASC. Severe TBI patients with lung injury had a significantly higher level of ASC in serum and serum-derived EVs compared to individuals without lung injury. Only EVs isolated from head trauma patients with gunshot wounds were of neural origin. Delivery of serum-derived EVs to HMVEC-L activated the inflammasome and resulted in endothelial cell pyroptosis. Thus, serum-derived EVs and inflammasome proteins play a critical role in the pathogenesis of TBI-induced lung injury, supporting activation of an EV-mediated neural-respiratory inflammasome axis in TBI-induced lung injury.

2715. Keskin, E., et al. (2021). "Rebar-induced transpalatal penetrating head trauma: a case report." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **37**(12): 3939-3943.

Penetrating head injuries caused by blunt or piercing objects are rare. In this paper, we present the case of a 9-year-old boy referred to our hospital with rebar-induced injury. The patient's neurological examination findings were normal. Computed tomography undertaken revealed that the rebar had entered through the oral cavity transorally-transpalatally, passing the frontal bone, and then exited the body by piercing the skin. The patient was taken to emergency surgery, and first, tracheostomy was performed. The rebar had been cut and shortened by the emergency rescue unit, which resulted in shortening the part of the foreign body that would pass through the brain parenchyma. During surgery, the rebar was carefully removed by following the route of the entry. All the defects caused by the foreign body were surgically repaired using a multidisciplinary approach, including neurosurgery and plastic and reconstructive surgery, by otolaryngology teams.

2716. Kesting, M. R., et al. (2017). "Classification of orbital exenteration and reconstruction." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **45**(4): 467-473.

Orbital exenteration (OE) is considered to be a mutilating surgical procedure reserved for relentlessly progressive neoplastic disorders or extensive facial trauma with unfavourable eye involvement. Malignant tumours,

accounting for the majority of ablative orbital surgeries, may be caused by primary orbital tumours or secondarily by neoplasias from the surrounding skin, the maxillary sinus or intracranial malignomas. Orbital exenteration following trauma is mostly caused by penetrating globe defects or extended infections with the danger of intracranial effects. Thoughtful resection planning, the exploitation of reconstructive possibilities as well as the consideration of adjuvant therapy are essential to provide the patient with the best available treatment. As a multitude of reconstructive procedures exist, it is of crucial importance to offer a disease-tailored treatment to achieve a successful patient outcome. After retrospective analysis of 45 orbital exenteration cases within the last decade, we developed a defect-driven classification for ablative orbital therapy followed by a guideline for reconstructive procedures. The classification as well as the reconstruction guideline will help the surgeon to restore anatomic boundaries and to promote physiological and psychological recovery for the patient.

2717. Ketharanathan, N., et al. (2019). "Combining Brain Microdialysis and Translational Pharmacokinetic Modeling to Predict Drug Concentrations in Pediatric Severe Traumatic Brain Injury: The Next Step Toward Evidence-Based Pharmacotherapy?" Journal of neurotrauma **36**(1): 111-117.

Evidence-based analgosedation in severe pediatric traumatic brain injury (pTBI) management is lacking, and improved pharmacological understanding is needed. This starts with increased knowledge of factors controlling the pharmacokinetics (PK) of unbound drug at the target site (brain) and related drug effect(s). This prospective, descriptive study tested a pediatric physiology-based pharmacokinetic software model by comparing actual plasma and brain extracellular fluid (brainECF) morphine concentrations with predicted concentration-time profiles in severe pTBI patients (Glasgow Coma Scale [GCS], <=8). Plasma and brainECF samples were obtained after legal guardian written consent and were collected from 8 pTBI patients (75% male; median age, 96 months [34.0-155.5]; median weight, 24 kg [14.5-55.0]) with a need for intracranial pressure monitoring (GCS, <=8) and receiving continuous morphine infusion (10-40 mug/kg/h). BrainECF samples were obtained by microdialysis. BrainECF samples were taken from "injured" and "uninjured" regions as determined by microdialysis catheter location on computed head tomography. A previously developed physiology-based software model to predict morphine concentrations in the brain was adapted to children using pediatric physiological properties. The model predicted plasma morphine concentrations well for individual patients (97% of data points within the 90% prediction interval). In addition, predicted brainECF concentration-time profiles fell within a 90% prediction interval of microdialysis brainECF drug concentrations when sampled from an uninjured area. Prediction was less accurate in injured areas. This approach of translational physiology-based PK modeling allows prediction of morphine concentration-time profiles in uninjured brain of individual patients and opens promising avenues towards evidence-based pharmacotherapies in pTBI.

2718. Kevin, L. G., et al. (2000). "An old injury with a modern twist." Anaesthesia **55**(2): 199.

2719. Khalid, M., et al. (2018). "Iatrogenic cavernous sinus air embolism during peripheral venous catheter insertion." Journal of Investigative Medicine **66**(2): 394-395.

Case report 86 year old male with advanced dementia admitted with worsening confusion for 2 weeks. Physical exam was significant for disoriented to place and time (baseline) but no neurological deficit. Labs and CXR were normal. Computed tomography (CT) of the head without contrast showed air in left cavernous sinus and right transverse foramen on C1 which tracked down into venous circulation of neck. He didn't have any central line placement, however it was later discovered that he had a peripheral catheter insertion with a poorly primed line for saline administration and was the most likely (TABEL PRESENTED) cause of air embolization. He was kept in Trendelenburg position and hyperbaric therapy was indicated, but deferred due to patient non-compliance in the setting of advanced dementia. Serial follow up neurological exam showed no deficits. Repeat CT head later showed resolution of air embolism. Echocardiography with bubble study showed normal left ventricular function. Cavernous sinus air embolism is associated with infection, penetrating trauma or complication of vascular interventions. The most common cause is peripheral or central venous catheter lines insertion. Air embolism should be consider one of the differentials if the patient has acute change in neurological function especially during venous cannulation. Diagnosis usually made by CT scan of the brain and treatment is 100% oxygen.

2720. Khalil, A. F. (1980). "Civilian gunshot injuries to the face and jaws." The British journal of oral surgery **18**(3): 205-211.

Eighteen patients with different types of civilian gunshot injuries to the face and jaw were studied clinically and radiographically and treated in our department. Ten patients had soft tissue injuries and eight had mandibular fractures with soft tissue injuries. The weapons responsible for the injuries were rifles in five cases, handguns in two cases, shotguns in four cases, air guns in five cases and shrapnel from landmine explosions in two cases. The injuries were due to intentional fights in three cases and were accidental in the other cases.

2721. Khalil, M., et al. (2021). "Pediatric mortality at pediatric versus adult trauma centers." Journal of Emergencies, Trauma and Shock **14**(3): 128-135.

Introduction: Pediatric trauma centers (PTCs) were created to address the unique needs of injured children with the expectation that outcomes would be improved. However, prior studies to evaluate the impact of PTCs have had conflicting results. Our study was conducted to further clarify this question. We hypothesize that severely injured children ≤ 14 years of age have better outcomes at PTCs and that better survival may be due to higher emergency department (ED) survival rates than at adult trauma centers (ATCs). Methods: A retrospective analysis of severely injured children (ISS>15) ≤18 years of age entered into the National Trauma Data Bank (NTDB) between 2011 and 2012 was performed. Subjects were stratified into 2 age cohorts; young children (0-14 years) and adolescents (15-18 years). Primary outcomes were emergency department (ED) and in-patient (IP) mortality. Secondary outcomes included in-hospital complications, hospital and ICU length of stay, and ventilator days. Outcome differences were assessed using multilevel logistic and negative binomial regression analyses. Results: A total of 10,028 children were included. Median ISS was 22 (Interquartile range 17-29). Adjusting for confounders on multivariate analysis, children ≤ 14 had lower odds of ED (0.42[CI 0.25-0.71], p=0.001) and IP mortality (0.73[CI 0.5-0.9], p=0.02) at PTCs. There were no differences in odds of ED mortality (0.81 [CI 0.5-1.3], p=0.4) or IP mortality (1.01 [CI 0.8-1.2], p=0.88) for adolescents between centers. There were no differences in complication rates between PTCs and ATCs (OR 0.86 [CI 0.69-1.06], p=1.7) but children were more likely to be discharged to home and have more ICU and ventilator free days if treated at a PTC. Conclusion: Young children but not adolescents have better ED survival at PTCs compared to ATCs.

2722. Khalil, N., et al. (1991). "Transcranial stab wounds: morbidity and medicolegal awareness." Surgical neurology **35**(4): 294-299.

In this series of eight patients with transcranial stab wounds, the importance of classifications of such wounds as a separate traumatic entity is stressed. The mechanisms of neuronal and vascular damage in these wounds are discussed and are found to be specific from other head injuries. Cerebral injury by stabbing is largely restricted to the wound tract. Frontal stabs (two cases) are accompanied by the least morbidity and mortality, while temporal stabs (four cases) are more commonly fatal. In transorbital stabs (two cases) carotid-cavernous fistulae resulted. Early recognition, administration of antitetanus serum and antibiotics, and debridement may minimize complications.

2723. Khalili, H., et al. (2021). "Risk factors for post-traumatic epilepsy." Seizure **89**: 81-84.

PURPOSE: The aim of the current study was to investigate the risk factors for post-traumatic epilepsy (PTE) in a large cohort of patients after severe non-penetrating civilian traumatic brain injury (TBI)., METHODS: This was a longitudinal study. All patients with a severe non-penetrating TBI, who were admitted at the neuro-intensive care unit of Shahid Rajaee Trauma Hospital, affiliated with Shiraz University of Medical Sciences, Shiraz, Iran, from 2015 until 2019, were studied. Severe TBI was defined as a Glasgow Coma Scale-Motor score below six. Post-traumatic epilepsy was defined as any seizures that occurred after being discharged from the hospital., RESULTS: In total, 803 patients with severe non-penetrating TBI were studied; 82 patients (10.2%) reported any late post-traumatic seizures (PTSs). A higher Glasgow outcome scale (extended) at discharge was significantly inversely associated with PTE [Odds Ratio (OR)= 0.76, 95% Confidence Interval (CI): 0.65-0.87; p = 0.0001]. Depressed skull fracture (OR= 1.88, 95% CI: 0.92-3.80; p = 0.081), epi-dural hematoma (OR= 1.67, 95% CI: 0.93-2.97; p = 0.083), and sub-dural hematoma (OR= 1.64, 95% CI: 0.96-2.78; p = 0.068) were associated with PTE as trends., CONCLUSION: Our study adds to the literature on the risk of PTE after severe non-penetrating civilian TBI. Our large sample size and also the application of a logistic regression analysis model may suggest that other variables (e.g., depressed skull fracture and intracranial hematoma) are indeed associated with the

Glasgow outcome scale (extended) at discharge and that is why they lost their significance in the model.

2724. Khan, A. A., et al. (1994). "Penetrating craniocerebral trauma. Report of 20 cases." Bangladesh Journal of Neuroscience **10**(1): 1-8.

20 cases of penetrating craniocerebral trauma managed surgically are reported. The commonest cause of injury was assault with crude weapons like teta, Dao, Spade and Axe. Other causes were RTA, bomb blast, fall on Bati and being gored by buffalo. The youngest patient was 8 months of age and the oldest 65 yrs. with an average of 26 years. Sixteen cases were male and 4 female. More than 50% of cases were admitted in the hospital within a short time after the trauma. But some cases were admitted as late as 7 days with grossly infected wounds. Fifteen cases had injury of the vault majority being parietal with involvement of the dominant hemisphere. Five cases were frontal basal injuries. Twelve cases were managed by debridement, 5 by craniectomy and 3 by craniotomy. In 16 cases the dura was repaired. Eleven cases had different degrees of brian laceration/swelling. Seven cases had intracranial haematoma, seven wound infection, one meningitis and one infected bone had minor neurological deficit, 4 cases were left with different degrees of disabilities. One case died.

2725. Khan, K. A., et al. (2019). "Penetrating head injury due to angle grinder: an occupational hazard." British journal of neurosurgery **33**(2): 202-206.

Penetrating head injury is a life threatening condition. In the workplace, these are mostly non missile type, low velocity civilian injuries caused by sharp objects. Angle grinders are used to cut stones, metal etc, and cause penetrating head injuries due to shattered rotating discs from the grinder at home and workplaces. We report a series of three cases of penetrating head injuries due to unsafe use of angle grinders. The relevant literature is reviewed and management of such cases is discussed.

2726. Khan, M. B., et al. (2014). "Civilian craniocerebral gunshot injuries in a developing country: presentation, injury characteristics, prognostic indicators, and complications." World neurosurgery **82**(1-2): 14-19.

BACKGROUND: Civilian craniocerebral gunshot injuries (CGIs) are rare but increasing in incidence in the developing world and there is scare literature on presentation, injury characteristics, prognostic indicators, and complications of brain trauma due to projectiles., METHODS: A retrospective review of 51 civilian patients with CGI who presented to the Aga Khan University Hospital between 1998 and 2011 was carried out. Presentation, injury characteristics, and complications were analyzed with emphasis on outcomes and prognostic indicators., RESULTS: There were 43 male and 8 female patients with an average age of 28.92 (+/-12.33) years. Twenty-three patients had a Glasgow Coma Scale (GCS) score of 13-15, 6 patients had a GCS score of 9-12, and 22 patients had a GCS score of 3-8 on admission. The overall mortality rate was 22% (n = 11). The most common postoperative neurologic deficits were motor deficits (19 patients) followed by aphasias (11 patients). On univariate analysis, admission GCS score and bi- or multilobar injuries were found to be highly predictive of neurologic outcome. There was no difference in outcomes between penetrating and perforating injuries. We also failed to find a statistically significant correlation between ventricular injury and outcomes in our patients., CONCLUSION: Admission GCS and number of lobes involved are highly prognostic of outcome. Patients with a GCS score >=9 and unilobar injury on computed tomographic scans may benefit the most from surgical management.

2727. Khan, M. R., et al. (1985). "Spent-bullet injuries in the head and neck region (report of seven cases)." The Journal of laryngology and otology **99**(12): 1319-1323.

2728. Khanam, S., et al. (2021). "Clinical Presentation and Management Strategies in Intraorbital Foreign Bodies." Case reports in ophthalmological medicine **2021**: 6645952.

The authors present a retrospective, observational case study of seven patients, who presented with retained Intra-Orbital Foreign Bodies (IOrbFBs) following penetrating orbital injury at a tertiary eye hospital over a period of one year. Cases were reviewed for epidemiological features, mechanism of injury, nature of foreign body, clinical features,

imaging modality, associated complications, management outcomes, and the final prognosis. The mean age of presentation was 27.43 years. Amongst the seven patients, two were children (aged <10 years). The male : female ratio was 4 : 3. Of the seven retained IOrbFBs, two were plastic, two wooden, and three metallic in nature (one gunshot injury, one ball projectile (commonly referred to as BB) injury, and one with knife). Two out of seven had no light perception at presentation. The periocular location of the foreign bodies was inferior in 4 cases and medial in 3 cases. Computed Tomography scan confirmed the diagnosis in five cases and Magnetic Resonance Imaging (MRI) was diagnostic in one. Surgical intervention was done in five cases, and two cases were managed conservatively. The authors conclude that favourable outcome can be achieved even without surgical removal in cases of inert metallic/inorganic IOrbFBs. The properties of plastic FBs can frequently render them invisible on imaging, or they may mimic chronic inflammatory conditions like tuberculosis. Long-standing wooden IOrbFBs evade identification radiologically due to prolonged hydration. The ultimate choice of intervention must be individualised, weighing the risks of retention against the risk of iatrogenic damage.

2729. Khanduja, S., et al. (2013). "Tractor nail as impacted foreign body: rare case scenario." International ophthalmology **33**(3): 291-293.

A patient presented with a metallic nail impacted in the right orbital floor after being hit by a projectile. The nail was disimpacted and removed as guided by the radiograph image. Radiography proved helpful in forming a coherent scheme for case management.

2730. Khanna, J. N. and R. Ramaswami (2019). "Protocol for the management of ankylosis of the temporomandibular joint." The British journal of oral & maxillofacial surgery **57**(10): 1113-1118.

Ankylosis of the temporomandibular joint (TMJ) is a severely deforming, disabling condition as a result of craniomandibular fusion caused mainly by condylar fractures with displacement of the meniscus. Ankylosis may be fibrous, fibro-osseous, or bony, and unilateral or bilateral. The severity of the deformity is based on the onset, duration, and type of ankylosis. Various surgical techniques have been described for treatment, but no single treatment is recommended because of inconsistent results and the high rate of failure. While our total experience extends to 300 cases, we have developed a protocol using the most recent 193 patients to address our earlier high failure rate. The onset was during childhood in 168 patients, and 25 were adults. We describe the protocol that we developed for these two groups. Our management included gap arthroplasty, costochondral grafting, temporalis flaps, ramus osteotomies, and transport distraction.

2731. Khara, M. and J. C. Herath (2019). "Suicide Decapitation by a Detonating Cord: A Case Report." The American journal of forensic medicine and pathology **40**(2): 140-143.

In the field of forensic pathology, suicides consist of a considerable portion of the workload. Among the many methods used to commit suicide, using a detonation cord explosive is quite unique. We report the case of a man who committed suicide by detonation cord resulting in decapitation. This case report highlights the fact that the injury patterns observed in explosion-related deaths can be highly variable and that in cases with isolated injuries postmortem imaging and histology are an important adjunct to the standard death investigation. The ultimate goal of explosion-related investigations should be geared toward a well-documented and complete postmortem examination with the appropriate use of ancillary studies that provide a clear interpretation of the mechanism, cause, and manner of death.

2732. Kharatishvili, I., et al. (2006). "A model of posttraumatic epilepsy induced by lateral fluid-percussion brain injury in rats." Neuroscience **140**(2): 685-697.

Although traumatic brain injury is a major cause of symptomatic epilepsy, the mechanism by which it leads to recurrent seizures is unknown. An animal model of posttraumatic epilepsy that reliably reproduces the clinical sequelae of human traumatic brain injury is essential to identify the molecular and cellular substrates of posttraumatic epileptogenesis, and perform preclinical screening of new antiepileptogenic compounds. We studied the electrophysiologic, behavioral, and structural features of posttraumatic epilepsy induced by severe, non-penetrating lateral fluid-percussion brain injury in rats. Data from two independent experiments indicated that 43% to 50% of

injured animals developed epilepsy, with a latency period between 7 weeks to 1 year. Mean seizure frequency was 0.3+/-0.2 seizures per day and mean seizure duration was 113+/-46 s. Behavioral seizure severity increased over time in the majority of animals. Secondarily-generalized seizures comprised an average of 66+/-37% of all seizures. Mossy fiber sprouting was increased in the ipsilateral hippocampus of animals with posttraumatic epilepsy compared with those subjected to traumatic brain injury without epilepsy. Stereologic cell counts indicated a loss of dentate hilar neurons ipsilaterally following traumatic brain injury. Our data suggest that posttraumatic epilepsy occurs with a frequency of 40% to 50% after severe non-penetrating fluid-percussion brain injury in rats, and that the lateral fluid percussion model can serve as a clinically-relevant tool for pathophysiologic and preclinical studies.

2733. Kharel Sitaula, R., et al. (2013). "Impacted iron nail in the orbit and maxillary sinus through a corneo-scleral perforation: a case report." Nepalese journal of ophthalmology : a biannual peer-reviewed academic journal of the Nepal Ophthalmic Society : NEPJOPH **5**(2): 268-271.

INTRODUCTION: Open globe injury is one of the commonest ophthalmic emergencies, and when accompanied by intraocular foreign bodies, the condition carries a poorer prognosis., OBJECTIVE: To report a rare case of perforating injury of the globe with an iron nail which got lodged in the maxillary sinus., CASE: A ten-year-old boy presented with the history of sudden painful loss of vision in his right eye. He reported that he was hit forcefully by the tail of a cow a day before the presentation. There was no perception of light in that eye. The ocular examination revealed a full thickness corneo-scleral perforation with prolapsed uveal tissue. The X-ray of the right orbit showed an impacted foreign body in the inferior orbit and computed tomography scan of the orbit confirmed the presence of a vertically impacted metal piece in the right orbit and right maxillary sinus. The repair of the perforation and removal of the impacted nail was done in two stages. The globe anatomy was maintained but the vision could not be restored due to the grave nature of the trauma., CONCLUSION: Perforating globe injury is an important cause of monocular blindness. 2734. Kharitonova, K. I., et al. (1990). "[The experimental and clinical use of gelatin sponges with kanamycin and gentamycin for the prevention and treatment of suppurative complications in neurosurgery]." Eksperimental'noe i klinicheskoe primenenie zhelatinovykh gubok s kanamitsinom i gentamitsinom dlia profilaktiki i lecheniia gnoinykh oslozhnenii v neirokhirurgii.(3): 9-11.

Antiseptic gelatin sponges with kanamycin and gentamicin, which were studied in experiments on animals and used in the clinic, are a reliable measure for the prevention of suppuration in craniocerebral surgery in planned operations and in combination with debridement in penetrating injury of the skull and brain. For therapeutic purposes, local application of the agents is effective in focal suppurative processes in the skull and brain after surgical debridement of the purulent focus (abscess of the brain, osteomyelitis of the skull, etc.).

2735. Khatib, B., et al. (2017). "Updates in Management of Craniomaxillofacial Gunshot Wounds and Reconstruction of the Mandible." Facial plastic surgery clinics of North America **25**(4): 563-576.

This article includes updates in the management of mandibular trauma and reconstruction as they relate to maxillomandibular fixation screws, custom hardware, virtual surgical planning, and protocols for use of computer-aided surgery and navigation when managing composite defects from gunshot injuries to the face.

2736. Khatib, B. N., et al. (2017). "Application of virtual surgical planning to staged management of self-inflicted gunshot wounds to the maxillofacial skeleton: The oregon protocol." Journal of oral and maxillofacial surgery **75**(10): e367-e368.

Purpose: Self-inflicted gunshot wounds to the craniofacial region result in devastating functional disabilities and esthetic deformities, which are further magnified by the associated psychological trauma. Because a substantial number of these patients return to work, return to their pre-injury life style, and have a low rate of suicide recidivism, adequate reconstruction is essential to their comprehensive rehabilitation. [1, 2] The purpose of this investigation is to review our experience with virtual surgical planning in the setting of self-inflicted, high-velocity gunshot wounds to the face and propose a treatment protocol. Methods: We retrospectively reviewed 10 cases of self-inflicted high velocity gunshot wounds to the face presenting to Legacy Emanuel Hospital, Portland, OR, between 2010-2017 that were treated with

virtual surgical planning and computer-aided surgery. We propose a protocol for maxillofacial reconstruction after complex ballistic injury that utilizes staged reconstruction using computer-aided surgery in the primary hospital setting. The protocol involves 1) damage/hemorrhage control, airway stabilization, and maxillomandibular stabilization as indicated; 2) debridement of non-viable bone and soft tissue; 3) virtual reconstruction using commercially available craniomaxillofacial computer program and “back-conversion” of virtual plan into navigation system; 4) navigation assisted reconstruction of midfacial skeletal anatomy; 5) computer aided oro-mandibular reconstruction with or without microvascular free tissue transfer using custom guide stents and cutting guides; 6) navigation assisted, computer-aided palatomaxillary reconstruction with microvascular free tissue transfer using cutting guides and guide stents as indicated; 7) navigation- assisted reconstruction of the internal orbit; 8) and confirmation of accurate reconstruction using intraoperative CT imaging. Data Analysis: Data analysis for this retrospective case series is limited to descriptive statistics obtained via chart review. Subjective comparison of the computer- assisted presurgical plan to the postoperative CT scan was completed intraoperatively. Jaw position, facial projection, separation of the nose and mouth, and oral competence was evaluated postoperatively at least one month after surgery. Results: All patients had severe disruption of the mandible, oral-nasal communication, massive hard and soft tissue avulsion and varied degrees of involvement of the orbits, midface. The computer-assisted surgery was successfully implemented in all patients and proved to be a useful adjunct for: the restoration of orbital volume, facial projection and symmetry; the inset of composite tissue free flaps, and the facilitation of dental implant supported prosthetic rehabilitation. The majority of these patients were successfully orally intubated: 3 arrived spontaneously ventilating and were orally intubated for airway protection, 1 arrived with a cricothyrotomy and the remaining 5 were orally intubated on arrival. The average number of operating room visits during the initial hospitalization was 4.7 and hospital course ranged from 7-59 days. All patients were treatment planned with virtual surgical planning, 1 patient underwent rigid fixation without grafting, 2 patients were reconstructed with non-vascularized bone grafts and 6 received microvascular free flaps. Four received a single fibula for mandibular reconstruction, 2 received a double fibula reconstruction of both maxilla and mandible and one received a fibula for the mandible and a radial forearm for reconstruction of the midface. All three patients reconstructed without microvascular tissue became infected. All patients survived their hospitalization, had their tracheostomies removed, had adequate midface and mandibular projection, excellent jawposition, separation of their nose and mouth and fair oral competence. Conclusion: Virtual surgical planning for complex ballistic injury facilitates efficient and accurate primary reconstruction.

2737. Khattak, A., et al. (2010). "Etiological factors of brain abscess." Journal of Medical Sciences **18**(4): 194-196.

Objectives: To find out the etiological factors of brain abscesses in patients admitted in Hayatabad Medical Complex, Peshawar in the year 2009. Material and Methods: This descriptive study was carried out in the Neurosurgery Units of Hayatabad Medical Complex, Peshawar from January to December 2009. Forty eight consecutive cases with brain abscesses were included in the study. Diagnosis of brain abscess was established in all patients with CT scanning. The patients were evaluated for the predisposing factors. Results: The study population included 31 males and 17 females. Mean age was 29.2 ± 2.3 years. The predisposing factors for brain abscess were noted in 43 (89.6%) patients while no etiological factor was found in 5 (10.4%). Contiguous focus of infection was found in 18 (37.5%) patients, hematogenous spread in 16(33.3%) and direct inoculation in 9 (18.8%) patients. Conclusion: Brain abscess is a fatal condition. Every patient with brain abscess should be evaluated for a possible source of infection. Contiguous focus of infection is the commonest etiological factor. However in a few cases, no source of brain abscess can be found. Particular attention should be given to the early recognition of etiological sources and proper prophylactic approach should be adopted to prevent development of brain abscess.

2738. Khau, A. and J. Melinek (2019). "Two Cases of Tandem Bullets-One Homicide and One Suicide." The American journal of forensic medicine and pathology **40**(3): 262-265.

We report 2 unusual cases of tandem bullets. Case 1 is a homicide involving a piggyback screw. Case 2 is a suicide involving multiple tandem bullets as a result of improper ammunition size. Tandem bullet injuries can have a wide variety of presentations. Therefore, it is essential that forensic pathologists understand the mechanisms of tandem bullet wounds and familiarize themselves with the autopsy and radiological findings seen in tandem bullet injuries. This report supports that use of incorrect caliber ammunition and the lodgment of foreign objects in the barrel of a gun are possible causes of tandem bullet injuries.

2739. Khazei, A., et al. (2007). "Potential missed cerebral arterial gas embolism in patients with in-hospital ischaemic stroke." Diving and Hyperbaric Medicine **37**(2): 58-64.

Cerebral arterial gas embolism (CAGE) has been characterised as under-diagnosed, under-treated, and under-reported. It is associated with a number of commonly performed diagnostic and therapeutic procedures, and penetrating trauma to the neck or chest. This study was carried out to determine the frequency with which physicians at a university-based, tertiary-care teaching hospital with a hyperbaric facility considered the diagnosis of CAGE in patients with a stroke occurring during, or shortly after, a procedure known to be high risk for CAGE. A retrospective chart review was undertaken from April 2002 to March 2003 to identify all patients who had suffered an in-hospital ischaemic stroke (IHIS) within four hours of a high-risk procedure or penetrating trauma, and presented with symptoms consistent with the diagnosis of CAGE. Of the 150 cases of "stroke as a post-admit morbidity", 46 were classified as an IHIS. In 15 of these 46, a diagnosis of CAGE could not be excluded. Symptom onset occurred during the procedure in three cases and within one hour in five cases. Procedures most commonly associated with IHIS were percutaneous coronary angioplasty (6) and cardiopulmonary bypass (6). In only one of the 15 cases was CAGE considered in the differential diagnosis. Only two patients were functioning independently at the time of discharge, whilst two died. This study suggests that in our hospital the diagnosis of CAGE is rarely considered in patients presenting with symptoms of IHIS within four hours of a high-risk procedure. These findings are important because untreated CAGE is associated with major mortality and morbidity.

2740. Khil'ko, V. A., et al. (1988). "[Use of a point-scale assessment of patient status in the surgical treatment of craniocerebral injuries]." Ispol'zovanie ball'noi otsenki sostoianiia bol'nykh pri khirurgicheskom lechenii cherepno-mozgovoi travmy.(3): 19-24.

The indications and contraindications for surgical treatment in craniocerebral trauma (CCT) were based on estimation of the patient's condition in marks; the dynamics of changes of the results of the estimation in the pre- and postoperative periods were studied. A total of 375 patients with CCT were examined in different medical institutions according to a unified method. Neurosurgical interventions were carried out on 155 patients. All patients who underwent operation when their condition was rated below 15 marks died on the immediate postoperative days, whatever their age and whatever the time of the operation after the trauma. The probability of a favourable outcome increased to 40% in a condition rated 21-30 marks on the day of the operation and reached 69% when it was above 30 marks.

2741. Khil'ko, V. A., et al. (1996). "[The characteristics of the biochemical reactions of the cerebrospinal fluid in victims with gunshot wounds of the skull and brain in relation to treatment outcome]." Osobennosti biokhimicheskikh reaktsii tserebrospinal'noi zhidkosti u postradavshikh s ognestrel'nymi raneniiami cherepa i golovnogo mozga v zavisimosti ot iskhoda lecheniia. **155**(5): 46-49.

Biochemical reactions of the liquor were investigated in 68 patients with gunshot wounds of the skull and brain and in closed treatment of the brain wound. The reactivity of biochemical system plays a certain role in the development of infectious complications. In dead people the developing pathogenetical biochemical syndromes having a sanogenic role of clearance from antigens of the injured tissues turn pathogenesis into thanatogenesis.

2742. Khil'ko, V. A., et al. (1994). "[The prediction of the cranioplasty outcomes after gunshot wounds of the skull and brain]." Prognozirovanie iskhodov kranioplastiki posle ognestrel'nykh ranenii cherepa i golovnogo mozga.(2): 32-80.

A number of application programs for IBM PC AT was worked out to meet the requirements of a new method applied for prognostication of cranioplasty results in patients with craniocerebral injuries. This method uses an old one based on Bayes formula. The authors analysed 155 craniocerebral injuries which were inflicted in Afghanistan in the period from September 1984 till November 1988. It was proved that such methods increase the accuracy of prognostication as far as the outcomes of reconstructive operations for gunshot craniocerebral injuries are concerned.

2743. Khirwadkar, H., et al. (2011). "Postoperative subdural haematoma and pneumocephalus mimicking TIA." BMJ case reports **2011**.

An 86-year-old man presented with left hand numbness and weakness 10 days after a resection of squamous cell carcinoma of the right side of the scalp. A CT head scan identified a right-sided, hypodense subdural collection without midline shift, with associated pneumocephalus. When the images were reviewed on bony settings, minute drill holes were identified penetrating the outer tables as expected, but also the inner table of the calvarium. With this knowledge, the initial clinical diagnosis altered significantly from that of a transient ischaemic attack to a working diagnosis of a subdural haematoma as a complication of the penetrating injury to the cranium, in a patient with an elevated international normalised ratio.

2745. Khodov, A. M., et al. (2012). "[Specific features of wounds with a self-defense traumatic weapon "Osa"]." Vestnik khirurgii imeni I. I. Grekova **171**(2): 50-51.

Specific features and outcomes of wounds with a traumatic weapon of self-defense "Osa" were analyzed in 24 patients. Mean age of the wounded was from 21 to76 years. In 20 patients there was a single wound, in 4 patients it was multiple, in 7--blunt, in 12--perforating and 5 patients had gutter wounds. All the patients were treated according to the principles of field military surgery. Five patients had severe wounds: penetrating fracture of the skull (2 of them died), fracture of the shoulder (1 case), injury of the main artery (1 case), of the pleura (1 case). The wounds were closed up by primary intention in 19 patients, by second intention in 4 patients. The authors' experience shows that a traumatic weapon of self-defense "Osa" rather often caused permanent harm to health and can be mortal. Active surgical strategy in treatment of such patients prevents the development of serious infectious complications.

2746. Khokhlov, A. P., et al. (1993). "The changes in the permeability of the blood-brain barrier when under neurosurgical intervention." Molecular and chemical neuropathology **20**(3): 197-202.

The aim of this research was to determine the influence of anesthesia, drugs, and neurosurgical trauma on the permeability of the blood-brain barrier (BBB) for macromolecules. Protein markers of oligodendrocytes and astroglia were used. The research methods were unique. Two groups of patients were formed: with neurosurgical brain trauma and without it. Everyone in both groups was subjected to anesthesia. The results were unexpected and did not depend on surgery: 1. Neurosurgical brain trauma did not change the permeability of BBB. 2. Anesthesia resulted in increasing permeability of BBB with peak upon 24-48 h. 3. High blood levels of neurospecific proteins proved protein synthesis in glial cells. 4. Massive transferring of brain antigens into blood did not stimulate antibody synthesis during a period of 21 d. According to the high blood levels of neural proteins, the antigen-antibody reaction took place in blood and autoimmune complexes were eliminated before penetration into the brain. A new mechanism of brain autoimmune safety is discussed.

2747. Khoo, L.-S. and T.-Y. Tan (2011). "Traumatic perilymphatic fistula secondary to stapes luxation into the vestibule: a case report." Ear, nose, & throat journal **90**(5): E28-31.

A penetrating ear injury with a perilymphatic fistula is not an uncommon occurrence in otolaryngologic practice, but stapes luxation is rare. We report the case of an 11-year-old boy who developed a traumatic perilymphatic fistula secondary to an atypical stapes luxation into the vestibule. After sustaining a penetrating injury to the right ear, the patient presented with otalgia, vertigo, vomiting, gait unsteadiness, and hearing loss. High-resolution computed tomography (HRCT) of the temporal bone detected pneumolabyrinth, indicating a perilymphatic fistula. The stapes had pivoted on the footplate at the oval window, and then it made an unusual 180degree flip and luxated deeply into the vestibule, with the capitulum stapedis pointing medially. Conservative management was chosen in view of the high surgical risks posed by the deeply luxated stapes and the likelihood of a fracture of the stapes footplate. This case illustrates the importance of an accurate diagnosis and interpretation of a traumatic perilymphatic fistula and stapes luxation as seen on HRCT of the temporal bone.

2751. Khudaverdyan, A. Y. (2016). "Trepanation in the Late Bronze Age and Early Iron Age in Armenia." Homo : internationale Zeitschrift fur die vergleichende Forschung am Menschen **67**(6): 447-461.

In this study, trepanations in ancient Armenia are discussed. In total, 10 cases were studied. Seven were male, 1 female and 2 were children. Age of the individuals ranged from 6 to 65 years. Among nine cases of surgical trepanations four had possible healing signs. In these cases the individuals showed evidence of previous trauma to the skull or infection (mastoiditis, tuberculosis), suggesting that the operation had been carried out for therapeutic purposes. This provides further support for the suggestion that trepanation (or trephination) was performed primarily for therapeutic purposes, and because of cranial infection or injury. In one case, a symbolic trepanation could imitate real penetration into the skull cavity. This study shows that archaeological sites of Armenia and anthropological materials have a potential to supply essential information on ancient history of the Armenian people and the region.

2753. Kieck, C. F. and J. C. de Villiers (1984). "Vascular lesions due to transcranial stab wounds." Journal of neurosurgery **60**(1): 42-46.

The cases of 109 patients with a transcranial or transorbital stab wound are presented. Angiography in 74 patients revealed 26 vascular lesions: 11 aneurysms, five carotid-cavernous fistulas, three other arteriovenous fistulas, three occlusions, two transections, and two instances of severe vascular spasm. The following important points and pitfalls are stressed: the 30% incidence of vascular lesions, the delayed onset of these lesions and neurological signs from 1 week to several months after trauma, and the incidence of delayed intracranial hemorrhage in four of 11 cases with traumatic aneurysms. The basal location of the lesions is described, and the authors warn against the misleading clinical picture of a trivial scalp wound in the absence of a "slot" fracture, with life-threatening neural and vascular damage on the opposite side. Aggressive investigation and treatment of these lesions are advocated because of the associated high morbidity and mortality rates, especially in patients with aneurysms.

2754. Kiel, R., et al. (2005). "[Wooden spike orbital injury]." Pfahlungsverletzung der Orbita. **222**(3): 252-254.

A 71-year-old female patient fell in her garden, inducing a skin wound on the temporal left eyebrow. Skin disinfection and wound closure were performed elsewhere, an X-ray image did not reveal a foreign body. She was referred to our service three days later with a progressive left periorbital swelling. Clinical inspection demonstrated a painfully, fluctuant swelling around the wound with an inflammatory pseudoptosis of the left eye. Vision was reduced on the left eye; anterior and posterior segments of both eyes were unharmed. After opening the wound sutures a purulent liquid was drained and a wooden fragment was found, measuring 22 x 0.5 mm. Because of restriction of abduction of the left eye, magnetic resonance imaging (MRI) was performed, detecting another organic intraorbital foreign body and a fracture of the left medial orbital wall. Anterior orbitotomy was performed and a wooden fragment was removed, measuring 47 x 0.6 mm. Under administration of intravenous antibiotics vision and ocular motility recovered

uneventfully. This case emphasizes the value of MRI in the diagnostics of retained wooden foreign bodies as well as the importance of a soigneuse inspection of skin wounds with a high risk for remaining foreign bodies.

2755. Kieser, J., et al. (2008). "Analysis of experimental cranial skin wounding from screwdriver trauma." International journal of legal medicine **122**(3): 179-187.

As part of a more extensive investigation of skin wounding mechanisms, we studied wounds created by five common screwdrivers (straight, star, square or Robertson, Posidriv and Phillips) on the shaven foreheads of 12 freshly slaughtered pigs. We fixed the different screwdriver heads to a 5-kg metal cylinder which was directed vertically onto each pig head by a droptube of 700 mm length. We examined skin lesions by photography and also by scanning electron microscopy (SEM). Our evaluation of differences in wound shape and size was based on geometric morphometric methods. Our results show that there are obvious morphological differences between the straight head and the other types. The straight-headed screwdriver penetrates the skin by a mode II crack which results in a compressed skin plug with bundles of collagen fibres forming skin tabs within the actual wound. The sharper-tipped screwdrivers wedge open the skin (mode I), with a clearly defined edge with no skin plugs. Geometric morphometric analysis indicates that shapes of skin wounds created by the five screwdriver types could be classified into three different groups. The straight head results in the most differentiated wound profile, with the Robertson or square and some specimens of star, and also the Posidriv and Phillips giving similar wound outlines. SEM evaluation of wounds created by a new and worn straight-head screwdrivers shows that the outline of the worn screwdriver head is reflected in the shape of the wound it created.

2756. Kihtir, T., et al. (1993). "Early management of civilian gunshot wounds to the face." The Journal of trauma **35**(4): 569-567.

We analyzed 54 civilian patients (1988-1992) with gunshot wounds (GSWs) of the face to review the management principles and results. Urgent airway control was needed in 18 cases (33%): by orotracheal intubation in 13, cricothyroidotomy in two, tracheostomy in two, and nasotracheal intubation in one. Central nervous system injury was seen in 12 (22%): 40% with orbital, 38% with mid-face, and 0% with lower face injuries. Two patients died of intracranial injuries (mortality, 4%). Vascular injury was present in five patients (9%), all detected by angiography. The local complication rate was 39% in the presence of intra-oral injury and 0% without intra-oral injury ($p < 0.001$). The maxilla was the most commonly fractured facial bone (41%) followed by the mandible in 28%. All maxillary, orbital, and zygomatic fractures were treated without reduction. One of the seven nasal fractures required open reduction for deformity. Six of the 15 mandible fractures were treated without reduction. Of eight patients treated with closed reduction, one developed nonunion. One patient treated with immediate open reduction developed osteomyelitis of the mandible and nonunion. Five patients (9%) had palate injuries. Two of them later developed intraoral fistulas following conservative treatment. The airway needs immediate attention in GSWs of the face. Computed tomographic scanning of the head or spine should be done when the bullet trajectory is above the lower face (the level of the mandible). Angiography is indicated when the trajectory of the bullet is suggestive. A conservative approach that effectively reduces the fractures is the procedure of choice. Open reductions should not be performed in the initial treatment.(ABSTRACT TRUNCATED AT 250 WORDS)

2757. Kikano, G. E. and K. C. Stange (1992). "Lead poisoning in a child after a gunshot injury." The Journal of family practice **34**(4): 498-504.

Lead poisoning is a common disease that, if not detected, can lead to developmental delay and other serious sequelae. We report the case of a child with retained intracranial lead pellets from a gunshot injury, in whom elevated blood lead levels were detected approximately 1 year after the injury. No environmental source of lead was found, and a twin sister living in the same dwelling had considerably lower lead levels. The patient's lead levels diminished after each of four courses of chelation, but rebounded each time to potentially toxic levels after termination of therapy. Physicians should be particularly alert in screening for elevated lead levels in children with retained bullet fragments. In patients in whom removal of the bullet fragments is impractical, the potential risks of long-term chelation therapy must be weighed against the risks of lead toxicity.

2758. Kilic, D., et al. (2011). "The factors affecting the morbidity and mortality in thoracic trauma: An analysis of 220 patients." Heart Surgery Forum **14**: S17.

Background: Thoracic trauma is one of the most challenging problems for thoracic surgeons. In this study we evaluate to the factors effects of trauma on mortality and morbidity. Method: A retrospective analysis of 220 cases of thoracic trauma, seen between 2003 and 2009, is presented. The majority of the patients were male (male-female ratio 3.7:1) and the average age was 45.1 (3-84) years. We used the injury severity score (ISS) to assess the severity of trauma. Also included associated with trauma location. Results: Blunt trauma (81%, n = 179), especially motor vehicle accidents (50.2%) and falls (16.1%) were the most frequent causes of chest injury. Also penetrating trauma was seen in 39 patients (19.7%). Mean hospital stay was 8.6 (1-35) days. Isolated thoracic trauma was seen in 126 patients. Rib fractures (n = 145), pulmonary contusion (n = 26), hemopneumothorax (n = 51), and isolated hemothorax (n = 43) were the most frequent lesions. Approaches were thoracotomy (n = 21), thoraco-abdominal insicion (n = 6), and median sternotomy (n = 2). Main indications for thoracotomy were pulmonary laceration (n = 5), great vessel injury (n = 3), and diaphragm rupture (n = 4). For the majority of cases observation and/or tube thoracotomy (47%). Mechanical ventilation (10%, n = 21) were sufficient and these patients' mean ISS was 62.8. Morbidity and Mortality ratios were 11% and 14% respectively. For patients who did not survive, the average ISS was 45.1.The average ISS for the total group was 23.8 (4-75). In a survival analysis the ISS was found to be the most significant determining survival (P < .0001). Compared ISS ratio between injuries included cranial (n= 27, mean ISS; 48.4 [SD: 23.9]), and abdominal (n = 12, mean ISS; 49 [SD: 22.3]) (P = .14). The patients with cranial trauma have a higher mortality rate (ratio; 9/18, 50%) then with abdominal (ratio; 1/11, 9%) (P = .022). Mean hospital stay higher in association with cranial trauma (13.4 [SD = 7.85]) than with abdominal trauma (9.8 [SD=4.15]) (P = .04). Conclusion: Mortality after thoracic trauma remains relatively high, especially in case of associated neurotrauma. The ISS is a valuable score for assessing the severity of trauma and predicting outcome.

2759. Kilty, S. and P. G. Murphy (2009). "Penetrating temporal bone trauma." The Journal of trauma **66**(3): E39-41.

2760. Kim, H. and A. Colantonio (2008). "Intentional traumatic brain injury in Ontario, Canada." The Journal of trauma **65**(6): 1287-1292.

BACKGROUND: Violence and traumatic brain injury (TBI) are two major public health concerns. This violence-related TBI, however, has not been studied in Canada and there is little literature on a profile of risk factors and injury severity regarding TBI because of self-inflicted/suicidal and assault/homicidal injury compared with unintentional TBI., METHODS: Cross-sectional study using the comprehensive data set (CDS) of Ontario trauma registry (OTR) from 1993 to 2001., SETTING: Data from a large trauma registry were used to assess demographic and injury-related characteristics, injury severity and incident time associated with TBI that were either caused unintentionally, were self-inflicted or resulted from an assault., RESULTS: This study identified 1,409 (8.0%) intentional TBIs and 16,211 (92.0%) unintentional TBIs. Of the intentional TBIs, 389 (27.6%) was self-inflicted TBI (Si-TBI) and 1,020 (72.4%) was other-inflicted TBI (Oi-TBI). The most common cause of Si-TBI was "jumping from high places" (32.1%), followed by "firearms" (30.6%). About half of Oi-TBI was because of "fight and brawl" (48.3%), followed by "struck by objects" (26.1%). Si-TBI was associated with younger age, female gender, and having more alcohol/drug abuse history. For Oi-TBI, younger age, male gender, having more alcohol/drug abuse history were independently associated., CONCLUSION: This research provides the first comprehensive overview of intentional TBI based on Canadian data. The CDS of the OTR provided the ability to identify who is at risk for intentional TBI. Prevention programs and more targeted rehabilitation services should be designed for this vulnerable population.

2761. Kim, H. K. and H. S. Park (2009). "Fibrin glue-assisted augmented amniotic membrane transplantation for the treatment of large noninfectious corneal perforations." Cornea **28**(2): 170-176.

PURPOSE: To evaluate and report the efficacy of fibrin glue (FG)-assisted augmented amniotic membrane transplantation (AMT) in patients with large corneal perforations., METHODS: In a retrospective case series, 10 patients with corneal perforations more than 2 mm in diameter were treated with "FG-assisted augmented AMT." A 5- or 7-ply "augmented amniotic membrane" (AM) was constructed by applying FG to each sheet of AM to repair the corneal perforation. The augmented AM was designed 0.5 mm larger than the diameter of the perforation. The augmented AM was transplanted onto the perforation site with 10-0 nylon suture. If needed, additional overlay AM was sutured on top., RESULTS: The mean ulceration diameter was 2.7 +/- 0.95 mm (range, 2-5 mm). All patients retained their own globes

after the procedure and had well-formed deep anterior chambers, and 90% of patients showed complete epithelialization over the AM. The mean reepithelialization time was 14.9 +/- 4.9 days (range, 10-24 days). No eyes showed evidence of infection or recurrent corneal melting during the follow-up period., CONCLUSIONS: FG-assisted augmented AMT was easily performed for repairing large corneal perforations. This surgical method was very helpful in stabilizing the wound in the early postoperative period.

2762. Kim, H. S., et al. (2019). "The efficacy of ECMO in patients of acute respiratory failure with severe traumatic injuries." Perfusion (Germany) **34**(1): 86.

Objective: We investigated efficacy of lung support-ECMO for patients who developed acute respiratory failure due to severe traumatic lung injuries but did not respond to conventional treatment. Methods: We retrospective reviewed the records of 23 consecutive patients who received lung support-ECMO due to acute respiratory failure due to severe trauma injuries between January 2007 and December 2015. The inclusion criteria for VV ECMO were based on the lung dysfunction measured with a PaO2/FiO2 ratio < 100 for a FiO2 of 1.0, pH<7.25 due to the lack of coorection in CO2 retention or incapable of maintaining one lung ventilation anesthesia during lung operation despite receiving the optimal treatment. VA or V-AV ECMO was performed for patients who the ejection fraction on 2D echocardiogram were below 20%(fig1). [Figure Presented] The continuous variable was expressed median(IQR). Results: 20 of the 23 patients were male and the age was 42(19, 48). The cause of acute lung injury were 11 cases of near-drowning, 4 traffic accidents, 2 crush injury to the chest, 2 fall down from significant height, a pulmo-nary hemorrhage due to gunshot to the chest, a mercury vapor poisoning, a paraquate pneumonitis and a hanging. 7 patients were accompanied by intracranial hemorrhage, and hypoxic brain damage was 2. Before the start of ECMO was the lowest PaO2/FiO 61.5(52.5, 73.2)mmHg 2, pH 7.26 (7.06, 7.32), PCO2 46(38.6, 73.2) mmHg, vasoactive inotropic score 2.22(0, 44.4), SOFA score 12(11, 15), and SAPS 2 score 56(44, 73). Dividing patients by the type of ECMO, 19 received VV ECMO, 2 initially received VA and VV followed by VV and V-AV ECMO, and 2 received V-AV. Of 12 patients were under-went CPR, 1 patient was E-CPR. 2 patients underwent operations just after VV ECMO; a left upper lobectomy due to gunshot and a repair of the right subclavian artery injury. The median support time of ECMO was 145(93, 205). Of the 23 patients required ECMO, 20 sur-vivors(83%) were discharged from the hospital after 28(14, 58) hospital day. Conclusion: We observed 87% in survival rates of lung support-ECMO patients who developed acute respira-tory failure due to severe traumatic injuries. Therefore, lung support-ECMO might be applied to severe trauma patients with acute respiratory failure who did not respond conventional treatment.

2763. Kim, J., et al. (2016). "Analysis of Facial Injuries Caused by Power Tools." The Journal of craniofacial surgery **27**(4): 953-957.

The number of injuries caused by power tools is steadily increasing as more domestic woodwork is undertaken and more power tools are used recreationally. The injuries caused by the different power tools as a consequence of accidents are an issue, because they can lead to substantial costs for patients and the national insurance system. The increase in hand surgery as a consequence of the use of power tools and its economic impact, and the characteristics of the hand injuries caused by power saws have been described. In recent years, the authors have noticed that, in addition to hand injuries, facial injuries caused by power tools commonly present to the emergency room. This study aimed to review the data in relation to facial injuries caused by power saws that were gathered from patients who visited the trauma center at our hospital over the last 4 years, and to analyze the incidence and epidemiology of the facial injuries caused by power saws. The authors found that facial injuries caused by power tools have risen continually. Facial injuries caused by power tools are accidental, and they cause permanent facial disfigurements and functional disabilities. Accidents are almost inevitable in particular workplaces; however, most facial injuries could be avoided by providing sufficient operator training and by tool operators wearing suitable protective devices. The evaluation of the epidemiology and patterns of facial injuries caused by power tools in this study should provide the information required to reduce the number of accidental injuries.

2764. Kim, J. and H. S. Jun (2020). "Traumatic Subarachnoid Hemorrhage and Subdural Hematoma Due to Acute Rebleeding of a Pseudoaneurysm with Dural Arteriovenous Fistula Between Inferolateral Trunk of the Internal Carotid Artery and Middle Cerebral Vein." World neurosurgery **143**: 315-318.

BACKGROUND: According to previous reports, pseudoaneurysms that are concomitant with a dural arteriovenous fistula (dAVF) are associated with penetrating trauma, blunt trauma, and skull fractures. Moreover, dAVFs between the inferolateral trunk of the internal carotid artery and middle cerebral vein are a rare disease manifestation. Pseudoaneurysms concomitant with dural arteriovenous fistulas (dAVF) are rare and traumatic pseudoaneurysms with dAVF typically developed slowly with less rebleeding than isolated traumatic aneurysms., CASE DESCRIPTION: Here, we report an extremely rare case of a traumatic pseudoaneurysm with a dAVF between the inferolateral trunk and middle cerebral vein. The traumatic pseudoaneurysm presented with acute pseudoaneurysm formation and rebleeding within 1 day of the trauma and was managed with direct surgery., CONCLUSIONS: The traumatic pseudoaneurysm was completely obliterated by surgical clipping, followed by decompressive craniectomy and postoperative coma therapy with propofol. Resulting from these surgical and postoperative treatments, 56 days after the operation the patient recovered fully and did not present any neurologic deficits.

2765. Kim, J. T., et al. (2010). "Total scalp replantation--salvage following prolonged ischaemia with poor prognostic factors." Journal of plastic, reconstructive & aesthetic surgery : JPRAS **63**(11): 1917-1920.

Case report of a salvaged total scalp, forehead, ear and cheek en-bloc replantation following an industrial avulsion injury with a warm ischaemia time of over 12 h. One arterial and two venous anastomoses using an interposed arterial graft instead of a vein graft was sufficient to produce a successful result. The patient was followed up for a two-year period. Scalp amputations can result in devastating disfigurement and psychological trauma especially in young female patients. The authors present a case with an unusually long ischaemia time in addition to several other poor prognostic factors. The key learning point and message here is that microvascular replantations achieve by far the best aesthetic and functional results compared with other procedures and should be attempted at all possible costs.

2766. Kim, J. W., et al. (2012). "Early reconstruction of orbital roof fractures: clinical features and treatment outcomes." Archives of plastic surgery **39**(1): 31-35.

BACKGROUND: Orbital roof fractures are frequently associated with a high energy impact to the craniofacial region, and displaced orbital roof fractures can cause ophthalmic and neurologic complications and occasionally require open surgical intervention. The purpose of this article was to investigate the clinical features and treatment outcomes of orbital root fractures combined with neurologic injuries after early reconstruction., METHODS: Between January 2006 and December 2008, 45 patients with orbital roof fractures were admitted; among them, 37 patients were treated conservatively and 8 patients underwent early surgical intervention for orbital roof fractures. The type of injuries that caused the fractures, patient characteristics, associated fractures, ocular and neurological injuries, patient management, and treatment outcomes were investigated., RESULTS: The patients underwent frontal craniotomy and free bone fragment removal, their orbital roofs were reconstructed with titanium micromesh, and associated fractures were repaired. The mean follow up period was 11 months. There were no postoperative neurologic sequelae. Postoperative computed tomography scans showed anatomically reconstructed orbital roofs. Two of the five patients with traumatic optic neuropathy achieved full visual acuity recovery, one patient showed decreased visual acuity, and the other two patients completely lost their vision due to traumatic optic neuropathy. Preoperative ophthalmic symptoms, such as proptosis, diplopia, upper eyelid ptosis, and enophthalmos were corrected., CONCLUSIONS: Early recognition and treatment of orbital roof fractures can reduce intracranial and ocular complications. A coronal flap with frontal craniotomy and orbital roof reconstruction using titanium mesh provides a versatile method and provides good functional and cosmetic results.

2767. Kim, K. A., et al. (2005). "Vector analysis correlating bullet trajectory to outcome after civilian through-and-through gunshot wound to the head: using imaging cues to predict fatal outcome." Neurosurgery **57**(4): 737-747.

OBJECTIVE: We identify radiographic imaging similarities found on head computed tomographic (CT) scans of patients with through-and-through gunshot wounds to the head with fatal outcomes., METHODS: A retrospective analysis was conducted over an 18-month period from June 2001 through December 2002. Two hundred seventeen gunshot wound patients were evaluated. Exclusion criteria included any patient with cardiopulmonary injury and instability, airway compromise, or extracranial injuries affecting prognosis. Thirty-seven patients with isolated gunshot

wounds to the head were included, 10 of which were fatal. Vital signs, examination results, Glasgow coma scale (GCS) score, intracranial pressure monitoring, surgical data, days in the intensive care unit, and CT scan appearance were collected. A Cartesian xyz coordinate system was created centered on the dorsum sella. Bullet pathways on CT scans were plotted and graphed onto a standardized magnetic resonance imaging scan., RESULTS: Ten patients progressed to brain death. GCS score and pupil irregularity were associated with fatal outcome ($P < 0.0001$). CT scans showed that brain shift was more common in survivors. Seventy percent of nonsurvivors had minimal brain shift. A tram-track sign on CT scans correlated with fatal outcome ($P = 0.005$). Vector analysis of nonsurvivors showed an area of the brain approximately 4 cm above the dorsum sella that, when penetrated through the midline, led to brain death ($P = 0.0006$). This zone was coined the zona fatalis., CONCLUSION: We confirm that GCS score and diabetes insipidus correlated with fatal outcome. In the setting of low-velocity gunshot wounds, fatal outcome and low GCS score were associated with a tram-track sign on CT scans. Bullet passage through a particular supra-dorsum sellar transventricular zone was associated with fatal outcome.

2768. Kim, L. H., et al. (2019). "Mortality prediction for civilian cerebral gunshot wounds: A decision-tree model based on a single trauma center." Journal of neurosurgery **131**(1): 102.

Introduction: Gunshot wound (GSW) remains one of the most lethal forms of head trauma. The lack of clear guidelines for managing civilian gunshot wounds complicates the surgical decision making process. We present a clinically applicable decision-tree model based on 15-year data from our level 1 trauma center. Methods: We retrospectively reviewed 95 consecutive patients who presented with cerebral GSWs between 2003 and 2018. Patients were divided into two cohorts based on survival status. Clinical information captured in our trauma database, EMR, and relevant imaging scans was reviewed for each patient. A decision-tree model was constructed based on variables showing statistically significant differences ($P=0.05$) between two groups on chi-square test. Results: After excluding patients who died at arrival and/or did not undergo brain imaging, 54 patients with radiologically confirmed intracranial injury were included. Survivors (53.7%) and non-survivors (46.3%) had similar average age and gender distribution. Non-survivors were significantly more likely to have self-inflicted ($P=0.049$) and perforating (entry and exit wound), as opposed to penetrating (entry wound only), injuries ($P=0.02$). Bi-hemispheric and posterior fossa involvement, cerebral herniation, and intraventricular hemorrhage (IVH) were the radiologic features more commonly present in patients who expired. Based on the decision-tree, in patients with Glasgow Coma Scale (GCS) >8, penetrating injury limited to a single hemisphere predicted survival. When initial GCS was 8 or lower, all patients with absent pupillary response failed to survive. Among patients with pupillary response, lack of 1) posterior fossa involvement, 2) cerebral herniation, 3) bi-hemispheric injury, and 4) IVH, was associated with survival. Conclusion: We present a decision-tree model to help neurosurgeons identify surgical candidates with favorable prognosis based on readily available clinical and radiological information in a time-sensitive setting. Further validation of the model in a large patient setting is recommended.

2769. Kim, L. H., et al. (2020). "Mortality prediction and long-term outcomes for civilian cerebral gunshot wounds: A decision-tree algorithm based on a single trauma center." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **75**: 71-79.

Gunshot wounds (GSW) are one of the most lethal forms of head trauma. The lack of clear guidelines for civilian GSW complicates surgical management. We aimed to develop a decision-tree algorithm for mortality prediction and report long-term outcomes on survivors based on 15-year data from our level 1 trauma center. We retrospectively reviewed 96 consecutive patients who presented with cerebral GSWs between 2003 and 2018. Clinical information from our trauma database, EMR, and relevant imaging scans was reviewed. A decision-tree model was constructed based on variables showing significant differences between survivors and non-survivors. After excluding patients who died at arrival, 54 patients with radiologically confirmed intracranial injury were included. Compared to survivors (51.9%), non-survivors (48.1%) were significantly more likely to have perforating (entry and exit wound), as opposed to penetrating (entry wound only), injuries. Bi-hemispheric and posterior fossa involvement, cerebral herniation, and intraventricular hemorrhage were more commonly present in non-survivors. Based on the decision-tree, Glasgow Coma Scale (GCS)>8 and penetrating, uni-hemispheric injury predicted survival. Among patients with GCS<=8 and normal pupillary response, lack of 1) posterior fossa involvement, 2) cerebral herniation, 3) bi-hemispheric injury, and 4) intraventricular hemorrhage, were associated with survival. Favorable long-term outcomes (mean follow-up 34.4months) were possible for survivors who required neurosurgery and stable patients who were conservatively managed. We applied clinical and radiological characteristics that predicted survival to construct a decision-tree to facilitate surgical decision-making for

GSW. Further validation of the algorithm in a large patient setting is recommended.

2770. Kim, L. J., et al. (2006). "Resolution of an infectious pseudoaneurysm in a cervical petrous carotid vein bypass graft after covered stent placement: case report." Neurosurgery **58**(2): E386-E386.

OBJECTIVE AND IMPORTANCE: Covered stenting of the carotid artery has been used to treat aneurysms and dissections. We describe a unique case of covered stenting in the setting of an infected psuedoaneurysm in a previously placed cervical-to-petrous vein bypass graft. Operating in an infected field and reopening a surgical wound at the craniocervical junction that had previously been exposed to penetrating trauma created substantial risks to open surgical repair. We therefore chose an endovascular strategy to repair this lesion., CLINICAL PRESENTATION: A 57-year-old diabetic man with a previously placed cervical-to-petrous vein bypass graft presented with chronic otitis media and acute hemorrhage from his right external auditory meatus. Evaluation revealed an infectious pseudoaneurysm of the vein graft at the skull base., TECHNIQUE: The patient was treated with intravenous antibiotics and endovascular placement of an 8-mm x 25-mm polytetrafluoroethylene-covered stent across the pseudoaneurysm. Angiography obtained 8 months later confirmed successful obliteration of the lesion., CONCLUSION: The patient's clinical outcome was excellent. Despite the active infection, covered stenting of the pseudoaneurysm was an effective treatment strategy, obviating the need for open debridement and graft revision.

2771. Kim, M.-H., et al. (2017). "The Use of Conjunctival Pedicle Flaps to Prevent Corneal Perforation in Graft-Versus-Host Disease." Seminars in ophthalmology **32**(4): 462-465.

PURPOSE: We report the clinical outcomes of two chronic graft-versus-host disease (cGVHD) corneal thinning cases that were successfully treated with conjunctival pedicle flaps in an effort to prevent impending corneal perforation., METHODS: The patients were treated with topical and systemic corticosteroids, therapeutic contact lenses, lubricants, and punctual plugs. Conjunctival pedicle flaps were used because conventional treatments had failed, and corneal perforation was imminent., RESULTS: Both patients were successfully treated with conjunctival pedicle flaps. Following conjunctival flap removal, one patient had corneal clarity restored following penetrating keratoplasty., CONCLUSIONS: Conjunctival pedicle flaps provided a strong barrier for the corneal surface and stabilized anterior chamber in cGVHD patients with impending corneal perforation following allogeneic hematopoietic stem cell transplant.

2772. Kim, M. K., et al. (2000). "Penetrating neck trauma in children: an urban hospital's experience." Otolaryngology--head and neck surgery : official journal of American Academy of Otolaryngology-Head and Neck Surgery **123**(4): 439-443.

OBJECTIVE: As the incidence of violent crime increases in our society, the rate of penetrating head and neck trauma in children also rises. The methods of management of pediatric penetrating neck wounds are addressed., METHODS: All clinical records of children younger than 18 years admitted with penetrating neck injuries between 1990 and 1997 were reviewed. The injuries were classified according to type and location of the neck wound. Demographic data, clinical presentation, diagnostic studies, and management techniques were evaluated., RESULTS: Thirty-five children aged 6 to 18 years old were evaluated for 31 missile wounds and 4 stab wounds. There were 30 boys and 5 girls. Fourteen percent of injuries were in zone 1, 60% in zone II, and 26% in zone III. Of the 33% of children with zone II penetrating neck traumas who underwent selective neck explorations, 86% had significant intraoperative findings. The mortality rates for zones I, II, and III were 60%, 29%, and 56%, respectively. The overall mortality rate was 40%., CONCLUSIONS: Penetrating neck trauma in children may lead to potentially life-threatening injuries. Selective management of penetrating head and neck injuries in children can be a safe and effective policy in an experienced trauma center.

2773. Kim, P. E., et al. (2002). "Radiographic assessment of cranial gunshot wounds." Neuroimaging clinics of North America **12**(2): 229-248.

Though advances in MRI will undoubtedly increase its use, particularly in the subacute period, CT will likely continue its primary role in the management of these injuries in the foreseeable future. The spectrum of imaging features of cranial gunshot injuries is vast, because they encompass all of the findings encountered in closed head injury

in addition to the wide variety of problems associated with penetration. Thus, only a brief summary of the many varied aspects of this complex problem is presented here as a review of the more salient issues.

2774. Kim, P. E. and C. S. Zee (1995). "The radiologic evaluation of craniocerebral missile injuries." Neurosurgery clinics of North America **6**(4): 669-687.

A brief overview of the imaging findings in craniocerebral missile injury is presented here. CT scanning has established itself as the primary imaging modality for the complex injuries seen in CMI as well as its acute and delayed complications. Plain x-ray, angiography, and magnetic resonance imaging have more limited but sometimes important roles in the management of these injuries. With regard to outcome prediction, imaging has also proved to be of some, albeit limited, usefulness, primarily as adjuncts to clinical criteria such as the GCS. Future research with CT as well as magnetic resonance imaging will likely expand the clinical role of these modalities, particularly in the realm of outcome analysis.

2775. Kim, R. C., et al. (1981). "Traumatic intracerebral implantation of Cladosporium trichoides." Neurology **31**(9): 1145-1148.

2776. Kim, S., et al. (2005). "Transorbital-intracranial injury by a chopstick: three-dimensional computed tomography." Acta ophthalmologica Scandinavica **83**(5): 609-610.

2777. Kim, S. H., et al. (2001). "Traumatic perilymphatic fistulas in children: etiology, diagnosis and management." International journal of pediatric otorhinolaryngology **60**(2): 147-153.

Post-traumatic perilymphatic fistulas have been described following ear and temporal bone injury, particularly in the setting of temporal bone fractures. However, indications for exploratory surgery in cases of trauma without temporal bone fracture are vague and not well described. We describe three children who presented with symptoms suggestive of perilymphatic fistula (PLF) without an associated temporal bone fracture: two with penetrating tympanic membrane injuries and one with blunt temporal bone trauma. All had symptoms of hearing loss and vestibular disturbance. Two of the children cooperated with ear-specific audiologic assessment, which demonstrated sensorineural hearing loss (SNHL) on the traumatized side. The third child showed audiometric evidence of a SNHL on the injured side, but due to his age, the degree of severity of the SNHL was unable to be appropriately addressed prior to the patient being surgically managed. All three children underwent exploratory surgery and were found to have bony defects in the region of the oval window. All were repaired with fascial grafts to the oval and round windows with complete resolution of vestibular symptoms. However, two of the three patients with documented post-operative audiograms suffered from persistent SNHL on the injured side. We conclude that exploratory middle ear surgery is indicated in patients suffering from blunt or penetrating temporal bone or middle ear trauma who demonstrate persistent vestibular symptoms, sensorineural hearing loss or radiographic evidence of oval window pathology. As this is a limited number of patients, a larger series may be warranted to study the actual incidence of post-traumatic PLF in the child with persistent hearing loss and vertigo after head or ear trauma.

2778. Kim, S.-H., et al. (2016). "Usability of Cryopreserved Aortic Allografts for Middle Hepatic Vein Reconstruction During Living-Donor Liver Transplantation." Journal of gastrointestinal surgery : official journal of the Society for Surgery of the Alimentary Tract **20**(5): 1049-1055.

Iliac vein allografts are suitable for middle hepatic vein (MHV) reconstruction during living-donor liver transplantation (LDLT), but their supply is often limited. Polytetrafluoroethylene (PTFE) grafts are easily available but have drawbacks of accidental gastric penetration and non-degradable foreign body. To replace the use of PTFE grafts, we started using cryopreserved aorta allografts (CAAs). This study presents the technical details and patency outcomes of using CAAs in MHV reconstruction. We reviewed the surgical techniques of CAA interposition and analyzed the patency rates in 74 patients who underwent LDLT during the 6-year study period. The two control groups received either cryopreserved iliac veins (n = 122) or PTFE grafts (n = 84). The surgical techniques for MHV reconstruction used to implant the CAA and PTFE grafts are very similar because the techniques developed for PTFE grafts were also applied to

CAAs. We inserted an arterial patch at the liver cut surface because the CAA wall is too thick to perform direct anastomosis. Two patients (2.7 %) underwent MHV stenting during the first month. The 1-year patency rate was 69.7 % in the CAA group vs. 39.2 % in iliac vein group vs. 57.2 % in PTFE group (p = 0.000). The overall graft and patient survival rates did not differ depending on the MHV interposition vessel materials (p > 0.1). CAAs combined with small-artery patches demonstrated high patency rates that surpass other vessel grafts, and thus, we suggest that CAA can be reliably used for MHV reconstruction when CAA is available.

2779. Kim, S. J. and I. S. Park (2013). "Urgent intracranial carotid artery decompression after penetrating head injury." Journal of Korean Neurosurgical Society **53**(3): 180-182.

We describe a case of intracranial carotid artery occlusion due to penetrating craniofacial injury by high velocity foreign body that was relieved by decompressive surgery. A 46-year-old man presented with a penetrating wound to his face. A piece of an electric angular grinder disc became lodged in the anterior skull base. Computed tomography revealed that the disc had penetrated the unilateral paraclinoid and suprasellar areas without flow of the intracranial carotid artery on the lesion side. The cavernous sinus was also compromised. Removal of the anterior clinoid process reopened the carotid blood flow, and the injection of glue into the cavernous sinus restored complete hemostasis during extraction of the fragment from the face. Digital subtraction angiography revealed complete recanalization of the carotid artery without any evidence of dissection. Accurate diagnosis regarding the extent of the compromised structures and urgent decompressive surgery with adequate hemostasis minimized the severity of penetrating damage in our patient.

2780. Kim, S. W., et al. (2013). "Self-inflicted trans-oral intracranial stab wound." Brain injury **27**(10): 1206-1209.

BACKGROUND: Intracranial stab wounds are low-velocity, penetrating injuries to the brain and fatality and outcome significantly depend on route, depth and location of cranial penetration. Due to the effective barrier provided by the adult calvarium, most injuries occur through the orbitae or temporal regions where bony layers are thin. Self-inflicted intracranial stab wounds are an even rarer form of traumatic brain injury, with common entry points being the orbital space and the nose. Intracranial brainstem injuries mostly result in death, with reported penetration areas being the pons or midbrain., CASE: The following report reviews a first reported case of self-inflicted intracranial stabbing via a trans-oral route with lesions to the medulla oblongata and cerebellum. Unlike previous cases of low velocity penetrating injuries to the brainstem, the patient underwent full neurologic recovery after manual knife removal and intensive rehabilitation., CONCLUSION: Self-inflicted transcranial injuries have been mentioned only briefly and sporadically in the literature. This article highlights a rare case of self-inflicted intracranial stabbing with a not yet reported entry route and brainstem lesion. Unlike the other fatal outcomes associated with such injuries, the patient underwent full neurological and functional recovery through a comprehensive approach that included intensive rehabilitation.

2781. Kim, S. W., et al. (2012). "Management of an unusual craniofacial impalement injury by a metallic foreign body." The Journal of craniofacial surgery **23**(2): e140-146.

Craniofacial penetrating injuries caused by foreign bodies other than bullets or glass from traffic crashes are quite rare. Hence, there is a lack of knowledge regarding systematic management strategies or analysis of complications for craniomaxillofacial surgeons. Between 2002 and 2010, 82 patients underwent surgery for penetrating craniofacial injuries in 2 craniomaxillofacial trauma centers. Among these patients, we included patients who had retained foreign metallic bodies. Data regarding age, sex, injury materials, entrance, injured structures, operative records, and complications were reviewed retrospectively for 8 patients. All of the patients were evaluated precisely in the emergency department without removal of retained materials, and a multidisciplinary team approach was performed for the removal of the foreign body under general anesthesia. In this study, 6 men and 2 women presented with penetrating injuries that retained metal objects. The mean age of the patients was 44.3 years. All of the patients were hemodynamically stable, and no active bleeding was found. However, all of the patients had postoperative complications. Three patients had damaged vascular structures, and 3 patients had injuries to facial nerve branches. Seven patients had posttraumatic stress disorder. Two patients underwent subsequent emergent procedures because of massive bleeding and cerebrospinal fluid leakage.Penetrating injuries in the head and neck regions are complicated. Although a multidisciplinary team approach was performed from initial management to outpatient management in

patients with unusual impalement injuries, numerous postoperative complications still remained. Preoperative patient informed consent was important.

2782. Kim, T. G., et al. (2019). "Relationship Between Nasal Fracture and Blowout Fracture: Can Nasal Fracture Be a Predictor of Blowout Fracture?" Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **77**(7): 1433.e1431-1433.e1436.

PURPOSE: Nasal and blowout fractures are the most common injuries from craniomaxillofacial trauma. Nasal fractures are easily diagnosed by clinical signs, such as pain and crepitus. However, blowout fractures are frequently asymptomatic and are easy to miss without computed tomographic (CT) scanning. This study analyzed the relation between the 2 fracture types to determine whether nasal fracture could be used as a predictor of blowout fracture., MATERIALS AND METHODS: CT scans of 1,368 patients who underwent reduction surgery for nasal fracture were retrospectively reviewed. The pattern of nasal fractures (n = 1,368) was classified as frontal or lateral according to the direction of impact. Blowout fractures (n = 297) were classified into 3 types according to the position of the fracture: medial, inferior, or inferomedial wall. After calculating the number of patients in each group, the relation between nasal and blowout fracture types was statistically analyzed., RESULTS: Of 305 patients with frontal-type nasal fractures, the incidence of medial, inferior, and inferomedial wall fracture was 26, 7, and 9, respectively. Of 1,063 patients with lateral-type nasal fractures, the incidence of medial, inferior, and inferomedial wall fracture was 118, 75, and 62, respectively. Medial wall fracture was most common in the 2 nasal fracture groups and showed a higher frequency in the lateral-type group., CONCLUSIONS: This study showed a strong relation between nasal fractures and medial wall blowout fractures. If nasal fracture is suspected, especially the lateral type, then thorough examination for medial wall blowout fracture, with a high index of suspicion, should be performed.

2783. Kim, T. G. and E. G. Sin (2021). "A Case of Penetrating Brain Injury Followed by Delayed Cerebrospinal Fluid Leakage." Korean journal of neurotrauma **17**(2): 168-173.

Although penetrating brain injury is rare, it is associated with high morbidity and mortality. In several studies, even if very few patients arrive at the hospital alive, half of them eventually die, and the other half have significant neurological sequelae. Cerebrospinal fluid (CSF) leakage caused by traumatic brain injury is common. Therefore, we should be aware of the complications, prognosis, and follow-up strategies of penetrating brain injuries. A 55-year-old man was brought to our hospital with diffuse cerebral contusion and skull fracture. Three weeks after successful surgery, the patient returned with a large amount of pneumocephalus and pneumoventricle caused by delayed CSF leakage. Fortunately, the patient was discharged without neurological deficits after reoperation. In the urgent situation of penetrating brain injury, the treatment and prognosis vary depending on the initial actions and clinical factors. In addition, we should be aware that a variety of complications, as well as CSF leakage, can occur in patients with penetrating brain injuries.

2784. Kim, T. W., et al. (2007). "Penetrating gunshot injuries to the brain." Journal of Korean Neurosurgical Society **41**(1): 16-21.

Objective: Civilian gunshot injuries to the brain are relatively rare and study of these injuries has been neglected in South Korea. We present our experience with penetrating gunshot injuries to the brain and review the outcome of surgical management, as well as other clinical predictors influencing the prognosis. Methods: We present a retrospective analysis of 13 patients with penetrating gunshot injuries to the brain who were treated at our hospital over a period of 22 years. Results: The Glasgow Coma Scale(GCS) score on admission was recorded to be: 3-5 in 1 patient, 6-8 in 3 patients, 9-12 in 2 patients and 13-15 in 7 patients. There were 11 patients who underwent surgical treatment, and the surgical mortality rate was 0%. The admission GCS score was the most valuable prognostic factor. The best results were found to be in patients admitted with an initial GCS higher than 13. There were no favorable outcomes in patients admitted with a GCS of 8 or lower. There was a correlation between the presence of a transventricular or bihemispheric trajectory and poor outcome. The patients admitted with unilobar wounds resulted in better outcome than those with bilobar or multilobar wounds. Retained deep intracranial bone or metal fragments were the most common postoperative complication. However, retained fragments did not increase the risk of infection or seizure. Conclusion: Our results suggest that a less aggressive approach, consisting of minimal local debridement and removal of the bone and metal fragments that are easily accessible, can be successfully used in civilian gunshot wounds to the brain.

2785. Kim, T.-W., et al. (2007). "Penetrating gunshot injuries to the brain." The Journal of trauma **62**(6): 1446-1451.

BACKGROUND: Civilian gunshot injuries to the brain are relatively rare and study of these injuries has been neglected in South Korea., METHODS: Thirteen patients with civilian craniocerebral gunshot injuries were admitted to the Chonnam National University Hospital during a period of 22 years. A retrospective analysis of these patients with regard to outcome and prognostic factors was performed., RESULTS: The Glasgow Coma Scale (GCS) score at admission was recorded to be 3 to 5 in one patient, 6 to 8 in three patients, 9 to 12 in two patients, and 13 to 15 in seven patients. The admission GCS score was the most valuable prognostic factor. Of the nine patients with a GCS score of more than 8, eight patients survived with favorable outcomes; of the four patients with a GCS score of less than 8, all had unfavorable outcomes (1 died, and 3 had severe disability). There was a correlation between the presence of a transventricular or bihemispheric trajectory and poor outcome., CONCLUSIONS: Patients with GCS scores of more than 8 or brain lesions limited to a single lobe of the brain can benefit from early aggressive management. Our results suggest that retained fragments after first debridement did not increase the risk of infection or seizure.

2786. Kim, U. R. and K. R. Sivaraman (2013). "Penetrating orbital injuries from plant material during pond and river diving." Indian journal of ophthalmology **61**(2): 76-77.

Diving into lakes and ponds is a common activity of rural children. We present two cases of penetrating orbital injuries from plant matter sustained in this manner. Such injuries pose a particular challenge because wooden foreign bodies are often missed during orbital exploration, and current imaging modalities cannot reliably identify retained organic material. When a patient presents with orbital penetration after a high-risk mechanism of injury, such as freshwater diving, the clinician must maintain a very high index of suspicion for retained wooden foreign body.

2787. Kim, Y. H., et al. (2018). "Unrecognized intraorbital wooden foreign body." Archives of craniofacial surgery **19**(4): 300-303.

Intraorbital wooden foreign bodies may present difficulties in diagnosis due to their radiolucent nature. Delayed recognition and management can cause significant complications. We present a case report that demonstrates these problems and the sequela that can follow. A 56-year-old man presented with a 3-cm laceration in the right upper eyelid, sustained by a slipping accident. After computed tomography (CT) scanning and ophthalmology consultation, which revealed no fractures and suggested only pneumophthalmos, the wound was repaired by a plastic surgery resident. Ten days later, the patient's eyelid displayed signs of infection including pus discharge. Antibiotics and revisional repair failed to solve the infection. Nearly 2 months after the initial repair, a CT scan revealed a large wooden fragment in the superomedial orbit. Surgical exploration successfully removed the foreign body and inflamed pocket, and the patient healed uneventfully. However, the prolonged intraorbital infection had caused irreversible damage to the superior rectus muscle, with upgaze diplopia persisting 1 year after surgery and only minimal muscle function remaining. We report this case to warn clinicians of the difficulties in early diagnosis of intraorbital wooden foreign bodies and the grave prognosis of delayed management.

2788. Kim, Y. U., et al. (2018). "The treatment of gunshot wound with maxillofacial fracture in a dog." Journal of Veterinary Clinics **35**(5): 215-217.

A one-year-old, intact male, 24 kg, mixed breed dog was referred to the Animal Medical Center, Iksan, Chonbuk, Korea for treatment of a gunshot wound to the head. Physical examinations revealed bilateral nasal bleeding and open-mouth breathing. Radiographic examination showed fracture of the right maxilla bone and multiple fractures of the nasal bone. A 1 cm × 1 cm× 1.8 cm region of mineral opacity material was observed in the right-cranial ventralnasal cavity and a 6 mm × 6mm× 9 mm region of mineral opacity material was present in the left-cranial dorsal-nasal cavity. The surgical procedure involved removal of bone fragments and the lodged bullet as well as the installation of three intraosseous wires. At two weeks after surgery, the patient exhibited no complications and had a good prognosis.

2789. Kin, K., et al. (2015). "[A Case of Transorbital Penetrating Brain Injury Caused by a Steel Wire Entirely Embedded in the Brain Parenchyma]." No shinkei geka. Neurological surgery **43**(10): 921-926.

Penetrating brain injury(PBI)is very rare in Japan. Because there is a very wide variety of pathological condition of PBI, the guideline for the treatment of PBI has not been established yet. We report the unique case of PBI caused by a steel wire piece completely embedded in the brain parenchyma. A 75-year-old man was brought to the emergency department due to ocular injury caused by a steel wire piece. Neurological examination revealed only left visual disturbance. CT scan revealed a steel wire piece located intraparenchymally between the left frontal lobe and the ventricles, but digital subtraction angiography showed no significant vascular injury in the surrounding structures. We performed an open surgery and removed the steel wire piece. Because the steel wire piece was completely embedded in the brain, we used intraoperative X-ray fluoroscopy to choose a less invasive approach for the brain. The patient suffered no additional neurological deficit and no sign of cerebral infection or seizure after surgery. He was discharged after a 4-week administration of antibiotics. In most cases of PBI caused by low velocity injury, foreign bodies are not completely embedded in the brain except for remnants after surgical removal. This is the first report of low velocity PBI caused by a foreign body completely embedded in the brain.

2791. King, D. J., et al. (2019). "A systematic review of cross-sectional differences and longitudinal changes to the morphometry of the brain following paediatric traumatic brain injury." NeuroImage. Clinical **23**: 101844.

Paediatric traumatic brain injury (pTBI) is a leading cause of disability for children and young adults. Children are a uniquely vulnerable group with the disease process that occurs following a pTBI interacting with the trajectory of normal brain development. Quantitative MRI post-injury has suggested a long-term, neurodegenerative effect of TBI on the morphometry of the brain, in both adult and childhood TBI. Changes to the brain beyond that of anticipated, age-dependant differences may allow us to estimate the state of the brain post-injury and produce clinically relevant predictions for long-term outcome. The current review synthesises the existing literature to assess whether, following pTBI, the morphology of the brain exhibits either i) longitudinal change and/or ii) differences compared to healthy controls and outcomes. The current literature suggests that morphometric differences from controls are apparent cross-sectionally at both acute and late-chronic timepoints post-injury, thus suggesting a non-transient effect of injury. Developmental trajectories of morphometry are altered in TBI groups compared to patients, and it is unlikely that typical maturation overcomes damage post-injury, or even 'catches up' with that of typically-developing peers. However, there is limited evidence for diverted developmental trajectories being associated with cognitive impairment post-injury. The current review also highlights the apparent challenges to the existing literature and potential methods by which these can be addressed.

2792. King, D. J., et al. (2020). "Lesion Induced Error on Automated Measures of Brain Volume: Data From a Pediatric Traumatic Brain Injury Cohort." Frontiers in Neuroscience **14**.

Structural segmentation of T1-weighted (T1w) MRI has shown morphometric differences, both compared to controls and longitudinally, following a traumatic brain injury (TBI). While many patients with TBI present with abnormalities on structural MRI images, most neuroimaging software packages have not been systematically evaluated for accuracy in the presence of these pathology-related MRI abnormalities. The current study aimed to assess whether acute MRI lesions (MRI acquired 7–71 days post-injury) cause error in the estimates of brain volume produced by the semi-automated segmentation tool, Freesurfer. More specifically, to investigate whether this error was global, the presence of lesion-induced error in the contralesional hemisphere, where no abnormal signal was present, was measured. A dataset of 176 simulated lesion cases was generated using actual lesions from 16 pediatric TBI (pTBI) cases recruited from the emergency department and 11 typically-developing controls. Simulated lesion cases were compared to the “ground truth” of the non-lesion control-case T1w images. Using linear mixed-effects models, results showed that hemispheric measures of cortex volume were significantly lower in the contralesional-hemisphere compared to the ground truth. Interestingly, however, cortex volume (and cerebral white matter volume) were not significantly different in the lesioned hemisphere. However, percent volume difference (PVD) between the simulated lesion and ground truth showed that the magnitude of difference of cortex volume in the contralesional-hemisphere (mean PVD = 0.37%) was significantly smaller than that in the lesioned hemisphere (mean PVD = 0.47%), suggesting a small, but systematic lesion-induced error. Lesion characteristics that could explain variance in the PVD for each hemisphere were investigated.

Taken together, these results suggest that the lesion-induced error caused by simulated lesions was not focal, but globally distributed. Previous post-processing approaches to adjust for lesions in structural analyses address the focal region where the lesion was located however, our results suggest that focal correction approaches are insufficient for the global error in morphometric measures of the injured brain.

2793. King, D. J., et al. (2020). "Developmental divergence of structural brain networks as an indicator of future cognitive impairments in childhood brain injury: Executive functions." Developmental cognitive neuroscience **42**: 100762.

Brain insults during childhood can perturb the already non-linear trajectory of typical brain maturation. The diffuse effects of injury can be modelled using structural covariance networks (SCN), which change as a function of neurodevelopment. However, SCNs are estimated at the group-level, limiting applicability to predicting individual-subject outcomes. This study aimed to measure the divergence of the brain networks in paediatric traumatic brain injury (pTBI) patients and controls, and investigate relationships with executive functioning (EF) at 24 months post-injury. T1-weighted MRI acquired acutely in 78 child survivors of pTBI and 33 controls underwent 3D-tissue segmentation to estimate cortical thickness (CT) across 68 atlas-based regions-of-interest (ROIs). Using an 'add-one-patient' approach, we estimate a developmental divergence index (DDI). Our approach adopts a novel analytic framework in which age-appropriate reference networks to calculate the DDI were generated from control participants from the ABIDE dataset using a sliding-window approach. Divergence from the age-appropriate SCN was related to reduced EF performance and an increase in behaviours related to executive dysfunctions. The DDI measure showed predictive value with regard to executive functions, highlighting that early imaging can assist in prognosis for cognition.

2794. King, D. J., et al. (2021). "Structural-covariance networks identify topology-based cortical-thickness changes in children with persistent executive function impairments after traumatic brain injury." NeuroImage **244**: 118612.

Paediatric traumatic brain injury (pTBI) results in inconsistent changes to regional morphometry of the brain across studies. Structural-covariance networks represent the degree to which the morphology (typically cortical-thickness) of cortical-regions co-varies with other regions, driven by both biological and developmental factors. Understanding how heterogeneous regional changes may influence wider cortical network organization may more appropriately capture prognostic information in terms of long term outcome following a pTBI. The current study aimed to investigate the relationships between cortical organisation as measured by structural-covariance, and long-term cognitive impairment following pTBI. T1-weighted magnetic resonance imaging (MRI) from n = 83 pTBI patients and 33 typically developing controls underwent 3D-tissue segmentation using Freesurfer to estimate cortical-thickness across 68 cortical ROIs. Structural-covariance between regions was estimated using Pearson's correlations between cortical-thickness measures across 68 regions-of-interest (ROIs), generating a group-level 68 x 68 adjacency matrix for patients and controls. We grouped a subset of patients who underwent executive function testing at 2-years post-injury using a neuropsychological impairment (NPI) rule, defining impaired- and non-impaired subgroups. Despite finding no significant reductions in regional cortical-thickness between the control and pTBI groups, we found specific reductions in graph-level strength of the structural covariance graph only between controls and the pTBI group with executive function (EF) impairment. Node-level differences in strength for this group were primarily found in frontal regions. We also investigated whether the top n nodes in terms of effect-size of cortical-thickness reductions were nodes that had significantly greater strength in the typically developing brain than n randomly selected regions. We found that acute cortical-thickness reductions post-pTBI are loaded onto regions typically high in structural covariance. This association was found in those patients with persistent EF impairment at 2-years post-injury, but not in those for whom these abilities were spared. This study posits that the topography of post-injury cortical-thickness reductions in regions that are central to the typical structural-covariance topology of the brain, can explain which patients have poor EF at follow-up.

2795. King, N. S. (2002). "Perseveration of traumatic re-experiencing in PTSD; a cautionary note regarding exposure based psychological treatments for PTSD when head injury and dysexecutive impairment are also present." Brain injury **16**(1): 65-74.

This case study describes the psychological treatment of a man with co-existing PTSD, head injury and mild dysexecutive impairment. It describes the detrimental consequences when the re-experiencing of a traumatic event

appears to have become a perseverated response. In this case, the perseveration meant that the most distressing part of the traumatic event became unavoidable and lead to it being continuously re-experienced without remittance over a very prolonged period (7-10 days). This type of re-experiencing has not been reported before. It potentially has significant implications for the treatment of PTSD in such circumstances. It may also have implications for behavioural models of PTSD in general.

2796. King, P. M., et al. (1994). "Correlation of trauma scoring and outcome in a Canadian trauma centre." Canadian journal of surgery. Journal canadien de chirurgie **37**(3): 185-188.

OBJECTIVE: To study the effectiveness of treatment and the outcome in trauma patients, and to correlate these with trauma scoring systems., DESIGN: A prospective study over 1 year of the probability of survival after trauma, based on TRISS methodology. A computerized database provided outcome statistics., SETTING: A regional trauma centre in a Canadian university teaching hospital serving regional and referral patients., PATIENTS: Three hundred consecutive patients treated at a single trauma unit. Two patients were excluded because of lack of physiologic data. Blunt injuries (94%) were most frequently from motor vehicle accidents (46%)., INTERVENTIONS: Those appropriate to multidisciplinary trauma management in a level 1 trauma centre., MAIN OUTCOME MEASURES: Survival (Z values) and injury severity (M values) for the total group and subsets were calculated for comparison of outcomes with the Multiple Trauma Outcome Study baseline and other Canadian centres for multisystem and single-system injuries., RESULTS: The mean Injury Severity Score was 21.16 and the mean Revised Trauma Score was 6.75. There were 51 (17%) deaths--a Z value for the study group of 2.26. The M value was 0.78. Forty of the 51 single-system injuries were head injuries and accounted for 15 deaths. The Z value for multisystem injuries only was 0.54, and the M value was 0.77., CONCLUSIONS: The TRISS method for analysing blunt trauma is comparable to other trauma scoring systems. The correlation of outcome analysis with other scoring systems is affected by exclusion rates, pre-referral resuscitation and single- versus multiple-injury mix of cases.

2797. King, R. B., et al. (2009). "The unique palladium-centered pentagonal antiprismatic cationic bismuth cluster: a comparison of related metal-centered 10-vertex pnictogen cluster structures by density functional theory." Inorganic chemistry **48**(17): 8508-8514.

Structures for the metal-centered 10-vertex pnictogen clusters M@Pn(10)(4+) (M = Ni, Pd, Pt; Pn = As, Sb, Bi) based on polyhedra with 3-fold, 4-fold, and 5-fold symmetry have been studied by density functional theory. Among these nine M/Pn combinations, only Pd@Bi(10)(4+) and Pt@Bi(10)(4+) are predicted to have the D(5d) pentagonal antiprism as the lowest energy structure in accord with experimental observation of this cluster in the ternary halide Bi(14)PdBr(10) as well as the prediction of the Wade-Mingos rules for these arachno systems. The lowest energy structures for the arsenic and antimony clusters M@Pn(10)(4+) (Pn = As, Sb) and Ni@Bi(10)(4+) are predicted to have structures derived from a tetracapped trigonal prism that has been severely distorted for M@As(10)(4+) (M = Pd, Pt). The volumes of the As(10) polyhedra other than the pentagonal prism are too small to contain interstitial palladium or platinum atoms so that major distortions are predicted for such clusters leading to partial opening of the polyhedron.

2798. King, R. E., et al. (2004). "Mandible fracture patterns: a suburban trauma center experience." American journal of otolaryngology **25**(5): 301-307.

PURPOSE: Mandible fractures are among the most frequently seen injuries in the trauma center setting. Recent shifts in the mechanism and age distribution of patients sustaining these injuries are well documented. This study attempts to define current, predictable patterns of fracture based on patient characteristics and mechanism of injury., MATERIAL AND METHODS: The charts of 134 patients with 225 mandible fractures treated over a 7-year period by the Otolaryngology-Head and Neck Surgery, Plastic and Reconstructive Surgery and Oral-Maxillofacial Surgery services, our institution, were retrospectively reviewed. Patients were categorized based on age, mechanism of fracture, and anatomic location of fracture. Multivariate analysis of data was performed to determine significant relationships among groups., RESULTS: Violent crimes such as assault and gunshot wounds accounted for the majority of fractures (50%) in this study, with motor vehicle accidents less likely (29%). Overall, parasymphyseal fractures were most frequent (35%), whereas angle and body fractures were also common (15% and 21%, respectively). There was a statistically significant association of motor vehicle accidents with parasymphyseal fractures (45%), and gunshot wounds with body fractures (36%), whereas assault victims had a higher than predicted frequency of angle fractures (27%) and fewer

parasymphyseal fractures (19%). Patients aged 17 to 30 were more likely to suffer from gunshot wounds, whereas older adults (age 31-50) were more likely to be assault victims. Patients over age 50 suffered fractures from falls at a higher than expected rate. Although children and young adults seemed to suffer more parasymphyseal fractures and older adults body fractures, these correlations failed to show statistical significance. Parasymphyseal fractures were most frequently associated with fractures at other sites within the mandible, ipsilateral body fractures being the most common., CONCLUSIONS: Updated data on the association of patient age and mechanism of injury with fracture pattern can guide treating physicians in anticipating and diagnosing traumatic mandible fractures.

2799. Kinoshita, A., et al. (1991). "Wound healing following stab injury on rat cerebral cortex." Neurological research **13**(3): 184-188.

We examined how wound healing was initiated and completed. Stab injury was made over the right parietal cortex with 2.5 mm depth and 4 mm length. Either 3 days, 7 days or 1 month after this operation, operated rats were perfused and fixed with 4% paraformaldehyde. The brains were removed, embedded in paraffin, cut coronally at a level of caudate-putamen complex and thin-sliced into 6 microns thick sections with a microtome. The sections were stained immunohistochemically for detection of glial fibrillary acidic protein (GFAP), and co-stained for myelination with Woelcke's staining method. Sections were also stained immunohistochemically for Laminin after pretreatment by pepsin. Furthermore, the sections were stained either haematoxylin-eosin staining, Laidlaw's Reticulum staining for evaluation of reticulin and phosphotungusten acid haematoxylin (PTAH) staining for delination of collagen. We, first, confirmed astrocytic proliferation induced by the stab injury. Then, astrocytes can be seen crowded around the injured site 7 days after injury. Both Laminin and Reticulum stain show the so-called neovascularization around the stab wound 7 days after injury when astrocytes proliferated most vigorously as mentioned above. PTAH stain showed collagenous fibre 1 month after injury when astrocytes congregated along the wound site, and Laminin fibres were localized to the injury site. Reticulin fibres disappeared. In conclusion, it takes more than a month for the wound site to regain the steady state.

2800. Kirby, S. and R. M. Sadler (1995). "Injury and death as a result of seizures." Epilepsia **36**(1): 25-28.

The literature contains little information regarding the incidence of injury or death in the general population caused by seizures. We prospectively surveyed all patient visits to the four emergency departments serving adults in the Halifax-Dartmouth metropolitan area (adult population 260,935) from September 1, 1990 to August 31, 1991 to identify patients treated as a result of a seizure. The medical examiner's records were also surveyed for deaths related to seizures. We identified 560 patient visits precipitated by seizures of all types and etiologies except those secondary to acute trauma. Injuries or deaths occurred during 84 of 560 seizures (15%). Sixty-three patients incurred 89 injuries during 77 seizures (some patients had more than one injury, and some patients had injuries on more than one occasion). The incidence of seizures resulting in injury was 29.5 in 100,000 population. The most common injuries were head contusions and head lacerations. Most injuries were minor and required little or no treatment. Deaths occurred during seven seizures (1.2%). The incidence of death as a complication of seizures was 2.68 in 100,000 population. Deaths were not restricted to patients with epilepsy. We conclude that the incidence of seizures causing injury or death in the general population was 32.2 in 100,000 population and that 15% of seizures brought to medical attention resulted in injury or death. Most injuries were minor but seven patients died during seizures, indicating that seizures remain a life-threatening event.

2801. Kirik, A., et al. (2020). "Prognostic factors in craniocerebral gunshot wounds: Analysis of 30 patients from the neurosurgical viewpoint." Kranyoserebral atesli silah yaralanmalarinda prognostik faktorler: Norosirurji bakis acisindan 30 hastanin analizi. **26**(6): 859-864.

BACKGROUND: Craniocerebral gunshot wounds (CGW) are the most lethal injuries of the cranium. CGW is mostly secondary to military conflicts but may also be seen in civilian life. These injuries also have severe consequences, such as epilepsy, hydrocephalus, infection and late-term cognitive dysfunctions. The present study aims to present our series of CGW and to discuss the prognostic factors and consequences of these injuries., METHODS: The data of patients who were treated in our department for CGW between 2011 and 2019 were retrospectively reviewed in this study. The injury type, wounding site, surgical management and outcomes were analyzed. Radiological evaluation was also performed., RESULTS: Thirty patients were treated with the diagnosis of CGW. All of the patients were male and the

mean age was 27.9 years. The frontal lobe was affected in 12 (40%) patients, while temporal lobe in eight, occipital lobe in six, parietal lobe in three, and posterior fossa in one patients. Twenty-three patients underwent surgical treatment, seven patients were treated conservatively. Thirteen (43.3%) patients died despite the treatment., CONCLUSION: Mortality in CGW is high. Ventricular injuries, bihemispheric or midline injuries, perforating injuries, brain stem injuries and low GCS score at admission are prognostic factors for CGW. Appropriate management is mandatory to obtain a better clinical outcome.

2802. Kirkpatrick, P. J. (1997). "Use of near-infrared spectroscopy in the adult." Philosophical transactions of the Royal Society of London. Series B, Biological sciences **352**(1354): 701-705.

Adult near-infrared spectroscopy is a potential method for observing changes in cerebral oxygenation non-invasively. Access of light to the adult brain requires requires penetration through extracranial tissues; hence the detection of changes in cerebral chromophore concentration can only be achieved by using near-infrared spectroscopy in the reflectance-mode thereby adding variables which are difficult to control. These include the effects of variable anatomy, different intra-optode distances and the presence of an extra- to intracranial collateral blood supply. Although movements of oxygenated haemoglobin concentration following specific cerebral stimuli can be demonstrated, the challenge of separating changes which occur within the extracranial compartment from those occurring in the intracranial compartments remains. Our experience with near-infrared spectroscopy in the three adult clinical scenarios of carotid endarterectomy, head injury and carbon dioxide stress testing will be presented. The influence of extracranial contamination is demonstrated, as are the methods we have developed to help control for extracranial contamination. Provisional experience with spatially resolved spectroscopy technology will also be presented.

2803. Kirmani, B. F., et al. (2013). "Role of intravenous levetiracetam in seizure prophylaxis of severe traumatic brain injury patients." Frontiers in neurology **4**.

Traumatic brain injury (TBI) can cause seizures and the development of epilepsy. The incidence of seizures varies from 21% in patients with severe brain injuries to 50% in patients with war-related penetrating TBI. In the acute and sub-acute periods following injury, seizures can lead to increased intracranial pressure and cerebral edema, further complicating TBI management. Anticonvulsants can be used for seizure prophylaxis according to the current Parameters of Practice and Guidelines in a subset of severe TBI patients, and for a limited time window. Phenytoin is the most widely prescribed anticonvulsant in these patients. Intravenous levetiracetam, made available in 2006, is now being considered as a viable option in acute care settings if phenytoin is unavailable or not feasible due to side-effects. We discuss current data regarding the role of intravenous levetiracetam in seizure prophylaxis of severe TBI patients and the need for future studies.

2804. Kirova, D., et al. (2002). "Use of metal laboratory splint in the management of a defective mandibular fracture." Bulgarian Medicine **10**(3): 17-18.

We present a case of defective mandibular fracture as a result of a severe firearm wound complicated by an inflamation process. The absence of a part of the mandible and tissues in the mouth floor required all individual approach to the reposition and final fixation of the fractured fragments.

2805. Kirschen, M. P., et al. (2019). "Epidemiology of Brain Death in Pediatric Intensive Care Units in the United States." JAMA pediatrics **173**(5): 469-476.

Importance: Guidelines for declaration of brain death in children were revised in 2011 by the Society of Critical Care Medicine, American Academy of Pediatrics, and Child Neurology Society. Despite widespread medical, legal, and ethical acceptance, ongoing controversies exist with regard to the concept of brain death and the procedures for its determination., Objectives: To determine the epidemiology and clinical characteristics of pediatric patients declared brain dead in the United States., Design, Setting, and Participants: This study involved the abstraction of all patient deaths from the Virtual Pediatric Systems national multicenter database between January 1, 2012, and June 30, 2017. All patients who died in pediatric intensive care units (PICUs) were included., Main Outcomes and Measures: Patient demographics, preillness developmental status, severity of illness, cause of death, PICU medical and physical length of stay, and organ donation status, as well as comparison between patients who were declared brain dead vs those who

sustained cardiovascular or cardiopulmonary death., Results: Of the 15344 patients who died, 3170 (20.7%) were declared brain dead; 1861 of these patients (58.7%) were male, and 1401 (44.2%) were between 2 and 12 years of age. There was a linear association between PICU size and number of patients declared brain dead per year, with an increase of 4.27 patients (95% CI, 3.46-5.08) per 1000-patient increase in discharges (P < .001). The median (interquartile range) of patients declared brain dead per year ranged from 1 (0-3) in smaller PICUs (defined as those with <500 discharges per year) to 10 (7-15) for larger PICUs (those with 2000-4000 discharges per year). The most common causative mechanisms of brain death were hypoxic-ischemic injury owing to cardiac arrest (1672 of 3170 [52.7%]), shock and/or respiratory arrest without cardiac arrest (399 of 3170 [12.6%]), and traumatic brain injury (634 of 3170 [20.0%]). Most patients declared brain dead (681 of 807 [84.4%]) did not have preexisting neurological dysfunction. Patients who were organ donors (1568 of 3144 [49.9%]) remained in the PICU longer after declaration of brain death compared with those who were not donors (median [interquartile range], 29 [6-41] hours vs 4 [1-8] hours; P < .001)., Conclusions and Relevance: Brain death occurred in one-fifth of PICU deaths. Most children declared brain dead had no preexisting neurological dysfunction and had an acute hypoxic-ischemic or traumatic brain injury. Brain death determinations are infrequent, even in large PICUs, emphasizing the importance of ongoing education for medical professionals and standardization of protocols to ensure diagnostic accuracy and consistency.

2806. Kirshner, H. S. and W. G. Webb (1982). "Word and letter reading and the mechanism of the third alexia." Archives of neurology **39**(2): 84-87.

Four patients, two with global aphasia and two with Broca's aphasia, demonstrated the seemingly paradoxical ability to read words but not their component letters. Picture naming was only moderately impaired, and repetition of word and letter names was intact, excluding both a generalized dysnomia and an articulatory disturbance as the cause of the literal alexia. Matching tests revealed processing deficits in three of the patients, more severe for letters than for words. Oral reading of word lists showed that short, high-frequency, and picturable words were read best, whereas nonsense trigrams, which require phonetic processing, were the most difficult. The residual reading of patients with severe Broca's or global aphasia and the "third alexia" appears to involve purely visual, nonphonetic mechanisms for word recognition, using posterior left hemisphere or even minor hemisphere centers. Letter reading, by contrast, along with phonetic reading of syllables, appears to be a more specialized, anterior left hemisphere process.

2807. Kirumbi, L., et al. (2018). "Assessing the effect of nurses' strike on intrapartum care in migori county, Western Kenya." International Journal of Gynecology and Obstetrics **143**: 466.

Objectives: Nurses offer critical care to patients, support all clinical care and are involved in management in health care facilities. Industrial strikes by nurses can lead to far reaching negative repercussions. Kenya experienced a nationwide nurses' strike from June to October 2017. This strike resulted in the partial or complete closure of some public healthcare institutions. Many patients seeking maternity care were forced to go to private facilities. Those who could not afford private care were presumably unattended in their homes. We studied the effect of the nurses' strike on key intrapartum outcomes. Method: East Africa Preterm Birth Initiative (PTBi-EA) aims to reduce neonatal mortality and morbidity due to prematurity across 17 health facilities, including two missionary facilities, in Migori County, Kenya. Monthly data is collected from maternity registers for all mothers admitted and babies born in each facility. We used data collected from April to December 2017 to compare the number of facility-based deliveries, neonatal mortality rate, overall stillbirth rate, in the following time periods: pre-strike (April-May 2017), during-strike (June-October 2017) and post-strike (November- December 2017). Results: A total of 6984 births were registered from April to December 2017. The monthly average of births decreased by 30% (from 1370 births to 413 births) from pre-strike to during-strike but recovered in the post-strike period to a monthly average of 1089 births. The overall stillbirth rate (per 1000 births) increased from 24.7 in the pre-strike period to 34.1 during-strike and then decreased to 28.4 post-strike. The neonatal mortality rate (per 1000 live births) also increased from pre-strike to during-strike (from 8.6 to 10.9) but changed to 9.1 post-strike. Conclusions: This analysis suggests that the nurses' strike compared to the pre-strike and post-strike period decreased access to patient care, which as a result adversely effected key intrapartum outcomes. The continuity of healthcare service delivery is key to improving and maintaining maternal, neonatal and child health care and outcomes.

2808. Kiss, L. and A. Remescu (2001). "[Injuries to the duodenum and pancreas in 42 operated cases]." Despre leziunile duodeno-pancreatice prin prisma a 42 de cazuri operate. **96**(1): 23-35.

42 consecutive patients who sustained injuries to the duodenum or/and pancreas were admitted to our hospital. Over a twenty year period 32 blunt injuries and 10 penetrating injuries were encountered. Penetrating injuries were always suspected and treated by time: following blunt injury diagnostic delay was encountered in 14 patients and insufficient surgical procedure because of intra-operative misinterpretation in 2 patients. Most of the patients had associated intra-abdominal organ injuries. Adjusts to diagnosis such as abdominal roentgenograms, serum amylase levels and gastroduodenography was not helpful. CT scan and ultrasound allowed to confirm the suspected diagnosis in 3 cases only. Intraoperative diagnosis was also challenging. Complete mobilization of the strictures surrounding the duodenum and the pancreas to provide entire exposure was necessary in 12 patients treated first in a peripheral hospital, diagnosis of the injury have been missed at first laparotomy and reoperation was necessary in all of them. Suture closure of the duodenum and drainage of the pancreatic region wee the most common reparative techniques used. More complicated procedures with pancreatic and/or duodenal resection were performed in 12 patients. Overall mortality in patients surviving more than 24 hours was 14%. Suture live dehiscence after delayed operation (4) and 2 deaths due to brain injury.

2809. Kita, T., et al. (1997). "The expression of tumor necrosis factor-alpha in the rat brain after fluid percussive injury." International journal of legal medicine **110**(6): 305-311.

To investigate the role of tumor necrosis factor-alpha (TNF alpha) after traumatic head injury in rats, moderate brain injury of 1000 mmHg was generated by an original fluid percussion injury device. TNF alpha levels in cerebrospinal fluid (CSF) gradually increased during the first 1 h, rose to a maximal elevation at 3 h and 6 h and returned to basal values by 24 h. Horseradish peroxidase tracer experiments revealed that primary microvascular damage appeared as early as 15 min after impact, but rapidly recovered and 1 h after impact secondary microvascular damage occurred in the hippocampus and parasagittal cortex. By immunoelectron microscopy, TNF alpha reactions were detected in the lysosomes of microglia accumulated at the impact site of the cortex 30 min after impact, and 1 h after impact these reactions were mainly detected at the glial cells (such as microglia and astrocytes) in the hippocampus and parasagittal cortex. Therefore the delayed microvascular damage observed in sites remote from the impact may be induced by TNF alpha which is synthesized mainly by glial cells. The present study suggests that TNF alpha conveyed from the microglial cells is one co-factor contributing to the fluid percussive brain edema formation after moderate brain injury.

2810. Kitakami, A., et al. (1999). "Transorbital-transpetrosal penetrating cerebellar injury--case report." Neurologia medico-chirurgica **39**(2): 150-152.

A 4-year-old boy presented with a transorbital-transpetrosal penetrating head injury after a butter knife had penetrated the left orbit. The knife tip reached the posterior fossa after penetrating the petrous bone. Wide craniotomy and the pterional, subtemporal, and lateral suboccipital approaches were performed for safe removal of the object. The patient was discharged with left-sided blindness, complete left ophthalmoplegia, and hypesthesia of the left face. Early angiography is recommended to identify vascular injury which could result in fatal intracranial hemorrhage.

2811. Kiyokawa, K., et al. (1999). "A surgical method for treating anterior skull base injuries." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **27**(1): 11-19.

Skull base surgery was performed on 18 patients with anterior skull base injuries. The operative technique consisted of opening the operative field in the anterior skull base via a coronal incision and a frontal craniotomy, debridement of the anterior skull base including the injured dura mater, performing drainage from the anterior skull base to the nasal cavity by ethmoidectomy, and reconstructing the resulting dural and anterior skull base defect using bilateral temporal musculo-pericranial flaps and a bone graft. Seventeen of the 18 patients recovered without any complications, although epidural abscesses in the anterior skull base had been present in four patients at the time of the operation. Only one patient developed an epidural abscess in the anterior skull base after the operation. None of the patients developed any other complications including meningitis, recurrent liquorrhoea or cerebral herniation. Satisfactory aesthetic results were achieved in 16 of the 18 patients. In one patient, uneven deformity of the forehead, which was caused by the partial sequestration of the frontal bone due to postoperative infection, was observed. In another patient, a depressed deformity of the forehead, which was caused by the partial loss of the frontalis muscle following the use of the frontal musculo-pericranial flap instead of a temporal musculo-pericranial flap, was observed.

Anterior skull base reconstruction using bilateral temporal musculo-pericranial flaps provides excellent results in terms of patient recovery and aesthetics.

2812. Kjelland, C. and W. Thirsk (2011). "Penetrating craniofacial trauma from a vice clamp: case report and discussion." CJEM **13**(1): 57-61.

Penetrating craniofacial trauma, although uncommon, has a high potential for death or serious morbidity from injury to vital neurovascular structures. An in situ facial foreign body, particularly if large, presents significant challenges beyond safe and timely removal. Airway management, stabilization of the object, management of increased intracranial pressure, and identification of injuries to local structures are all issues that may require addressing. We present a case of penetrating facial trauma from a vice clamp, with an in situ foreign body, that illustrates several of these challenges and provides a forum for their discussion.

2813. Klages, U., et al. (1975). "[Survival time, capacity of action and radiological diagnosis after gunshot wounds of the cranium (author's transl)]." Uberlebenszeit, Handlungsfahigkeit und rontgenologische Diagnostik bei Schussverletzungen des Schadels **76**(4): 307-319.

Three cases of suicidal temporal gunshots. Different circumstances in the clinical course and in the ability of action.--In one case there was a bullet tract in the lower temporal region with considerable destruction of the base of the skull, followed by immediate inability of action and early death. Another case with a transtemporal gunshot without radiological signs of a laceration of the base of skull showed severe disturbance of cerebral functions for some days and remaining blindness. In the third case there was a pistol shot in the temporal region with retained missile, full ability of acting and undisturbed consciousness. Causative for the differences in the effect of the gunshots are differences of weapons and amunition and the anatomical position of the wound track in the temporal region. Discussion about the role of concussion of the brain by different rate of transgression of energy from the missile to the skull. Reference to the importance of X-ray analysis and to a radiographic documentation of the findings in such cases.

2814. Klancnik, M., et al. (2018). "PENETRATING ORBITOCRANIAL INJURY." Acta clinica Croatica **57**(4): 792-796.

- A case of a 37-year-old female patient is presented. The patient was admitted to the Surgical Emergency Unit after accidental fall on a metal rod when she had sustained stab injury of the right orbit with penetration into the right frontal brain lobe. Multi-slice computed tomography (MSCT) showed penetrating injury and fracture of the right orbital roof without eyeball damage and endocranial impressed bone fragments into the right frontal brain lobe. Urgent surgical intervention was performed by a maxillofacial surgeon and neurosurgeon, including reposition of bone fragments of the orbital roof and cranioplasty. Reconstruction of Tenon's capsule of the right eyeball was performed by an ophthalmologist. From the intraoperative wound swab of the orbit, Bacillus cereus was isolated, therefore the patient was administered ciprofloxacin and rifampicin as recommended by an infectious disease (ID) specialist. Follow up brain MSCT at 15 days and magnetic resonance imaging of the brain at 25 days showed brain edema in the right frontal area and signs of local brain abscess. Intravenous administration of the ciprofloxacin and metronidazole antibiotics with corticosteroids for edema suppression were ordered by the ID physician. Fourteen weeks after this therapy, brain MSCT showed complete abscess regression and no neurologic deficit with only mild psychomotor changes.

2815. Klapper, S. R., et al. (1995). "Atypical mycobacterial infection of the orbit." Ophthalmology **102**(10): 1536-1541.

PURPOSE: To describe the clinical presentation and successful management of an orbital infection caused by Mycobacterium abscessus, a formerly unrecognized cause of orbital disease after penetrating trauma., METHODS: An orbital infection due to M. abscessus is described, and previously reported ocular and extraophthalmic infections caused by M. abscessus are reviewed., RESULTS: A 5-year-old boy had acute, painless visual loss shortly after being struck in his left lower eyelid with a fishing rod. Radiologic evaluation established a mass in the orbital apex. Initial biopsy and cultures of the apex mass were negative; however, additional orbital exploration and cultures demonstrated M. abscessus to be the causative organism. The orbital infection was treated successfully with long-term oral clarithromycin. Review of the literature on ocular/adnexal and soft tissue infections caused by atypical mycobacteria shows characteristic clinical and histopathologic features., CONCLUSIONS: To the authors' knowledge, only seven

patients with atypical mycobacterial infections of the ocular adnexa have been reported. The patient reported in the current study illustrates the difficulty in establishing the preoperative diagnosis of atypical mycobacterial infections of the orbit. A chronic draining wound or a localized orbital abscess, after penetrating trauma, should alert the physician to the possibility of an M. abscessus infection. Clarithromycin, an oral macrolide antibiotic, appears to be the most effective medical therapy for these patients.

2816. Klein, D. M. and M. E. Cohen (1978). "Pasteurella multocida brain abscess following perforating cranial dog bite." The Journal of pediatrics **92**(4): 588-589.

2817. Kleinsasser, N., et al. (1996). "[Nasal cerebral heterotopic tissue (nasal glioma) in the adult: a rare cause of primary cerebrospinal fluid rhinorrhea]." Nasale zerebrale Heterotopie (nasales Gliom) des Erwachsenen: seltene Ursache einer primaren Rhinoliquorrhoe. **75**(8): 483-487.

BACKGROUND: Nasal cerebral heterotopia is a congenital lesion that is mainly detected in early childhood. The rare cases of this disorder found in adult patients are located intranasally. A common symptom is compromised nasal air passage. Clinical findings include polypoid masses in either the nasal cavity or the paranasal sinuses. To our knowledge, primary cerebrospinal fluid (CSF) rhinorrhea has been reported only twice in these patients., PATIENT: A 64-year-old female patient presented with CSF rhinorrhea proven by beta 2-transferrin testing. Previous head injury or intranasal manipulation were excluded. Anterior rhinoscopy revealed a watery drainage from the right middle meatus. CT scan showed a defect in the lateral roof of the right ethmoid sinus, approximately 5 mm in diameter; MRI revealed a mass in the right ethmoid and frontal sinuses, penetrating the anterior skull base. The lesion was resected by an extranasal approach. It showed a fibrous connection to the frontal lobe. Histologically, the lesion consisted of neural tissue composed of gray and white matter, both with a normal structuring. Dura and skull base were reconstructed. There were no signs of a CSF leak postoperatively., RESULTS AND CONCLUSIONS: The differential diagnosis of CSF rhinorrhea includes traumatic events and neoplasms, elevated intracranial pressure, and connate lesions as encephaloceles and, in rare cases, nasal cerebral heterotopia.

2818. Klevno, V. and M. Kislov (2017). "A rare case of injury of head with a construction plug-driving gun." Rechtsmedizin **27**(4): 372.

Background. Cases of penetrating injury of the head with construction tools are rather rare in forensic medicine. However, we have encountered such a case. Material and methods. It appeared from the investigation materials submitted for review that the foreman heard a groan and found a construction worker, lying on the floor, with the bit of the plug-driving gun protruding from his left orbital region. The construction worker was taken to medical facility in an extremely severe condition. Results. Computer tomography identified penetrating injury of the head. The wound canal passed through medial parts of the left orbit, penetrated into the cranial cavity damaging the upper wall of the left orbit. The condition of the patient remained extremely severe regardless of the treatment undertaken, it aggravated progressively, and the death occurred on the 11th day following the trauma. Examination of the wound canal identified that it passes through periorbital fat (not damaging the left eye ball), damages the inner and superior wall of the left orbit, the matter of the left and right hemispheres of the brain, pia mater and ends in a non-perforating manner near dura mater of the right hemisphere of the brain (total length of the wound canal is 19.7 cm, along a certain part of its length it had a distinct cylindrical form with a diameter of 0.8 cm with a layer of construction foam). Discussion and conclusions. This example clearly shows that thorough examination of the wound canal and its context is important for identify the injuring tool with maximum precision.

2819. Klimek, L., et al. (1993). "[A new procedure for removal of foreign bodies in the area of the head]." Ein neues Verfahren zur Entfernung von Fremdkopern im Kopfbereich. **96**(4): 213-216.

Identification and extraction of penetrating cranial foreign bodies can cause problems in some cases. Small fragments localized deep in the orbit or cerebrum can be especially hard to detect. Severe bleeding and traumatized anatomy can make orientation difficult. We used a new localizing device, computer-assisted surgery (CAS), to good effect in six such cases. CAS is a localizing technique designed to assist the head surgeon during surgery, providing real-time position information. The method is based upon a three-dimensional volume model of the patient's skull generated

by preceding computed tomography imaging procedures (CT or MRI). Intraoperative correlation of a 3D-model and the patient's skull allows for real-time position display of a surgical instrument on the monitor screen. Thereby the surgeon is able to localize even small foreign bodies without extensive exploration. In the case of multiple foreign bodies the surgeon calls up a simple documentation facility recording which of the visible fragments have already been extracted. We successfully used the system for extraction of orbital foreign bodies in four and intracerebral foreign bodies in two cases. In a 4-year-old child with gunshot injury the bullet was located in the precentral region and was easily extracted with the CAS system. In a 21-year-old man 39 glass fragments were extracted from the left orbit. In a 36-year-old man a bone fragment was dislocated to the apex of the orbit directly under the optic nerve. Location and extraction were achieved without damage to the orbital structures with the help of the CAS system.

2820. Klimo, P., Jr. and B. T. Ragel (2010). "Introduction: military neurosurgery, past and present." Neurosurgical focus **28**(5): Introduction.

For a physician has the worth of many other warriors, both for the excision of arrows and for the administration of soothing drugs. Homer, Iliad XI.514-515 Ever since armed conflict has been used as a means to settle disputes among men, there have been those who have been tasked to mend the wounds that ravage a soldier's body from the weapons of war. The Iliad portrays the pivotal 10th year of the legendary Trojan War, during which a schism in the Greek leadership prolongs the extended siege of the city of Troy. In the midst of this martial epic come the lines quoted above, quietly attesting to the value of the military physician, even under the crude conditions of the Greek Dark Age. They are uttered by Idomeneus, one of the foremost Greeks, when he is enjoining one of his comrades, Nestor, to rescue the injured Greek physician Machaon and take him back from the line to treat his wounds. He is afraid that Machaon will be captured by the Trojans, a loss far greater than that of any other single warrior. Duty to country has helped shape the careers of many neurosurgeons, including iconic US figures such as Harvey Cushing and Donald Matson. This issue of Neurosurgical Focus celebrates the rich history of military neurosurgery from the wars of yesterday to the conflicts of today. We have been humbled by the tremendous response to this topic. The 25 articles within this issue will provide the reader with both a broad and an in-depth look at the many facets of military neurosurgery. We have attempted to group articles based on their predominant topic. We also encourage our audience to read other recently published articles. The first 8 articles relate to the current conflicts in Afghanistan and Iraq. The lead article, written by Randy Bell and colleagues from the National Naval Medical Center and Walter Reed Army Medical Center, discusses what is arguably one of the most important contributions by military neurosurgeons from these 2 conflicts: the rapid and aggressive use of decompressive craniectomies. This is followed by articles on decompressive craniectomy techniques by Ragel and colleagues and cranioplasty outcomes by Stephens and colleagues. After reading these articles, the reader will come away with an appreciation of the often complex nature of wartime penetrating and closed-head injuries and the remarkable recovery that many injured soldiers make with time.

2821. Kline, D. G. and H. J. LeBlanc (1971). "Survival following gunshot wound of the pons: neuroanatomic considerations. Case report." Journal of neurosurgery **35**(3): 342-347.

The successful treatment of a civilian gunshot wound of the vermis and pons is described. A large missile fragment was removed from a depth of 2 cm within the pons at the level of the facial colliculus. Despite initial coma and subsequent irregular respiration with sleep apnea, the patient survived. Neurological, radiographic, and operative findings are correlated with the anatomy of the pons.

The authors report a case of injury of the anterior cranial fossa by foreign body penetrating through the orbit with rhinorrhoea and brain damage in a child. Early operation prevented primary and secondary complications.

2823. Klodnicki, M., et al. (2010). "A grisly event in the Kenai Peninsula." Emergency radiology **17**(5): 423-425.

We report an unusual manifestation of penetrating facial trauma. It was suffered by a recreational fly fisherman who was hiking away from a casting spot when he fell and was impaled by a section of his graphite flyrod. The

circumstances of his injury, its clinical manifestations, and its imaging findings are discussed. Emergency physicians and radiologists should be aware of the computed tomography appearance of impaled foreign bodies and their capability to penetrate deeply to reach critical vascular and neurologic structures. The role of imaging in penetrating trauma to the face and skull base for guiding appropriate intervention is emphasized.

2824. Kloss, K. (1977). "[Stab wounds of the brain. A case report (author's transl)]." Ein Beitrag zu den Stichverletzungen des Gehirns. **89**(16): 551-553.

The case history is presented of a 10-year-old boy who stabbed himself accidentally during play with a knife which penetrated deep into the temporal lobe of the brain via the orbit. The child was fully conscious on admission to hospital without any obvious neurological signs. The knife was removed surgically and the immediate postoperative findings of ptosis, chemosis and slight restriction of movement of the left eye regressed rapidly.

2825. Klug, W. (1968). "[Perforating brain-skull injuries caused by accidents and their treatment]." Unfallbedingte perforierende Schadel-Hirn-Verletzungen und deren Behandlung. **322**: 609-614.

2826. Klugar, M., et al. (2014). "The effectiveness of hyperbaric oxygen therapy on mortality in adults with craniotrauma: A systematic review protocol." JBI Database of Systematic Reviews and Implementation Reports **12**(12): 54-66.

Review question/objective What is the effectiveness of hyperbaric oxygen therapy (HBOT) on the mortality of patients with craniotrauma? Background Craniotrauma and traumatic brain injury (TBI) is a major health problem worldwide and across all ages. It is a major cause of death and disability.1,2 Disability, as a result of TBI, has significant functional, social and economic consequences.2,3 According to the Institute of Health Information and Statistics in the Czech republic, TBI occurs at a frequency of 150 cases per 100,000 inhabitants which is about 36 000 per year; in 2009, 32,589 cases was hospitalized.4 Traumatic brain injury in the age group of 45 years was the leading cause of death in 2003;1 however, more recent studies showed a variation in age groups and a shift towards older adults, especially in high income countries.5 A TBI incidence of 150 to 300 cases per 100,000 people per year has been reported in North America and Europe. Over 200 cases per 100,000 are admitted to hospital in Europe. The incidence is even worse in low-income and middle-income countries.6 The World Health Organization estimates that TBI will be the third highest cause of global mortality and disability by 2020.7 Mass et al.,8reported that TBI is classified by clinical severity, as determined by Glasgow Coma Scale (GCS); structural damage, as determined by computer tomography scans (CT) or magnetic resonance (MR); and the mechanism of TBI, whether closed or penetrating. There are three recognized degrees of TBI: mild; moderate; and severe.8,9,10 Traumatic brain injury could appear as a monotrauma, which means that only the brain is affected by injury. Traumatic brain injury could also manifest as part of a polytrauma, in which injury of two or more physical regions or organ systems are present, with at least one of the injuries being life-threatening.11 According to clinical and experimental results reported by Adamidese et al.,3 brain damage may not solely be caused by primary injury alone, but may progress during the following hours and days as secondary damage.3,12 Menon13 analogously stated that the basic principle for neuro-intensive care is that ischemia due to injury leads to further damage of brain tissues. The causes of secondary damage can be intracranial (brain lesions, edema, increased intracranial pressure, seizures, vasospasm, and infection) or general (hypotension, hypoxia, hyper/hypocapnia, hyper/hypoglycemia, anemia, coagulopathy, pyrexia, electrolyte imbalance, and infection).3 According to Gopinath et al.14 and Bouma et al.,15 the reduction of the brain blood flow and brain supply occurs within the first 24 hours. A lack of oxygen leads to a reduction of oxidative phosphorylation. The resources of glucose obtained from anaerobic glycolysis are used for output of energy.This process causes an excessive accumulation of lactate and deprives the energy for protein synthesis. Bergsneider et al.,16 Lifshitz et al.,17 Verweij et al.18 and Sahni et al.19 reported that this inefficient anaerobic metabolism leads to a reduction of energy in cells and initiates a cascade of biochemical processes that causes mitochondrial dysfunction, prolonged metabolism and death of cells. Ng et al. reported that cell death, such as necrosis and apoptosis, does not appear only in the areas immediately surrounding the site of injury, but also in further areas.20 Van der Brink et al. also presented results that showed the significant correlation of the partial pressure of oxygen in brain tissue ischemia and the end outcome.21 Many standard therapeutical approaches can be used for the care of traumatic brain injury patients, with the exception of standard intensive care monitoring. the specific values that should be measured and calculated include intracranial pressure, cerebral blood flow, cerebral perfusion pressure, jugular

blood oxygen and lactate. The general aim for the care of traumatic brain injury patients is to optimize cerebrovascular haemodynamics including head elevation to 30°, sedation, paralysis, barbiturate–induced coma, cerebrospinal fluid drainage, artificial ventilation-appropriate oxygenation, osmotherapy, therapeutic hypothermia, hyperventilation, decompressive crani tomy.3,8 Hyperbaric oxygen therapy (HBOT) is not used as standard therapy.3,25 Hyperbaric oxygen therapy as a potential treatment has been discussed since the beginning of hyperbaric medicine.12 Hyperbaric oxygen therapy is characterized by inhalation of pure oxygen (FiO2 = 100%) in a hyperbaric chamber under pressure that is higher than atmospheric pressure, which is 1 ATA (atmosphere absolute).22,23 The range of pressure used for HBOT is between 1.5 ATA and 3 ATA for 30 to 120 minutes.3,12,19,22,24-29 An inhalation of oxygen at a pressure of 3 ATA increases partial pressure of arterial oxygen to 200 kPa and more,which leads to the dissolution of O2/100ml blood in plasma from 6.6 to 6.8 ml. This quantity of oxygen is sufficient for the metabolic needs of basic vital organs and tissues.30 According to Huang and Obenhaus,22 HBOT was shown to be neuro-protective in many neurological diseases. Theoretically, the usage of HBOT should lead to a decrease in brain cell damage as well as mortality. Pressure that is above atmospheric increases oxygen delivery to brain cells and enhances aerobic metabolism, which leads to the restoration of mitochondrial functions.25 The clinical studies of varied design, including randomized controlled trials (RCTs), quasi-experimental, and case studies, were focused on substantiating the effect of HBOT on the damaged brain as a result of TBI. Patients included into these studies had suffered from acute or chronic TBI of mild to severe degree, both in civilian and military environment. Adults with TBI of varied causes were also included. The size of patient groups was below 170 patients. The examined HBOT was set from 1.5 ATA for 60 minutes to 2.4 ATA for 90 minutes. The number of HBOT sessions received by patients was between30 to 40.19,23-29,31 Most of the studies investigated the effect of HBOT alone or as an additional therapy to standard regimen.19,26,27,29,31 Other studies compared outcomes in patients who had underwent HBOT against those who were treated by standard regimen or NHO.24,28 Rockswold et al.25 compared HBOT combined with NBH against standard regimen. Investigators were focused on examining heterogeneous outcomes using various scales, including Glasgow Outcome Scale (GOS),25 Disability Rating Scale (DRS), Rancho Los Amigos Scale (RLAS),19 and Glasgow Coma Scale (GCS).19,23-29,31 A range of monitored variables were also examined, including intracranial pressure (ICP), continuous metabolic monitoring (microdialysis of lactate, glucosis, pyruvate), critical level of brain tissue PO2, cerebral blood flow (CBF), oxygen toxicity markers (IL-6, IL-8), and mortality.24,25,27 The Joanna Briggs Institute Database of Systematic Reviews and Implementation Reports, Cochrane Library and PROSPERO register were searched for systematic reviews conducted on the same topic. A systematic review focused on HBOT in the context of TBI was previously conducted in 2004 by Bennett et al.32 and published in 2012 by the same authors.33 The title of the systematic review from 2012 was “Hyperbaric oxygen therapy for the adjunctive treatment of traumatic brain injury”.33 This systematic review was conducted according to Cochrane methodology. Authors included solely RCTs that compared the effects of treatments with HBOT against those without HBOT. Participants were patients suffering from acute TBI as a result of blunt injury and had been admitted to intensive care unit or intensive neurosurgical units. Authors divided outcomes in two groups: primary (functional outcomes and mortality) and secondary (activities of daily living, ICP, magnetic resonance imaging, progress in GCS, adverse effects of HBOT, and cost-effectiveness). Compared to the systematic reviewss conducted by Bennett et al.,33 we will follow Joanna Briggs Institute methodology and we will not focus only on RCTs but also on other types of study designs as well. For many reasons, including financial, technical, capacity etc., it is particularly difficult to conduct RCTs of high quality in the field of hyperbaric medicine. On the other hand, th re are a lot of studies of high quality with designs other than RCTs. As specified in our inclusion criteria, we do not solely include acute TBI but will also include chronic TBI. Bennett et al.33 included studies with patients below the age of 18. We will therefore exclude any studies that involved children. Moreover, it is particularly important to look at the critical status of patients with acute craniotrauma and the initiation of HBOT, as some authors have recommended postponing HBOT until the patient is stabilized.34 Collectively, we will consider the initiation of HBOT in acute craniotrauma patients as part of the intervention for the systematic review. 1. Within the first 24 hours 2. After 24 hours 3. After 48 hours 4. After “stabilization” of patients (one week). Our systematic review will be conducted at the end of 2014, more than two years since the systematic review by Bennett et al.33 was written, thus more recent studies could be found. This review will undertake rigorous, systematic, consecutive and logical steps, which are aimed to critically appraise, summarize, analyze, and interpret collected data to present existing knowledge about the effects of HBOT on mortality of adults with cranial trauma.

2828. Knerlich, F. and R. Verheggen (2005). "Neurological picture. Feeding cats might be dangerous: penetrating orbital and brain injury without neurological deficits." Journal of neurology, neurosurgery, and psychiatry **76**(10): 1359.

2829. Knowlin, L. T., et al. (2018). "Cardiac injury following penetrating chest trauma: Delayed diagnosis and successful repair." Journal of Pediatric Surgery Case Reports **39**: 45-47.

Penetrating cardiac trauma is rare and often results in poor outcomes in the pediatric population. Clinical presentation may range from relative stability to cardiovascular collapse and arrest. We present a case of a cardiac gunshot injury in an 11 year old who was shot in the back, sustaining a through and through injury to left chest. The missile projectile penetrated the left ventricle with subsequent diaphragmatic and splenic injury. The cardiac injury was not identified on initial examination or intraoperative repair of diaphragmatic injury. After becoming unstable in the pediatric intensive care unit, a bedside thoracotomy was performed and the cardiac injury was successfully repaired. In the setting of penetrating thoracic trauma, a normal cardiac exam, echocardiography, or intraoperative findings should not eliminate the possibility of a cardiac injury. The key factor for patient survival is early diagnosis of injury and emergent intervention. Background: Penetrating cardiac trauma is rare and often results in poor outcomes in children. Clinical presentation may range from relative stability to cardiovascular collapse and arrest. Case report: We present a case of an 11-year old male who was shot in the back sustaining a through and through injury to left chest. A missile projectile penetrated the left ventricle with subsequent diaphragmatic and splenic injury. A cardiac injury was not identified during initial examination or laparoscopic repair of a diaphragmatic injury. Five hours after the initial presentation, the child became unstable in the pediatric intensive care unit, a bedside thoracotomy was performed and the cardiac injury was identified and successfully repaired. Conclusion: In the setting of penetrating thoracic trauma, a normal cardiac exam, echocardiography, or intraoperative findings should not eliminate the possibility of a cardiac injury. The key element for patient survival is early diagnosis of injury and emergent intervention.

2830. Knudson, S. A., et al. (2021). "Same-Admission Microvascular Maxillofacial Ballistic Trauma Reconstruction Using Virtual Surgical Planning: A Case Series and Systematic Review." Craniomaxillofacial Trauma and Reconstruction.

Study Design: Retrospective case series; systematic review. Objective: It is unknown whether the use of virtual surgical planning (VSP) to facilitate same-admission microsurgical reconstruction of the mandible following acute maxillofacial ballistic trauma (MBT) is sufficient to achieve definitive reconstruction and functional occlusion. Methods: A single-center retrospective analysis was conducted for patients who underwent microsurgical reconstruction of the mandible using VSP after acute MBT. The PubMed/MEDLINE, Embase, ScienceDirect, and Scopus databases were systematically reviewed using blinded screening. Studies were evaluated via thematic analysis. Results: Five patients were treated by same-admission and microsurgical reconstruction of the mandible using VSP. We observed an average of 16.4 ± 9.1 days between initial presentation and reconstruction, an average length of stay of 51.6 ± 17.9 days, 6.2 ± 2.8 operations, and 1.6 ± 0.9 free flaps per patient. Four types and 8 total flaps were employed, most commonly the anterior lateral thigh flap (37.5%). Care yielded complete flap survival. Each patient experienced at least 1 minor complication. All patients achieved centric occlusion, oral nutrition, and an approximation of their baseline facial aesthetic. Follow up was 191.0 ± 183.9 weeks. Systematic review produced 8 articles that adhered to inclusion criteria. Consensus themes in the literature were found for clinical goal and function of VSP when practicing MBT reconstruction, yet disagreement was found surrounding optimal treatment timeline. Conclusions: Same-admission microsurgical reconstruction after MBT is safe and effective to re-establish mandibular form and function. VSP did not delay reconstruction, given the need for preparation prior to definitive reconstruction.

2831. Knutson, K. M., et al. (2014). "Neural correlates of apathy revealed by lesion mapping in participants with traumatic brain injuries." Human brain mapping **35**(3): 943-953.

Apathy, common in neurological disorders, is defined as disinterest and loss of motivation, with a reduction in self-initiated activity. Research in diseased populations has shown that apathy is associated with variations in the volume of brain regions such as the anterior cingulate and the frontal lobes. The goal of this study was to determine the neural signatures of apathy in people with penetrating traumatic brain injuries (pTBIs), as to our knowledge, these have not been studied in this sample. We studied 176 male Vietnam War veterans with pTBIs using voxel-based lesion-symptom mapping (VLSM) and apathy scores from the UCLA Neuropsychiatric Inventory (NPI), a structured inventory of

symptoms completed by a caregiver. Our results revealed that increased apathy symptoms were associated with brain damage in limbic and cortical areas of the left hemisphere including the anterior cingulate, inferior, middle, and superior frontal regions, insula, and supplementary motor area. Our results are consistent with the literature, and extend them to people with focal pTBI. Apathy is a significant symptom since it can reduce participation of the patient in family and other social interactions, and diminish affective decision-making. 2832. Knutson, K. M., et al. (2013). "Injured brain regions associated with anxiety in Vietnam veterans." Neuropsychologia **51**(4): 686-694.

Anxiety negatively affects quality of life and psychosocial functioning. Previous research has shown that anxiety symptoms in healthy individuals are associated with variations in the volume of brain regions, such as the amygdala, hippocampus, and the bed nucleus of the stria terminalis. Brain lesion data also suggests the hemisphere damaged may affect levels of anxiety. We studied a sample of 182 male Vietnam War veterans with penetrating brain injuries, using a semi-automated voxel-based lesion-symptom mapping (VLSM) approach. VLSM reveals significant associations between a symptom such as anxiety and the location of brain lesions, and does not require a broad, subjective assignment of patients into categories based on lesion location. We found that lesioned brain regions in cortical and limbic areas of the left hemisphere, including middle, inferior and superior temporal lobe, hippocampus, and fusiform regions, along with smaller areas in the inferior occipital lobe, parahippocampus, amygdala, and insula, were associated with increased anxiety symptoms as measured by the Neurobehavioral Rating Scale (NRS). These results were corroborated by similar findings using Neuropsychiatric Inventory (NPI) anxiety scores, which supports these regions' role in regulating anxiety. In summary, using a semi-automated analysis tool, we detected an effect of focal brain damage on the presentation of anxiety. We also separated the effects of brain injury and war experience by including a control group of combat veterans without brain injury. We compared this control group against veterans with brain lesions in areas associated with anxiety, and against veterans with lesions only in other brain areas. Copyright Published by Elsevier Ltd.

2834. Ko, K. (1998). "Superimposed holographic image-guided neurosurgery. Technical note." Journal of neurosurgery **88**(4): 777-781.

Computerized tomography scanning-derived narrow band reflection holograms of patients undergoing craniofacial procedures were created to evaluate the applicability of superimposing these three-dimensional images (3-D) on the operative field during neurological surgery. These sterilized radiological holograms were positioned over the surgical site by using bone sutures as registration points between the skull and the 3-D image to serve as a visual template between the patient and surgeon. Surgeries were then performed with the surgeon looking through the radiological hologram at the patient. Holograms were accurate to within 2 mm (plus or minus) of the actual calvarial anatomy. The use of the holographic image as a visual guide during surgery eliminated intraoperative guesswork or free-handed contouring. To the author's knowledge, this is the first report of the superimposed holographic image used in situ during surgery.

2835. Ko, K., et al. (2005). "Holographic interferometry of cerebral pulsations." Surgical neurology **63**(2): 118-122.

BACKGROUND: Holographic interferometry is a noninvasive method used to analyze the mechanical displacement affecting an object undergoing deformation. This technique has been primarily applied to inanimate entities owing to the difficulty in producing stress forces in living subjects. In this report, the possibility of harnessing cerebral pulsations as a displacement force to produce interferograms in neurosurgical patients was studied., METHODS: This work evaluates the application of this technology to patients with areas of calvarial defects. Using a pulse ruby laser, holographic interferograms were created in neurosurgical patients with areas of calvarial loss. The cardiac cycle was used to trigger the firing of the laser., RESULTS: The holographic interferograms were accurate up to within 0.5 mm in outlining the region of bony deficiency., CONCLUSION: Holographic interferometry imaging was successfully accomplished using cerebral pulsations as a cyclic displacement-producing force. This method accurately outlined the area of bony loss. A discussion of this technology is included.

2836. Kobayashi, M. and P. F. Mellen (2009). "Rubber bullet injury: case report with autopsy observation and literature review." The American journal of forensic medicine and pathology **30**(3): 262-267.

Rubber bullets are one of the less-lethal (nonlethal) weapons, which are increasingly used to incapacitate dangerous individuals, avoiding use of firearms. An autopsy examination of a man who was shot with improved rubber bullets revealed that the bullet caused pulmonary contusion. The bullet was 30 g in weight and consisted of a sponge foam nose with 40-mm diameter and a plastic body. He was not incapacitated and died of suicidal gunshot wound. The case raised a question as to how severe an injury is necessary to deter a person without causing death. A variety of rubber bullets have been used in the world, and they have occasionally produced severe or lethal injuries. A review of the literature demonstrated that the feature of injuries appeared to be related to the type of missile. It becomes more important for a forensic pathologist to be familiar with rubber bullets and injuries caused by them as the use of less-lethal weapon increases.

2837. Kocak, A. and M. H. Ozer (2004). "Intracranial migrating bullet." The American journal of forensic medicine and pathology **25**(3): 246-250.

Retained bullets and fragments following a civilian gunshot injury are quite frequent in practical neurosurgery. It is usually possible to extract the foreign body surgically, while rare cases are conservatively treated because of technical reasons. Conservative treatment may present complications, and a rare form of this presentation is migration of the bullet. A 20-year-old man presented with migrating bullet from a supratentorial to opposite infratentorial area. We consider that in the migrating bullet fragment cases, if there is no contraindication, the most reasonable treatment is its urgent surgical removal. This report reveals a supratentorial bullet migrating to the infratentorial contralateral area, and related literature considering the different mechanisms of migration is discussed.

2838. Kochanek, P. (2019). "Controversies in brain injury-preclinical data helps." Journal of neurotrauma **36**(13): A151.

Despite considerable support for therapeutic efficacy for a number of acute therapies targeting traumatic brain injury (TBI) in pre-clinical studies in individual laboratories, there has been a failure of translation to successful clinical trials. Many explanations for this have been suggested, with concerns raised with regard to both the pre-clinical and clinical investigations. In an attempt to address this translation failure, we developed Operation Brain Trauma Therapy (OBTT), a multicenter pre-clinical therapy and biomarker screening consortium for severe TBI. The approach taken by OBTT has attempted to target two of the perceived major limitations in preclinical research; 1) the need to test drugs simultaneously across multiple models, in order to address the multiple TBI endophenotypes that are identified clinically on imaging, and 2) the need for a higher level of rigor in carrying out pre-clinical therapy screening. OBTT has screened 12 therapies (nicotinamide, erythropoietin, cyclosporine, simvastatin, levetiracetam, glibenclamide, Kollidon VA-64, AER-271, amantadine, minocycline, E64d and P7C3-A20) in >1500 rats across three TBI models (parasagittal fluid percussion [FPI], controlled cortical impact [CCI], and penetrating ballistic-like brain injury [PBBI]). We assigned 22-points per model across behavioral and histological outcomes, generating an overall score for each therapy. Two therapies, levetiracetam and glibenclamide ranked the highest. Only levetiracetam showed efficacy in multiple models. Glibenclamide showed marked model dependence, with efficacy largely restricted to CCI?uggesting potential use in contusion. Thus, precisionbased clinical trials may be needed and could be directed by a pre-clinical multi-model screening approach. Another potentially important finding from OBTT is that the pre-clinical literature may be overly optimistic. We conclude that although there are many challenges to successfully carrying out rigorous pre-clinical therapy screening, the work of OBTT suggests that rigorous multicenter preclinical therapy screening may represent an important avenue to enhance the chance for successful translation. Finally, several potential paradigms for pre-clinical therapy development based on the OBTT approach will be presented.

2839. Kochanek, P., et al. (2016). "Operation brain trauma therapy: Synopsis of the first nine therapies in multi-center preclinical drug screening." Journal of neurotrauma **33**: A135.

OBTT is a multi-center pre-clinical drug and biomarker screening consortium supported by the U.S. DoD. It evaluates therapies across three severe TBI models (parasagittal fluid percussion injury [FPI], controlled cortical impact [CCI] and penetrating ballistic-like brain injury (PBBI) in rats). FPI is the mildest model while PBBI is the most severe. OBTT's goals are 1) to define therapies showing efficacy across models which should have the best chance for clinical

translation, and/ or 2) to define model-dependent therapeutic effects to guide precision medicine-based clinical trials. The results of the first 5 therapies tested by OBTT (nicotinamide, erythropoietin, cyclosporine [CsA], simvastatin, and levetiracetam) were published in J Neurotrauma. OBTT has assessed 4 additional therapies (glibenclamide, kollidon-VA64, AER 271, and amantadine). Only levetiracetam has shown benefit in multiple models, including benefit in at least one model on cognitive outcome, histology, and serum biomarker levels. The second most successful drug, glibenclamide demonstrated improved motor function and reduced contusion volume, but benefit was largely restricted to CCI. Several other therapies showed model dependent effects (tissue sparing by nicotinamide in CCI, some benefit from CsA in FPI but toxicity in PBBI, and benefit from amantadine on behavior in PBBI but deleterious effects in FPI). Glial fibrillary acidic protein (GFAP) has performed well as a serum biomarker showing correlations with histology and theranostic utility. Levetiracetam merits additional pre-clinical and clinical investigations. However, it failed to show benefit in our micropig model. Glibenclamide also merits additional investigations in contusion. Amantadine may require testing in penetrating TBI. Finally, our work suggests utility of GFAP in pre-clinical screening.

2840. Kochanek, P., et al. (2017). "Overview of the first 12 therapies evaluated by operation brain trauma therapy, a pre-clinical multi-center consortium for TBI." Journal of neurotrauma **34**(13): A77.

Operation brain trauma therapy (OBTT) is a multi-center pre-clinical drug and biomarker screening consortium supported by the US DoD. OBTT screens therapies across three models in rats (parasagittal fluid percussion injury [FPI], controlled cortical impact [CCI] and penetrating ballistic-like brain injury [PBBI]) reflecting a range of phenotypes. Our goals include 1) to define therapies efficacious across models with the best chance for clinical translation, and 2) to define model-dependent effects to guide trials in targeted pathologies. The results of the first 5 therapies tested (nicotinamide, erythropoietin [EPO], cyclosporine [CsA], simvastatin, and levetiracetam) were published. OBTT has now screened 10 therapies, with ongoing testing of drugs 11-12. Drugs 6-12 include glibenclamide, kollidon-VA64, AER-271, amantadine, minocycline, E-64d and P7C3-A20. Levetiracetam showed benefit in multiple models. The second most successful drug, glibenclamide showed multiple benefits in CCI. Other therapies showed model dependent effects: tissue sparing by nicotinamide in CCI, benefit from CsA in FPI but toxicity in PBBI, benefit from amantadine in PBBI. Serum glial fibrillary acidic protein (GFAP) and Ubiquitin carboxy-terminal hydrolase-L1 were assessed at 4 and 24 h. GFAP predicted 21 d histology and drug effects. Levetiracetam merits additional testing and is being evaluated in our large animal model. Glibenclamide and Amantadine merit additional testing in contusion and penetrating brain injury, respectively. Our data support theranostic use of serum GFAP.

2841. Kochanek, P., et al. (2019). "Exploring additional approaches to therapy ranking in operation brain trauma therapy." Journal of neurotrauma **36**(13): A5.

Operation brain trauma therapy (OBTT) is a multicenter pre-clinical therapy and biomarker screening consortium. It screened 12 therapies (nicotinamide, erythropoietin, cyclosporine, simvastatin, levetiracetam, glibenclamide, Kollidon VA-64, AER-271, amantadine, minocycline, E64d and P7C3-A20) in >1500 rats across three TBI models (parasagittal fluid percussion [FPI], controlled cortical impact [CCI], and penetrating ballistic-like brain injury [PBBI]). We assigned 22-points per model across behavioral and histological outcomes, generating an overall score for each therapy. Levetiracetam and glibenclamide ranked the highest. We now take two additional therapy ranking approaches. First we examined therapeutic efficacy within models. Second, to maximize positive signals, we examined the impact of eliminating negative points. Several findings emerged. Using a minimum threshold of ≥+3-points to reflect efficacy within models, no therapy produced a signal in PBBI. Levetiracetam, which produced the highest overall score, produced its strongest signal in FPI, however, no other therapy in FPI reached threshold. In contrast, levetiracetam, glibenclamide, nicotinamide, and Kollidon VA-64 all met/exceeded threshold in CCI (in that order). Eliminating negative points did not impact scoring for levetiracetam; it generated no negative points across models. However, glibenclamide, nicotinamide, Kollidon VA64, minocycline, and simvastatin all reach threshold (in that order). Eliminating negative points, levetiracetam and glibenclamide remained the highest scoring therapies; both generated ≥2X the points of any other therapy. Glibenclamide showed maximal efficacy in CCI. We conclude, levitiracetam and glibenclamide merit additional pre-clinical/clinical study, with model dependence for glibenclamide. Eliminating negative points minimally impacted our conclusions. Alternative therapeutic approaches should also be explored across OBTT, particularly in PBBI (i.e., targeting regeneration, cell-based therapies, or combination therapy).

2842. Kochanek, P. M., et al. (2012). "Cross model comparison of behavior, neuropathology, and serum biomarkers after controlled cortical impact, parasagittal fluid percussion, and penetrating ballistic-like brain injury: Results from operation brain trauma therapy." Journal of neurotrauma **29**(10): A23.

Introduction Operation Brain Trauma Therapy (OBTT) is a unique multi-center pre-clinical drug-screening consortium and the first systematic multicenter cross-model comparison in the TBI field. Hypothesis: controlled cortical impact (CCI), fluid percussion (FPI), and penetrating ballistic-like brain injury (PBBI) yield differences in neuropathology and biomarker profiles at injury levels generating behavioral deficits. Methods In all three models, male, adult Sprague-Dawley rats (total n = 140) were subjected to TBI using the established protocol at each center. Rats studied in the FPI model also had indwelling arterial catheters to monitor acute effects of drug administration on MAP and blood gases, and in each site, body temperature was controlled. In each model, established outcomes were evaluated including various motor and cognitive tasks over 21d. The motor tasks assessments were completed by d10 at all sites. Subsequently, Morris water maze (MWM) was used to assess cognitive function, including a hidden platform paradigm and probe trial across sites. At 21d, rats were sacrificed and in each model serial brain sections were assessed for lesion volume and either hemispheric or cortical tissue volume loss. Serum was obtained at 4h post-TBI to quantify initial levels of UCHL-1 and GFAP as assessments of neuronal and astrocyte damage resulting from primary injury, respectively. Results Motor testing revealed deficits in 1) beam walking and beam balance tasks after CCI, 2) rotarod performance after PBBI, and 3) cylinder task performance after FPI (all $P < 0.05$ vs. sham). Average latency to find the hidden platform (across all testing days) on the MWM paradigm was increased 19 - 12%, 121 - 13%, and 18 - 14% of sham in CCI, PBBI, and FPI, respectively ($P < 0.05$ vs. sham in CCI and PBBI). Lesion volume was 11.18 - 1.16%, and 15.01 - 2.38% of contralateral hemisphere in CCI, and PBBI, respectively and 2.84 - 0.57% of the contralateral cortex in FPI. Lesion volume in both CCI and PBBI were greater than FPI, $P < 0.05$. Surprisingly, serum UCHL-1 levels at 4h after injury were highest after FPI ($P < 0.004$ vs. CCI and $P < 0.001$ vs. PBBI) while serum GFAP levels at 4h were highest after CCI ($P < 0.0001$ vs. FPI), intermediate in PBBI ($P < 0.0003$ vs. FPI), but also modestly increased in FPI ($P = 0.04$ vs. sham). Conclusions We conclude that CCI, FPI, and PBBI produced distinct functional deficits, neuropathology, and early biomarker profiles. Our findings support the concept that cellular injury mechanisms and therapeutic targets may differ across TBI models and/or injury severities suggesting that multi-model therapeutic screening could provide unique insight into therapy development for clinical translation.

2843. Kochanek, P. M., et al. (2014). "Multicenter comparison of five therapies reveals therapeutic potential for levetiracetam: Operation brain trauma therapy." Journal of neurotrauma **31**(12): A105.

Operation Brain Trauma Therapy (OBTT) is a multi-center pre-clinical drug and biomarker screening consortium testing therapies for TBI. OBTT utilizes the parasagittal fluid percussion injury (FPI), controlled cortical impact (CCI), and penetrating ballistic-like brain injury (PBBI) models in rats to screen therapies at three sites using rigorous/blinded protocols. Identical groups (sham, TBI-vehicle, TBIlow dose, and TBI-high dose) are used across sites and motor, cognitive, histological, and serum biomarker outcomes assessed over 21 d. The code for each outcome is simultaneously broken across sites and therapies are given an overall score (maximum = 22 points/model). The first five therapies tested included nicotinamide (50 or 500 mg/kg IV at 15 min and 24 h), erythropoietin (EPO, 5000 or 10,000U/ kg IV at 15 min), cyclosporin-A (CsA, 10 or 20 mg/kg, IV at 15 min and 24 h), simvastatin (1 or 5 mg/kg POX14 d), or levetiracetam (54 or 170 mg/kg IV at 15 min). Dosing was literature-based. The first four therapies produced modest/no effects across models. Nicotinamide showed some motor benefit and tissue sparing in CCI, EPO showed no benefit across models, CsA showed tissue sparing in FPI but toxicity in CCI and PBBI, Simvastatin showed modest motor benefit across models but no cognitive or histological benefit. Levetiracetam, however, showed benefit on multiple outcomes including on MWM and probe trial in FPI, motor function, MWM, and tissue loss in CCI, and probe trial in PBBI. In OBTT, Levetiracetam, given as a single IV bolus early post-TBI, shows promise. It merits exploration of therapeutic window, dose optimization, testing in models with second insults, and testing in our large animal model. Support: US Army, W81XWH-10-1-0623.

2844. Kochanek, P. M., et al. (2018). "Operation Brain Trauma Therapy: 2016 Update." Military medicine **183**(suppl_1): 303-312.

Operation brain trauma therapy (OBTT) is a multi-center, pre-clinical drug and biomarker screening consortium for traumatic brain injury (TBI). Therapies are screened across three rat models (parasagittal fluid percussion injury, controlled cortical impact [CCI], and penetrating ballistic-like brain injury). Operation brain trauma therapy seeks to define therapies that show efficacy across models that should have the best chance in randomized clinical trials (RCTs)

and/or to define model-dependent therapeutic effects, including TBI protein biomarker responses, to guide precision medicine-based clinical trials in targeted pathologies. The results of the first five therapies tested by OBTT (nicotinamide, erythropoietin, cyclosporine [CsA], simvastatin, and levetiracetam) were published in the Journal of Neurotrauma. Operation brain trauma therapy now describes preliminary results on four additional therapies (glibenclamide, kollidon-VA64, AER-271, and amantadine). To date, levetiracetam was beneficial on cognitive outcome, histology, and/or biomarkers in two models. The second most successful drug, glibenclamide, improved motor function and histology in CCI. Other therapies showed model-dependent effects (amantadine and CsA). Critically, glial fibrillary acidic protein levels predicted treatment effects. Operation brain trauma therapy suggests that levetiracetam merits additional pre-clinical and clinical evaluation and that glibenclamide and amantadine merit testing in specific TBI phenotypes. Operation brain trauma therapy has established that rigorous, multi-center consortia could revolutionize TBI therapy and biomarker development.

2845. Kochanek, P. M., et al. (2016). "Approach to Modeling, Therapy Evaluation, Drug Selection, and Biomarker Assessments for a Multicenter Pre-Clinical Drug Screening Consortium for Acute Therapies in Severe Traumatic Brain Injury: Operation Brain Trauma Therapy." Journal of neurotrauma **33**(6): 513-522.

Traumatic brain injury (TBI) was the signature injury in both the Iraq and Afghan wars and the magnitude of its importance in the civilian setting is finally being recognized. Given the scope of the problem, new therapies are needed across the continuum of care. Few therapies have been shown to be successful. In severe TBI, current guidelines-based acute therapies are focused on the reduction of intracranial hypertension and optimization of cerebral perfusion. One factor considered important to the failure of drug development and translation in TBI relates to the recognition that TBI is extremely heterogeneous and presents with multiple phenotypes even within the category of severe injury. To address this possibility and attempt to bring the most promising therapies to clinical trials, we developed Operation Brain Trauma Therapy (OBTT), a multicenter, pre-clinical drug screening consortium for acute therapies in severe TBI. OBTT was developed to include a spectrum of established TBI models at experienced centers and assess the effect of promising therapies on both conventional outcomes and serum biomarker levels. In this review, we outline the approach to TBI modeling, evaluation of therapies, drug selection, and biomarker assessments for OBTT, and provide a framework for reports in this issue on the first five therapies evaluated by the consortium.

2846. Kochanek, P. M., et al. (2016). "Synthesis of Findings, Current Investigations, and Future Directions: Operation Brain Trauma Therapy." Journal of neurotrauma **33**(6): 606-614.

Operation Brain Trauma Therapy (OBTT) is a fully operational, rigorous, and productive multicenter, pre-clinical drug and circulating biomarker screening consortium for the field of traumatic brain injury (TBI). In this article, we synthesize the findings from the first five therapies tested by OBTT and discuss both the current work that is ongoing and potential future directions. Based on the results generated from the first five therapies tested within the exacting approach used by OBTT, four (nicotinamide, erythropoietin, cyclosporine A, and simvastatin) performed below or well below what was expected based on the published literature. OBTT has identified, however, the early post-TBI administration of levetiracetam as a promising agent and has advanced it to a gyrencephalic large animal model--fluid percussion injury in micropigs. The sixth and seventh therapies have just completed testing (glibenclamide and Kollidon VA 64), and an eighth drug (AER 271) is in testing. Incorporation of circulating brain injury biomarker assessments into these pre-clinical studies suggests considerable potential for diagnostic and theranostic utility of glial fibrillary acidic protein in pre-clinical studies. Given the failures in clinical translation of therapies in TBI, rigorous multicenter, pre-clinical approaches to therapeutic screening such as OBTT may be important for the ultimate translation of therapies to the human condition.

2847. Kodadek, L. M., et al. (2015). "Retained transcranial knife blade with transection of the internal carotid artery treated by staged endovascular and surgical therapy: technical case report." Neurosurgery **11 Suppl 2**: E372-E375.

BACKGROUND AND IMPORTANCE: We describe the use of proximal and distal endovascular coil embolization of the internal carotid artery followed by operative removal of a retained foreign object transecting the petrocavernous portion of the internal carotid artery., CLINICAL PRESENTATION: A 20-year-old man sustained a stab wound to the left temporal skull and presented with a retained knife blade. He reported a headache at presentation, but remained neurologically intact with a Glasgow Coma Scale of 15. Computed tomography imaging and subsequent angiography

confirmed complete transection of the petrocavernous segment of the left internal carotid artery with effective tamponade by the knife blade in situ and satisfactory collateral flow across the Circle of Willis. Coil embolization of the left internal carotid artery was performed. Retrograde embolization of the petrocavernous internal carotid segment distal to the injury was performed via vertebral and posterior communicating artery access. Antegrade embolization of the internal carotid artery proximal to the injury was completed and the patient was transferred to the operating room for craniectomy and foreign body extraction. Postoperative computed tomography angiography revealed no parenchymal hemorrhage, mass effect, or midline shift, and successful embolization of the internal carotid artery. At 6-week follow-up, the patient remained neurologically intact with no infectious or vascular complications., CONCLUSION: Staged endovascular and surgical therapy provides complete assessment and effective control of damaged vessels when retained intracranial foreign bodies are present. Given the high risk of vascular injury with retained transcranial foreign bodies, this strategy should be considered a safe approach for these challenging cases.

2848. Kodadek, L. M., et al. (2015). "Retained transcranial knife blade with transection of the internal carotid artery treated by staged endovascular and surgical therapy: Technical case report." Operative Neurosurgery **11**(2): E372-E375.

BACKGROUND AND IMPORTANCE: We describe the use of proximal and distal endovascular coil embolization of the internal carotid artery followed by operative removal of a retained foreign object transecting the petrocavernous portion of the internal carotid artery. CLINICAL PRESENTATION: A 20-year-old man sustained a stab wound to the left temporal skull and presented with a retained knife blade. He reported a headache at presentation, but remained neurologically intact with a Glasgow Coma Scale of 15. Computed tomography imaging and subsequent angiography confirmed complete transection of the petrocavernous segment of the left internal carotid artery with effective tamponade by the knife blade in situ and satisfactory collateral flow across the Circle of Willis. Given the high risk of vascular injury with retained transcranial foreign bodies, this strategy should be considered a safe approach for these challenging cases.

2849. Koehler, P. J. (2012). "Eduard Hitzig's experiences in the Franco-Prussian War (1870-1871): the case of Joseph Masseau." Journal of the history of the neurosciences **21**(3): 250-262.

It is well known that Fritsch and Hitzig published the results of their experiments on cortical stimulation in 1870, the year in which the Franco-Prussian War (FPW) broke out. Several tall stories are found about Hitzig's role in the FPW; stories that have not been well documented. During this war, he worked at the military hospital in Nancy, where he was allowed to admit to his ward soldiers with head wounds. He made a close observation of the 20-year-old French soldier Joseph Masseau, who suffered from a right-sided cerebral abscess following a gunshot wound sustained during the Loire campaign on December 10, 1870 and was looked after in the military hospital of Nancy in January and February 1871. Hitzig related the clinical and autopsy observations to his recent experimental findings. A translation into English of part of the case report is provided.

2850. Koenigs, M., et al. (2009). "Superior parietal cortex is critical for the manipulation of information in working memory." The Journal of neuroscience : the official journal of the Society for Neuroscience **29**(47): 14980-14986.

In recent years, theoretical perspectives on posterior parietal function have evolved beyond the traditional visuospatial processing models to include more diverse cognitive operations, such as long-term and working memory. However, definitive neuropsychological evidence supporting the superior parietal lobule's purported role in working memory has been lacking. Here, we studied human brain lesion patients to determine whether the superior parietal lobule is indeed necessary for working memory. We assessed a wide range of memory functions in three participant groups: superior parietal lesions (n = 19), lesions not involving superior parietal cortex (n = 146), and no brain lesions (n = 55). Superior parietal damage was reliably associated with deficits on tests involving the manipulation and

rearrangement of information in working memory, but not on working memory tests requiring only rehearsal and retrieval processes, nor on tests of long-term memory. These results indicate that superior parietal cortex is critically important for the manipulation of information in working memory.

2851. Koestler, J. and R. Keshavarz (2001). "Penetrating head injury in children: a case report and review of the literature." The Journal of emergency medicine **21**(2): 145-150.

Head trauma is exceedingly common in children, but rarely presents as a penetrating injury to the skull. Most of the recommendations on evaluation, management, and follow-up of such injuries are based on the adult literature. We report a case of penetrating head injury from a tapered metal object in a 4-year old child.

2852. Kogan, A., et al. (2019). "Does duration of donor brain injury impact heart transplantation outcomes?" Clinical transplantation **33**(8): e13660.

AIM: We aimed to study the implications of pre-transplantation time intervals on HT outcomes., METHODS: Brain injury time (BIT) was defined as the period from the donor brain injury to brain death declaration. Brain death interval (BDI) was defined as the period from brain death to application of an aortic cross-clamp during donor heart procurement. Allograft ischemia was defined as the time from donor aortic cross-clamp to aortic unclamping. End points included mortality and rejections., RESULTS: Between 1997 and 2017, we assessed 173 patients. Kaplan-Meier analyses showed that prolonged donor BIT, BDI, allograft ischemia, and total injury time had no significant effect on mortality and rejections. Patients were subdivided into short BIT (<97 hours, n = 87) and long BIT (>=97 hours, n = 86) groups. No differences in rejection scores nor in time to first rejection were noted. Kaplan-Meier analysis showed a similar long-term survival in the two groups. Sub-analysis of both groups according to their median BDI (12 hours) revealed no differences in mortality or time to rejection., CONCLUSIONS: Pre-transplantation time intervals do not affect mortality or rejection. Our findings have important clinical implications regarding HT allocation and organ availability.

2853. Kohli, A. and N. K. Aggarwal (2006). "Firearm fatalities in Delhi, India." Legal medicine (Tokyo, Japan) **8**(5): 264-268.

Studies on firearm fatalities in various countries have been published. However, pattern and incidence of fatal firearm injuries in Delhi has largely gone unreported. This study was taken up with the objective of reporting the pattern and incidence of fatal firearm injuries in Delhi and comparing it with the pattern seen in other countries. One hundred and seven firearm fatalities autopsied during the last 6 years were studied. 46.7% victims were aged between 20 and 30 years and 90.7% were males; similar findings were seen in other countries. 92.6% were victims of homicidal attacks, 6.5% suicidal and 0.9% accidental. This is in sharp contrast to the pattern in other countries where suicides were the predominant group and homicides accounted for a small number of cases. A high presence of illegal country made guns was an explanation for this trend. Single firings were the norm. Chest (39%) and head (29.6%) were the two most common entry sites for the bullets, a pattern somewhat similar to that of other countries. Survival time, cause of death and recovery of projectiles was also studied. Elimination of illegal country made guns is of the utmost importance in order to curb the high homicidal firearm fatality rate in this region.

2855. Kohlmann, R., et al. (2015). "Community-acquired adult Escherichia coli meningitis leading to diagnosis of unrecognized retropharyngeal abscess and cervical spondylodiscitis: a case report." BMC infectious diseases **15**: 567.

BACKGROUND: Escherichia coli is a rare cause of community-acquired meningitis in adults unless predisposing factors are present (e.g., previous penetrating cranio-cerebral injury or neurosurgery, immunosuppression, chronic alcoholism, history of cancer, diabetes mellitus, advanced age)., CASE PRESENTATION: We describe the case of a 53-year-old woman, resident in Germany, suffering from community-acquired bacterial meningitis caused by CTX-M-9 type extended spectrum beta-lactamase producing Escherichia coli. Because typical predisposing factors were not apparent,

pathogen identification resulted in expanded diagnostics to exclude a distant or contiguous primary focus. By magnetic resonance tomography, a previously unrecognized large retropharyngeal abscess with cervical spondylodiscitis was detected. In retrospect, the patient had complained about neck pain for a few weeks prior to meningitis onset, but the symptoms were interpreted as being related to a herniated disk. Meningitis and osteomyelitis resolved completely under surgical treatment and meropenem therapy., CONCLUSION: In case of adult Escherichia coli meningitis, underlying diseases should always be carefully excluded, especially if predisposing factors are not apparent.

2856. Kohlmeier, R. E., et al. (2001). "Suicide by firearms: a 15-year experience." The American journal of forensic medicine and pathology **22**(4): 337-340.

A retrospective review of 1704 cases of suicide involving firearms investigated by the Bexar County Medical Examiner's office between 1984 and 1998 was performed. The age distribution was similar in male and female victims, and the type of weapon was not associated with age. Approximately 78% of the victims used a handgun (87% of female and 76% of male victims). In 4.0% of head wound cases, the site of the entrance wound was the back of the head. Thus, this report refutes the common belief that all gunshot wounds to the back of the head represent homicides. In 1.9% of the cases, the wounds were inflicted at intermediate range. With handguns, the right temple was the most common site, but with rifles and shotguns, the most common site was the mouth.

2857. Koike, M., et al. (2013). "Differences in expression patterns of cathepsin C/dipeptidyl peptidase I in normal, pathological and aged mouse central nervous system." The European journal of neuroscience **37**(5): 816-830.

Cathepsin C (CC) (EC 3.4.14.1, dipeptidyl peptidase I) is a lysosomal cysteine protease that is required for the activation of several granule-associated serine proteases in vivo. CC has been shown to be constitutively expressed in various tissues, but the enzyme is hardly detectable in central nervous system (CNS) tissues. In the present study, we investigated the regional and cellular distribution of CC in normal, aging and pathological mouse brains. Immunoblotting failed to detect CC protein in whole brain tissues of normal mice, as previously described. However, low proteolytic activity of CC was detected in a brain region-dependent manner, and granular immunohistochemical signals were found in neuronal perikarya of particular brain regions, including the accessory olfactory bulb, the septum, CA2 of the hippocampus, a part of the cerebral cortex, the medial geniculate, and the inferior colliculus. In aged mice, the number of CC-positive neurons increased to some extent. The protein level of CC and its proteolytic activity showed significant increases in particular brain regions of mouse models with pathological conditions--the thalamus in cathepsin D-deficient mice, the hippocampus of ipsilateral brain hemispheres after hypoxic-ischemic brain injury, and peri-damaged portions of brains after penetrating injury. In such pathological conditions, the majority of the cells that were strongly immunopositive for CC were activated microglia. These lines of evidence suggest that CC is involved in normal neuronal function in certain brain regions, and also participates in inflammatory processes accompanying pathogenesis in the CNS.

2858. Kojima, T., et al. (1987). "Successful removal of air gun bullets from the third ventricle." Neurosurgery **20**(2): 322-325.

A patient with air gun bullets in the 3rd ventricle associated with delayed ventricular hemorrhage is presented. Through an anterior transcallosal approach, the surgeon successfully removed the bullets without any significant permanent sequelae.

2859. Kok, Y. O., et al. (2010). "Foreign bodies of the face: A Singapore perspective." Annals of the Academy of Medicine Singapore **39**(11): S186.

Background/Hypothesis: Facial foreign body (FB) implantation can present as frustrating diagnostic and therapeutic dilemmas to both patients and surgeons. Judicious use of computed tomography (CT) scans may help localise FBs and reduce repeat surgeries. The authors aimed to identify risk factors predictive of multiple FB removal surgeries and propose imaging recommendations. Methods: The authors conducted a retrospective review of 31 patients who underwent surgical exploration and removal of facial FB. Variables studied were injury mechanism, anatomical location of FB, depth and tissue plane of implantation, FB material, dimensions, preoperative imaging, number of surgeries performed, presence of facial fractures and neurovascular complications. Results: Thirty-one

patients underwent surgical removal. Mean age was 34 years (80.6% males). Commonest FB material was glass (35.5%). Majority of FB injuries was work (48.4%) and motor vehicle accidents-related (35.2%). Orbital and periorbital involvement (70.8%) was most common and 40.9% of them had associated ocular injuries. Of the patients, 45.2% required more than one surgery. Fifty percent of them (n = 7) had FB implanted in facial bones. Concomitant fractures were present and fixation was needed in all. Orbitozygomatic fracture was most common (67%). FB material most associated with fractures was metal (78%). The other 50% (n = 7) were penetrating wounds with small calibre FBs missed on superficial visual inspection during the first surgery. CT scan after initial failed FB removal resulted in successful removal in all cases. Discussion & Conclusion: Based on the authors' experience, X-rays are limited in facial FB localization. CT scans should be considered in patients with risk factors of suspected facial fractures, periorbital injuries, metal FBs, ballistic injuries and deep penetrating wounds with small calibre FBs not visible on superficial visual inspection. These recommendations may lead to better clinical outcomes in future similar cases.

2860. Koko, A. M., et al. (2018). "Camel bite: An uncommon cause of penetrating head injury in a preteenager." British journal of neurosurgery **32**(1): 93.

Objectives: To describe an unusual case of penetrating head injury caused by camel bite and outline the management. Design: Case report. Subjects: Twelve year old boy with head injury caused by camel bite. Methods: A twelve year old boy was referred from primary health care centre with alteration in level of consciousness and fever, fifteen days after bitten by father's camel. The camel had picked up the boy by its teeth, shaken him and thrown away onto the ground. At presentation his Glasgow coma score was thirteen and febrile with axillary temperature of 38.9 degree celsius. There was both right and left sided temporo-parietal wound with eviscerated brain tissue. Brain Computed tomography scan showed bilateral temporo-parietal bone fractures, abscesses and depressed segment on the left side and surrounding edema. Patient was optimised with, intravenous fluids, intravenous antibiotics and anticonvulsant. Subsequently had bilateral temporo-parietal craniectomies, eleva-tion of depress segment, debridement and drainage of abscesses. Patient improved remarkably and parents were counselled for cra-nioplasty after three months. Results: Patient had good outcome and is being planned for cranioplasty. Conclusions: Management of camel bites injury can be challenging to both the Neurosurgeon and patients due to its complexities, as can present with both penetrating and blunt traumatic brain injury in an individual. The index case had occurred in rutting season (November-March), therefore care should be taking when handling camels especially during this period.

2861. Köksal, V. and T. M. Guler (2015). "Acute cortical blindness due to depressed occipital skull fracture: A pediatric case." Child's Nervous System **31**(10): 1981.

Objective: Although linear skull fractures are common in children, depressed fractures constitute 25% of cases. A depressed skull fracture is defined as the displacement of bony fragments below the level of the whole thickness of skull through the dura or also the brain parenchyma. The depressed skull fractures are classified as open fractures and closed fractures according to the integrity of the overlying skin. Neurological findings according to depressed skull fractures are related with the severity of the trauma, compression of the broken bone to the parenchyma, the presence of contamination in open depressed fractures and the dural damage. Also the functions of the cortical area under compression affects the kinds of neurological deficits. The development of acute blindness is a very rare complication of depressed skull fractures reported in the literature. The depression of the bony island into the sagittal sinus also makes it difficult to repair for this case. Methods: 6-year old male admitted to the emergency department with acute blindness after car accident. CT scan showed a depressed skull fracture of closed type in the occipital region. Emergent decompressive surgery was done because of the presence of acute blindness during admission to the hospital. The superior sagittal sinus preserved well during surgery. Results: It was obtained during admission that a bony island was depressed over the superior sagittal sinus causing 1-1.5 cm compression to the parenchyma related with visual field. Because of acute visual loss emergent surgery was applied. Visual loss was totally improved by the second day postoperatively. Conclusion: Types of depression fracture, neurological status of the patient and presence of neurological findings can affect necessity and also the time of surgery. In the presence of acute blindness emergent surgery should be done also for closed type depressed skull fractures.

2862. Kok-van Alphen, C. C., et al. (1982). "Automutilation of the cornea. I. Ophthalmological aspects." Documenta ophthalmologica. Advances in ophthalmology **52**(3-4): 327-332.

Automutilation of the cornea occurs more frequently than is generally supposed. The patient, particularly at his first visit, certainly will not reveal the cause of the cornea lesion. In two University Eye Clinics 19 patients were seen in whom the diagnosis of automutilation of the cornea could be made. It is important for the ophthalmologist to bear the possibility of automutilation in mind. In 6 of our patients corneal grafts were performed. All these grafts failed because of further automutilation. Corneal transplantation is certainly not indicated; these operations were performed because the patient's true condition had not been spotted in time. Better forms of treatment are tarsorrhaphy or the application of closely occluding bandages. In this way fair results were obtained in 2 cases. It is wrong to force the patient to a confrontation (i.e. to tell him that automutilation is suspected). Confrontation can lead to more severe mental disorders. In all cases psychiatric treatment is absolutely essential. The ophthalmological prognosis for this condition is poor and psychiatric help is quite often refused.

2863. Kolasa, P. and Z. Kaurzel (2001). "[Post-traumatic pulsating exophthalmus coexisting with congenital carotid-cavernous fistula]." Pourazowy wytrzeszcz tetniacy na tle wrodzonej przetoki szyjno-jamistej. **35 Suppl 5**: 58-63.

Pulsating exophthalmus develops most frequently in the course of penetrating or bitemporal head trauma. Idiopathic form is even more rare. Orbit venous system over-loading with pathological arterial blood infiltration is the cause of pulsating exophthalmus. A patient with congenital carotid-cavernous fistula (right eyeball enlargement and noise), suffering from head trauma after road accident has been presented. Carotid-cavernous fistula was diagnosed and than treated casually by endovascular closure of the infiltration between internal carotid artery and cavernous sinus. After 5-month treatment regression of the noise and exophthalmus was observed.

2864. Kolodziejczyk, D. and W. D. Hirsch (1992). "[Epidural "sulmycin implant" coverage for local prevention of infection in surgical management of open craniocerebral injuries]." Epidurale "Sulmycin Implant"-Abdeckung zur lokalen Infektionsprophylaxe bei der operativen Versorgung offener Schadel-Hirn-Verletzungen. **22**(6): 272-275.

In various series reported in the literature on the operative management of severe head injuries with compound depressed skull fractures and penetrating wounds of the brain, the rates of infection differ from 1 to 17%. In this paper the operative experience with 22 cases of penetrating head injuries is discussed. In conventional operative therapy, depressed skull fracture and lacerated dura were covered by "Sulmycin Implant" containing Gentamycin as a helpful bacteriological barrier. 18 patients survived, 7 patients had severe neurological defects, 5 patients had mild neurological deficits and 6 patients recovered completely. There were no signs of suppurative complications in superficial wounds or in the brain. 4 patients died due to their severe brain damage with multiple contusional lesions. Postoperative complications were as follows: one patient suffered extradural and one patient subdural rebleeding. Another patient with a frontal base skull fracture suffered a pneumatocele because the fracture was not correctly covered. The revision was done successfully using the "Sulmycin Implant". Presently, however, the intradural use of "Sulmycin Implant" is not recommended without further testing for the level of gentamycin in the cerebrospinal fluid which is released by the "Sulmycin Implant".

2865. Komabayashi, Y., et al. (2005). "Case of an intraorbital wooden foreign body penetrating the maxillary sinus." Practica Oto-Rhino-Laryngologica **98**(11): 861-864.

A 62-year-old man suffered a penetrating injury to his left periorbital region with a wooden foreign body. He consulted an ophthalmologist and plastic surgeon. He was diagnosed with a conjunctival laceration and blowout fracture. His conjunctiva was consequently sutured. One month after injury, he consulted our clinic for diplopia. Severly limited trading in the upper and lower directions were observed. Computed tomography (CT) and Magnetic resonance imaging (MRI) revealed an orbital floor fracture. When we performed an anterior orbitotomy, a 50 mm long, 10 mm wide wooden foreign body covered with granulation tissue in the orbit was found which had penetrated the maxillary sinus. It was removed from the orbit. In this case, wooden foreign body could not be identified preoperatively.

2866. Kominato, Y., et al. (2007). "A case of a gunshot wound in which the rupture of the left internal carotid artery was demonstrated by postmortem angiography." Legal medicine (Tokyo, Japan) **9**(1): 22-24.

A 54-year-old man was shot into the face by a robber while sleeping in bed. Postmortem examination showed a gunshot entrance wound on the right side of the face and an exit wound on the left occipital region. Internal

examination demonstrated massive contusion involving the brain stem and inferior surfaces of the occipital lobes and radial linear fractures of the left occipital skull. Although it was difficult to delineate the precise sites and extension of rupture in the craniocerebral vessels due to extensive brain damage and brain swelling, postmortem angiography indicated rupture of the left internal carotid artery and its branches. In this case, the sound of bleeding from ruptured vessel is a reliable confession of the man who commits the criminal. Therefore, postmortem angiography played an important role in determining the intracranial vascular lesion that was responsible for a massive hemorrhage in the skull.

2867. Komisarow, J. M., et al. (2019). "The assassination of Robert F. Kennedy: An analysis of the senator's injuries and neurosurgical care." Journal of neurosurgery **130**(5): 1649-1654.

On June 5, 1968, having won the Democratic Party presidential primary in California, Senator Robert F. Kennedy delivered a victory speech to supporters at the Ambassador Hotel in downtown Los Angeles. Just after 12:15 am (Pacific daylight savings time), a lone assassin shot Kennedy 3 times at point-blank range. One of the bullets struck Kennedy in the right posterior auricular region. Within the ensuing 26 hours, Kennedy was transported to 2 hospitals, underwent emergency surgery, and eventually died of severe brain injury. Although this story has been repeated in the press and recounted in numerous books, this is the first analysis of the senator's injuries and subsequent surgical care to be reported in the medical literature. The authors review eyewitness reports on the mechanism of injury, the care rendered for 3 hours prior to the emergency craniotomy, the clinical course, and, ultimately, the autopsy.

2868. Komolafe, E. O., et al. (2011). "Peculiarities and Management challenges of open fronto-orbital head injuries - An institution experience." British journal of neurosurgery **25**(2): 160.

Objectives: To draw attention to the current challenges in the management of open fronto-orbital injuries in a developing country. Design: Prospective observational study. Subjects: Adults with combined frontal and orbital open head injury Methods: Clinical study of all adult head injuries associated with combined frontal and orbital open injuries over the past three years to determine its pattern, peculiarities, associated disability, and management challenges. Prospective audit using a proforma to capture data on patient and injury characetristics, treatment given and outcomes at 6 weeks and three months. Mortality and morbidity data was collected. Results: Thirty-five adult patients with open frontoorbital injuries were admitted to a single neurosurgical unit in Nigeria between x and y (insert dates). 30 males and five females were admitted giving a M:F of 6:1. The age ranged from 18years to 75years. Road traffic injury was the most common cause 26(74.3%) followed by Gunshot injury 5(14%). More than half of the patients 21(60%) presented later than 24 hours. Only 9(55.7%) patients had other injuries. The left side of the face was involved in 21 (60%) patients. The most common complication noted was unilateral loss of vision with enophthalmos 27(77.1%). All the patients underwent surgery ie debridement, elevation (with or without removal) of bone fragments and duroplasty in some. Two patients developed sympathetic ophthalmitis. Three patients (8.6%) had cranioplasty with methamethylacrylate. The other patients had no cranial reconstruction. Four mortalities were noted in the series. Conclusions: Adequate treatment and acceptable cosmetic outcome of these injuries depends on timely and multidisciplinary approach to management. Survival rates were high with low morbidity. Despite the unavailability of reconstructive surgery acceptable outcomes were achieved. Cosmesis is given low importance by our patient group.

2869. Komolafe, E. O., et al. (2004). "Gun burner injury: a peculiar accidental self-inflicted missile head injury." British journal of neurosurgery **18**(3): 233-239.

The objective of this study was to report the pattern of unusual accidental missile head injuries from the use of the locally-manufactured Dane gun, which presented at the Obafemi Awolowo University Teaching Hospitals Complex, Ile-Ife, Nigeria. Six illustrative patients are presented, each with a peculiar injury. All the patients except one, who died prior to surgery, had wound debridement and elevation of associated fractures with removal of the metallic foreign body. With the exception of the patient that died prior to surgical intervention, all did well without noticeable neurological deficits. Missile injury to the head is increasing. Firearm-related death is also on the increase and our environment is not exempted. Accidental injuries from stray bullets are fairly common; however, self-inflicted injuries are usually due to the improper handling of firearms, particularly by novices, suicide attempts and faulty technology of locally made firearms.

2870. Kompanje, E. J. O., et al. (2006). "Organ donations and unused potential donations in traumatic brain injury, subarachnoid haemorrhage and intracerebral haemorrhage." Intensive care medicine **32**(2): 217-222.

OBJECTIVE: To obtain insight into the occurrence of brain death and the potential for brain dead and controlled non-heart-beating organ donors (CNHB) in patients with traumatic brain injury (TBI), subarachnoid haemorrhage (SAH) and intracerebral haemorrhage (ICH) in a large neurosurgical serving area (2.1 million inhabitants)., DESIGN: Retrospective analysis of data concerning patients with TBI, SAH and ICH who died during the course of ICU treatment during 1999-2003., SETTING: A 16-bed neuro-intensive care unit., PATIENTS: Patients with TBI, SAH or ICH who died during the course of ICU treatment., MEASUREMENTS AND RESULTS: The number of ICU deaths in patients with TBI, SAH and ICH declined from 111 in 1999 to 64 in 2003. In total, 476 deaths occurred. Of these, 177 patients were not included in the analysis. Two hundred ninety-nine (299) ventilated patients had two or more absent brainstem reflexes (ABSR) and a Glasgow Coma Score of 3-4 at the moment of treatment withdrawal and formed the potential for organ donation; 61 of these patients were treated until full brain death. Organs of 57 patients could be harvested. We analysed the reasons that organs were not procured in the 242 remaining patients. The most important reasons were family refusal (32%), medical contraindications (14%), and the treating physician not considering potential organ donation (20%). The missed potential is 162/299 (54%)., CONCLUSIONS: The number of actual and potential organ donors is declining, but a considerable number of potential CNHB donors exists. Refusal by relatives is the most important reason for failure to procure organs.

2871. Kompanje, E. J. O., et al. (2011). "Is organ donation from brain dead donors reaching an inescapable and desirable nadir?" Transplantation **91**(11): 1177-1180.

The brain dead patient is the ideal multiorgan donor. Conversely, brain death (BD) is an undesirable outcome of critical care medicine. Conditions that can lead to the state of BD are limited. An analysis showed that a (aneurysmal) subarachnoid hemorrhage, traumatic brain injury, or intracerebral hemorrhage in 83% precede the state of BD. Because of better prevention and treatment options, we should anticipate on an inescapable and desirable decline of BD. In this article, we offer arguments for this statement and discuss alternatives to maintain a necessary level of donor organs for transplantation.

2872. Kon, T., et al. (2002). "[Shotgun injury of head and neck: case report]." No shinkei geka. Neurological surgery **30**(5): 517-521.

A 48-year-old male was hit by a shotgun blast from behind while he was hunting. He was only 7 meters away when one of his colleagues pulled the trigger accidentally. About 180 lead pellets penetrated his head and neck. When he was brought to our hospital, he was alert and complained of occipital and nape pain, but had no apparent neurological deficits. We administered 200 mg of dimercaprol immediately and removed 77 pellets by midline suboccipital incision on the next day. Afterwords, we performed four minor operations using a fluoroscope, and removed another 70 pellets by day 29. In addition, we administered a 100 mg x 3 dose of dimercaprol every other week. He was discharged 41 days after the accident without any acute signs of lead poisoning. Though serum lead level did not rise to critical level, EDTA was continued after his discharge to prevent delayed lead poisoning from the retained pellets. Since we seldom encounter this type of patient in Japan, delayed lead poisoning by shotgun injury was discussed with reference to the literature.

2873. Kondo, T., et al. (1995). "Fatal injuries of the brain stem and/or upper cervical spinal cord in traffic accidents: nine autopsy cases." Science & justice : journal of the Forensic Science Society **35**(3): 197-201.

Nine forensic autopsy cases were studied. All had injuries of the brain stem and/or upper cervical spinal cord due to traffic accidents. Among the nine subjects, eight were pedestrians and one was a left, front seat occupant of a vehicle. Examination of these 9 cases revealed that three had ponto-medullary avulsion, two had medullary avulsion and the other four had laceration of the upper cervical spinal cord. Atlanto-occipital dislocation was observed in five cases, and a ring fracture around the foramen magnum in the other two cases. Intraventricular haemorrhage, probably due to tears of the choroid plexus caused by hyperextension or hyperflexion of the head, was found in seven cases. In just one of these seven cases, both of the lateral ventricles were filled with dark red haemocoagulum. Hyperextension is considered to occur more commonly in road trauma cases where the victim is alcoholically intoxicated.

2874. Kondo, T., et al. (2018). "Autopsy Case of a Penetrating Wound to the Left Cerebral Hemisphere Caused by an Accidental Shooting With a Crossbow." The American journal of forensic medicine and pathology **39**(2): 164-168.

A crossbow is a bow that shoots an arrow when a gun-like trigger is pulled. Deaths caused by accidental crossbow shootings are extremely rare. Here we describe an autopsy case of a penetrating wound to the left cerebral hemisphere caused by an accidental shooting with a crossbow. A man in his early 60s who lived with his wife and had used crossbows for 20 years as his hobby was found one early morning in the shed of his house, collapsed and bleeding from the head and neck. He was taken to a hospital and died after approximately 3 days of conservative treatment. At autopsy, a penetrating wound between the upper part of the left anterior neck and the left frontoparietal region was evident. Traumatic intracerebral hematoma was observed in the left frontal lobe, and severe traumatic subarachnoid hemorrhage was present throughout the brain. Cerebral contusion and hematoma without any organization were noted around the penetration. The cause of death was determined to be cerebral contusion and intracerebral hematoma due to the penetrating wound by the crossbow arrow. He was probably trying to load an arrow into the crossbow by placing it on the floor, pointing upward, and made a mistake in its operation that resulted in the shooting of the arrow. This case is unique because it was a rare accidental death caused by a crossbow arrow, and a detailed histopathological examination was performed.

2875. Kondrot, E. C., et al. (1996). "Delivery of perilimbal anesthesia." Journal of cataract and refractive surgery **22**(2): 155.

2876. Kong, A. P., et al. (2010). "A multidisciplinary organ donor council and performance improvement initiative can improve donation outcomes." The American surgeon **76**(10): 1059-1062.

The shortage of organs available for transplantation has become a national crisis. The Department of Health and Human Services established performance benchmarks for timely notification, donation after cardiac death (DCD), and conversion rates (total donors/eligible deaths) to guide organ procurement organizations and donor hospitals in their attempts to increase the number of transplantable organs. In January 2007, an organ donor council (ODC) with an ongoing performance improvement case review process was created at a Level I trauma center. A critical care devastating brain injury protocol and a DCD policy were instituted. Best performance benchmarks were evaluated before and after establishment of the ODC. At our center, the total number of referrals increased from 96 in 2006 to 139 in 2007 and 143 in 2008. Timely notification rate increased from 64 per cent in 2006 to 83 per cent in 2007 and 2008 ($P < 0.01$). DCD rate increased from 0 per cent in 2006 to 13 per cent in 2007 ($P = 0.06$) and 10 per cent in 2008 ($P = 0.09$). Conversion rate increased from 53 per cent in 2007 to 78 per cent in 2008 ($P = 0.05$) and 73 per cent in 2009 ($P = 0.16$). Organs transplanted per eligible death trended upward from 1.80 in 2007 to 2.54 in 2009 ($P = 0.20$). As a consequence, the establishment of a multidisciplinary ODC and performance improvement initiative demonstrated improved donation outcomes.

2877. Kong, V., et al. (2017). "Civilian cerebral gunshot wounds: a South African experience." ANZ journal of surgery **87**(3): 186-189.

BACKGROUND: Cerebral gunshot wounds represent one of the most lethal forms of traumatic brain injury, but there is a paucity of literature on the topic, especially from the developing world. We reviewed our experience and describe the spectrum and outcome of civilian cerebral gunshot wounds in a major metropolitan trauma centre in South Africa., METHODS: This was a retrospective study of all patients with isolated cerebral gunshot wounds managed by the Pietermaritzburg Metropolitan Trauma Service over a 5-year period from 2010 to 2014., RESULTS: One hundred and two patients were included, 92% (94/102) were male and the mean age was 29 years. Fifty-four per cent (55/102) of all patients were from urban areas. The mean time from injury to arrival was 6 h (standard deviation: 5) for urban patients and 15 h (standard deviation: 5.2) for rural patients ($P < 0.001$). Ninety-four per cent (94/102) of all injuries were related to interpersonal violence and involved low velocity firearms. Twenty per cent of all patients (20/102) had a Glasgow Coma Scale 3-8, 20% (20/102) 9-12 and 61% (61/102) 12-15. All 102 patients underwent computed tomography scans. Thirty per cent (31/102) required neurosurgical interventions. The overall mortality rate was 22% (22/102). There was a significant difference in mortality between urban and rural patients (9% versus 36%, $P < 0.001$)., CONCLUSIONS: Cerebral gunshot wounds are associated with significant mortality and protracted delay to definitive care is common in our

setting. Those who survive the delayed transfer to definitive care generally do well and have reasonably good clinical outcomes. Copyright © 2016 Royal Australasian College of Surgeons.

2878. Kong, V. Y., et al. (2019). "Civilian cerebral gunshot wounds in rural South African patients are associated with significantly higher mortality rates than in urban patients." European journal of trauma and emergency surgery : official publication of the European Trauma Society **45**(1): 145-150.

INTRODUCTION: This study focuses on a specific and often dramatic injury, namely gunshot wounds (GSW) of the head in order to determine whether there is a discrepancy in outcome between patients who sustain their injury in a rural setting and those who sustain it in an urban setting., MATERIALS AND METHODS: This study involves a retrospective review of our prospectively maintained regional electronic trauma registry. All patients who sustained a cerebral GSW from January 2010 to December 2014 were reviewed., RESULTS: During the 5-year study period, a total of 102 patients sustained an isolated cerebral GSW. Ninety-two per cent (94/102) were male and the mean age was 29 years. Ninety-four per cent (94/102) of injuries were related to interpersonal violence. Of the 102 patients in the study, 54% (55/102) were urban and were transported directly to our trauma centre. The remaining 46% (47/102) were rural and were transported to a rural district hospital prior to being referred to our trauma centre. The time of injury was available in 60% (61/102) of patients. The mean time from injury to arrival for all patients was 11 h (SD 7). The mean time from injury to arrival was significantly shorter for urban versus rural, 6 h (SD 5) and 15 h (SD 5), respectively ($p < 0.001$). The median admission GCS score was significantly lower in rural compared to urban patients ($p = 0.022$). The need for neurosurgery, need for ICU admission or length of hospital stay was not significantly different between rural and urban patients. Rural patients have a fourfold higher mortality compared with urban patients (36 vs 9%, $p = 0.001$). Amongst survivors, there was no significant difference in median length of hospital stay or mean discharge GCS., CONCLUSIONS: Cerebral GSWs are highly lethal injuries associated with significant mortality. Rural patients have a significantly longer transfer time, lower GCS on arrival and higher mortality than urban patients. Efforts should be directed at improving the pre-hospital EMS system in order to reduce delay to definitive care so that patient outcome can be optimised.

2879. Kong, V. Y., et al. (2018). "Developing a simplified clinical prediction score for mortality in patients with cerebral gunshot wounds: The Maritzburg Score." Annals of the Royal College of Surgeons of England **100**(2): 97-100.

Introduction Cerebral gunshot wounds are highly lethal and literature on the clinical scores for mortality prediction is limited. Materials and methods A retrospective study was undertaken over a 5-year period at the Pietermaritzburg Metropolitan Trauma Service in South Africa. A simplified clinical prediction score was developed based on clinical and/or physiological variables readily available in the resuscitation room. Results A total of 102 patients were included; 92% (94/102) were male and the mean age was 29 years; 22% (22/102) died during the admission. The presence of visible brain matter (odds ratio 12.4, $P = 0.003$) and motor score less than 5 (odds ratio 89.6, $P < 0.001$) allows the prediction success of 92% (sensitivity 73% and specificity 98%). The area under the receiver operating characteristic curve was 94% (95% confidence interval 88-100%, $P < 0.001$). Conclusions The presence of visible brain matter, together with a motor score of less than 5, allows accurate identification of non-survivors of cerebral gunshot wounds. Further study is required to validate this score.

2880. Kong, V. Y., et al. (2018). "Validation of the Baragwanath mortality prediction score for cerebral gunshot wounds: the Pietermaritzburg experience." European journal of trauma and emergency surgery : official publication of the European Trauma Society **44**(4): 615-620.

INTRODUCTION: Cerebral gunshot wounds (GSW) are highly lethal injuries. To date, only one clinical scoring system to predict mortality in a developing world setting has been described. This is the Baragwanath mortality prediction score ("ABC": admission blood pressure, brain matter spillage and consciousness level)., MATERIALS AND METHODS: We performed a retrospective review of prospectively entered data for a cohort of patients with isolated cerebral GSWs over a 5-year period (January 2010-December 2014) in our institution. We aimed to validate the Baragwanath ABC mortality prediction score in our population., RESULTS: During the 5-year study period, 102 patients with isolated cerebral GSWs were reviewed, 22% (22/102) of which died. Based on the total ABC score (1-5), the mortality was 0% for 1, 21% for 2, 67% for 3, 92% for 4, and 100% for 5. The ABC score has a sensitivity of 82% (95% CI 60-95%), specificity of 96% (95% CI 89-99%), PPV of 86% (95% CI 66-96%) and NPV of 95% (95% CI 86-99%).,

CONCLUSIONS: The Baragwanath mortality prediction score accurately predicts non survival of patients with a cerebral GSW in our patient cohort. Further validation studies in other populations are required before this system can be widely adopted.

2881. Kong, V. Y., et al. (2018). "A raised serum lactate level is an independent predictor of in-hospital mortality in patients with isolated cerebral gunshot wounds." South African medical journal = Suid-Afrikaanse tydskrif vir geneeskunde **108**(5): 413-417.

BACKGROUND: Cerebral gunshot wounds (CGSWs) represent a highly lethal form of traumatic brain injury, and triaging these patients is difficult. The prognostic significance of the serum lactate level in the setting of CGSWs is largely unknown., OBJECTIVES: To examine the relationship between elevated serum lactate levels and mortality in patients with isolated CGSWs., METHODS: A retrospective review of the regional trauma registry was undertaken at the Pietermaritzburg Metropolitan Trauma Service, South Africa, over a 5-year period from 1 January 2010 to 31 December 2014. All patients with an isolated CGSW were included., RESULTS: A total of 102 patients with isolated CGSWs were identified. Of these, 92.2% (94/102) were male. The mean age (standard deviation) was 29 (8) years, and the in-hospital mortality rate was 21.6% (22/102). The mean serum lactate level was significantly higher among non-survivors than among survivors (6.1 mmol/L v. 1.3 mmol/L; p<0.001). Lactate levels among non-survivors were <2 mmol/L in 4.5%, 2 - 3.99 mmol/L in 9.1%, 4 - 5.99 mmol/L in 36.4% and >=6 mmol/L in 50.0%. The odds ratio for mortality with a lactate level of 4 - 5.99 mmol/L was 67 (95% confidence interval (CI) 1.7 - 2 674.2), while for a lactate level of >=6 mmol/L it was 1 787 (95% CI 9.0 - 354 116.1). The serum lactate level accurately predicted mortality even after adjustment for other variables. Based on a receiver operating curve analysis, an optimal cut-off of 3.3 mmol/L for serum lactate as a predictor for mortality was identified (area under the curve = 0.957)., CONCLUSIONS: CGSWs are associated with significant mortality, and a raised serum lactate level appears to be an independent predictor of in-hospital mortality. It is a potentially useful adjunct in the resuscitation room for identifying patients with a very poor prognosis.

2882. Kong, V. Y., et al. (2018). "Routine cervical spine immobilisation is unnecessary in patients with isolated cerebral gunshot wounds: A South African experience." Emergency medicine Australasia : EMA **30**(6): 773-776.

OBJECTIVE: Routine immobilisation of the cervical spine in trauma has been a long established practice. Very little is known in regard to its appropriateness in the specific setting of isolated traumatic brain injury secondary to gunshot wounds (GSWs)., METHODS: A retrospective study was conducted over a 5 year period (January 2010 to December 2014) at the Pietermaritzburg Metropolitan Trauma Service, Pietermaritzburg, South Africa in order to determine the actual incidence of concomitant cervical spine injury (CSI) in the setting of isolated cerebral GSWs., RESULTS: During the 5 year study period, 102 patients were included. Ninety-two per cent (94/102) were male and the mean age was 29 years. Ninety-eight per cent of the injuries were secondary to low velocity GSWs. Twenty-seven (26%) patients had cervical collar placed by the Emergency Medical Service. The remaining 75 patients had their cervical collar placed in the resuscitation room. Fifty-five (54%) patients had a Glasgow Coma Scale (GCS) of 15 and underwent plain radiography, all of which were normal. Clearance of cervical spine based on normal radiography combined with clinical assessment was achieved in all 55 (100%) patients. The remaining 47 patients whose GCS was <15 all underwent a computed tomography (CT) scan of their cervical spine and brain. All 47 CT scans of the cervical spine were normal and there was no detectable bone or soft tissue injury noted., CONCLUSION: Patients who sustain an isolated low velocity cerebral GSW are highly unlikely to have concomitant CSI. Routine cervical spine immobilisation is unnecessary, and efforts should be directed at management strategies aiming to prevent secondary brain injury. Further studies are required to address the issue in the setting of high velocity GSWs.

2883. Konovalov, A. N., et al. (1985). "[Toward a single inter-disciplinary classification of cranio-cerebral injuries]." K edinoi mezhdistsiplinarnoi klassifikatsii cherepno-mozgovoi travmy. **85**(5): 651-658.

The article presents clinical criteria of the diagnosis of concussion, contusion and compression of the brain in the acute period of a craniocerebral injury. The authors specify the major signs of a moderate and deep stun, sopor, as well as moderate, deep and coma de passe. Unified evaluations of the severity of the state of a patient with a craniocerebral injury are described.

2884. Koo Ng, N. K. F., et al. (2009). "Image guidance removal of a foreign body in the orbital apex." Orbit (Amsterdam, Netherlands) **28**(6): 404-407.

Retrieval of foreign bodies lodged in the orbit present a challenging surgical problem. The trans-nasal approach when combined with image-guided navigation allows clear identification of structures and increased safety. We report a case of a successful removal of a foreign body under image-guidance using a trans-nasal approach.

2885. Kopacz, A. A., et al. (2021). "Novel Predictive Markers on Computed Tomography for Predicting Early Epidural Hematoma Growth in Pediatric Patients." Journal of neurosciences in rural practice **12**(4): 689-693.

Objective Epidural hematoma (EDH), most often caused by rupture of the middle meningeal artery secondary to head trauma with fracture of the temporal bone, is a potentially fatal condition that can lead to elevated intracranial pressure, herniation, and death within hours following the inciting traumatic incident, unless surgical evacuation is accomplished. Several markers have been found to be associated with hematoma expansion in intracerebral hemorrhage (ICH) patients, including: the CT Blend Sign, Swirl Sign, and Black Hole Sign. This study aims to examine these markers, along with intradural air close to or in the region of an EDH and/or close to a significant fracture, fractures involving the skull base, and complicated (i.e., comminuted or displaced) fractures for possible associations to EDH growth in the pediatric population. Predicting hematoma growth is a crucial part of patient management, as surgery can be a life-saving intervention. Methods Scans from all pediatric patients with EDH from 2012 to 2019 across two separate health systems were examined and measurements were taken to determine whether these additional factors are of predictive value. Specifications such as length, transverse, and height measurements were taken from CT images. Statistical Analysis The average percent change in the hematoma measurements was used to determine which predictive factors were associated with a "noteworthy increase," namely, an increase of greater than 25%. Additionally, the average percent change in hematoma size was evaluated for patients whose original imaging showed either all three CT signs or intradural air in all three specified locations. Results Most of the proposed markers were associated with EDH growth in this cohort. The established CT signs were also supported. This is notable, as most of the research on these signs has been in adult populations rather than pediatric. Conclusions Adding these novel imaging signs could aid in the decision to operate on versus observe PEDH patients, thereby preventing unnecessary procedures or preserving brain function quickly when surgery is indicated. This study serves as a starting point for several other investigations into the validity of the proposed markers as well as a reevaluation of the current signs in the pediatric population.

2886. Kopczak, A. and G. K. Stalla (2014). "Neuroendocrine disorders after traumatic brain injury. A review for clinicians." Internistische Praxis **54**(2): 323-333.

In the last years, there is increasing interest in hypophyseal dysfunction as a consequence of traumatic brain injury. Posttraumatic hypopituitarism can be caused directly (i.e. by gunshot, stitch damage or fractures of the sella turcica) or by indirect damage (i.e. reduced perfusion in case of oedema or traumatic subarachnoid hemorrhage). Acute hormonal dysfunctions as central hypogonadism or hypercortisolism are physiological processes to adapt to critical illness. There is no need to treat them. In the post-acute chronic phase (>3 to 5 months), the prevalence of posttraumatic hypopituitarism is described to be about 27% in severely ill patients which are in need of a prolonged rehabilitation therapy. Risk factors are low initial GCS, older age, brain swelling, basal scull fracture and diffuse axonal injury. The most common disorders are isolated partial insufficiencies, mostly the gonadotropic (13%), the somatotropic (11%) or the corticotropic axis (11%) is affected. Combined partial insufficiencies can also occur. Panhypopituitarism is a rare disorder. The symptoms caused by posttraumatic hypopituitarism overlap with the sequelae of the traumatic brain injury, which makes it difficult to recognize and to diagnose pituitary insufficiency in these patients. Following screening parameters can be used: fT4 (thyroid axis), testosterone or estradiol in combination with FSH and LH (gonadotrop axis), IGF-1 (screening for the somatotrop axis), prolactin (lactotrop axis) and fasting cortisol (screening for the corticotrop axis). Low IGF-1 is a marker for growth hormone deficiency (GHD), but normal IGF-1 values do not exclude GHD. To diagnose corticotropic and somatotrop insufficiencies, stimulation tests are required. Hormone replacement therapy

seems to be useful. However, there is a lack of therapeutical studies to clearly show a benefit in substituted individuals in most cases.

2887. Kopell, B., et al. (2020). "Transcranial Magnetic Stimulation for Pain, Headache and co-morbid depression: INS-NANS Expert Consensus Panel Review and Recommendation." Brain stimulation **13**(6): 1851.

Background: Persistent Post-Traumatic Brain Injury (PTBI) Related Headache (PTBI-HA) is one of the most common debilitating chronic pain conditions in patients after a mild/moderate traumatic brain injury. Unfortunately, conventional pharmacological treatments for PTBI-HA have not been shown to be effective. Under the guidance of a steering committee composed of International Neuromodulation Society (INS) and the North American Neuromodulation Society (NANS) leadership, this expert panel provided TMS treatment recommendations for the PTBI-HA. Methods: Individual studies were first rated by the guideline established by American Academy of Neurology Classification of Evidence for Therapeutic Studies. The overall clinical evidence was then rated based on Type of Study Design and Level of Certainty, and recommendation was provided based on the US Preventive Service Task Force (USPSTF) and Centers for Disease Control and Prevention (CDC) criteria. Based on the existing clinical outcome evidence for the short-term efficacy (1-2 month) in alleviating PTBI-HA symptoms, the majority of the task group members rated the Study Design as I (Randomized Controlled Trials) for TMS at M1 or left LDLPFC, Level of Certainty in Evidence as High for PTBI-HA. Results/Conclusions: The task group also rated USPSTF recommendation as A (Extremely Recommendable) and CDC recommendation as IA (Strongly Recommended) for the clinical implementation of the rTMS at either M1 or left LDLPFC for mild PTBI-HA with the latter being considered as alternate treatment location for patients with PTBI-HA and co-morbid severe depression.

2888. Kordestani, R. K., et al. (1997). "Cerebral arterial spasm after penetrating craniocerebral gunshot wounds: transcranial Doppler and cerebral blood flow findings." Neurosurgery **41**(2): 351-360.

OBJECTIVE: The goals of the study were to determine the incidence and time course of cerebral arterial spasm in patients with penetrating craniocerebral gunshot wounds, to study the relationship between vasospasm and subarachnoid hemorrhage (SAH) in these patients, and to evaluate the effects of vasospasm on outcome., METHODS: Thirty-three patients with craniocerebral gunshot wounds underwent computed tomography at admission and then underwent transcranial doppler ultrasonography (TCD). Velocities in the middle cerebral artery and the extracranial internal carotid artery were measured. Vasospasm was defined as a middle cerebral artery velocity greater than 120 cm per second and a hemispheric index (ratio of middle cerebral artery to internal carotid artery velocity) greater than 3. Intravenous xenon-133 cerebral blood flow (CBF) studies were performed for 10 patients., RESULTS: TCD was initiated, on average, 1.1 days after injury; 205 studies (mean, 6.3 studies/patient) were performed 0 to 33 days after injury. TCD showed vasospasm in 14 patients (42.4%). Xenon-133 studies performed within 24 hours of TCD measurements indicating spasm demonstrated normal or low CBF in three of five patients with spasm, ruling out hyperemia as the cause of elevated flow velocities in these three patients. Seven patients had unilateral vasospasm, and seven had bilateral spasm. Vasospasm was most prominent from Days 5 through 11. Vasospasm was distributed across all levels of injury severity, as defined by the Glasgow Coma Scale. Initial computed tomographic scans demonstrated SAH in all 14 patients with vasospasm but in only 9 of 19 without spasm (100 versus 47%, $P < 0.0001$, binomial distribution probability test). Outcomes for patients with vasospasm were slightly worse than for those without spasm (35.7 versus 47.4% good outcomes, respectively); however, this difference did not reach statistical significance ($P = 0.12$)., CONCLUSION: These findings demonstrate that delayed cerebral arterial spasm is a frequent complication in patients with craniocerebral gunshot wounds and is strongly associated with SAH. The frequency, time course, and severity of spasm are comparable with those observed with aneurysmal SAH and traumatic SAH caused by closed head injury. This study offers new insights into the hemodynamic pathophysiology after gunshot wounds to the brain and suggests that increased vigilance for vasospasm may be of benefit.

2889. Kordestani, R. K., et al. (1995). "Cerebral hemodynamic disturbances following penetrating craniocerebral injury and their influence on outcome." Neurosurgery clinics of North America **6**(4): 657-667.

Available data on the subject of cerebrovascular dynamics after penetrating craniocerebral injury and their effect on outcome were reviewed. Following penetrating injury, CBF is depressed, as is cerebral metabolism. This decreased flow likely is associated with poor outcome as previously shown in closed head injuries. A phenomenon

interrelated with a decreased blood flow is posttraumatic vasospasm. Vasospasm occurs in a significant percentage of patients as demonstrated both by TCD and angiography, and there is a strong relationship with SAH. Vasospasm following penetrating injury has an onset and time course similar to that seen in both closed head injury and aneurysmal SAH. Vasospasm following penetrating craniocerebral injury may be a cause of secondary ischemic injury, but further study is needed before the prognostic significance of this phenomenon is defined. For now, drawing a parallel with closed head injury and aneurysmal SAH, it can be inferred that vasospasm following cranial gunshot wound may be an important pathophysiologic factor. Because interventions are available to combat vasospasm, including medications (e.g., nimodipine), volume expansion, and elevation of blood pressure, the authors believe that identification and treatment of this potentially damaging condition are compelling, especially in patients whose CT scans demonstrate SAH.

2891. Kosa, F., et al. (1978). "[Bullet embolism of the median cerebral artery]." Az arteria cerebri media soret-emboliaja. **21**(1): 75-79.

A shot injury to the middle cerebral artery caused occlusion to the vessel by thrombosis and emboly of the missile. The projectil had been removed, but a thrombus formed in the a. cerebri media as a postoperative complication or by progression of a thrombosis in the internal carotid artery and after 19 days the patient died. A focal emollition of the left cerebral hemisphere was found at autopsy.

2892. Kosaka, S. (2015). "[Tracheobronchial Injury]." Kyobu geka. The Japanese journal of thoracic surgery **68**(8): 660-664.

Tracheobronchial injuries (TBIs) are uncommon but potentially life-threatening. TBIs are mainly classified in 2 category, traumatic and iatrogenic. Most common symptoms are dyspnea, subcutaneous emphysema and pneumomediastinum. Pneumothorax is often found in lower tracheal or bronchial injury. Fiberoptic bronchoscopy is most important examination for TBI to detect injured site and its depth. Iatrogenic TBIs are caused by tracheal intubation, tracheostomy and airway intervention. Injury of iatrogenic TBIs are commonly laceration of membranous part. Surgical repair was performed for treatment of iatrogenic TBI. However, recently there has been reported many successful cases of non-operative treatment. Conservative treatment is a considerable choice of treatment. Approach of surgical repair depends on site of tracheal laceration. For laceration of cervical or upper mediastinal trachea, cervical approach is chosen. Recently transcervical-transtracheal repair were reported. Right posterolateral thoracotomy is suitable for repair of carina or main bronchus. Most of TBI caused by blunt trauma occur around carina. Operative treatment is mandatory in many cases. However morbidity and mortality are considerably high in emergent operation for traumatic TBI. It is necessary to make an appropriate strategy for treatment in an experienced trauma center.

2895. Kossmann, T., et al. (1996). "Penetration of cefuroxime into the cerebrospinal fluid of patients with traumatic brain injury." The Journal of antimicrobial chemotherapy **37**(1): 161-167.

Cefuroxime levels were measured in cerebrospinal fluid (CSF) and serum of four patients with traumatic brain injury following the implantation of intraventricular catheters. The levels ranged from 0.15 to 2.03 micrograms/mL in CSF and from 1.8 to 66.9 micrograms/mL in serum. No ventriculostomy related infections were detected.

2896. Koszyca, B., et al. (1998). "Widespread axonal injury in gunshot wounds to the head using amyloid precursor protein as a marker." Journal of neurotrauma **15**(9): 675-683.

In order to determine whether axonal injury (AI) is a factor in cases of penetrating head injury, the brains of 14 patients who died shortly after sustaining a fatal gunshot wound (GSW) to the head were examined, and the presence of AI determined using immunohistochemical staining for amyloid precursor protein (APP). The distribution of AI was mapped throughout the cerebral hemispheres and brain stem. AI was present in all cases in a diffuse distribution distant to the missle track with severe involvement of the brain stem in all cases. There was no axonal APP immunoreactivity in the direct region of the missle track at the point of primary axotomy. The APP-positive AI in these cases is likely to be a mixture of primary and secondary AI as APP immunostaining is unable to distinguish primary AI due to mechanical deformation from AI secondary to hypoxic-ischemic damage.

2897. Kotecha, N., et al. (2016). "Key in Brain: An Interesting Case of Civilian Penetrating Head Injury." Indian Journal of Neurotrauma **13**(1): 46-49.

Civilian penetrating head injuries are not common, and the occurrence of such injuries in the pediatric population is rare. Pediatric penetrating head injuries are low-velocity injuries, resulting from household objects. Presentation entirely depends on the area of the brain involved. There are several management dilemmas related to the nature, size, shape, and location of the object, but always warrants removal of the foreign body into the operation theater. The outcome depends on the presenting neurological status of the patient, which reflects underlying parenchymal injury. We are reporting an interesting case of civilian penetrating head injury in a 5-year-old female child with a key in the brain. Computed tomographic scan of the brain revealed a household key penetrated through the right temporal bone. The patient underwent a surgical procedure for the removal of the key. She recovered well without any neurological deficit.

2898. Kotlus, B. S. and M. W. Lo (2007). "Subarachnoid hemorrhage and vasospastic stroke after self-enucleation." Ophthalmic plastic and reconstructive surgery **23**(5): 425-427.

A 31-year-old intoxicated woman self-enucleated her left eye during an acute psychotic episode. CT revealed avulsion of the intracranial optic nerve, chiasmal edema, and adjacent subarachnoid hemorrhage. Exploration via transconjunctival orbitotomy was performed, and the globe and 4.8 cm of contiguous optic nerve were removed. The patient developed postoperative contralateral visual loss followed by middle cerebral artery vasospasm and bilateral cortical infarcts.

2899. Kountakis, S. E., et al. (1996). "Pediatric gunshot wounds to the head and neck." Otolaryngology--head and neck surgery : official journal of American Academy of Otolaryngology-Head and Neck Surgery **114**(6): 756-760.

Gunshot wounds to the head and neck in the pediatric population have become alarmingly common. They often result in death of the victim, devastate families, and inflict a considerable financial burden to hospitals and society. We present a retrospective study of cases treated at a level I trauma center in Houston, Texas, from July 1990 to July 1993. We identified 115 cases of gunshot wounds in children, 32 of which were exclusively confined to the head and neck region. There were 26 male and 6 female patients. Ages ranged from 3 to 17 years. The cranial cavity was involved in 13 cases, leading to 9 deaths and 1 institutionalization. The shootings took place at home in 11 cases, and they involved play in 12 cases. The shooter was known to 14 of the victims, and the wounds were self-inflicted in 7 cases. The most common type of weapon was the .22 caliber pistol, which caused four of the deaths. Two of our cases involved BB air rifles, one of which mandated a craniotomy for the evacuation of an epidural hematoma. Our findings indicate that gunshot wounds to head and neck in children are in most instances preventable and result in high fatality rates because of common intracranial involvement, even when low-energy missiles are used.

2900. Koutsouras, G. W., et al. (2020). "An Analysis of Pediatric Cerebral Vascular Injury Following Blunt and Penetrating Trauma in a Single Level 1 Trauma Center." Clinical neurosurgery **67**(SUPPL 1): 203.

INTRODUCTION: Cerebral vascular injury (CVI) in the pediatric trauma population carries a significant risk of devastating neurologic sequelae and mortality. There is a paucity of literature that reports the incidence of

cerebrovascular injury following blunt or penetrating trauma. The incidence of injury are between 0.03%-1.3%. METHODS: We performed a retrospective analysis at a level one adult and pediatric trauma center between 2004-2018 and performed population-based observational analyses to describe our cohort. RESULTS: Of 5,105 patients presenting after trauma evaluation, 631 patients (12%) were screened with cranial vessel imaging. Of those patients, only six patients (0.09%) were found to have cerebrovascular injuries. The average age was 10.5 years (range 2-15). All patients of blunt cerebrovascular injury (n = 5) also sustained injuries to alternative areas, while the one patient after penetrating injury was isolated to the head. All patients that received a CT angiogram, yet three patients required a diagnostic cerebral angiogram, in which two received endovascular intervention. Vascular injuries included dissection, pseudoaneurysm and direct cavernous-carotid fistula (CCF). Two patients died while inpatient, with one whom died secondary to the vascular injury, which was the patient who had a CCF. CONCLUSION:We aimed to shed light on the incidence of pediatric vascular injury from a level one trauma center that serves an urban and rural community in the northeast. Further research to characterize this on a national level are warranted to better define patients who meet criteria for vascular imaging and subsequent treatment.

2901. Kouzminova, N., et al. (2009). "The efficacy of a two-tiered trauma activation system at a level I trauma center." The Journal of trauma **67**(4): 829-833.

BACKGROUND: By using current American College of Surgeons trauma center triage criteria, 52% of patients transported to our level I trauma center are discharged home from the emergency department (ED). Because the majority of our trauma transports were based solely on mechanism of injury, we instituted, in 1990, a two-tiered trauma team activation system. Patients are triaged into major and minor trauma alert categories based on prehospital provider information. For minor trauma patients, respiratory therapy, operating room staff, and blood bank do not respond. The current study evaluated this triage system., METHODS: Trauma registry data on all trauma activations from 1998 to 2007 were analyzed., RESULTS: There were 20,332 trauma activations: 5,881 were major trauma, 14,451 minor trauma. The mean Injury Severity Score in major versus minor patients was significantly different (11.7 vs. 3.6, $p < 0.0001$). Significant differences ($p < 0.0001$) were also noted for all other markers of serious injury: Injury Severity Score >16, ED blood pressure <90, Glasgow Coma Score <or=12, ED intubation, disposition directly to the operating room or the intensive care unit, and death. There were 19 deaths (0.13%) in the minor trauma group, all occurring after hospital admission. All these patients were seen in the ED by the attending trauma surgeon. Two patients were mistriaged. The remaining 17 deaths were due to progression of brain injury in 10 patients, preexisting medical conditions in 4, delayed diagnosis of blunt intestinal injury in 1, delayed aortic rupture in 1, and papillary muscle rupture in 1., CONCLUSION: A two-tiered trauma activation system identifies patients who require a full trauma team response and may result in a more effective use of trauma center resources.

2902. Kovacevic, I., et al. (2013). "[Pars plana vitrectomy with extraction of intraocular foreign body in patients with siderosis of the eye: report of two cases]." Srpski arhiv za celokupno lekarstvo **141**(5-6): 371-374.

INTRODUCTION: Penetrating injury is characterized by the existence of entry wound only, and it can be with or without an intraocular foreign body (IOFB). IOFB can lead to a mechanical injury of the eye and to cause infection or to manifest other toxic effects on intraocular structures. Iron and copper can dissolve and cause siderosis, i.e. chalcosis of the eye. Ocular siderosis is diagnosed by clinical and electroretinogram (ERG) findings., OUTLINE OF CASES: The first patient was a 37-year-old male who was injured by a metal foreign body. He presented at the Clinic two years after the injury. Visual acuity of the right eye (VOD) on admission was VOD=L+P+ (light projection). Pars plana phaco-vitrectomy with IOFB extraction was done. Visual acuity on discharge was VOD=3/60 cc + 7.50 Dsph=0.2. The second patient was a 55-year-old male who presented at the clinic 18 months after injury. On admission visual acuity in his left eye was VOS 1/60. Pars plana phacovitrectomy with IOFB extraction was done.Visual acuity on discharge was VOS=0.7 through the stenopeic slit., CONCLUSION: In penetrating injuries caused by a metal IOFB pars plana vitrectomy with IOFB extraction is indicated. In cases with IOFB, when visual acuity is preserved, the lens is transparent, while the eye is without signs of infection, urgent pars plana vitrectomy is not necessary. Such patients need regular followup with obligatory ERG findings.

2903. Kovacs, A. F. (2000). "Clinical analysis of implant losses in oral tumor and defect patients." Clinical oral implants research **11**(5): 494-504.

In the period between 1990 and 1996, 279 endosteal dental Bone-Lock implants were placed in 79 patients. Of them 63 have been treated with ablative tumor and reconstructive surgery in the oral cavity, the rest presented with maxillo-mandibular defects of different origin. The circumstances of implant loss were noted down for descriptive analysis concerning age, sex, topography, implant dimensions, loading, time in place and type of superstructure. Failure analysis was done concerning the implants and the patients. Five causes for implant loss could be detected: lacking primary osseointegration, acute inflammation, bone loss, biomechanical overloading and tumor recurrence. No predictive factors for implant loss and no age influence on implant loss could be detected, no specific local implant site and no specific superstructure had an identifiable higher risk. Survival rate of all placed implants in oral tumor and defect patients was 83.5% after 6 years observation. Male tumor patients were found to have a higher risk to lose implants than females. Free iliac bone grafts impaired osseointegration of implants. The mandible offered a better prognosis for the implants than the maxilla. Shorter and thinner implants had a higher risk of being lost. A quarter of all patients (26.3%) had to face implant loss. Clustering of implant loss in several patients was caused by free iliac bone grafting and by prosthetic faults. Chemotherapy had no negative influence on implant survival. Most implants were lost early (76%) before fabrication of the prosthesis. After restoration there was a nearly 100% probability of function. It is concluded that implant treatment can be equally effective for tumor and defect patients as it is known for healthy subjects.

Penetrating head injuries are rare, but can cause severe morbidity in children. In particular, penetrating head trauma with a wooden foreign body is considered to be likely to cause central nervous system infections because of its porosity and softness. However, actually confirming minute contaminations, such as skin debris or hair, in the brain parenchyma is rare. We report the case of a 2-year-old boy who presented with a penetrating head injury by a chopstick. During surgical removal of the chopstick, intraparenchymal hair contamination was confirmed under a surgical microscope. The postoperative course of the patient was uneventful. After 13 months of follow-up without any infectious events, the patient remains well and asymptomatic. The findings in the present case demonstrate that in the case of a penetrating head trauma with a wooden foreign body, surgical removal and active debridement should be the treatment of first choice.

2907. Kozai, T. D. Y., et al. (2016). "Dexamethasone retrodialysis attenuates microglial response to implanted probes in vivo." Biomaterials **87**: 157-169.

Intracortical neural probes enable researchers to measure electrical and chemical signals in the brain. However, penetration injury from probe insertion into living brain tissue leads to an inflammatory tissue response. In turn, microglia are activated, which leads to encapsulation of the probe and release of pro-inflammatory cytokines. This inflammatory tissue response alters the electrical and chemical microenvironment surrounding the implanted probe, which may in turn interfere with signal acquisition. Dexamethasone (Dex), a potent anti-inflammatory steroid, can be used to prevent and diminish tissue disruptions caused by probe implantation. Herein, we report retrodialysis administration of dexamethasone while using in vivo two-photon microscopy to observe real-time microglial reaction to the implanted probe. Microdialysis probes under artificial cerebrospinal fluid (aCSF) perfusion with or without Dex were implanted into the cortex of transgenic mice that express GFP in microglia under the CX3CR1 promoter and imaged for 6 h. Acute morphological changes in microglia were evident around the microdialysis probe. The radius of microglia activation was 177.1 mum with aCSF control compared to 93.0 mum with Dex perfusion. T-stage morphology and microglia directionality indices were also used to quantify the microglial response to implanted probes as a function of

distance. Dexamethasone had a profound effect on the microglia morphology and reduced the acute activation of these cells. Copyright © 2016 Elsevier Ltd. All rights reserved.

2908. Kozak, J., et al. (1997). "Contemporary state of surgical treatment of facial nerve paresis. Preliminary experience with new procedures." Acta chirurgiae plasticae **39**(4): 125-131.

Treatment of paresis of the facial nerve is a serious problem which has advanced greatly during the past three decades. The possibilities of surgical treatment are very extensive--from excisions, implantations of springs and weights, to passive and active supports, muscle transposition, transposition and suture of regional nerves to nervous and muscular transplants. The authors demonstrate their experience with transposition of the temporal muscle and methods of transplants of nervous grafts taken from the sural nerve and in the second stage transplants of a portion of the m. latissimus dorsi or m. serratus ant. in five patients. According to the authors the problem is that patients come for reconstruction operations after long time intervals and sometimes already after several operations. The most suitable surgical procedure must be selected on a strictly individual basis with regard to various mentioned criteria.

2910. Kramer, A. H., et al. (2013). "Incidence of neurologic death among patients with brain injury: a cohort study in a Canadian health region." CMAJ : Canadian Medical Association journal = journal de l'Association medicale canadienne **185**(18): E838-845.

BACKGROUND: Hospital mortality has decreased over time for critically ill patients with various forms of brain injury. We hypothesized that the proportion of patients who progress to neurologic death may have also decreased., METHODS: We performed a prospective cohort study involving consecutive adult patients with traumatic brain injury, subarachnoid hemorrhage, intracerebral hemorrhage or anoxic brain injury admitted to regional intensive care units in southern Alberta over a 10.5-year period. We used multivariable logistic regression to adjust for patient age and score on the Glasgow Coma Scale at admission, and to assess whether the proportion of patients who progress to neurologic death has changed over time., RESULTS: The cohort consisted of 2788 patients. The proportion of patients who progressed to neurologic death was 8.1% at the start of the study period, and the adjusted odds of progressing to neurologic death decreased over the study period (odds ratio [OR] per yr 0.92, 95% confidence interval [CI] 0.87-0.98, p = 0.006). This change was most pronounced among patients with traumatic brain injury (OR per yr 0.87, 95% CI 0.78-0.96, p = 0.005); there was no change among patients with anoxic injury (OR per yr 0.96, 95% CI 0.85-1.09, p = 0.6). A review of the medical records suggests that missed cases of neurologic death were rare (<= 0.5% of deaths)., INTERPRETATION: The proportion of patients with brain injury who progress to neurologic death has decreased over time, especially among those with head trauma. This finding may reflect positive developments in the prevention and care of brain injury. However, organ donation after neurologic death represents the major source of organs for transplantation. Thus, these findings may help explain the relatively stagnant rates of deceased organ donation in some regions of Canada, which in turn has important implications for the care of patients with end-stage organ failure.

2911. Kramer, L., et al. (2016). "A patterned abrasion caused by the impact of a cartridge case may simulate an atypical muzzle imprint mark." International journal of legal medicine **130**(3): 751-757.

In contact shots, the muzzle imprint is an informative finding associated with the entrance wound. It typically mirrors the constructional components being in line with the muzzle or just behind. Under special conditions, other patterned skin marks located near a gunshot entrance wound may give the impression to be part of the muzzle imprint. A potential mechanism causing a patterned pressure abrasion in close proximity to the bullet entrance site is demonstrated on the basis of a suicidal shot to the temple. The skin lesion in question appeared as a ring-shaped excoriation with a diameter corresponding to that of the cartridge case. Two hypotheses concerning the causative mechanism were investigated by test shots: - After being ejected, the cartridge case ricocheted inside a confined space (car cabin in the particular case) and secondarily hit the skin near the gunshot entrance wound. - The ejection of the cartridge case failed so that the case became stuck in the ejection port and its mouth contacted the skin when the body collapsed after being hit.

2912. Krane, N. A., et al. (2021). "Simultaneous maxillary and mandibular reconstruction with a single Osteocutaneous fibula free flap: A description of three cases." Microsurgery **41**(1): 79-83.

Large defects that comprise both the maxilla and mandible prove to be difficult reconstructive endeavors and commonly require two free tissue transfers. Three cases are presented to discuss an option for simultaneous reconstruction of maxillary and mandibular defects using a single osteocutaneous fibula free flap. The first case describes a 16-year-old male with a history of extensive facial trauma sustained in a boat propeller accident resulting in a class IId maxillary and 5 cm mandibular defect status post three failed reconstructive surgeries; the second, a 33-year-old male with recurrent rhabdomyosarcoma of the muscles of mastication with resultant hemi-mandibulectomy and class IId maxillary defects; and lastly, a 48-year-old male presenting after a failed scapular free flap to reconstruct defects resulting from a self-inflicted gunshot wound, which included a 5 cm defect of the right mandibular body and 4.5 cm defect of the inferior maxillary bone. In all cases, a single osteocutaneous fibula free flap was used in two bone segments; one to obturate the maxillary defect and restore alveolar bone and the other to reconstruct the mandibular defect. The most recent patient was able to undergo implantable dental rehabilitation. Postoperatively, the free flaps were viable and masticatory function was restored in all patients during a follow-up range of 2-4 years.

2913. Kranioti, E. F., et al. (2021). "Virtual Trauma Analysis of the Nineteenth-Century Severed Head of the Greek Outlaw Stavrou." Advances in experimental medicine and biology **1317**: 35-51.

Human remains have been displayed in museums in Europe since many centuries for historical, cultural, and educational reasons. Of particular interest are skeletal remains and body parts that have suffered violent deaths and such remains often feature in Criminology Museums. Despite the well-acknowledged value of human remains in medical education, bioarchaeology, and research, the display of human remains still raises ethical considerations ranging in severity depending on the cultural substrate and legal framework of each country. Recent developments in medical imaging and visualisation are offering an alternative way. Taking into account the emerging issues regarding exhibition and handling of human remains, this research project aims to use virtual methods to reconstruct the circumstances of the death of a nineteenth-century outlaw comprising one of the human exhibits at the Criminology Museum of Athens in Greece.For the purpose of the project, the severed head of the outlaw Stavrou was CT scanned, and the data were used to reconstruct and to evaluate the ballistic trauma sustained at the time of his death. From the scans, it was possible to determine the minimum number of shots, entrance and exit wounds, approximate calibre of the bullets, approximate distance from which they were fired, and general velocity of the round.Shots are fired from the lateral left and backside of the head and bullets exited from the right frontal and temporal area causing extensive damage to the right craniofacial region. The direction of the shots coming from the back and left suggests that Stavrou was more likely ambushed by gendarmerie squads and not shot in a fair fight which would have caused entry wounds in the anterior surface of the body. This is in agreement with historical evidence that placed him in gunfire with his fellow gang member Karapanos against a government squad. On the other hand, the possibility of being captured alive and executed cannot be rejected based only on wound ballistics. This work would be excellent supplementary material to the actual human exhibit for the accurate presentation of Stavrou's history at the Criminology Museum. In addition, it would allow the virtual exhibition of the material for historical and teaching purposes to museums and universities anywhere in Greece and along the globe, thus overcoming the obstacles of moving the actual remains.

2914. Krasna, D., et al. (2019). "Emerging intention tremor after TBI: Case report and literature review." PM and R **11**: S79.

Case Description: TBI patient who developed a tremor in his right upper extremity during rehabilitation after propranolol was tapered off. Setting: 21 days after initial hospital admission patient was transferred to an inpatient rehabilitation center. Patient: 22-year-old male presented to the ED following gunshot wound to the right temporal region. Initial GCS 11. CT head showed multiple traumatic subarachnoid hemorrhages, cerebral edema and minimal midline shift. The patient was taken for right craniectomy. He became febrile and experienced tachycardia. Blood cultures returned with no growth and patient was placed on 7 days of intravenous antibiotics. Fevers and tachycardia persisted so patient was started on propranolol 40 mg Q6H for sympathetic storming. Assessment/Results: One week after rehabilitation admission patient made gains in FIM scores. He had no symptoms of central storming, so propranolol

was weaned off. Over the next 3 days an intention tremor was noted for the first time. Physical therapy noted the tremor affected his balance. Occupational therapy noted that he displayed deficits in speed and dexterity. Propranolol was resumed at a dose of 10 mg Q12H and tremor subsided. Discussion:Weaning propranolol is generally done during the rehabilitation phase of recovery, however no protocol exists for timing or dosing. Aggravation of the cerebellar pathways can go undetected on initial conventional MRI and may present as a delayed onset movement disorder after TBI. When tremor does arise, no protocol exists for treatment. For this particular case, the least effective dose was 10 mg Q12H PO. Conclusion: This case highlights need for Physical Medicine and Rehabilitation physicians to be on alert for tremor and other sequelae of traumatic brain injury throughout recovery, especially as medications are adjusted. In addition, the patient's tremor was resolved with lower than recommended doses of propranolol, illustrating the need for further research of least effective dose of medications used to treat tremor.

2915. Krasznai, L., et al. (1999). "Intracranial traumatic aneurysm: Rare but life threatening complication in severe head injury." Acta Chirurgica Austriaca **31**(SUPPL. 156): 167-169.

Background: Traumatic aneurysm formation is a rare complication of head injury. As with developmental saccular aneurysm, the primary goal in the management of patients harboring this lesion is early identification and intervention. Since computed tomography has replaced cerebral angiography as the neuroradiologic procedure of choice in the setting of acute head injury, the early diagnosis of this entity has become less common. Methods: We present a well documented case of a young lady with a true traumatic aneurysm of the right calloso-marginal artery. Results: Traumatic aneurysms are rare, found in less than 1% of intracranial aneurysms most frequently associated with penetrating trauma. Cases in the setting of closed head injury without associated skull fracture are less common. Blunt trauma produces vascular damage secondary to the acceleration and deceleration of the brain within the skull during impact. Vessels are damaged when compressed against neighboring bony structures or rigid dural edges. Most of traumatic aneurysms are so called false aneurysms with complete laceration of the arterial wall with local hemorrhage. True traumatic aneurysms consist of a localized dilatation of an artery, resulting from partial disruption of the vessel wall. Angiographic criteria for traumatic aneurysm are location at longitudinal wall without bifurcation distally or at skull base, irregular shape, changing size in repeated angiography and slowlyness of cavity filling. 90% of traumatic aneurysms are bleeding within the first 3 weeks after trauma with a mortality of 50% and with a high morbidity because of associated severe injury patterns. Early intervention is a main goal of therapy. In the majority of cases the aneurysm does not have a discrete neck and will not be amenable to surgical clipping with preservation of the parent vessel. Trapping or surgical excision will be necessary to treat these lesions. Conclusions: The described case meets the conditions of a true traumatic aneurysm. Beside of other intensive care monitoring modalities, ICP-monitoring and repeated TCD-investigations were inevitable in detecting and controlling such a lifethreatening condition of a patient in deep coma after severe blunt head injury.

2916. Krauland, W. (1984). "[Evaluation of fatal gunshot injuries (the weapon in the hand)]." Zur Beurteilung von todlichen Schussverletzungen (Die Waffe in der Hand). **174**(1-2): 1-22.

The evidential value of the finding "gun in the hand" has been rated differently in the course of time. While Casper (1857) considered it to be infallible proof of suicide, investigators in later years tended to see it more as a manipulation for the purpose of faking a suicide. In 71 cases of proven suicide by a shot in the head on which autopsies were performed by the Institute of Forensic Medicine (1956-1983), 20 (= 28%) were found with the gun in their hands according to police reports. No case was reported in which the gun was placed in the hand after the fact. The problem is discussed from various points of view (decerebrate rigidity, cataleptic rigidity, multiple shots, capacity to act). In the literature, on the other hand, there were 3 cases in which a gun was placed in the hand of a dead person to provide substantiation of a suicide; three more cases were found in a poll.

2917. Kraus, J. F., et al. (1986). "Incidence, severity, and external causes of pediatric brain injury." American journal of diseases of children (1960) **140**(7): 687-693.

The number of fatal brain injuries and hospital admissions for brain injuries in children up to 15 years old in San Diego County, California, were ascertained from emergency room and hospital records, coroners' reports, death certificates, and nursing home and extended-care records for 1981. The annual brain-injury rate per 100 000 children was 185 (235 for boys and 132 for girls). The major causes of pediatric brain injury were falls (35%), recreational
