13. SUPPLEMENTARY NOTES

14. ABSTRACT

Algorithms for the management of blunt TBI have been published and widely utilized[1, 2, 3],however, no such algorithms for the management of penetrating TBI have ever been published. Hence, this proposal for an international and multidisciplinary effort to generate new evidence and consensus-based clinical practice guidelines has been undertaken in conjunction with the Brain Trauma Foundation in Stanford University which has long been a global leader in clinical practice guideline generation[2] and the Seattle International Brain Injury Consensus Conference (SIBICC) effort[1, 4]. We first convened a steering committee and delineated key topics related to penetrating TBI for evidence-based research on Oct, 2021 and established PICOT (mnemonic derived from clinical research question elements: Patient, Intervention, Comparison, Outcome and Time) lead questions from which to frame a literature search strategy enumerated in our Yr 1 Qtr 1 report. From the initial series of meetings of international multidisciplinary experts using the Delphi method of consensus, a publication titled " Rationale and Methods for Updated Guidelines for the Management of Penetrating TBI" (Hawryluk G et al, 2022)[5] was produced as one of the first deliverables. The subaward agreement between co-investigators from Stanford Univ. and Oregon Health Sciences Univ. (OHSU) was finalized on June 15, 2022 which decided on a Statement A (public) distribution of the resulting recommendations in line with their institutions' research efforts to perform the systematic literature review. The preliminary report of this Literature Review forms the body of this report. This evidence will then form the basis for the best practice guidelines to be eventually disseminated to civilian and military neurosurgical communities.

1. INTRODUCTION

Guidelines for the management of traumatic brain injury were the first surgical clinical practice guidelines published[3] and their implementation has been credited with an approximate 50% reduction in mortality. The Brain Trauma Foundation's guidelines are respected and compliance with them is mandated for US trauma centers to maintain trauma accreditation. The Brain Trauma Foundation has published adult[3, 6, 8] and pediatric severe TBI[9] management guidelines as well as those related to combat TBI (https://www.braintrauma.org/coma/guidelines), pre-hospital care[10] and prognosis[11]. In most cases these guidelines have been subjected to updates and modernization. The penetrating TBI guidelines, however have not been updated for almost 20 years.

As guideline methodology has evolved, increased rigor has diminished the role of expert opinion in the generation of clinical practice guidelines. It is axiomatic that management algorithms based on expert opinion must inherently bridge published evidence and its limitations with the realities of patient care. As such, modern evidence-based guidelines have excluded consensus-based algorithms because the methodology used to generate them is unique. This has led to a void in the literature leaving non-expert practitioners without guidance and insufficient attention to advances emanating from recent studies.

The proposed effort under this study, "The Development of Best Practice Penetrating TBI Guidelines for Military and Civilian Patients", (Award # W81XWH21C0102), or the pTBI Guidelines Study (short title) will unite key military and civilian resources and investigators with long-standing experience and successful track-records developing and disseminating clinical practice guidelines. The Lead investigators are herein cited: Dr. Ghajar is President of the Brain Trauma Foundation and he has overseen the development of the entire portfolio of guidelines since the organization's inception. Dr. Hawryluk recently co-chaired the recent Seattle International Severe Traumatic Brain Injury Consensus Conference and first-authored the resulting high-impact publication. Dr. Bell is the immediate past Chair of Neurosurgery at Walter Reed and a respected expert in military neurosurgery and endovascular procedures – and in particular management of penetrating and blast TBI. We believe that the combined expertise and experience of this group will ensure the success of the proposed work. The retirement of Dr. Bell from the US military last June 30, 2022 has prompted his designation of Dr. Bradley Dengler (LTC, MC, USA), staff neurosurgeon at WRNMMC as incoming lead investigator to ensure continuity of this collaborative multi-institutional initiative. As a retired civilian, Dr. Bell has rejoined the pTBI Guidelines study as a Co-investigator. The Memoranda of departure and acceptance of both outgoing and incoming PIs have been approved by the DoD and are included in the Annexes section of this report (Annexes B and C). Recognizing the proposal goals as aligned for Program Evaluation through Literature Review, the WRNMMC IRB ruled in April 17, 2021 that the pTBI Guidelines study is Not Research and will not require further IRB supervision with regards Continuing Reviews.

2. KEYWORDS: Penetrating Traumatic Brain Injury, military and civilian patients, Clinical Practice Guidelines,

3. ACCOMPLISHMENTS

A. Creation of a Steering Committee and resulting work products

One of the stated goals of the study was the creation of a steering committee and its first deliverable. This was done by identifying the 21 internationally recognized Subject Matter Experts (SMEs) on Penetrating Traumatic Brain Injury (pTBI) and As stated in our Yr 1 Qtr 1 report, a total of 55 PCOT (nemonic derived from clinical research question elements: Patient, Intervention, Comparison, Outcome and Time) questions were surveyed and resolved among Subject Matter Experts (SMEs) to frame a literature search strategy in a series of

weekend and teleconferencing meetings concluded last October – November, 2021. Surveys taken as to how PCOT lead questions were evaluated and weighted are annexed (Annex D). The topics ranged from prehospital, hospital, critical care, operative, diagnostic and post-hospital issues and opened the path to a systematic review which would form the basis of Clinical Practice Guideline recommendations.

B. Publication

From conference notes and records, the investigators were able to organize provisional material which was publication-worthy. The resulting article "Rationale and Methods for Updated Guidelines for the Management of Penetrating Traumatic Brain Injury" was published in the 2022 issue of the journal *Neurotrauma Reports* as the study's early second deliverable.

C. Finalizing the Standford Univ – Oregon Health Sciences University (OHSU) Subaward Agreement and Preliminary Results of Systematic Literature Review

As the collaborating sites in Stanford University and the Oregon Health Sciences University (OHSU) responsible for the systematic Literature Review finalized their Subaward agreement, last June 15, 2022, OHSU assigned staff proceeded to implement a first pass literature review from searches through all databases outlined in the published methodology.

The OHSU investigators searched Ovid Medline ®, EMBASE, and Cochrane CENTRAL without date limits for reports and studies of any size for evidence on the management of penetrating brain injury. Our searches returned 6,077 citations and abstracts with studies published from 1945 to 2022 (Annex E). We are in the process of abstract and full-text article review of these publications.

The literature includes a large number of case reports, so OHSU designated staff are pulling many more full-text articles than they normally would for a review as typically case reports are not included due to their low quality of evidence. It is anticipated that at full-text level many of these case reports will end up being excluded because they do not provide information on how the pTBI was managed, but reviewers will have to evaluate the full-text to determine that.

4. Impact

The vast majority of severe traumatic brain injury encountered in the civilian sector mechanistically results from closed injury (blunt force, motor vehicle accidents, falls, etc.). The enormously successful guidelines referenced above[6] address this injury pattern, with some translational application to penetrating injury. The penetrating head injury that occurs in civilian settings is associated with an extremely high early mortality (70-90%)9, and therefore meaningful study from this perspective is scarce. Secondary to the longest period of continuous armed conflict in the history of the United States, military surgeons have encountered and cared for a concentration of survivable penetrating brain injury that has resulted in significant advances in the surgical and critical care of these patients. This study and care has resulted in a proportionally higher survival of military service members when compared to historical civilian counterparts[9]. While not unique to the military population, it is an injury pattern that active duty service men and women are subjected to by virtue of what they encounter on the field of battle. This project is an opportunity for military physicians and its system to collaborate with their civilian counterparts in the creation of a guidelines that has direct application to the battlefield setting, and is translatable to the care of civilian patients as well.

5. Changes/Problems

In 2 succeeding Quarterly Reports (Yr 1 Qtr 2 and Yr 1 Qtr 3), we reported on Stanford University's objection to DFAR 252.204-7000- Disclosure of Information, requesting that this clause be removed, but if this Flowdown cannot be deleted, Stanford requests adding the following language under a new section above the list of FARs/DFARs Flowdowns. (see italics)

- "*Contractor's work under this Agreement is Fundamental Research, as confirmed in the attached statement from the Prime Awarding Agency. Fundamental Research means basic and applied research in science and engineering, the results of which ordinarily are published and shared broadly within the scientific community, as distinguished from proprietary research and from industrial development, design, production, and product utilization, the results of which ordinarily are restricted for proprietary or national security reasons, as defined by NSDD 189. Contractor is a University performing fundamental research under this subcontract and, as such, no additional limitations or restrictions should be placed on Contractor's ability to exercise its rights in publications and data first produced in the performance of this Contract. As such, the following clauses are not applicable to Contractor or the work being performed under this Subcontract."*

Further, Stanford Univ. and Oregon Health Sciences University (OHSU) restated their objection in detail:

"Stanford and OHSU's work and any products produced in the course of its fundamental research during this Project are freely distributable. HJF will not provide any restricted information to Stanford of OHSU in the course of this work. Stanford and OHSU's results, data, and processes are approved for public release; there are no restriction on dissemination."

"Stanford needs to confirm that our deliverables under the project are subject to Distribution Statement A – meaning that they are also approved for public release and distribution is unlimited. If HJF does not have Distribution Statement A, due to the clause, Stanford must request written confirmation from the AFRL Contracting Officer regarding which Distribution Statement applies to Stanford and OHSU's scope of work and deliverables. Stanford must have this clearly confirmed up-front that our work will not be subject to a publication restriction, which is why receiving anything other than Distribution Statement A is an issue."

With the resolution of the Distribution issue upon signing of the Subaward Agreement between Stanford U and OHSU, the consistent use of Distribution A in all reports for this study has been adopted.

6. Products

The resulting products from the study efforts so far have been: (1) the establishment of a Steering Committee (one of the study's main a aims and a deliverable) (2) the formulation of PCOT (nemonic derived from clinical research question elements: Patient, Intervention, Comparison, Outcome and Time) lead questions to support the framework of the systematic Literature Review became the 2nd deliverable, (3) the publication, "Rationale and Methods for Updated Guidelines for the Management of Penetrating Traumatic Brain Injury" was published in the 2022 issue of the journal Neurotrauma Reports based on conference notes and papers from the Steering Committee meetings. The published manuscript is the study's early 3rd deliverable.

APPENDIX B. Memo from Outgoing PI

Walter Reed National
Military Medical Center

March 6, 2022

MEMORANDUM FOR USAMMRA CONTRACTING OFFICER

FROM: Randy S. Bell
CAPT, MC, USN
PI for BA200139:
W81XwH-21-C-0102

SUBJECT: Change of PI for BA200139: W81XwH-21-C-0102

1. I have received orders to proceed to the retirement list effective 01 SEP 2022. The actual date will be 05 JUL 2022. Effective 30 JUN 2022, I am requesting transfer of PI for this project to LTC Bradley Dengler. LTC Dengler is already a subject matter expert working on this project, and is eminently qualified to assume the role of PI. LTC Dengler will assume administrative control of this project. I will retain operational control to help insure the completion of the statement of work.

2. My point of contact will remain (240) 381 – 2528.

APPENDIX D. Evaluation of PCOT Questions

***Color Legend:**

- **Survey of PCOT questions (w consensus > 80%)**
- **Points nearing Consensus (70-79.9%)**
- **Points w/o Consensus (<70%)**

Preliminary Results of First Survey

October 16, 2021

Points of Consensus (>80%) [13]

- **Penetrating head injury can be conceptualized as (1) low velocity missile (2) high velocity missile and (3) non-missile (96.4%)**
- **High velocity missile wounds to the brain can be survivable (100%)**
- salvageability should be assessed early in the course of caring for all penetrating brain injury patients (82.1%)
- GCS score should be considered when determining salvageagility in pTBI (96.4%)
- Patient age should be considered when determining salvageagility in pTBI (92.9%)
- Patient age should be considered when determining salvageagility in pTBI (92.9%)
- A high velocity penetrating missile injury that traverses the thalamus is typically non-survivable (85.7%)
- A high velocity penetrating missile injury that traverses the brainstem is typically non-survivable (92.9%)
- Organ donor services be routinely consulted following a determination that a penetrating TBI is not salvageable?(100%)
- All patients with penetrating brain injury should be screened for traumatic cerebrovascular injury (85.7%)
- Catheter angiography is required to screen for traumatic pseudoaneurysms when a questionable lesion is identified on a CTA. (89.3%)
- Catheter angiography is required to screen for traumatic pseudoaneurysms when metallic fragments cause problematic artifact on a screening CTA. (92.9%)
- A consultant/staff/faculty neurosurgeon must be present when any intracranial foreign body is removed. (92.9%)

Points Nearing Consensus (70-79.9%) [2]

- Catheter angiography is not required in all cases to screen for delayed pseudoaneurysms following pTBI. (75%)
- True or False: All pTBI patients should receive antibiotic prophylaxis following their injury. (75%)

Points Without Consensus (<70%) [10]

- MR imaging is contraindicated in patients with one or more post-traumatic intracranial metallic foreign bodies. (67.9%)
- CT angiography is not sufficiently sensitive for delayed pseudoaneurysm detection and cannot be the sole vascular imaging performed (67.9%)
- The timing following a pTBI when you consider an initial screening examination for delayed pseudoaneurysm formation. (No suggestion of consensus, most popular selection only got 22% of the vote.
- When a delayed pseudoaneurysm is detected a period of observation is acceptable to determine if it may undergo spontaneous resolution. (50%)
- Following a negative screening study for delayed traumatic pseudoaneurysms, it is not mandatory to perform another, additional follow up examination at a later time point. (55.6%)
- Open or endovascular treatment is not mandatory for ALL identified traumatic pseudoaneurysms. (67.9%)
- It is not acceptable to remove a non-missile penetrating intracranial foreign body in an angiogram suite which cannot function as an operating room. (73.1%)
- Proximal vascular control must be secured before removing any non-missile penetrating intracranial foreign body. (66.7% False)
- The presence of an endovascular balloon in a proximal vessel that can be readily inflated is not an acceptable sole form of proximal vascular control when removing a non-missile penetrating intracranial foreign body. (66.7%)

A consultant/staff/faculty neurosurgeon or someone directly under their supervision is the only individual who can remove

Preliminary Results of Second Survey
November 1, 2021

Points of Consensus Survey (>80%) [16]

- Assessing and correcting problems with the ABC's is the initial priority of the first responders in pTBI (96.9%)
- Classification system for pTBI for this guideline will be 1) missile injury, 2) blast fragment injury, 3) low velocity injury (96.9%)
- Traumatic aneurysms (TA) bear high risk of death or additional injury if they rupture (87.5%)
- Open or endovascular surgery required for TA's with size increase over time (87.5%)
- Proximal control in surgery should be considered when there is risk of damaging large proximal vessels (96.8%)
- Proximal vascular control should be considered in surgery with penetrating injury through anterior skull base (80.7%)
- Proximal vascular control should be considered in surgery with penetrating injury through the pterion region (83.9%)
- Proximal vascular control should be considered in surgery with obvious injury to large intracranial vessel (100%)
-Treatment should be more strongly considered for a larger TA than a small one (80.7%)
- pTBI is the preferred abbreviation for penetrating brain injury (87.5%)
- Coil occlusion is an acceptable treatment for a TA (96.8%)
- Prophylactic antibiotics should be administered with penetrating air sinus injury (84.4%)
- Prophylactic antibiotics should be administered with grossly contaminated pTBI (100%)
- MR imaging risks brain damage from heat when ferromagnetic (known or unknown) is present intracranially (84.4%)
- MR imaging risks brain damage from induced motion of an intracranial ferromagnetic (known or unknown) metal foreign body (96.9%)
- Pupillary exam should be considered with determining salvageability/survivability (100%)

Points Nearing Consensus (70-79.9%)

- high quality CTA without metal artifact sufficient to screen for TA's without need for catheter angiogram (75%)
- If TA detected in a delayed fashion, a period of observation is acceptable to determine if spontaneous resolution will occur if treatment expected to cause infarct in eloquent brain (74.2%)

Points Without Consensus (<70%) [

- Neither salvageability (41.9%) nor surviveability (38.1%) nor a distinct and different term (19.6%) were preferred
- No distinct preference on when follow up neurovascular screening exam to be performed with initial normal exam. No additional exam (18.8%), 2nd exam 7-14 days (43.75%), 2nd exam 14-21 days (28.13%), 2nd exam 21-28 days (3.13%), 2nd exam after 30 days (6.25%)
- TA's have similar mortality and rupture risks as true saccular aneurysms (31.3%)
- No consensus based on size for mandatory treatment of TA's (< 2mm- 6.5%; 2-5 mm 19.4%; 5-7 mm 29%; >10 mm 3.2%; There is no size at which treatment of a TA is mandatory)
- MR angiography should be strongly considered in pTBI with non metallic objects (53.3%)
- MR imaging when ferromagnetic objects present intracranially relatively (46.9%) or absolutely (53.1%) contraindicated.
- First meaningful GCS score after pTBI is in the field (31.3%), in the trauma bay (50%), in the neurocritical care unit (18.8%).
- Initial lab coag values should be considered when determining salvageability (62.5%)
- ISS should be considered when determining salvageability (56.3%)

1. (1998). "Posttraumatic risk for seizures related to severity of injury." Annals of internal medicine 128(8): 704.

---

2. (2000). "Minerva." British medical journal 321(7256): 308.

---

3. (2001). "Prompt intervention lowers seizure risk after traumatic brain injury." Drugs and Therapy Perspectives 17(9): 12-15.

The occurrence of seizures in the first week after traumatic brain injury is a well known phenomenon, and prophylactic administration of anticonvulsants for the initial week after brain injury is considered standard treatment. The incidence of these seizures can have devastating effects on metabolic processes (e.g. glucose utilisation) within the brain. The actual frequency of early post-traumatic seizures may be as high as 20% and may not be detectable except by electroencephalogram (EEG). The main clinical risk factors for seizures are younger age, greater severity of brain injury and subdural haematoma, and penetrating wounds. If seizures are suspected early after the injury, anticonvulsants should be used at dosages achieving plasma concentrations approaching the higher end of the therapeutic range (see Patient care guidelines). Continuous EEG monitoring may also be warranted. The prompt treatment of status epilepticus, first with high doses of benzodiazepines and then with anticonvulsants, is very important in determining a good outcome after brain trauma. The development of chronic epilepsy is more common with more severe injuries (e.g. brain contusion) and may influence the decision to continue prophylactic anticonvulsants.

---

4. (2005). "Clinical Trial of New Elastomer for Maxillofacial Prosthetics." Multicenter Trial of CPE for Maxillofacial Prosthetics.

Maxillofacial prosthetics is a subspecialty of prosthodontics, providing the clinical rehabilitation treatment of patients who have lost parts of the face due to cancer, trauma, or birth defects. It is an orphan field that:, - treats few patients, making the subspecialty unprofitable for manufacturers to develop new materials;, - offers fundamental rehabilitation and improvement in the quality of life to patients who may have exhausted personal or third party funding; and, - provides a dental solution to an essentially medical problem., Silicone rubber materials have been used for facial rehabilitation for more than 4 decades with few improvements. There is a clear need for new, alternative, and more economic materials for extraoral maxillofacial prostheses. Research at Gulf South Research Institute in New Orleans by the Principal Investigator and others in the 1970s and 1980s developed an alternative low-cost thermoplastic industrial rubber material (chlorinated polyethylene, CPE) that met all toxicological (safety) and physical (effectiveness) requirements. A Phase 2 clinical trial at the time yielded equivocal results when compared to conventional but costly silicone rubber products., This research is a controlled, randomized, single-crossover, double-blinded investigator-initiated multicenter Phase 3 clinical trial treating 100 patients that evaluates:, - experimental thermoplastic CPE; and, - control silicone (Silastic Adhesive A/MDX4-4210) materials for non-inferiority of CPE based on functional and subjective characteristics, and on the quality of life., The clinical centers of the trial are at M.D. Anderson Cancer Center in Houston, Texas, and at the Toronto Sunnybrook Regional Cancer Centre in Toronto, Canada.

5. (2006). "Internet-Based Treatment for Children With Traumatic Brain Injuries & Their Families: Counselor Assisted Problem Solving." Improving Mental Health Outcomes of Child Brain Injury.

A traumatic brain injury (TBI) is caused by a strong blow, jolt, or penetration to the head that disrupts normal brain functioning. A TBI can range from a mild concussion to severe brain damage. Falls, assaults, and motor vehicle accidents account for more than 50% of TBIs. Physical symptoms of a TBI can be subtle to severe and can include nausea, memory loss, mood swings, blurred vision, and light-headedness. This type of injury can be very stressful for families and can result in feelings of anxiety, burden, and depression among family members. A child who experiences a TBI will often display new social and behavioral problems, leading to further parental distress and increased family dysfunction. Recent studies have shown that problem-solving interventions can reduce caregiver distress and improve child adjustment following a TBI. However, access to skilled therapists and specialized care for this kind of psychosocial treatment is often limited in many communities. In such communities, the Internet offers a new way to meet the mental and other health needs of individuals with TBIs. This study will evaluate the effectiveness of an Internet-based psychosocial treatment in improving problem solving, communication skills, stress management strategies, and coping among teens who have had a TBI and their families., Families participating in this study will be randomly assigned to either an Internet-based counselor-assisted problem-solving (CAPS) group or an Internet resource comparison group (IRC). Participants assigned to CAPS will work with a trained counselor who will guide them through a 6-month structured online problem-solving and skill-building program via one-on-one videoconference sessions. Families assigned to IRC will receive computers, high speed Internet access, and links to brain injury information and resources, but no access to the CAPS Web site content. The effectiveness of CAPS will be assessed after treatment and at 6- and 12-month follow-up evaluations.

7. (2008). "Recombinant Human Growth Hormone During Rehabilitation From Traumatic Brain Injury." A Phase II, Randomized Controlled Trial of Recombinant Human Growth Hormone During Rehabilitation From Traumatic Brain Injury.

1. Patient selection and enrollment. Participants will be recruited into the study from subjects admitted for acute inpatient rehabilitation in the North Texas Traumatic Brain Injury Model Systems (NT-TBIMS) affiliated rehabilitation units. Our goal is to enroll participants who have the potential for neuroregeneration, but who suffered a sufficiently severe injury that the chance of full recovery (to normal pre-injury function) is low. Over a 4 year enrollment period, we plan to randomize 168 subjects into the study (with the anticipation that 71 will complete each arm of the trial)., Inclusion Criteria, 1. Non-penetrating TBI, 2. Age 18 - 50 years., 3. Admission to a North Texas Traumatic Brain Injury Model System-affiliated rehabilitation unit within 8 weeks of injury. Enrollment in TBI-MS database not required., 4. Randomization within 2 - 10 weeks of injury., 5. Rancho Los Amigos Rating IV or better at the time of randomization. Should not be at Rancho IV level for more than 4 weeks before randomization., 5. GH deficiency diagnosed by either of the following two criteria:, 1. . Peak GH response to L-arginine stimulation test < 1.4 microg/L; or, 2. . Plasma IGF-1 level 1 SD below the expected median for age and body weight. 6. Availability of caregiver to oversee administration of medications. 7. Reasonable expectation for completion of outcome measures 8. Residence inside the United States., Exclusion Criteria:, 1. History of pre-existing neurologic disease (such as epilepsy, brain tumors, meningitis, cerebral palsy, encephalitis, brain abscesses, vascular malformations, cerebrovascular disease, Alzheimer's disease, multiple sclerosis, or HIV-encephalitis), 2. History of premorbid disabling condition that interfere with outcome assessments, 3. Contraindication to rhGH therapy. (hypersensitivity to rhGH or any of the components of the supplied product, including metacresol, glycerin, or benzyl alcohol), 4. Penetrating traumatic brain injury, 5. Diabetes mellitus., 6. Obesity (BMI > 30)., 7. Active infection., 8. Active malignant disease., 9. Acute critical illness, heart failure, or acute respiratory failure, 10. Previous hospitalization for TBI > 1 day, 11. Membership in a vulnerable population (prisoner), 12. Pregnancy. Women of childbearing age will be given a pregnancy test during screening to exclude pregnancy., 13. Lactating females, We will measure baseline IGF-1 as

well as carry out L-arginine GH stimulation tests prior to entry into the study, and measure IGF-1 levels again at completion of the treatment phase., 2. Treatment. After obtaining informed consent, we will measure IGF-1 levels as well as perform dynamic GH testing. Eligible patients will be randomization in a double-blind fashion to (Group 1) rhGH subcutaneously or (Group 2) placebo. The GH treatment arm will receive a starting dose of 400 microg/day, with increases (or decreases) in dose by 100-200 microg/day each month, monitoring for side effects, until goal IGF-1 (in the upper quartile of the range for age and body weight) is reached up to maximum dose of 1,000 microg/day. Dose adjustments may be modified by the investigators for participants receiving oral estrogens or other circumstances know to influence GH dosing or atypical responses to treatment. Doses for participants receiving placebo will also be adjusted monthly to maintain the blinding., The treatment will be overseen by a board certified endocrinologist (Dr. Auchus), according to practice guidelines recently released by the Endocrine Society "Clinical Guidelines for Evaluation and Treatment of Adult Growth Hormone Deficiency". The principle is that therapy is started at a relatively low dose and increased monthly, adjusting for the occurrence of adverse effects. In this study, to accommodate both GH-deficient and GH-sufficient strata, the treatment goal is serum IGF-1 as close as possible to the upper limit for the age-adjusted reference range without exceeding this normal range., The objective of randomization is to produce study group comparable with respect to known and unknown risk factors, to remove investigator bias in the recruitment and allocation of participants and to guarantee that statistical tests have valid significance levels. To balance factors that may influence treatment outcome, randomization will be stratified and blocked, by two factors:, 1. Age (< 35 years vs. > 35 years), 2. Severity of injury (duration of post-traumatic amnesia < 20 days vs. > 20 days). Each combination of factors forms a stratum and randomization is allocated within each stratum. GH Stimulation Test: After obtaining informed consent, an 18 - 20 g IV catheter is placed in a forearm vein. 5 ml of blood is sampled at baseline, and afterwards L-arginine is infused over 30 minutes (in 100 mL NS, dose 0.5 g/kg up to a maximum of 30 g). Blood is sampled at 30, 60, and 90 minutes after starting the infusion of the L-arginine. All blood samples are centrifuged and serum frozen at -20oC within 15 minutes of collection. All serum specimens are assayed for glucose and GH. Growth Hormone deficiency is defined as a peak response to arginine infusion < 1.4 ng/mL. Growth Hormone insufficiency is defined as peak GH response < For IGF-1 levels, we will use the age and gender normative data based on 3,961 healthy subjects., 3. Safety Assessments. Safety will be assessed by clinical evaluations at 1, 2, 3, and 4.5 months after initiating therapy. At these evaluations participants and their caregivers will be asked about possible adverse effects of GH treatment, including fluid retention, paresthesias, joint stiffness, peripheral edema, arthralgias, and myalgias. Additionally, blood will be obtained for assessment of glucose, free T4, lipid profile, and insulin level. The dose of GH (or placebo) will be adjusted by the study physician depending on the occurrence and severity of adverse effects., 4. Outcome Measures. Table 3 summarizes the functional and neuropsychologic tests we will use to assess outcome in our study. This battery of measures was developed by the NCMRR TBI Clinical Trials Network to maximize power in TBI clinical trials compared to a single measure alone. These measures are designed to capture a broad perspective of functional and cognitive parameters that are important following TBI, and utilizes scales that have a long history in TBI research. Further, there is convincing evidence that they can be reliably administered 6 - 12 month after injury., 5. Biochemical tests. Plasma GH and IGF-1 levels will be measured by the Clinical Contracts Research Laboratories at UT Southwestern Medical Center (CLIA ID No. 45D0659587), using commercially-available immunoassays. This laboratory will also carry out the safety lab assessments (glucose, insulin, free T4, lipid profile. Results will be available within 1 week to allow randomization within the time window, and to allow dose adjustments in a timely fashion., 6. Statistical Analysis and Sample size calculation. This is a Phase II study, designed to assess feasibility and obtain information about dosing efficacy and magnitude of effect. There are two features of the study design that are relatively novel to TBI clinical trials, which merit some introduction. The first is the use of a futility (non-inferiority) design, and the second is the use of a composite outcome statistic., The goal of Phase II studies is to provide information about side effects and toxicities in the type of patients for whom the treatment is intended, determine the logistics of administration, provide estimates of treatment costs, and obtain some information about expected effect size. For reasons discussed above,

we believe that such information is not yet available regarding the use rhGH in the early phase after TBI, and that a Phase II study designed to obtain this information is warranted. Drugs that remain promising after Phase II studies generally proceed to Phase III clinical trials, which typica ly require many hundreds of patients and are usually conducted at multiple centers and at great expense., Futility design trials were pioneered in cancer chemotherapy studies, and have recently been used in Phase II clinical trials of neurological disorders such as Parkinson's disease and stroke. A traditionally designed study focuses on efficacy, with a null hypothesis that the treatment arms are equivalent. In such studies, the assumption is that a false positive result is riskier than a false negative result (that it is riskier to falsely assume than an ineffective therapy works than it is to discard a potentially effective treatment). In such studies, it is customary to set alpha at 0.05 (the likelihood of a false positive result less than 5%), and beta at 0.2 (the likelihood of a false negative result--that a beneficial effect will be missed is less than 20%). A futility design incorporates the view that in the early phases of clinical development of a new therapy, it is in fact riskier to discard a potentially useful treatment than it is to fail to definitively identify efficacy, since that can only be done in a phase III study. Thus, in a phase II futility study the null hypothesis is that treatment has promise and will therefore produce results exceeding a meaningful threshold. Thus, alpha of 0.1 (as set in our study) in a futility study means that the chance of beneficial effect being missed is less than 10%. In a futility design, if the efficacy threshold is not met, the null hypothesis is rejected and further study of the treatment is considered futile42. Thus, for the primary hypothesis, the design of our study is that of a futility (non-superiority) study, powered to not reject a potentially useful therapy, rather than prove efficacy., The second relatively novel feature of our study is the use of a composite outcome statistic. A composite outcome statistic takes into account the fact that in a complex disorder such as TBI, there are multiple domains of dysfunction, and a single scale (such as the GOS-E or a given neuropsychometric test) may not be optimally sensitive to identify functionally important deficits in all patients. There are several mathematical approaches to the need to compare two groups with respect to more than one outcome. The options available include using Bonferroni or other adjustments for multiple comparisons, reducing the dimensions of the problem by averaging the outcomes, or applying a global test based on a multiple correlated binary outcomes43,44. Of these, the latter approach has been found to be useful in a variety of clinical settings. Incorporating several different measures, which although correlated measure different domains of dysfunction after TBI, significantly lowers the sample size required. We have elected to use a composite outcome statistic developed by the NIH TBI Clinical Trials Network, which will be used in the Citocholine Brain Injury Treatment (COBRIT) study. This measure was developed by a subcommittee of the NIH network that included clinicians, neuropsychologists, and biostatisticians, including Dr. Diaz-Arrastia and Dr. Sureyya Dikmen (who will serve in the DSMB for this trial). In our study, the use of a composite statistic lowers the sample size from 228 to 164., All participants in the GH treatment arm may not achieve goal serum IGF-1 values in the first month, yet data will be analyzed in an intention-to-treat manner., Primary Hypothesis:, 1. . Treatment with recombinant human Growth Hormone (rhGH) in the subacute period after TBI results in improved functional outcome 6 months after injury, as measured by the Composite Outcome Score of the TBI Clinical Trials Network . Secondary Hypotheses:, 2. . Treatment with rhGH results in increased IGF-1 levels., 3. . rhGH treatment results in improved bone mineral density and lean body mass 6 months after injury., 4. . Benefits of rhGH treatment persist up to 1 year after injury, 5. . Low GH response to L-arginine stimulation at baseline is associated with poor functional outcome., 6. . Low IG -1 levels at baseline are associated with poor functional outcomes., 7. . rhGH treatment is more effective in patients who have low IGF-1 levels at baseline., 8. . rhGH treatment is more effective in patients who have low GH response to L-Arginine stimulation at baseline.

9. (2009). "A Randomized, Double blind, Placebo-Controlled Dose Escalation Study to Investigate the Safety and Pharmacokinetics after Single and Multiple Doses of SLV334 in Sequential Cohorts of Patients with Moderate and Severe Traumatic Brain Injury. Estudio con escalada de dosis, aleatorizado, doble ciego, controlado con placebo que investiga la seguridad y farmacocinetica tras dosis unicas y multiples de SLV334 en cohortes secuenciales de pacientes que sufren traumatismo cerebral moderado y severo."

INTERVENTION: Product Name: SLV334 Product Code: SLV334 Pharmaceutical Form: Solution for infusion CAS Number: 182821-33-6 Current Sponsor code: SLV334 Other descriptive name: {(3S)-3-[({1-[(2R)-2-carboxy-4-(1-naphthyl)butyl] cyclopentyl}carbonyl)amino]-2oxo-2,3,4,5-tetrahydr Concentration unit: mg/ml milligram(s)/millilitre Concentration type: equal Concentration number: 25- Pharmaceutical form of the placebo: Solution for infusion Route of administration of the placebo: Intravenous use, CONDITION: Moderate and severe Traumatic Brain Injury (TBI), Traumatismo cerebral moderado y severo. ; MedDRA version: 9.1, Level: PT, Classification code 10060690, Term: Traumatic brain injury, PRIMARY OUTCOME: Main Objective: The aim of the study is to determine the safety and tolerability of SLV334 after a single intravenous (i.v.) dose of 1000 mg SLV334 and after multiple i.v. doses of 1000 mg SLV334 and 2000 mg SLV334 (up to 3 days, b.i.d.) compared to placebo in patients with moderate and severe Traumatic Brain Injury (TBI). Primary end point(s): Safety: ; The primary outcome measure will be the safety of SLV334 including mortality, adverse events (AE), serious adverse events (SAE), vitals signs, laboratory variables and ECG; ; Pharmacokinetics:; In cohorts 1-3, pharmacokinetics measurements of SLV334 plasma levels will be measured at 6 time-points up to 24 hours after start of the first infusion. In cohort 4, plasma levels of SLV334 will be measured at 12 time-points up to 24 hours after the first dose of Day 3.; ; Pharmacodynamics:; - Biomarkers for Endothelin Converting Enzyme (ECE) and Neutral Endopeptidase (NEP): ET-1, Big-ET-1, BNP, ANP and cGMP.; - Biomarkers for apoptosis and necrosis (alpha II-spectrin breakdown products, UCH-L1 and BA252). Secondary Objective: -To determine the pharmacokinetics of SLV334 after a single dose of 1000 mg; SLV334 and after multiple doses of 1000 mg SLV334 and 2000 mg SLV334 (up to 3 days, b.i.d.) in subjects with moderate and severe TBI.; - To assess the effect of SLV334 on clinical assessments such as intracranial pressure (ICP), cerebral perfusion pressure (CPP) and therapy intensity level (TIL).; - To assess in a sub-sample of subjects

(those with a ventricular catheter or microdialysis), SLV334 levels in the cerebrospinal fluid (CSF) and/or microdialysis compared to systemic levels.; - To assess in a sub-sample of subjects (as previously), the influence of single and multiple doses of i.v. SLV334 on neurohormone activities/conc.s related to the mode of action (neutral endopeptidase [NEP] and endothelin converting enzyme [ECE] and markers for apoptosis, necrosis and neural damage in the cerebrospinal fluid (CSF) and/or microdialysis compared to placebo and compared to systemic (plasma) levels., INCLUSION CRITERIA: 1. Male or female subjects, age between 16 and 70 years, inclusive [the lower age limit will be 18 if required by local regulations]; 2. TBI diagnosed by history, clinical examination with Glasgow Coma Scale (GCS) of 12 or less; 3. Evidence of TBI confirmed by abnormalities on Computed Tomography (CT) scan; 4. Clinical indication to monitor ICP; 5. Randomization and drug treatment with study drug possible within 8 hours after closed [non-penetrating] head trauma; 6. Informed Consent is given. Are the trial subjects under 18? yes Number of subjects for this age range: F.1.2 Adults (18-64 years) yes F.1.2.1 Number of subjects for this age range F.1.3 Elderly (>=65 years) yes F.1.3.1 Number of subjects for this age range

10. (2009). "Safety and Tolerability of Oxycyte in Patients With Traumatic Brain Injury (TBI)." A Randomized, Placebo Controlled, Double-Blind, Single Dose, Dose Escalation Study to Evaluate the Safety and Tolerability of Oxycyte in Patients With Severe Non-Penetrating Traumatic Brain Injury.

This is a randomized, placebo controlled, double-blind, single dose, dose-escalation study to evaluate the safety and tolerability of Oxycyte in patients with severe non-penetrating Traumatic Brain Injury administered in conjunction with 50% to 80% oxygen and standard of care treatment., At each dose level, patients receiving Oxycyte will be compared to a control group of patients who will receive Normal Saline (NS); all patients will receive 50% oxygen or greater, if per standard of care for a particular patient based on his / her condition, up to a maximum of 80%., Ischemic brain damage is found in 80% of patients who die from severe head injury and studies have shown that early, transient cerebral hypoperfusion of unknown origin is present in about 40% of these patients. In several early research studies, it is documented that about one-third of severe head injured patients have reduced brain oxygen tension (<25 mm Hg) especially during the first 6 to 12 hours following severe head injury. In this group of patients with low brain oxygen, the clinical prognosis is poor with death being a frequent outcome., Based on a belief that increased brain oxygen levels would prove beneficial in the TBI patient, it is theorized that perfluorocarbon-enhanced oxygen delivery may provide the same or greater benefit. PFCs are especially attractive in this setting for several reasons; first, because they transport oxygen without the need for erythrocytes and hemoglobin and can thus perfuse and oxygenate "peri-contusional" brain tissue in which it has been shown that capillaries are so narrowed as to impede red blood cell (RBC) transport; secondly, perfluorocarbon (PFCs) actually increase oxygen transport and oxygen tension in the tissues, which cannot be achieved with normobaric hyperoxia alone.

11. (2010). Rechtsmedizin 20(4).

The proceedings contain 302 papers. The topics discussed include: sleepless in Zurich - prevalence of benzodiazepines and z-drugs in routine hair samples; screening and quantitation of 9 synthetic CB1 receptor agonists in serum by LC-MS/MS; cardiopulmonary resuscitation related changes in post mortem magnetic resonance and computed tomography; application of the 3ds max computer software in forensic reconstruction of bone fractures - presentation of cases; micro-CT analysis of gunshot wounds for estimating the firing range; numerical description of x-ray fronto-orbiculo-maxillary shape in image analysis as a high distinctive tool for development of the system of identification of persons and human remains; signs of starvation - reconstruction of nutritional life histories by isotopic analyses of hair; vitreous chemistry - methodological and interpretational considerations; circadian biomarkers for estimating trace deposition time; and wound pattern simulation - augmented reality in mobile learning applications as part of hands-on training for medical students at Hanover Medical School.

12. (2011). "Treadmill Training at Constant or Different Speeds for People With Traumatic Brain Injury." Effect of Time Varying Walking Velocity in Body-Weight Supported Treadmill Training.

Objectives: To test the effectiveness of using time varying walking velocity in Body-Weight Supported Treadmill Training (BWSTT) as compared to using constant velocity in subjects with Traumatic Brain Injury (TBI). We hypothesize that using time varying velocity will result in a greater improvement in ambulatory function., Study Population: 30 adult subjects with a clinical diagnosis of non-penetrating TBI and with functional deficits in gait will be enrolled. Subjects will be recruited from NIH, affiliated hospitals/clinics, and in the community., Design: This pilot study will use an instrumented treadmill (Bertec Co., Columbus, Ohio) and a force controlled harness system called ZeroG (Aretech LLC, Ashburn, Virginia). Subjects will be randomly assigned to one of two groups (12 subjects per group): the first group will receive BWSTT at a constant velocity (also known as standard treadmill training); and the second group will receive BWSTT at randomized time varying velocity. BWSTT at time varying velocity consists of two components: 1) subjects passively adjusting their walking speed to the continuously changing speed of the treadmill; and 2) subjects actively changing their walking speed by following the instructed walking speed displayed on a monitor screen while the treadmill is automatically adjusted to the subjects speed. Each group will receive 8 gait training sessions (30 minutes per session, twice per week) for four weeks. Gait performance will be tested before (pre-test) and after (post-test) the 8 session gait training program., Outcome Measures: The primary outcome measures are parameters representing gait performance: maximum walking speed, self-selected walking speed, cadence, stride length, percentage of swing, stance and double stance periods, gait symmetry, Time Up and Go (TUG), and Dynamic Gait Index (DGI) scores. The secondary outcome measure is physical and cognitive effort exerted during the training session as evaluated by grip-strength test and LNS (Letter-Number Sequencing) test.

13. (2012). "Corticosteroids." Pediatric Critical Care Medicine 13(1 SUPPL.): S61-S63.

The recommendation regarding steroid administration to treat severe TBI in pediatrics is based on two reports of one class II trial, which indicates that steroid treatment is not associated with improved functional outcome, decreased mortality, or reduced ICP. Significant suppression of endogenous cortisol levels was documented with dexamethasone treatment and trends toward increased incidence of pneumonia were observed. Given the lack of evidence for benefit in children and the potential for harm from infectious complications and known suppression of the pituitary adrenal axis, the routine use of steroids to treat children with severe TBI to lower ICP or improve functional outcomes or mortality is not recommended.

---

14. (2012). "The effect of Erythropoietin Alfa in traumatic brain injury." Comparison of the effect of Erythropoietin alfa and Placebo on Glasgow Coma Scale Score and Glasgow Outcome Score of the patients with moderate to severe traumatic brain injury.

INTERVENTION: Control group will recieve 2cc of intravenous normal saline in a single dose Intervention 1: Intervention arms patients will receive 400 IU/Kg Erythropoietin Alfa, intravenously, in a single dose. Intervention 2: Control group will recieve 2cc of intravenous normal saline in a single dose. Intervention arms patients will receive 400 IU/Kg Erythropoietin Alfa, intravenously, in a single dose Placebo Treatment - Drugs, CONDITION: External causes of morbidity and mortality Traumatic Brain Injury. ; External causes of morbidity and mortality V01-Y98, PRIMARY OUTCOME: GCS score. Timepoint: Admission time, 24 hourse. 7 days. Method of measurement: Clinical assessment (Physical examination)., SECONDARY OUTCOME: Decrease in hospital stay. Timepoint: Day of discharge. Method of measurement: days. Glasgow Outcome Scale Score. Timepoint: 6th mounth. Method of measurement: Clinical assessment (Physical examination)., INCLUSION CRITERIA: Inclusion and exclusion Criteria were as follows: Patients with blunt head trauma; GCS equal or less

than 13 in admission time; patient admitted in hospital less than 8 hours after trauma, Exclusion Criteria: Patient’s GCS above 13 in admission time; patients with GCS=3 and pupils without reaction to light in admission time; penetrating head injury; O2-Sat bellow 90% in admission time; admission after 8 hours of injury; any critical injury in any part of the body except for head; patient with history of CPR before the intervention; any kind of severe pre-existing systemic co-morbidity; history of hypersensitivity to any injected drug; any patients with drug history of anticoagulant therapy; age under 4 years or above 70 years

15. (2012). "Rivastigmine Patch in Veterans With Cognitive Impairment Following TBI." Rivastigmine Patch in Veterans With Cognitive Impairment Following TBI.

Traumatic brain injury (TBI) represents one of the most significant health risks related to military duty; rapidly becoming the "signature injury" of the Iraq and Afghanistan conflicts. TBI patients often experience multiple cognitive problems, with disturbances in memory, attention, and executive functions among the most common. Disturbances in memory as well as attention are particularly problematic, as disruption of these relatively basic cognitive functions may exacerbate or cause additional disturbances in executive function, communication and other more complex cognitive domains. These cognitive deficits, especially when memory is affected, significantly impact day-to-day functioning and are the source of lingering disability and distress to the affected individuals. However, despite advances made in TBI care, treatment of cognitive deficits in TBI lag behind, forcing clinicians to provide treatment without the guidance of evidence-based scientific data. This proposal aims to begin the process of providing clinicians with evidence-based guidelines for pharmacological management of Veterans with TBI suffering from persistent cognitive deficits following their injuries. This aim will be accomplished by conducting a clinical trial in Veterans suffering from moderate to severe posttraumatic memory impairment following TBI. Specifically, this proposal will evaluate the efficacy and safety of rivastigmine transdermal patch, an intermediate-acting cholinesterase inhibitor, in this population., The investigators hypothesize that rivastigmine transdermal patch will be more effective than, and equally safe as, placebo in the treatment of moderate to severe posttraumatic memory impairment in Veterans with TBI when tested in a randomized, multi-site, parallel design, placebo-controlled trial, at a 12-week endpoint. The exploratory hypothesis states that compared to placebo, rivastigmine patch will be more effective and equally safe in the treatment of patients who will continue in a randomized, placebo-controlled phase for a total of 26 weeks. To test these hypotheses we will evaluate the effect and the safety of rivastigmine 9.5 mg/24 hours (10cm2) transdermal patch in 138 Veterans who meet or exceed the criteria for closed, non-penetrating, mild TBI and who present at baseline with moderate to severe memory impairment. Memory impairment will be defined as a Total Recall index (Trials 1-3) of the Hopkins Verbal Learning Test-Revised (HVLT-R) that is at least 25% lower than the intelligence-adjusted expected score, as assessed by the Wechsler Adult Intelligence Scale - Fourth Edition (WAIS-IV) Information and Vocabulary subtests. The study consists of a screening period, one-week single-blind, placebo run-in phase, and a 12-week double-blind acute treatment phase (Phase I). Subjects will be randomized 1:1 to rivastigmine transdermal patch 9.5mg/24 hours (10cm2) or matching placebo. During Phase I, there will be an initial 4-week titration period followed by an 8-week continuation phase. Following the 12-week acute treatment phase, randomized patients will continue in the double-blind phase (Phase II) for additional 14 weeks or until study treatment period ends. Recruitment stage ended 2.25.16. Efficacy will be determined by comparing the proportion of patients in each treatment group who are classified as responders at week 12. Secondary measure of functional capacity assessing the impact of memory improvement on real-world functioning, other measures of cognitive domains affected in TBI, namely attention, working and episodic memory and executive functions, as well as measures of mood and quality of life will be examined. Study findings will contribute to the body of evidence needed to establish standards of care for Veterans with posttraumatic memory impairment and other cognitive deficits.

18. (2014). "Direct Cortical Measurement of the Intensity and Pattern of Current Flow Produced by TDCS." Direct Cortical Measurement of the Intensity and Pattern of Current Flow Produced by TDCS.

Noninvasive brain stimulation (NBS) represents a promising set of tools for neurotherapeutics and rehabilitation. In a literature search, NBS has been tested for over seventy neurologic and psychiatric conditions. NBS may complement existing medical treatments, especially for neurologic indications without suitable pharmacotherapies (e.g. tinnitus, dyskinesias) or for patients with pharmaco-resistant illness (e.g. intractable epilepsy, severe depression)., In particular, transcranial direct current stimulation (tDCS) modulates brain activity by delivering low intensity unidirectional current through the scalp. Rather than induce action potentials, tDCS modulates resting neuronal transmembrane potential to influence brain plasticity. Moreover, from a pragmatic perspective, tDCS' benefits include its low cost, portability, and ease of use. Furthermore, tDCS can easily be combined with other interventions such as mental imagery, computerized cognitive interventions, or robot-assisted motor activity., Current physiological understanding of how TDCS affects brain plasticity at a synaptic, cellular, and a network level is limited. Experimentally, spontaneous neuronal firing activity under the anode generally increases, while firing activity under the cathode decreases, although the precise effects probably depend on the orientation of the axons to the electric field (Nitsche and Paulus, 2000, Bindman

et al., 1964, Creutzfeldt et al., 1962, Purpura and McMurtry, 1965). The neuromodulatory effects of tDCS have also been broadly attributed to LTP- and LTD-like mechanisms of synaptic plasticity, involving modulation of NMDA-receptor activity, and sodium and calcium channel activity (Hattori et al., 1990, Islam et al., 1995, Liebetanz et al., 2002). Furthermore, functional neuroimaging studies have revealed both local and distant network effects induced by tDCS, probably mediated by interneuronal circuits (Lefaucheur, 2008)., Advancing the investigators mechanistic understanding of how tDCS affects cortical excitability on a local and distributed level is necessary to (1) customize stimulation parameters (e.g. electrode size, positioning, current intensity and duration) to precisely target brain regions and maximize therapeutic outcomes, (2) confirm safety outcomes for vulnerable patient populations (e.g. children, patients with skull defects and implanted hardware). Previously, patients with a scalp or skull defect have been excluded from stimulation (Bikson, 2012) protocols because of a theoretical risk of current shunting through highly conductive CSF collections. However patients with penetrating brain injury, stroke, or previous brain surgery are precisely those who may most benefit from these technologies., Computational models using finite element methods (FEM) aim to determine the pattern and intensity of current flow through the brain by incorporating both (1) stimulation parameters and (2) patient characteristics such as underlying anatomy and tissue properties (e.g. size and position of skull defect relative to electrode configuration) (Bikson 2012). For example, one computational model incorporating electrode configuration and skull defect size and properties (Datta et al., 2010) predicts that the majority of electrode configurations surrounding the skull defect (with the exception of stimulating directly on top of a small skull defect) will not significantly increase the peak cortical electrical field intensity. Rather, current is directed to the edges of the bony defect, which may be counterproductive to therapeutic goals. Another computational case study on a stroke patient demonstrated that a relatively conductive stroke lesion concentrated current in the perilesional areas, and that placement of the reference electrode (e.g. right should, right mastoid, right orbitofrontal, and contralateral hemisphere) significantly altered the path of greatest current flow (Datta et al., 2011)., Yet, these modeling predictions are limited in their clinical application, as experimental validation is necessary. Quantitative d termination of the electrical field at the neural tissue level is required to establish efficacy and safety for a given individual (Bikson 2012). To the investigators knowledge, there are no published studies that have empirically confirmed the predicted patterns and current flow intensities predicted by these models. This proposed experimental study represents the first-in-kind to quantify voltage intensities, as measured at the brain surface, in response to various stimulation parameters, and will represent a significant advance in the field of noninvasive neurostimulation

19. (2014). "The effect of riluzole on spinal cord injury." The effect of riluzole on motor and sensory function of patients with post- traumatic acute spinal cord injury.

INTERVENTION: Intervention 1: Rilozul therapy will be performed in group A and after 6 months, sensory, motor and pain examinations will be done in all of patients. Rilozul will be administrated 50mg PO (by mouth) every 12 hours continuing for 4 weeks. Intervention 2: Placebo will be administrated to control group and after 6 months, sensory and motor examinations will be done. Placebo Placebo will be administrated to control group and after 6 months, sensory and motor examinations will be done. Rilozul therapy will be performed in group A and after 6 months, sensory, motor and pain examinations will be done in all of patients. Rilozul will be administrated 50mg PO (by mouth) every 12 hours continuing for 4 weeks. Treatment - Drugs, CONDITION: Injury of nerves and lumbar spinal cord at abdomen, lower back and pelvis level Spinal injury. ; Injury of nerves and lumbar spinal cord at abdomen, lower back and pelvis level, PRIMARY OUTCOME: Motor injury. Timepoint: Primary, 6 weeks and 6 months following end of treatment. Method of measurement: Frankel classification. Pain. Timepoint: Primary, 6 weeks and 6 months following end of treatment. Method of measurement: Visual Analog Scale. Sensory injury. Timepoint: Primary, 6 weeks and 6 months following end of treatment. Method of measurement: Frankel classification., SECONDARY OUTCOME: Side effects. Timepoint: Primary, 6 weeks and 6 months following end of treatment. Method of measurement: Physical examination., INCLUSION CRITERIA: INCLUSION CRITERIA:,

1. acute spinal cord injury with Frankel Impairment Scale level A to C;, 2. 18 to 70 years old;, 3. Informed consent;, 4. C4 to L2 vertebral fractures, Exclusion criteria:, 1. Hepatic or renal disorders;, 2. Penetrating brain trauma;, 3. Traumatic brain injury;, 4. Pregnancy or Breastfeeding;, 5. Recent alcohol consumption;, 6. Neurological or psychiatric disorders;, 7. Life threatening injuries;, 8. Unable to receive riluzole orally

20. (2014). "Effects of Methylphenidate on the Acute Management of Patients with Severe and Moderate Traumatic Brain Injury."

INTERVENTION: Intervention 1: Patients in the treatment(case) group will receive methylphenidate 20 mg/kg per dose PO BID by the second day of admission for two weeks. Intervention 2: Patients in the control group will receive placebo 20 mg/kg per dose PO BID by the second day of admission for two weeks. Patients in the control group will receive placebo 20 mg/kg per dose PO BID by the second day of admission for two weeks. Patients in the treatment(case) group will receive methylphenidate 20 mg/kg per dose PO BID by the second day of admission for two weeks. Treatment - Drugs, CONDITION: Moderate and Severe Traumatic Brain Injury., PRIMARY OUTCOME: Cognitive function. Timepoint: During 3 and 6 months of follow-up. Method of measurement: Using cognitive measuring tests., SECONDARY OUTCOME: Disability Rating Score. Timepoint: During 3 and 6 months of follow-up. Method of measurement: DRS specific tests. GCS. Timepoint: During 3 and 6 months of follow-up. Method of measurement: GCS specific tests. GOSE. Timepoint: During 3 and 6 months of follow-up. Method of measurement: GOSE specific tests. Lenght of ICU stay. Timepoint: Total ICU treatment duration. Method of measurement: Based on patients' file and record. Lenght of overall hospital stay. Timepoint: Total hospital treatment duration. Method of measurement: Based on patients' file and record., INCLUSION CRITERIA: INCLUSION CRITERIA: ages between 16 and 60; having a history of non-penetrating traumatic brain injury with a GCS=6-8 (Severe) and GCS 9-12 (Moderate) without multi organ injury or failure., Exclusion criteria: not agreeing to enter the study; not being able to tolerate nasogastric Feeding; dying in 48 hours of admission; having a history of pre-morbid neurologic disease, psychosis, major affective disorder, developmental disability, ADHD, currently abusing alcohol or recreational drugs. taking psychoactive medications other than anticonvulsants. having systemic diseases that could have affected the results eg. Diabetes or psychiatric problems, pregnancy or likely to become pregnant; mental retardation, behavioral problems, impairments in vision, hearing, or motor function that were severe enough to preclude participation in the research tasks.

22. (2015). Sinapse 15(1).

The proceedings contain 47 papers. The topics discussed include: cerebrotendinous xanthomatosis: casuistry of the CHUC metabolic disorders consult and a review of the literature; spontaneous intracranial hypotension: an etiology of headache; incomplete HANAC (hereditary angiopathy, nephropathy, aneurysms, and muscle cramps) syndrome and the first COL4A1 gene mutation in Portugal (G236T); multiple penetrating brain injury by nail guns: case description and review of the literature; apomorphine in advanced Parkinson's disease: an option when other therapeutic

fails; multiple sclerosis is an index disease in multiple autoimmune syndromes?; childhood-acquired demyelinating syndromes; MS Forecast: an electronic tool to simulate MS prognosis; metabolic and mitochondrial diseases: myths and facts; depression and anxiety n multiple sclerosis: clinical and demographic associations in a cohort of patients; optic neuritis as presenting manifestation of BehcAciret's disease with multisystem involvement; olfactory dysfunction and cognitive impairment in primary progressive multiple sclerosis; and the role of phonemic verbal fluency test on the assessment of cognitive performance in multiple sclerosis.

---

23. (2015). "Effect of Exercise Training on Physical, Cognitive, and Behavioral Function in People With TBI." Effect of Exercise Training on Physical, Cognitive and Behavioral Function in Patients With Traumatic Brain Injury.

Objective, The broad objective of this study is to examine the effects of moderate and more intense aerobic exercise as an intervention on cognitive performance, physical functioning and health-related quality of life in patients with chronic (more than 12 months post-injury) traumatic brain injury (TBI). Importantly, structural and biological brain changes will be measured to examine whether functional outcomes are related to exercise-induced adaptations. It is hypothesized that in the chronic phase of persons with TBI, there will be improved: 1) cognitive function, 2) physical fitness and fatigue severity, 3) motor performance and balance, and 4) mood and depressive symptoms, in those that performed the exercise intervention compared to a control group. It is also hypothesized that these functional improvements will be related to exercise intensity, improved cortical connectivity, dopamine transmission gene scores, and blood biomarkers related to neuroand angio-genesis., Study Population, 80 ambulatory adults with non-penetrating TBI will be enrolled. Subjects will be recruited from NIH, affiliated hospitals/clinics and the community., Design, All subjects will perform baseline assessments including cognitive and behavioral performance, brain imaging, fitness, motor and balance testing, and selected blood and genetic testing. Thereafter, subjects will be randomized to either a waitlist control, or one of two exercise conditions: 1) 30 minutes at a fast pace, moderate-intensity (rapidresistive exercise; RET); 2) 30 minutes at higher-intensity (aerobic exercise; AET). Both exercise groups will perform the exercise on an elliptical trainer 3 times a week, for a session duration of 45 minutes including warm-up and cool-down. The RET group will focus on rapid reciprocal motion with minimal resistance, while the AET group will exercise at an elevated intensity known to produce an aerobic effect. After 12 weeks, all groups will repeat the baseline assessments (3 month follow-up). Following this assessment, the waitlist control group will be randomized to either RET or AET and the exercise groups will cease formal supervised exercise sessions. A third assessment visit will be performed after an additional 12 weeks (6 month follow-up)., Outcome Measures, Cognitive performance will be tested and interpreted compared to norms. Performance on motor and balance tasks will be assessed with the Smart Balance Measurement System and the GAITRite System. Physical fitness will be determined by peak oxygen consumption and aerobic threshold as measured by pulmonary gas exchange during an exercise tolerance test on the treadmill. Structural brain volumes will be determined by magnetic resonance imaging (MRI) and cortical connectivity will be quantified using resting state functional MRI and Diffusion Tensor Imaging (DTI) to evaluate integrity of and changes in white matter tracts in response to exercise. Blood will be collected to quantify the presence of biomarkers (such as VEGF, BDNF and IGF-1) and dopamine transmission. Other self-reported measures of quality of life, fatigue severity, depression and sleep quality would also be collected.

31. (2018). "Using Propranolol in Traumatic Brain Injury to Reduce Sympathetic Storm Phenomenon." Using Propranolol in Traumatic Brain Injury to Reduce Sympathetic Storm Phenomenon: A Prospective Randomized Clinical Trial Injury to Reduce Sympathetic Storm Phenomenon: A Prospective Randomized Clinical Trial.

The sympathetic storming events can be triggered by suctioning, repositioning, or environmental stimuli. To differentiate sympathetic storming from similar conditions, symptoms and signs have to occur in TBI patients a minimum of 1 cycle per day for 3 consecutive days (body temperature of 38.5 °C or more, heart rate at least 120 beat / min, systolic blood pressure > 140 mmHg, respiratory rate > 20 breaths / min, in presence of dystonia, diaphoresis, agitation and laboratory investigations confirm elevated serum catecholamines. Beta blockers has a cardio protective effect via lowering heart rate, stroke volume and mean arterial blood pressure which limits myocardial O2 consumptions and guards against myocardial infarction. They also have neuron protective effects via reducing cerebral blood flow thus lowering O2 and glucose consumption as cerebral metabolism is reduced. Propranolol a nonselective B receptor antagonists works on &bgr;1 receptors in brain, heart, and kidney and &bgr; 2 receptors in lungs, liver, skeletal muscles, eye and arterioles.We suppose that using Beta - adrenergic receptor blockers as propranolol blunts the sympathetic storming phenomenon as it is a nonselective &bgr; inhibitor and has a lipophilic property which enables it to penetrate blood brain barrier.

32. (2019). "Abstracts From the 47th Annual Meeting of the Society for Neuroscience in Anesthesiology and Critical Care." Journal of neurosurgical anesthesiology 31(4).

The proceedings contain 116 papers. The topics discussed include: induction of diffuse axonal brain injury based on rotational acceleration in rats; functional roles of the Alpha2delta-2 gabapentin receptor at the climbing fiber to purkinje cell synapse in the cerebellum; neuronal mechanisms of unconsciousness in an absence seizure model; optical pharmacokinetics of intra-arterial delivery of Cy5 labeled cell penetrating peptide -TAT to 9L brain tumors; comprehensive perioperative optimization and enhanced recovery clinical pathway for complex spine surgery patients: university of Florida experience; external ventricular drain management practices in Thailand: results of the EPRACT study; and facetime live chat between patient and family during awake craniotomy: patient and family centered care in neuroanesthesia.

33. (2019). "The BONANZA trial- a randomised controlled trial that is testing whether a management strategy guided by early brain tissue oxygen monitoring in patients in with severe traumatic brain injury improves long term neurological and functional outcomes." The BONANZA Trial -a randomised controlled trial in patients with severe traumatic brain injury that will determine whether a neuro-intensive care management strategy guided by continuous brain tissue oxygen (PbtO2) monitoring and intracranial pressure (ICP) monitoring will improve neurological and functional outcomes at 6 months measured by the GOSE, when compared to standard care using ICP monitoring alone.

INTERVENTION: Patients in the intervention arm will have continuous PbtO2 and ICP monitoring. Cerebral hypoxic episodes will be treated according to the BONANZA PbtO2 optimisation strategy. The PbtO2 treatment algorithm is a set of physiologic interventions that vary depending on the clinical scenario. The physiological interventions are tiered in a hierarchical fashion, with less aggressive interventions attempted before more aggressive manoeuvres. Three abnormal clinical scenarios are possible: 1. Isolated intracranial hypertension: PbtO2 is greater than or equal to 20 mmHg and ICP is greater than target. 2. Isolated cerebral hypoxia: PbtO2 is less than 20 mmHg and ICP is within the satisfactory range. 3. Simultaneous cerebral hypoxia and intracranial hypertension: PbtO2 is less than 20 mmHg and ICP is greater than target. All therapies are administered when the patient is in intensive care. Tier 1 therapies include sedation and analgesia. A broad range of agents may be used, most commonly Propofol, Midazolam, Morphine and Fentanyl. Vasopressors or drugs that are used to improve blood pressure may also be given in order to improve blood flow to the brain. Commonly used vasopressors are Noradrenaline and Adrenaline. Osmotherapy may also be administered to reduce the water content of the brain and reduce brain swelling. Commonly used osmotics include Mannitol and Hpertonic saline. The doses of all these drugs mentioned are variable and are usually given via an infusion that is titrated according to the patients response. Tier 2 therapies include the use of neuromuscular blockade agents like Cisatracurium. The dose is variable and may be given intermittently as a bolus or via infusion depending on each patient scenario. Other tier 2 therapies include blood tranfusion, and adjustments to the ventilator in order to optimize levels of oxygen and carbon dioxide in the patients blood. Tier 3 therapies are largely optional and include lowering the patients te, CONDITION: Injuries and Accidents - Other injuries and accidents Neurological - Other neurological disorders Severe traumatic brain injury; ; Severe traumatic brain injury, PRIMARY OUTCOME: Neurological outcomes measured using the Glasgow Outcome Score - Extended (GOS-E)[6 months post injury.], SECONDARY OUTCOME: Mortality (all cause)., ; [ICU discharge, ; Hospital discharge] Quality of life assessments (QOL) using EQ5D.[6 months post injury], INCLUSION CRITERIA: Patients >17 years who have suffered a non-penetrating severe TBI and who require ICP monitoring (in the judgement of the treating clinician).

34. (2019). "The effects of oral glibenclamide in patients with traumatic brain injury." A clinical trial of effects of oral glibenclamide on size of brain contusions and their peripheral edema in patients with moderate and severe traumatic brain injury.

INTERVENTION: Intervention 1: Intervention group: Oral glibenclamide 15 mg (three tablet, 5 mg each, chemidarou Pharmaceutical Company), daily for 10 days. Intervention 2: Control group: Placebo agent (Barij Essence Pharmaceutical Company, 3 tablets Daily, for 10 days., CONDITION: Brain contusion. ; Focal traumatic brain injury, PRIMARY OUTCOME: Brain contusion volume. Timepoint: On admission, day 3 and 7 days after intervention. Method of measurement: CT-volumetry of brain contusions., SECONDARY OUTCOME: Glasgow Outcome Scale (GOS). Timepoint: On Discharge time and 3 months later. Method of measurement: Physical Examination. Precontusional edema volume. Timepoint: On admission, day 3 and 7 days after intervention. Method of measurement: CT-volumetry of brain contusions., INCLUSION CRITERIA: INCLUSION CRITERIA: Patients aged between 18 and 75 years with documented closed head injury patients with non-penetrating brain injury Having brain contusions on initial brain CT scan GCS: 5-13 without influence of sedations upon admission Random blood sugar more than 70 mg/dl before the intervention Patients without a lesion on brain CT which urges a surgical evacuation at any time of hospital admission (Surgical EDH, SDH, ICH or midline shift>5mm and decompressive craniectomy) Patients without severe renal disorder from past history or Cr>2.5 Patients without severe liver disease from past history or total bilirubin above 1.5 times of normal value.

---

35. (2019). "Fluid administration strategy in severe traumatic brain injury." Restricted versus liberal fluid administration strategy in severe traumatic brain injury (RELIST). A randomized clinical trial.

INTERVENTION: The study will recruit patients aged 14 or above (14 is the age of adulthood in Saudi Arabia) who are victims of severe TBI (GCS < 9) within 24 hours of the incidence of trauma. The main intervention of the study is controlling the fluid balance in the first 7 days to keep it Â± 500 ml /day as compared to no interference with balance in the control group. Otherwise, both groups are treated similarly, according to our unit protocol adopted from guidelines of Brain Trauma Foundation. Intervention: Maintaining a 24 hours balance of +/- 500 ml , for the first 7 days. While following the TBI protocol as per the guidelines. Daily balance may be controlled using diuretics, and if needed vasopressors to maintain hemodynamic targets. Control: This group also follows the TBI protocol as per the guidelines, except there is no interference with the fluid balance, CONDITION: Isolated, non penetrating severe traumatic brain injury (GCS < 9) ; Injury, Occupational Diseases, Poisoning ; Intracranial injury, PRIMARY OUTCOME: Percentage of patients with favorable Glasgow Outcome Scale (4 or 5) upon ICU discharge, SECONDARY OUTCOME: ; 1. Percentage of patients with favorable GOS at 6 months; 2. ICU length of stay and mortality; 3. Development of pulmonary oedema; 4. Days on TBI management protocol; 5. Days on mechanical ventilation;, INCLUSION CRITERIA: 1. Age = 14 years 2. Severe TBI (GCS <9) 3. Within 24 hours of the incidence of trauma provided that the resuscitation phase is complete (post-resuscitation phase) 4. Isolated non-penetrating head injury 5. Clinical necessity for ICP management per BTF recommendations 6. Mechanically ventilated, without any evidence of respiratory dysfunction (P/F ration = 250). 7. Hemodynamically stable or on vasopressor support for standardized CPP management according to BTF recommendations: MAP = 65 mmHg 8. SBP = 90 mmHg

36. (2019). "Free Dermal Fat Autografts in Craniofacial Wounds." Fat to the Future, Dermal Time 3: Prospective, Single-Blind, Randomised Controlled Trial of Free Dermal Fat Autografting for Treatment of Complex Craniofacial Wounds.

A complex craniofacial wound is a wound on the head or face that will not heal, despite efforts to heal the wound with standard treatments, such as antibiotics and surgery to clean the wound. Currently, there are no good treatment options for these types of complex craniofacial wounds. This study will evaluate what happens when free autologous dermal fat grafting is used to help treat complex

craniofacial wounds by evaluating the area where the graft was placed to better understand how these types of grafts function. Free autologous dermal fat grafting is the process of taking fat from under the outer layer of skin and moving it to another part of the body of the same individual. Although free autologous dermal fat grafts have been used for many decades in plastic and reconstructive surgery to help a variety of patients suffering from different problems, only one study has used them to help heal complex craniofacial wounds. This use of free autologous dermal fat grafting is not considered to be experimental or an investigational product by the US Food and Drug Administration (FDA). Still, the use of free autologous dermal fat grafting has not been formally evaluated to understand how these types of grafts help patients with complex craniofacial wounds.

37. (2020). "ErythroPOietin Alfa to Prevent Mortality and Reduce Severe Disability in Critically Ill TRAUMA Patients." A Randomised, Double-blind, Placebo-controlled Trial of Erythropoietin Alfa Versus Placebo in Mechanically Ventilated Critically Ill Patients Following Traumatic Injury.

Trauma can cause many injuries, some of which are life-threatening and require treatment in, an intensive care unit (ICU). Despite best available treatment and therapies, people who, sustain a critical traumatic injury are at greater risk of death or long-term disability., From 2010 to 2015, approximately 9% of people admitted to an ICU in Australia and New Zealand, for treatment of their injuries, did not survive. In Victoria, 6-months post injury,, approximately 31% of people who were critically injured developed severe disabilities or, died., Following a traumatic injury, a number of complex pathways are activated by the body. These, pathways can occur over hours or weeks and may lead to damage of cells, tissues or blood, vessels and may destroy other healthy tissue. The treatment of traumatic injury focuses on, trying to minimise further damage that can occur after the initial injury., Erythropoietin is a glycoprotein hormone essential for erythropoiesis and was first purified, in 1977. Its human recombinant analogues known as erythropoiesis stimulating agents (ESAs), are approved for human therapeutic use. However, erythropoietin is also a pleiotropic, cytokine with effects beyond just erythropoiesis. Studies in animals have demonstrated the, potential protective effects of erythropoietin to organs including the brain, kidney, liver, and heart, and anti-inflammatory properties., Previous research suggests the use of the ESA called epoetin alfa, increases the number of, patients surviving severe trauma and reduces the risk of disability in those who survive., The primary aim of the study is to determine the efficacy of epoetin alfa compared to placebo, in reducing mortality and severe disability at six months in critically ill trauma patients., 2500 mechanically ventilated ICU patients admitted with a primary trauma diagnosis presenting, to the ICU will be recruited into the study from participating study centres in Australia,, New Zealand, Europe, and Saudi Arabia.

---

38. (2020). "International Trial of Efficacy of Cytoflavin in Head Trauma." International, Multicenter, Randomized, Single Blind, Placebo-controlled Study of Efficacy and Safety of CITOFLAVIN® in the Acute Period of Head Injury in Adults.

The study will access the efficacy and safety of treatment with CITOFLAVIN® in patients with, non-penetrating moderately severe traumatic brain injury (TBI). The study recruits patients, 18-60 years with TBI, corresponding to the clinical diagnosis of brain contusion, with GCS, score 9 -14 at the time of inclusion , with the estimated time of initiation of therapy, within 24 hours from the estimated or established time of trauma, with post-traumatic, amnesia, confusion or disorientation and absence of indications for neurosurgery or other, surgical intervention under general anesthesia., Cytoflavin® (Inosine + Nicotinamide + Riboflavin + Succinic Acid) is a combination drug,, which improves cerebral blood flow, activates metabolic processes in the central nervous, system, restores impaired consciousness, promotes regression of neurological symptoms and, improvement of cognitive functions of the brain.

---

39. (2021). "Abstracts from Issue 50 of EJVES Vascular Forum: Editors: Melina Vega de Ceniga and Anne Lejay." European Journal of Vascular and Endovascular Surgery 61(5): 867-869.

Selected Abstracts from the Journal of Vascular Surgery Extracorporeal Treatment with High Intensity Focused Ultrasound of an Incompetent Perforating Vein in a Patient with Active Venous Ulcers: Alfred Obermayer, Jean-François Aubry and Nesrine Barnat Introduction: Endovenous techniques such as ultrasound guided foam sclerotherapy, thermal methods, or glues are generally recommended to occlude incompetent veins. However, these methods can be technically challenging and risky for patients with severe atrophic skin disorders like lipodermatosclerosis or atrophie blanche. High intensity focused ultrasound (HIFU), which has been shown to coagulate and occlude veins successfully, may offer an alternative method. This case report details ultrasound guided HIFU to occlude non-invasively a refluxing perforator vein causing active ulcers. Report: A 95 year old man presented to the Institute for Functional Phlebology (Melk, Austria) with painful recurrent ulcers in his left medial calf. His limb was scored C2,3,4a, b,6, Ep, Ap, Pr,18 according to the Clinical, Etiology, Anatomic, Pathophysiology (CEAP) classification. Lower limb ultrasound revealed a refluxing posterior tibial perforating vein, measuring 2.7 mm in diameter at the level of the fascia. Extracorporeal HIFU pulses were delivered to this vein with the Sonovein device (Theraclion, Malakoff, France). Sonication was applied for eight seconds at a mean acoustic power of 80 W. The patient was followed up for three months post-treatment and occlusion was evaluated by duplex ultrasound. There were no complications during treatment or follow up. Three months after the treatment, reflux was abolished and the two initially active ulcers had healed. Discussion: Although this is an early report, this study shows that HIFU can be successful in ablation of incompetent perforator veins in the treatment of venous leg ulcers. Posterior Cerebral Circulation Stroke Secondary to Foetal Origin of Posterior Communicating Artery: An Indication for Carotid Endarterectomy: Lydia Mann, Ryan Preece, Liz Haslam, Sharath C.V. Paravastu, Richard A. Bulbulia and Sachin R. Kulkarni Introduction: Posterior cerebral circulation strokes are most commonly caused by posterior vasculature in situ thrombosis, cardiac emboli, or arterial dissection. However, the foetal origin of the posterior communicating artery is an anatomical variant of the cerebral circulation that results in communication between the internal carotid and posterior cerebral circulation. Therefore, rarely this can result in posterior cerebral territory infarction from internal carotid artery thrombo-embolism. This is the report of a case in which a patient suffered posterior circulation stroke secondary to this anatomical variation of the circle of Willis. Report: A 71 year old male patient was admitted to the stroke team with seizures, headache, and confusion. Examination revealed a left sided homonymous hemianopia. Diffusion weighted magnetic resonance imaging (MRI) of the brain 36 hours into his admission revealed an acute right posterior circulation infarct with extensive haemorrhagic transformation. Duplex ultrasound three days later revealed a heavily calcified right internal carotid artery mixed echogenicity plaque with 80%–90% stenosis. Subsequent computed tomography angiography showed a large right foetal variant posterior communicating artery. Following improvement in functional status, the patient underwent uneventful carotid endarterectomy to reduce risk of future stroke. Discussion: In patients presenting with posterior circulation infarction, clinicians should consider embolism from an atheromatous internal carotid artery via the variant foetal origin of posterior communicating artery. If detected, consideration should be given to undertaking carotid endarterectomy to reduce future stroke risk if no other source is detected. Surgical Explantation of a Fenestrated Endovascular Abdominal Aortic Aneurysm Repair Device Complicated by Aorto-Enteric Fistula: Caroline Caradu, Valérian Vosgin-Dinclaux, Emilie Lakhlifi, Vi cent Dubuisson, Eric Ducasse and Xavier Bérard Introduction: Alarming outcomes have been reported following infected endovascular aortic aneurysm repair (EVAR) device explantation. Infected fenestrated EVAR (FEVAR) exposes patients to even worse procedural risks. Report: A 67 year old man with a prior history of FEVAR presented with impaired general condition, abdominal and back pain, and increased C reactive protein. Computed tomography angiography revealed a collection around the aortic graft bifurcation and 18F-fluorodeoxyglucose–positron emission tomography (FDG-PET) revealed increased FDG uptake at this level, confirmed by labelled white blood cells, all favouring graft infection. A thoracophrenolumbotomy was performed and revealed an aorto-enteric fistula which was treated by small bowel resection. The left renal artery was transected at the distal end of the bridging stent and a

thoracorenal bypass was performed. The thoracic aorta was cross clamped above the coeliac trunk for complete graft excision. Meanwhile, the right kidney was perfused with 4°C Ringer lactate solution. In situ reconstruction was accomplished with a bifurcated antimicrobial graft sutured below the superior mesenteric artery with re-implantation of the right renal artery. The patient was left with a laparostomy for definitive abdominal closure, restoration of the digestive tract, and omental wrap 72 hours later. Broad spectrum antibiotic therapy was initiated peri-operatively and reduced to sulfamethoxazole/trimethoprim for a total duration of six weeks after one sample was positive for Moraxella osloensis. Eleven months later, the patient was free from re-infection, with no fever or inflammatory syndrome. Discussion: Total explantation of stent grafts with tissue debridement and post-operative antibiotic therapy is the gold standard when dealing with infected EVAR. As with type IV thoraco-abdominal aneurysm open repair, FEVAR device explantation requires additional protective measures to prevent visceral ischaemia and renal impairment. In agreement with the European Society for Vascular Surgery guidelines, such patients should be referred to dedicated vascular centres with expertise in surgical repair, anaesthetics, and post-operative intensive care. Histological Analysis of a Long Term Patent Subintimal Canal in the Superficial Femoral Artery: Tormod Lund, Aud Svindland, Dag Bay, Jon O. Sundhagen, Jonny Hisdal and Tor Flørenes Introduction: Subintimal angioplasty (SIA) was introduced in the late 1980s and is a supplement to bypass surgery. Adaptation of the technique has been hampered by high rates of early intervention to maintain patency, but the long term assisted patency is good. Report: The superficial femoral and popliteal artery containing a patent subintimal canal were explanted from a patient who died in the authors' ward. Histological analysis indicated that the lumen was created in the medial layer of the vessel wall. A collagen rich neointima and fragmented internal elastic lamina were observed, presumably as a result of activated smooth muscle cells. The luminal surface was partly covered by a single layer of CD31, von Willebrand factor, and partly CD144 positive cells. An early atherosclerotic lesion was observed distally in the subintimal canal. Discussion: Remodelling and neo-cellularisation of the vascular wall after SIA are described. Notably, hallmarks of early and late stage atherosclerotic disease were evident throughout the subintimal canal. These observations require confirmation in a larger number of specimens but underscore the need for surveillance after SIA. Estimating the “Pull” on a Pullthrough Wire: A Pilot Study: Arindam Chaudhuri, Frederic Heim and Nabil Chakfe Objective: Pullthrough/body floss wires are used to track endovascular devices across tortuous aorto-iliac anatomy encountered during endovascular repair of abdominal or thoracic aortic aneurysms. The tension imparted on such wires is arbitrary and has never been quantified. This pilot study attempted to quantify the tension used to stiffen the floppy hydrophilic wires typically used in such a scenario. Methods: Two linked experiments were undertaken, the first by tasking 13 blinded vascular surgeons (eight male, five female; mean age 36 ± 11 years, including nine trainees) with pulling a long floppy hydrophilic wire (Radifocus Guidewire M Stiff, Terumo UK, Bagshot, Surrey, UK) attached at the other end to a horizontally configured industrial scale (HDN-N Hanging Scale, Kern & Sohn GmbH, Balingen, Germany), to simulate what they individually felt was an “appropriate” tension; the second by using the derived average tensioning force to set up a pullthrough wire within a rigid life like aorto-iliac model to assess whether a test device (16F Sentrant Introducer Sheath, Medtronic Limited, Watford, UK) could be delivered over such a tensioned wire in both brachiofemoral and femorofemoral configurations. Results: The mean tension exerted by the group on the wire was 38.3 ± 14.8 N (equivalent to 3.9 kgf). Pullthrough wire tensioning was undertaken by fixing one end and applying a 3.9 kg weight at the other. The test device was successfully deployed into the infrarenal aortic position and also across the aortic bifurcation, via brachiofemoral and femorofemoral pullthrough configurations, respectively. Conclusion: Successful test device deliveries suggest that a minimum tension equivalent to almost 4 kgf applied to a floppy wire can provide “stiffening” to allow device tracking across tortuous aorto-iliac anatomy. More studies are needed to ascertain whether lower tensions can be applied; these results may help provide a platform for other such studies depending on configuration, aortic geometry, and device or wire/tension characteristics. A Gardening Session Turns Into a Life Threatening Aortic Transection: Ania Raszka, Theodoros Thomopoulos, Jean-Marc Corpataux, Dieter Hahnloser, Alban Longchamp and Justine Longchamp Introduction: Penetrating injuries to the sub-diaphragmatic aorta are challenging, with high mortality

rates. Most penetrating aortic trauma results from gunshots or stab wounds. This case reports a successful aortic bypass, following partial aortic transection caused by an accidental fall on a utility knife. Report: A healthy 82 year old woman was admitted to the emergency department following penetrating abdominal trauma following an accidental fall on an 18 cm long utility knife. On admission, the patient was haemodynamically stable, with no neurological deficit. Computed tomography angiography revealed multiple abdominal injuries to the stomach, duodenum, L4-L5 left vertebrae, and infrarenal abdominal aorta. The patient underwent urgent midline laparotomy, followed by successful aortic repair using a 14 mm polyester graft. The gastric and duodenal lesions were repaired with an omental patch. The post-operative course was uneventful. Discussion: Penetrating abdominal trauma with visceral lesions and aortic transection are high risk injuries, albeit rarely described in the literature. A low threshold for imaging, and multidisciplinary management by vascular and visceral surgeons are essential for timely recognition and successful intervention. Intravenous Lobular Capillary Haemangioma (Pyogenic Granuloma) of the Superior Vena Cava: Case Report and Literature Review: Elisabeth Blaya, Vincenzo Vento, Salomé Kuntz, Laurence Bruyns, Mickael Ohana, Noelle Weingertner, Anne Lejay and Nabil Chakfé Introduction: Intravascular lobular capillary haemangioma is a rare benign intravascular tumour, especially in large vessels. This is the report of a case and associated literature review. Report and literature review: This is the report of the first case of an intravenous lobular capillary haemangioma (ILCH) of the superior vena cava (SVC). A 30 year old female presented with a collateral thoraco-abdominal venous circulation. Chest computed tomography angiography, thoracic magnetic resonance imaging, and positron emission tomography revealed an intraluminal SVC tumour extending from the left brachiocephalic venous trunk to the distal third of the SVC. No re-operative biopsy was indicated. An en bloc tumour excision was performed, followed by reconstruction of the SVC with an L shaped, ringed polytetrafluoroethylene (PTFE) prosthesis. Histopathology revealed the presence of an ILCH with free margins. A review of the literature identified 64 cases of ILCH to date, all of which underwent total resection. When reported, no recurrences were found during follow up. Discussion: In this case, the ePTFE reconstruction of the SVC must be checked regularly for any adverse events. Although ILCH is a benign tumour with no risk of recurrence, regular surveillance is advised. Surgical Management of a Patient with an Internal Carotid Artery Stenosis, Eagle Syndrome, and Internal Carotid Artery Tortuosity: A Case of Four Pathologies of the Carotid Arteries: Grigol Keshelava, Rati Kurdadze and Devi Tsiklauri Introduction: In 1937, W.W. Eagle first described two clinical cases of elongated styloid process causing compression of adjacent anatomical structures. A case of left internal carotid artery (ICA) stenosis, Eagle syndrome (bilateral), ICA tortuosity, and occlusion of the right carotid arteries is presented. Report: A 67 year old man was referred following ischaemic stroke two months previously. Computed tomography (CT) revealed the pathologies described. Intervention was performed under general anaesthesia. The digastric muscle was transected, and the styloid process was resected. Carotid endarterectomy with end to end anastomosis between the crossed ends of the ICA was carried out using a temporary shunt due to occlusion of the contralateral carotid arteries. The patient was discharged on the third post-operative day. Discussion: The case described shows that one stage surgical treatment of ICA stenosis, coiling, and Eagle syndrome gives good results.

40. (2022). "A Pilot Multicentre Cluster Randomised Trial to Compare the Effect of Trauma Life Support Training Programmes on Patient and Provider Outcomes." A Pilot Multicentre Cluster Randomised Trial to Compare the Effect of Trauma Life Support Training Programmes on Patient and Provider Outcomes.

Introduction:, Trauma accounts for nearly 10% of the global burden of disease. Several trauma life support, programs aim to improve trauma outcomes. There is no evidence from controlled trials to show, the effect of these programs on patient outcomes. We describe the protocol of a pilot study, that aims to assess the feasibility of conducting a cluster randomised controlled trial, comparing Advanced Trauma Life Support (ATLS) and Primary Trauma Care (PTC) with standard, care., Methods and analysis:, We will pilot a pragmatic three-armed parallel, cluster randomised, controlled trial in, India,

where neither of these programs are routinely taught. We will recruit tertiary, hospitals and include trauma patients and residents managing these patients. Two hospitals, will be randomised to ATLS, two to PTC, and two to standard care. The primary outcome will be, all cause mortality at 30 days from the time of arrival to the emergency department. Our, secondary outcomes will include patient, provider, and process measures. All outcomes except, time to event outcomes will be measured both as final values as well as change from baseline., We will compare outcomes in three combinations of trial arms: ATLS versus PTC, ATLS versus, standard care, and PTC versus standard care using absolute and relative differences along, with associated confidence intervals. We will conduct subgroup analyses across the clinical, subgroups men, women, blunt multisystem trauma, penetrating trauma, shock, severe traumatic, brain injury, and elderly. In parallel to the pilot study we will conduct community, consultations to inform the planning of the full-scale trial.

---

41. Aarabi, B. (1987). "Comparative study of bacteriological contamination between primary and secondary exploration of missile head wounds." Neurosurgery 20(4): 610-616.

Aerobic and anaerobic bacterial contamination of scalp wounds, indriven bone fragments, and brain tracks were studied in two groups (A and B) of nonrandomized patients with missile head wounds in a 20-month study of patients from the front lines of the Iran-Iraq war. In the 53 Group B patients, the primary debridements, most of which had been performed within 24 hours after injury, were deemed insufficient and a secondary definitive exploration was performed. Group A patients (62) had primary definitive explorations at Nemazee Hospital after a mean of 66.5 hours since injury. All of the patients had been started on dexamethasone and a combination of either ampicillin and chloramphenicol or crystalline penicillin G and chloramphenicol after field evacuation. The contamination rate of scalp wounds, bone fragments and brain tracks was slightly higher in Group A (38.4%, 22.2%, and 29.6% respectively, for Group A and 31.9%, 19.5%, and 27% for Group B, respectively). Staphylococcus albus among the gram-positive and Acinetobacter among gram-negative bacteria were the most common infecting organisms. Fifty per cent of the bacteria cultured from the brain tracks of Group A and 30.8% of those cultured from Group B patients were gram-negative. A total of 125 patients in four groups was included in our overall study of victims of missile wounds that violated the dura mater. Four patients developed meningitis at Nemazee Hospital (3 postoperatively and 1 after facial penetration). Two patients in Group B were admitted with meningitis (1 with an accompanying abscess), 1 of them 20 days and the other 60 days after exploration at two different centers.(ABSTRACT TRUNCATED AT 250 WORDS)

42. Aarabi, B. (1988). "Traumatic aneurysms of brain due to high velocity missile head wounds." Neurosurgery 22(6 Pt 1): 1056-1063.

Two hundred twenty-three of 255 consecutive patients underwent cerebral angiography 16.9 +/- 11.6 days (SD) after high velocity missile injury to the head over a 29-month study period. Shell fragments were the most frequent projectiles (73.7%), and penetrating wounds were the most frequent injuries (61%). During the study, 2 patients (1 with an ophthalmic and the other with an anterior cerebral artery aneurysm) presented with delayed traumatic intracerebral hematoma; the first patient had had negative angiography 90 days earlier, and the second patient was admitted from a rehabilitation center after operation in another center 25 days earlier for a penetrating left frontal shell fragment injury. Six of 223 patients (2.7%) had dormant aneurysms (4 middle and 2 anterior cerebral arteries). Seven of 8 patients were operated on again to exclude their aneurysms from the cerebral circulation. Two of 8 patients died postoperatively (1 within 24 hours and another 51 days after discharge from the hospital in a vegetative state). Fragments penetrating temporal, temporoparietal, or pterional areas had a significantly greater chance of causing arterial injury (chi 2 = 11.46, P less than 0.001). There was a significant chance of having an aneurysm if a hematoma was seen at operation or on computed tomography of the head (chi 2 = 4.18, P less than 0.05). The penetrating mode of injury and shell fragments crossing the midline were two variables for which the statistical significance had a P value of

0.08. It is concluded that war casualties with penetrating shell fragment injuries near the pterion, especially when harboring intracerebral hematomas, should undergo cerebral angiography to rule out vascular injuries of the brain.

---

43. Aarabi, B. (1989). "Causes of infections in penetrating head wounds in the Iran-Iraq War." Neurosurgery 25(6): 923-926.

Factors seemingly influential in postoperative central nervous system infections were evaluated in 379 patients who sustained missile wounds to the head during the Iran-Iraq War. The mean wound age was 49 hours. The site of injury and presence of retained bone and/or shell fragments did not have a significant effect on infection rate. Thirty-three of 379 patients developed cerebrospinal fluid (CSF) fistulas of which 12 (36%) were associated with infection. The infection rate was 6 of 346 (1.7%) in the absence of CSF leaks. There was a statistically significant association between CSF fistula and infection. All 6 positive cultures in patients with CSF fistulas were gram-negative. Thirty-two patients died during the study, a mortality rate of 8.4%. The mortality rate from infection was 1.8%. Two hundred seventy-seven of 347 patients were followed for a mean of 22 +/- 17 months during which time 2 patients were readmitted with central nervous system infections, both due to CSF leakage. CSF fistulas were the main predisposing factor in postdebridement central nervous system infections in this study.

---

44. Aarabi, B. (1990). "Surgical outcome in 435 patients who sustained missile head wounds during the Iran-Iraq War." Neurosurgery 27(5): 692-695.

Variables important in predicting the final postsurgical outcome of 435 patients who sustained missile head wounds during the Iran-Iraq War were evaluated over a 99-month period. The type of projectile, site of injury, and presence or absence of foreign material did not seem to have a significant effect on the final outcome. Of the patients with a perforating type of injury, 48.8% had a poor surgical outcome as compared with 19.9% with a penetrating type and 15.6% with a tangential type. This difference is statistically significant (chi 2 = 14.7 and 17.1, respectively; p less than 0.001). The most important factor in predicting overall outcome was the Glasgow Coma Scale (GCS) score at the time of admission. Mortality and morbidity contributing to a poor surgical outcome were noted in only 6% of patients with a GCS score at admission of 13 to 15, in 24.6% of those with a GCS score of 9 to 12, in 57% of those with a GCS score of 6 to 8, and in 65% of those with a GCS score of 3 to 5. Of the 71 patients who died, 75% had a score of 3 to 8. Perforating projectiles or those traversing two or more dural compartments were statistically significant in contributing to mortality and morbidity (chi 2 = 17.2; p less than 0.001). The incidence of focal neurological deficit was 100, 90.6, 88, and 52.2% in patients with GCS scores of 3 to 5, 6 to 8, 9 to 12, and 13 to 15, respectively. The two best predictors of mortality in this group of patients were a low GCS score and infection.

45. Aarabi, B. (1995). "Management of traumatic aneurysms caused by high-velocity missile head wounds." Neurosurgery clinics of North America 6(4): 775-797.

Trauma is implicated as a significant factor in the genesis of fewer than 1% of intracranial aneurysms. With the introduction of powerful neuroimaging technology, slowly but definitely, predictive variables are being added to solve this seemingly deadly pathology resulting from projectile injuries of the brain. This article discusses recent literature, nonprojectile penetrating traumatic aneurysms, iatrogenically induced traumatic aneurysms, materials and methods, traumatic aneurysms, and results.

49. Aarabi, B. and J. Kufera (2013). "Predictors of outcome in gunshot wounds of the head." Neuroepidemiology 41(3-4): 241.

Objective: Civilian gunshot wounds to the head (GSWH) are deadly. Predictors of clinical outcome due to GSWH were analyzed over a 24-month period. Methods: We posited two questions: 1) What percentage of subjects with GSWH died across the state of Maryland; and 2) What were the predictors of good outcome (GOS) following GSWH? Demographics, clinical, imaging and acute care data of 786 civilians who sustained GSWH were analyzed. Univariate and regression analyses were used to analyze the data. Results: Of this cohort (N = 786 patients), 594 died at the scene and 122 died following admission to 8 Level I-III Trauma Centers. Seventy patients made it to TBI rehabilitation of which 30 (3.8%) had surgery. From the 69 patients who were admitted to this Level I Trauma Center, 78.6% were male, mean age was 34.8, injury severity score 26.7, GCS 7.1, and abnormal pupillary response to light (APR) was present in 47.4% of patients. CT scan indicated midline shift in 17.5%, obliteration of basal cisterns in 42.5%, intracranial hematomas in 35% and intraventricular hemorrhage in 55% of cases. Two subsets of admissions were studied: (1) 27 patients who died during acute care and (2) 15 patients who had a good outcome when followed a mean of 39 months. Missile trajectory ($p < 0.001$), admission GCS ($p < 0.001$), APR ($p = 0.002$), patency of basal cisterns ($p = 0.01$), age ($p = 0.02$) and intraventricular bleed ($p = 0.03$) had significant relationship with outcome. Stepwise multivariable logistic regression analysis indicated that GCS and patency of basal cistern were significant determinants of outcome. Exclusion of GCS from the regression models indicated missile trajectory and APR were significant players in determining outcome. Conclusions: GCS at admission, APR to light, patency of basal cisterns and the trajectory of the missile were significant determinants of outcome in civilian GSWH.

---

50. Aarabi, B., et al. (1998). "Central nervous system infections after military missile head wounds." Neurosurgery 42(3): 500-509.

OBJECTIVES: To evaluate variables instrumental in central nervous system infections after military missile head wounds, using uni- and multivariate analysis in 964 patients during the 8-year Iran-Iraq War., METHODS: Factors considered in this retrospective study were: the types of projectile, mode of injury, paranasal sinus involvement, number of lobes involved, transventricular injuries, place of exploration (base hospital or Nemazee Hospital), cerebrospinal fluid (CSF) fistulas, Glasgow Coma Scale (GCS) score, retained bone, and retained shell fragments., RESULTS: During the study period, 105 patients (11%) developed central nervous system infections, including 20 abscesses, 1 case of cerebritis, 2 cases of fungus cerebri, and 82 cases of meningitis. gram-negative organisms, especially Klebsiella pneumoniae, were the most frequent offending organisms. Forty-one percent of the 133 deaths were due to infections, but the death rate from infection was only 4.4%. Univariate analysis showed mode of injury, number of lobes involved, ventricular penetration, paranasal sinus involvement, CSF fistulas, place of exploration, GCS score, and retained bone fragments to have significant bearing on the incidence of central nervous system infections. On the other hand, multivariate regression analysis disclosed the following factors each enhancing infection: CSF fistulas ($chi2 = 46.526$), transventricular injuries ($chi2 = 13.4790$), and paranasal petrous sinuses involvement ($chi2 = 4.2221$). When compared with primary exploration at the Nemazee Hospital, both exploration at a base hospital and no exploration at all were associated with increased chances of infection ($chi2 = 4.7629$ and 8.3220, respectively). Additionally, when tangential, crossed penetrating, and uncrossed penetrating injuries were compared with through-and-through injuries, the uncrossed penetrating mode was associated with less infection ($chi2 = 0.1652$, 2.6353, and 5.0817, respectively). Only two patients were readmitted for

new evidence of infection 3 and 5 months after missile head wounds, one definitely due to and the other on suspicion of CSF fistulas. One hundred and thirty-seven of 587 patients with retained bone fragments were followed a mean of 42 months with no evidence of delayed infection., CONCLUSION: In this study, CSF fistulas and transventricular and paranasal sinus injuries all were associated with increased chances of central nervous system infections after military missile head wounds. Infection rate was lower in penetrating injuries not crossing into another dural compartment. Exploration at the Nemazee Hospital, despite delays in evacuation, had less incidence of infection than surgery at a base hospital within the first 24 hours of injury. Retained bone and metal fragments, a lower GCS score at the time of admission, secondary exploration at the Nemazee Hospital, and number of lobes involved were less important when evaluated in a multivariate regression model.

51. Aarabi, B., et al. (2000). "Prognostic factors in the occurrence of posttraumatic epilepsy after penetrating head injury suffered during military service." Neurosurgical focus 8(1): e1.

In this retrospective study, the authors evaluated confounding risk factors, which are allegedly influential in causing unprovoked posttraumatic epilepsy, in 489 patients from the frontlines of the Iran-Iraq War. Four hundred eighty-nine patients were followed for 6 to154 months (mean 39.4 months, median 23 months), and important factors precipitating posttraumatic epilepsy were evaluated using uni- and multivariate regression analysis. One hundred fifty-seven (32%) of 489 patients became epileptic during the study period. The results of univariate analysis indicated a significant relationship between epilepsy and Glasgow Outcome Scale (GOS) score ($X2 = 76.49$, $p < 0.0001$, $df = 2$), Glasgow Coma Scale score at admission ($X2 = 19.48$, $p < 0.0001$, $df = 3$), motor deficit ($X2 = 11.79$, $p < 0.001$, $df = 1$), mode of injury ($X2 = 10.731$, $p < 0.05$), transventricular injury ($X2 = 6.9$, $p < 0.008$, $df = 1$), dysphasia ($X2 = 5.3$, $p < 0.02$), central nervous system infections ($X2 = 5.3$, $p < 0.02$), and early-onset seizures ($X2 = 4.1$, $p < 0.04$, $df = 1$). The results of multivariate analysis, on the other hand, indicated that the GOS score and motor deficit were of greater statistical importance ($X2 = 35.24$, $p < 0.0001$; and $X2 = 7.1$, $p < 0.07$, respectively). Factors that did have much statistically significant bearing on posttraumatic epilepsy were the projectile type, site of injury on the skull, patient age, number of affected lobes, related hemorrhagic complications, and retained metallic or bone fragments. Glasgow Outcome Scale score and focal motor neurological deficit are of particular importance in predicting posttraumatic epilepsy after missile head injury.

52. Aarabi, B., et al. (2014). "Predictors of outcome in civilian gunshot wounds to the head." Journal of neurosurgery 120(5): 1138-1146.

OBJECT: Civilian gunshot wounds to the head (GSWH) are often deadly, but some patients with open cranial wounds need medical and surgical management and are potentially good candidates for acceptable functional recovery. The authors analyzed predictors of favorable clinical outcome (Glasgow Outcome Scale scores of 4 and 5) after GSWH over a 24-month period., METHODS: The authors posited 2 questions: First, what percentage of civilians with GSWH died in the state of Maryland in a given period of time? Second, what were the predictors of favorable outcome after GSWH? The authors examined demographic, clinical, imaging, and acute care data for 786 civilians who sustained GSWH. Univariate and logistic regression analyses were used to analyze the data., RESULTS: Of the 786 patients in this series, 712 (91%) died and 74 (9%) completed acute care in 9 trauma centers. Of the 69 patients admitted to one Maryland center, 46 (67%) eventually died. In 48 patients who were resuscitated, the Injury Severity Score was 26.2, Glasgow Coma Scale (GCS) score was 7.8, and an abnormal pupillary response (APR) to light was present in 41% of patients. Computed tomography indicated midline shift in 17%, obliteration of basal cisterns in 41.3%, intracranial hematomas in 34.8%, and intraventricular hemorrhage in 49% of cases. When analyzed for trajectory, 57.5% of bullet slugs crossed midcoronal, midsagittal, or both planes. Two subsets of admissions were studied: 27 patients (65%) who had poor outcome (25 patients who died and 2 who had severe disability) and 15 patients (35%) who had a favorable outcome when followed for a mean period of 40.6 months. Six patients were

lost to follow-up. Univariate analysis indicated that admission GCS score ($p < 0.001$), missile trajectory ($p < 0.001$), surgery ($p < 0.001$), APR to light ($p = 0.002$), patency of basal cisterns ($p = 0.01$), age ($p = 0.01$), and intraventricular bleed ($p = 0.03$) had a significant relationship to outcome. Multivariable logistic regression analysis indicated that GCS score and patency of the basal cistern were significant determinants of outcome. Exclusion of GCS score from the regression models indicated missile trajectory and APR to light were significant in determining outcome., CONCLUSIONS: Admission GCS score, trajectory of the missile track, APR to light, and patency of basal cisterns were significant determinants of outcome in civilian GSWH.

54. Aaronson, A., et al. (2016). "Aggression following traumatic brain injury: Could seizures play a role?" Journal of Neuropsychiatry and Clinical Neurosciences 28(3): e33.

Background: Aggression following penetrating TBI (pTBI) occurs in up to 1/3 of pTBI patients. The link between frontal lobe lesions and aggression has been demonstrated, however some people with lesions in parts of the brain not generally associated with disinhibition, violence or fear will also show aggressive behavioral changes. It has also been noted that some forms of post-TBI aggression and posttraumatic epilepsy may stem from overlapping network connectivity, leading some to theorize that the brain areas involved in seizures may also play a role in aggression. Objective: Compare patients who developed seizures following pTBI to those who did not develop seizures following pTBI on the Neuropsychiatric Inventory (NPI) aggression subscale to determine if presence of seizures predicts aggressive behavior. Determine if location of lesion has an effect on this correlation. Methods: 159 patients with pTBI were drawn from the Vietnam Head Injury Study registry. Patients with pTBI were divided according to presence (N=69) or absence (N=90) of seizures following injury. Aggression was

assessed using the aggression subscale of the NPI. Lesion location was determined using voxel-by-voxel assessment of CTs. Results: A chi-square analysis indicated that patients who developed seizures following TBI were more likely to have elevated NPI aggression scores than patients without seizures (x2 = 9.563, p value=0.003). There was no statistically significant correlation between NPI score and location of lesion in the population with seizures. Conclusion: Patients who developed seizures following pTBI were more likely to engage in aggressive behavior postinjury, regardless of lesion location.

55. Aaronson, D., et al. (2022). "Lead Toxicity Due to Retained Intracranial Bullet Fragment: A Case Report and Review of the Literature." Brain injury 36(SUPPL 1): 60.

Background: Lead toxicity (plumbism) secondary to retained lead bullet fragments is a rare complication in patients with gunshot wounds. To our knowledge, there has not been a definitive case reported of lead toxicity due to retained intracranial bullet fragments. Case Description: A 23-year-old man presented after being found down. Computed tomography scan of the head revealed bullet fragments within the calvarium adjacent to the left transverse sinus. During follow-up he developed symptoms of plumbism with paraesthesias in his bilateral hands and thighs, abdominal cramping, and labile mood. Plumbism was confirmed with sequentially elevated blood lead levels. The patient opted for surgical removal of the bullet fragments, which lead to a reduction in blood lead levels and resolution of his symptoms. Conclusions: Although rare, lead toxicity from retained intracranial bullet fragments should be considered in patients who have suffered a gunshot wound to the head and have symptoms of lead toxicity with elevated blood lead levels. For safe and easily accessible intracranial bullet fragments in patients with plumbism, surgical intervention may be indicated.

56. Abarca-Olivas, J., et al. (2011). "Perforating brain injury from a speargun. A case report." Neurocirugia (Asturias, Spain) 22(3): 271-275.

A case of a perforating brain injury caused by a speargun in a suicide attempt is described. Although this kind of injuries has been previously reported, the present case is specially interesting because the patient showed no neurological deficit after surgery. Some advices about the medical and surgical management are proposed based on this case and our literature review. The use of antibiotics and antiepileptic drugs and the anterograde extraction of the harpoon aided by the performance of a craniotomy surrounding the exit point are recommended.

57. Abd Elaziz, M. S., et al. (2017). "Stromal lenticule transplantation for management of corneal perforations; one year results." Graefe's archive for clinical and experimental ophthalmology = Albrecht von Graefes Archiv fur klinische und experimentelle Ophthalmologie 255(6): 1179-1184.

PURPOSE: To study application of stromal lenticules extracted by femtolaser small incision lenticule extraction (SMILE) surgery as a surgical adjuvant to seal corneal perforations., METHODS: Corneal stromal lenticules obtained through SMILE surgery with central thickness 100 mum or more were fixed over corneal perforation sites using 10-0 nylon interrupted stitches with an overlying single layer of amniotic membrane. Seven patients who had been followed up for a minimum of 12 months were assessed using slit-lamp biomicroscopy, fluorescein stain, tonometry, and best spectacle-corrected visual acuity (BSCVA) measurements. Postoperative complications were recorded throughout the follow up period., RESULTS: Corneal perforations had successfully been sealed in all 7 patients; 3 patients (42.9%) exhibited improved postoperative BSCVA. During the follow-up period of one year, no signs of re-perforation or infections were detected in any patient., CONCLUSIONS: These early findings suggest that the use of corneal stromal lenticules could be a safe and efficient surgical adjuvant for corneal perforation closure with potential clinical application, together with amniotic membrane, as relatively simple and low cost temporary measures to prepare perforated corneas for further definitive procedures.

59. Abdallah, O. I., et al. (2022). "Surgical Reconstruction of a Traumatic Superior Sagittal Sinus Injury Using Synthetic Vascular Graft in a Resource-Limited Civilian Field Hospital During the Syrian Civil War." World neurosurgery 159: 126-129.

BACKGROUND: Traumatic dural sinus injuries following penetrating brain injury are rare but are often associated with significant morbidity and mortality. The management of significant defects is operative and can be challenging. In modern civilian practice, patients with these injuries typically receive extensive preoperative investigation and advanced perioperative monitoring., METHODS: We report a case of successful operative management in a frontline civilian field hospital of a 33-year-old man who sustained a shrapnel injury to the junction of the middle and posterior thirds of the superior sagittal sinus during the Syrian Civil War., RESULTS: The injury was repaired successfully with a polytetrafluoroethylene graft. The postoperative course was uncomplicated. Anticoagulation was commenced 2 days postoperatively. The patient was discharged 5 days postoperatively with a GCS of 15 and mild weakness of the limbs bilaterally., CONCLUSIONS: Immediate repair of dural sinus injuries is feasible in the context of a low-resource wartime environment and should be attempted without delay. To our knowledge, this is the first case of successful use of a synthetic vascular graft for repair of a dural venous sinus injury in an ill-equipped hospital.

61. Abdoli, A. and A. Amirjamshidi (2009). "Work-related penetrating head trauma caused by industrial grinder tool." Archives of Iranian medicine 12(5): 496-498.

Nonmissile low-velocity penetrating brain injuries are unusual among civilian population. Work-related penetrating head wounds are rarer among this group. Here, we report two rare cases of penetrating head wounds caused by industrial grinder tool. The patients (both men) were struck to the head by detached blades of the grinder tool. Depressed fractures, penetrated bone fragments, and dural lacerations were all treated by the routine fashion. Paranasal sinus damage and further cerebrospinal fluid leakage were also treated conservatively. The reported cases are unexpected variants of injuries that neurosurgeons may come across and their management is still beyond the scope of textbooks. Skill and experience of the general neurosurgeons can handle the cases properly but prevention of such incidents using safer and guarded instruments should be stressed to manufacturers.

62. Abdulazeez, M. M., et al. (2018). "Intracranial ricocheted-bullet injuries: An overview and illustrative case." Journal of Acute Disease 7(5): 186-190.

The impact of a bullet by firearm is a mortal entity that in recent years has been on the rise due to the increase in crime, confrontations, among other acts of violence. Brain injuries by firearm account for 33.3% of all fatal injuries from this type of weapon. This resulted in a significant number of disabilities with its burden cost at a global level. The types of bullet injuries to the head include: penetrating (inlet without outlet), perforating (through and through), tangential (not enter the skull, causing coupe injury), ricochet (intracranial bouncing of bullet) and careening (rare, enter skull but not brain, runs in the subdural space). There are several situations that can occur once the bullet enters the body or into the intracranial cavity. Unmatched association of the bullet trajectory with the final position of the bullet

within the body raise the suspicion for additional phenomena involvement, this can be explained by either internal bullet ricochet or internal bullet migration. The former usually represents an active movement and the latter is a passive movement. Intracranial ricocheting of bullets forms up to 25% of all penetrating bullet injuries to the skull. Such bullets types are commonly tumbling and have an unpredictable trajectory. The surgical management for intracranial bullet injury developed over decades from the time of Harvey Cushing and the World War I till the present. Now, the accepted intervention ranges from simple wound care to a proper surgery that includes hematoma evacuation, removal of only accessible bone fragments and foreign bodies, dural repair and wound debridement with or without decompressive craniectomy. Also, intracranial pressure monitoring is generally indicated. We reported a thirty-three years old male, victim of homicidal bullet injury to the head, presented with Glasgow Coma Scale score of 8 (best eye response: 2, best motor response: 4, best verbal response: 2), upon examination a right parietal (near vertex) inlet without outlet was found. The poor prognostic factors in this patient included bi-hemispheric involvement, associated acute subdural hematoma with interhemispheric extension, ricochet type of injury and effacement of sulci. Intracranial ricocheted-bullet injury is a special entity of bullet injury to the head with its particular ballistics and management that deserve highlighting by the trauma team to gain fluent treatment and better outcome.

63. Abdulbaki, A., et al. (2012). "Transorbital craniocerebral occult penetrating injury with cerebral abscess complication." Case reports in ophthalmological medicine 2012: 742186.

Transorbital intracranial penetrating injury is an uncommon mechanism of head injury. These injuries can be occult during the initial clinical presentation. Certain patients develop an intracranial cerebral infection. Herein, we report a 5-year-old child with an occult transorbital intracranial penetrating injury caused by a pen. A retained pen tip was found at the superior orbital roof and was not noticed at initial presentation. This was complicated by a right frontal lobe cerebral abscess. This paper emphasizes the importance of orbitocranial imaging in any penetrating orbital injury. A review of the literature on intracranial infection locations in relation to the route and mechanism of injury is included to complement this report.

64. Abdulla, M. A. H., et al. (2017). "Cellular inflammatory response to penetrating trauma caused by transplantation surgery in the brain." British journal of neurosurgery 31(2): 122.

Objectives: Large proportion of cells that are transplanted surgically into the brain die early after procedure. The remainder display suboptimal survival and integration patterns owing to ongoing inflammatory and immunological processes. This study aimed to probe cellular contribution to inflammation induced by surgical trauma. Design: Laboratory experiment. Subjects: 64 adult female SD rats. Methods: Rats were assigned to 3 groups. Each group underwent a unilateral stereotactic procedure on the striatum: 1) Needle insertion for 2 minutes, 2) Excitotoxic (Quinolinic acid) lesion induction, 3) Lesion induction followed by needle insertion after 2 weeks. Immunohistochemistry and stereology were undertaken at 4 time points post-procedure: 1 hour, 24 hours, 72 hours and 1 week. Groups were compared to matched controls on respective time points. Analysis was done using 2way ANOVA with Bonferroni and Tukey's tests. Results: Significant recruitment of microglia, macrophages and circulating monocytes to injury site was noted 72 hours after needle insertion ($P<0.05$), this response was augmented upon lesion induction ($P< 0.001$). Cell numbers appeared to be fading by 1 week and approached baseline by 2 weeks. A second surgery at 2 weeks resulted in an amplified cellular response compared to first procedure ($P<0.001$). Conclusions: Although delayed, inflammatory cells reaction to surgical trauma contributes to neural graft site hostility. Cells appear to be primed after first injury and subsequent trauma tends to result in a more enhanced response.

65. Abe, T., et al. (1986). "Partial disconnection syndrome following penetrating stab wound of the brain." European neurology 25(3): 233-239.

A case of callosal disconnection syndrome caused by a penetrating stab wound of the brain is reported. A portion of the genu and the inferior splenium of the corpus callosum were sectioned by an ice pick without any other significant cerebral damage. We could detect incomplete disconnection left visual alexia by tachistoscopy. It would now appear that the inferior part of the splenium has a significant functional role in transmitting visual verbal codes from the right to the left cerebral hemisphere, but the remaining superior fibers of the splenium may carry some information, albeit less efficiently than the intact structure.

66. Abla, A. A., et al. (2011). "Delayed presentation of traumatic cerebral and dural arteriovenous fistulae after a BB gun accident in a pediatric patient: case report." Neurosurgery 68(6): E1750-1755.

BACKGROUND AND IMPORTANCE: To present a case of traumatic cortical and dural arteriovenous fistula (AVF) after a BB gun accident., CLINICAL PRESENTATION: The patient presented with a small left frontal subdural hematoma and small contusions in the left frontal lobe after he was shot with a BB. He had no skull fractures or significant midline shift. The patient, who was neurologically intact, was discharged after 3 days of observation and having undergone serial computed tomography imaging. Five days later, the patient developed lethargy and emesis. Computed tomography showed a 5 x 3 x 5 cm intraparenchymal hematoma in the left frontal lobe. Emergency evacuation of the hematoma revealed a cortical AVF, which was resected. Postoperative angiography showed a dural AVF of the left middle meningeal artery, draining into the superior ophthalmic vein and a dural vein. The dural AVF was embolized with n-butyl cyanoacrylate. The patient was discharged after 3 days with no deficits., CONCLUSION: The subdural hematoma and contusions were caused by a BB, which often are used in low-velocity and small caliber weapons. Not all BB guns are low velocity, and the consequences can be dramatic. The BB gun used here was pneumatic. The patient had no skull fractures. Several days of stable imaging and normal examinations suggested nothing sinister. His initial bleeds appeared disproportionate to the mechanism. The delayed presentation of the debilitating hematoma in this case stresses the need for vigilance on the part of practitioners and families when patients have a suspicious bleed.

67. Abookasis, D., et al. (2013). "Monitoring hemodynamic and morphologic responses to closed head injury in a mouse model using orthogonal diffuse near-infrared light reflectance spectroscopy." Journal of biomedical optics 18(4): 045003.

The authors' aim is to assess and quantitatively measure brain hemodynamic and morphological variations during closed-head injury (CHI) in mice using orthogonal diffuse near-infrared reflectance spectroscopy (o-DRS). CHI is a type of injury to the head that does not penetrate the skull. Usually, it is caused by mechanical blows to the head and frequently occurs in traffic accidents, falls, and assaults. Measurements of brain optical properties, namely absorption and reduced scattering coefficients in the wavelength range from 650 to 1000 nm were carried out by employing different source-detector distance and locations to provide depth sensitivity on an intact scalp over the duration of the whole experiment. Furthermore, alteration in both cortical hemodynamics and morphologic markers, i.e., scattering power and amplitude properties were derived. CHI was induced in anesthetized male mice by a weight-drop model using ~50 g cylindrical metal falling from a height of 90 cm onto the intact scalp producing an impact of 4500 g cm. With respect to baseline, difference in brain physiological properties was observed following injury up to 1 h post-trauma. Additionally, the reduced scattering spectral shapes followed Mie scattering theory was quantified and clearly shows changes in both scattering amplitude and power from baseline indicating structural variations likely from evolving cerebral edema during CHI. We further demonstrate high correlation between scattering amplitude and scattering power, with more than 20% difference in slope in comparison to preinjury. This result indicates the possibility of using the slope also as a marker for detection of structural changes. Finally, experiments investigating brain function during the first 20 min postinjury were conducted and changes in chromophore concentrations and scattering were observed. Overall, our experiments demonstrate the potential of using the proposed

technique as a valuable quantitative noninvasive tool for monitoring brain physiology following CHI injury at the bedside and/or at the field.

68. Aboud, N. D., et al. (1995). "Assessment and management of manual traumatic enucleation." Australian and New Zealand journal of ophthalmology 23(1): 55-57.

BACKGROUND: Gouging injuries represent a rare, severe form of orbital trauma. We report a case of manual traumatic enucleation., METHOD: Records of the patient were reviewed., RESULTS: The outcome of this case was loss of the globe with an uncomplicated recovery., CONCLUSIONS: Without attention to the particular principles of assessment and management outlined in this report, a satisfactory outcome is not assured.

---

69. Abraham, Z. S., et al. (2021). "Jael's syndrome: Case report and literature review." International journal of surgery case reports 88.

Introduction and importance: Jael's syndrome, an intentional injury caused by a knife in the face or skull is a rare encounter in clinical and forensic practice, rarely involving an impacted knife. Clinical and radiographic diagnosis is essential to identify severity of injury and location of the retained knife. To the best of our knowledge, this is the first reported novel case of Jael's syndrome in Tanzania. Case presentation: We present the case of a 31-year old man admitted at Muhimbili National Hospital following an impacted knife. The stab wound extended to the medial wall of left orbit and ended just before the optic foramen associated with vitreous hemorrhage and the retained knife caused superoposterior displacement of the globe. Multidisciplinary management was instituted including prompt evaluation, imaging and surgical removal of the knife under general anesthesia. Clinical discussion: Plain skull X-ray revealed an extensive retained blade and computerized tomography (CT) showed the tip of the blade adjacent to the right styloid process with no neurovascular compromise. Initial concern was the left eye that was reported to be viable by ophthalmologists. Incredibly, the patient had no initial sequelae from such an extensive injury and had unremarkable recovery with no complications apart from the wound to left inferior rectus muscle that was conservatively managed. Simple withdrawal of the retained knife was successful. Conclusion: Craniofacial retained knives are rare. Thorough prompt initial evaluation and intervention is vital since improper management can be devastating.

71. Abramowicz, S., et al. (2017). "Facial Fractures in Patients With Firearm Injuries: Profile and Outcomes." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons 75(10): 2170-2176.

PURPOSE: Firearm injuries (FAIs) are a major public health issue in the United States. The objective of this study was to examine characteristics and outcomes of patients presenting to emergency departments (EDs) with facial fractures attributed to FAIs., MATERIALS AND METHODS: The Nationwide Emergency Department Sample for the years 2008 to 2013 was used. All patients who visited EDs with FAIs and facial fractures were selected. The study focused on the following variables: 1) demographic characteristics, 2) types of facial fractures, 3) disposition status after ED visit or subsequent hospitalization, 4) charges (ED and hospitalization), and 5) patient outcomes. The inclusion criteria were a visit to a hospital-based ED with facial fractures and an external cause of FAI. Descriptive statistics were used to summarize findings. Multivariate logistic regression analysis was used to examine the simultaneous effects of patient-related factors on ED death., RESULTS: During the study period, a total of 15,469 patients (mean age, 34 years) visited hospital-based EDs with facial

fractures attributed to FAIs. Most were uninsured male patients. The most common etiology of FAIs was assault. The most common facial fractures were open mandibular fractures and open maxillary and/or malar bone fractures. Approximately 27% of patients had a concomitant intracranial injury. After the ED visit, 74% were admitted. The mean ED charge per patient was $6,403, and the total ED charge across the United States was $76.48 million. The mean hospitalization charge per patient was $167,203. The total hospitalization charge across the United States was $1.9 billion. Patients with intracranial injuries (odds ratio [OR], 21.21; 95% confidence interval [CI], 7.16 to 62.85; P < .01), uninsured patients (OR, 4.24; 95% CI, 1.44 to 12.51; P < .01), and patients residing in areas with high household incomes (OR, 5.60; 95% CI, 2.51 to 12.46; P < .01) were high-risk groups for ED death., CONCLUSIONS: FAIs require substantial resources for stabilization and treatment by EDs. This study highlights the burden and impact of facial fractures in patients with FAIs in the United States.

73. Acar, N., et al. (2020). "Early and Ultraearly Administration of Tranexamic Acid in Traumatic Brain Injury: Our 8-Year-Long Clinical Experience." Emergency medicine international 2020: 6593172.

INTRODUCTION: The most important result of head trauma, which can develop with a blunt or penetrating mechanism, is traumatic brain injury. Tranexamic acid (TXA) can be used safely in multiple trauma. Recent studies showed that TXA can be useful in management of intracerebral hemorrhage, especially in reducing the amount of bleeding. The TXA given in the first 3 hours has been shown to reduce mortality. The aim of our study was to evaluate the effectiveness of tranexamic acid used in patients with traumatic brain injury., METHOD: Patients with trauma in the emergency room between January 2012 and January 2020 were screened in this retrospective study. The inclusion criteria were being over the age of 18 years, tranexamic acid administration in the emergency department, and traumatic brain injury on brain computerized tomography (CT) and control CT imaging after 6 hours., RESULTS: The number of study patients was 51. The median score of GCS was 12.00 (8.00-15.00). Subdural hemorrhage and subarachnoid hemorrhage were the most common findings on brain CT scans. In the group TXA treatment for less than 1 hour, the arrival MAP was low and the pulse was high (p=0.022 and p=0.030, respectively). All the patients were admitted with multiple trauma. None of the 51 patients had thrombotic complications and died due to head injury., CONCLUSION: TXA appears to be a safe drug with few side effects in the short term in head injuries. According to our experience, it comes to mind earlier in multiple trauma, especially in head trauma with pelvic trauma.

---

74. Acarturk, S., et al. (1994). "Reconstruction of the wide palate defects with temporal osteocutaneous island flaps." European Journal of Plastic Surgery 17(4): 195-198.

The temporal osteocutaneous island (TOCI) flap was first performed in reconstruction of palatal defects by Furnas. It consists of temporoparietal fascia, galea, pericranium and the cortical layer of parietal bone covered with pericranium. In this study, we present five patients with wide palatal defects treated by TOCI flaps. The causation of the wide palatal defects were gun-shot wounds in two patients

and unsuccessful reconstruction of congenital cleft palate during early childhood in three patients. All patients were adult. TOCI flaps were performed in two stages. At first, the TOCI flap was elevated and covered with a split thickness skin graft. In the second stage (approximately 1.5 months later), the flap was elevated based on the superficial temporal artery as an island flap. It was then transferred to the palatal defect via a cheek tunnel and sutured to the edges of the defect. There was no need for bone fixation. The length of the pedicle of the flap was sufficient in size to easily reach the anterior part of the palate. No serious complications were seen. One minor oronasal fistula occurred; this was repaired by local flaps. The TOCI flaps improved speech only partially. In conclusion, we believe this procedure is a good method for reconstruction in wide palatal defects which need three layer closure. This procedure is not a satisfactory solution for complete correction of speech defects.

75. Acharya, A., et al. (2020). "An Unusual Case of Penetrating Injury Skull with Metallic RCC Rod in A Child - A Rare Case Scenario with Review of Literature." Neurology India 68(6): 1462-1464.

Penetrating head injuries can be the result of numerous intentional or unintentional events, including missile wounds, stab wounds, and motor vehicle or occupational accidents (nails, screw-drivers). Penetrating head injuries in children constitute even a smaller part of the total number of traumatic head injuries seen in casualty. We report a case of neuro-trauma who was operated in our institution. A 6-year-old female presented in casualty with an iron rod penetrating into the skull.

77. Achola, K. A., et al. (2022). "Implementing the WHO Safe Childbirth Checklist modified for preterm birth: lessons learned and experiences from Kenya and Uganda." BMC health services research 22(1): 294.

BACKGROUND: The WHO Safe Childbirth Checklist (SCC) contains 29 evidence-based practices (EBPs) across four pause points spanning admission to discharge. It has been shown to increase EBP uptake and has been tailored to specific contexts. However, little research has been conducted in East Africa on use of the SCC to improve intrapartum care, particularly for preterm birth despite its burden. We describe checklist adaptation, user acceptability, implementation and lessons learned. METHODS: The East Africa Preterm Birth Initiative (PTBi EA) modified the SCC for use in 23 facilities in Western Kenya and Eastern Uganda as part of a cluster randomized controlled trial evaluating a package of facility-based interventions to improve preterm birth outcomes. The modified SCC (mSCC) for prematurity included: addition of a triage pause point before admission; focus on gestational age assessment, identification and management of preterm labour; and alignment with national guidelines. Following introduction, implementation lasted 24 and 34 months in Uganda and Kenya respectively and was supported through complementary mentoring and data strengthening at all sites. PRONTO® simulation training and quality improvement (QI) activities further supported mSCC use at intervention facilities only. A mixed methods approach, including checklist monitoring, provider surveys and in-depth interviews, was used in this analysis. RESULTS: A total of 19,443 and 2229 checklists were assessed in Kenya and Uganda, respectively. In both countries, triage and admission pause points had the highest rates of completion. Kenya's completion was greater than 70% for all pause points; Uganda ranged from 39 to 75%. Intervention facilities exposed to PRONTO and QI had higher completion rates than control sites. Provider perceptions cited clinical utility of the checklist, particularly when integrated into patient charts. However, some felt it repeated information in other documentation tools. Completion was hindered by workload and staffing issues. CONCLUSION: This study highlights the feasibility and importance of adaptation, iterative modification and complementary activities to reinforce SCC use. There are important opportunities to improve its clinical utility by the addition of prompts specific to the needs of different contexts. The trial assessing the PTBi EA

intervention package was registered at ClinicalTrials.gov NCT03112018 Registered December 2016, retrospectively registered.

78. Achram, M., et al. (1980). "Angiographic aspects of traumatic intracranial aneurysms following war injuries." The British journal of radiology 53(636): 1144-1149.

Intracranial aneurysms following head injuries occur very rarely. Only 15 cases following injuries by missiles or shrapnel have been reported in the world literature. The angiographic findings in seven cases injured during the recent fighting in Lebanon, are described. The relatively high frequency of occurrence of these aneurysms in our cases might be explained by the fact that they were injured by low velocity missiles. A high velocity missile would disrupt an artery completely. It is also of interest that most of the aneurysms originated from arterial branches along the path of the foreign body, but not in contact with it. Unlike congenital aneurysms, they bore no relationship to arterial bifurcations and, unlike aneurysms following closed-head injuries, none involved the large basal arteries. None of them had a neck, and a mass effect due to bleeding was found in six of the cases.

79. Ackall, F., et al. (2017). "Laryngeal gunshots: Case report and literature review." Otolaryngology - Head and Neck Surgery (United States) 157(1): P228.

Objectives: Penetrating laryngeal injuries secondary to gunshot wounds (GSWs) are rare, especially in the postwar era. This study presents a case of GSW to the larynx as well as a review of the current literature. Methods: We present a case of laryngeal trauma secondary to a GSW. Institutional medical records were reviewed and analysis of the current literature was performed. Results: A 29-year-old man was shot multiple times at close range. One GSW involved the anterior neck and larynx. He did not have stridor or dyspnea on presentation. Direct laryngoscopy was performed, and findings included significant glottic edema and anterior laryngeal injury with injury to the anterior thyroid cartilage. Tracheotomy was performed, and postoperative laryngeal computed tomography confirmed destruction of the anterior thyroid lamina. The anterior commissure soft tissue appeared intact and stent was not placed. Staged transcervical open reduction internal fixation was performed. A gastric feeding tube was placed and the patient remained nil per os for 3 weeks without allowing for tracheotomy speaking valve use. At 1 month followup, the patient had a raspy voice but was swallowing without difficulty. Indirect laryngoscopic examination revealed mild glottic edema with good glottic closure. Conclusions: Acutely, laryngotracheal trauma secondary to GSWs can be life threatening and requires urgent airway stabilization. Maintaining a patent airway as well as voice and swallow function are long-term goals but can be challenging to accomplish. In cases of major laryngeal trauma, early surgical exploration of the larynx and repair should be considered to reduce the risk of glottic web formation.

80. Acosta, J. A., et al. (1998). "Lethal injuries and time to death in a level I trauma center." Journal of the American College of Surgeons 186(5): 528-533.

BACKGROUND: The purpose of this study was to identify the causes and time to death of all trauma victims who died at a level I trauma center during an 11-year period., STUDY DESIGN: Autopsies were performed on all patients who died secondary to trauma. Retrospective review of these autopsies was carried out and appended to existing trauma registry data. Standard definitions were used to attribute the cause of death in each case. Preventable deaths were determined by a standardized peer review process., RESULTS: Between January 1985 and December 1995, a total of 900 trauma patients died. This represented 7.3% of all major trauma admissions (12,320). Seventy percent of these patients died within the first 24 hours of admission. Thoracic vascular and central nervous system (CNS) injuries were the most common causes of death in the first hour after admission to the hospital. CNS injuries were the most common causes of death within the 72 deaths after admission. Acute inflammatory processes (multiple organ failure, acute respiratory distress syndrome, and pneumonia) and pulmonary emboli were the leading causes of death after the first 72 hours. Overall, 43.6% (393 of 900) of all

trauma deaths were caused by CNS injuries, making this the most common cause of death in our study. The preventable death rate was 1%., CONCLUSIONS: The first 24 hours after trauma are the deadliest for these patients. Primary and secondary CNS injuries are the leading causes of death. Prevention, early identification, and treatment of potentially lethal injuries should remain the focus of those who treat trauma patients.

81. Adakal, O., et al. (2022). "Concurrent impalement of two orbits in a child: A case report." International journal of surgery case reports 90: 106727.

INTRODUCTION: Orbital impalement is a serious and potentially life-threatening trauma if the brain or vessels at the base of the skull are affected. The authors report the results and aftermath of the management of a case of post-traumatic retention of an intra-orbital metallic foreign body., CASE PRESENTATION: A 5-year-old boy was struck by a motorcycle while crossing a road. His head struck the handlebars of the motorcycle with a left facial-orbital impact point. The examination revealed a foreign body penetrating the orbit at the level of the left upper eyelid with limitation of adduction. The radiological assessment confirmed the intra-orbital presence of the foreign body with probable fracture of the inner wall of the eyeball. Surgical exploration through the palpebral wound revealed an intact eyeball and an incarceration of the medial rectus muscle by a fracture of the internal wall. After delicate and meticulous removal of the foreign body, hemostasis was ensured and the wound was sutured. The evolution was satisfactory, without sequelae or visual prejudice., DISCUSSION: Imaging, i.e. a CT scan and a standard X-ray, is necessary to evaluate the lesions before adapting a therapeutic attitude. The choice of the approach for extraction must meet two cardinal concerns: extraction of the foreign body and minimal dissection or manipulation of the noble structures of the eye and its adnexa., CONCLUSION: Intra-orbital foreign bodies are rare but potentially serious. The type of the foreign substance, its intra-orbital extension and related lesions, as well as the extraction process, all influence the prognosis.

82. Adam, A., et al. (2016). "Incidence of traumatic brain injury in a Ghanaian Tertiary Hospital." Journal of Medical and Biomedical Sciences 5(2): 5-12.

Traumatic brain injury (TBI) is considered as one of the most silent epidemics and its incidence is rising worldwide due to injuries associated with the increased use of motor vehicles and bad road network, particularly in middle-income and low-income countries including Ghana. The aim of this study was to assess the incidence of TBI, cause of injury as well as outcomes of patient's care in the Tamale Teaching Hospital in Ghana. This retrospective study was carried out at the Tamale Teaching Hospital, the only Tertiary referral hospital in the whole of the savanna ecological zone of Ghana over 43 months from January 2009 to July 2012. All patients admitted into the hospital and diagnosed as having TBI were included in the study. The medical records of a total of 671 patients who were diagnosed with TBI were reviewed. Information regarding the age, sex, occupation and initial external cause of injury was retrieved. Data regarding length of hospital stay and treatment outcome were also retrieved. External cause of injury was classified according to International Classification of Diseases (ICD) guidelines as Road Traffic Accidents (RTA) (irrespective of type), fall from height, assault, gunshot, game or sport related accident and other causes. Road traffic accident accounts for relatively high incidence of hospitalized TBI. Majority of the patients were male within the 21-30 year age group. The high number of Intensive Care Unit (ICU) fatalities may indicate that more resources and facilities (intensive care nurses and equipment to monitor intracranial pressure) are needed to help in the management of cases particularly head injuries.

84. Adams, G. and C. R. Nelms (1976). "Complicated mandibular fractures." Otolaryngologic clinics of North America 9(2): 453-464.

In many mandibular fractures, proper alignment of the fragments is only a portion of the management program. Consideration must be given to the possibility of numerous other complications, and the patient should be carefully evaluated for injuries of the cervical spine, skull, head, and chest. The medical background, age, and other factors, such as the patient's ability to cooperate and follow the physician's instructions, may determine the method of applied treatment.

87. Adeagbo, B. A., et al. (2008). "Homicides committed by youth assailants: a retrospective study." The American journal of forensic medicine and pathology 29(3): 219-223.

The pediatric population has received considerable attention in the forensic community; the youth assailant of homicide, however, is understudied. The authors retrospectively reviewed all cases referred to the Forensic Pathology Section of the Medical University of South Carolina between January 1991 and May 2006. Cases included in the study were homicides in which 1 or more assailants were 19 years of age or younger. The cases were examined as to the cause and manner of death, victim age, gender, race, incident location, weapon used, assailant-victim relationship, assailant age, gender, race, motive, and postmortem toxicology results. Assailant information was obtained from forensic records at Medical University of South Carolina, police department records, and online search engines of South Carolina State newspaper archives confirmed by law enforcement reports. The youth assailants were predominantly black men, 15 to 19 years of age (range, 4-19 years). Most victims were black male acquaintances, and the motive was most often an argument. The most common cause of death was cerebral laceration because of a gunshot wound. The incident occurred in the home in 41% of cases, followed by the street in 31%. Victim toxicology was frequently positive for cocaine, marijuana, and alcohol.

---

88. Adebonojo, S. A. (1993). "Management of chest trauma: a review." West African journal of medicine 12(2): 122-132.

The incidence of chest trauma has increased significantly since the turn of the century especially in developed countries where rapid means of transportation has become part of daily life. Although gunshot wounds (GSWs) were the commonest causes of chest trauma in wartime, road traffic accidents (RTAs) have become the scourge of peacetime and modern civilization. Chest trauma is more common in males during the 2nd to the 5th decades of life with an average age of 40 years reducing their life expectancy by another 40 years at the most productive and active period of their lives. Despite improvement in ambulance service and rapid mobilization of victims from the scene of accident, about

10% of chest injured patients will die on the spot and another 5% die within an hour of reaching the hospital. Of the remaining 85%, five percent will require emergency thoracotomy for various reasons while 80% will respond to resuscitative measures and tube thoracostomy drainage alone. The primary aims in the management of chest trauma are prompt restoration of normal cardiorespiratory functions, control of haemorrhage, treatment of associated injuries and prevention of sepsis. Although the overall survival rate of trauma has improved in recent years, deaths are often due to airway obstruction, exsanguinating haemorrhage, flail chest, tension pneumothorax, cardiac tamponade and associated intracranial, intraabdominal and skeletal injuries.

---

92. Adeloye, A. and E. L. Odeku (1971). "A syndrome characteristic of tangential bullet wounds of the vertex of the skull." Journal of neurosurgery 34(2 Pt 1): 155-158.

Six patients with tangential missile wounds of the vertex of the skull presented symptoms of limb paresis which were more marked proximally in the arms and distally in the legs where there was also sensory loss of a cortical type. Carotid cerebral angiography and operative treatment showed patency of the longitudinal sinus and injury to the medial aspects of the frontoparietal cortex. The term "longitudinal sinus syndrome" formerly applied to these cases is therefore a misnomer since the main underlying cause is cortical injury and not thrombotic occlusion of the superior longitudinal sinus, as previously suspected.

94. Adem, C., et al. (1999). "[The persistence of a spheno-occipital synchondrosis in an adult]." Persistance de la synchondrose spheno-occipitale chez l'adulte. 80(8): 863-865.

The postnatal development of the central skull base is a complex process: at least 25 separate ossification centers are assimilated in the maturing sphenoid and occipital bones. Some synchondroses may only be partially fused and persist during adulthood. We report the case of a 30-year-old man with a penetrating trauma of the central skull base. Skull computed tomography demonstrated a rare anatomic variant: incomplete fusion of the spheno-occipital synchondrosis. Knowledge of the normal skull base development and of its variants may prove helpful in differentiating a post-traumatic injury from a normal variant.

95. Adeolu, A. A., et al. (2013). "Epidemiology of neurotrauma in Ife-Ijesha zone of Nigeria." World neurosurgery 80(3-4): 251-254.

BACKGROUND AND OBJECTIVE: Trauma remains one of the important causes of severe disability and high mortality. In this study, we looked at the epidemiology of neurotrauma in our region

so as to highlight essential factors for trauma prevention program., METHODOLOGY: This is a cross-sectional study of all neurotrauma cases admitted to the neurosurgery service of our hospital over an 18-month period. Information was obtained on patients' demographic data, etiology of injury, duration of injury, site, and cause of accident among others., RESULTS: One hundred forty-three patients were included in the study. The injuries occurred mostly in males and in the third decade. Most of the patients were students and traders. Eighty-one percent of the accidents were due to road traffic crash (RTC), and the most common contributory factors were head-on collision (46.2%) and overtaking (28.6%). Five of six patients who had RTC in the first decade of life were pedestrians. There were more crashes within the cities. None of the patients who had motorcycle accidents used helmet and only four patients used seatbelts at the time of the accident. Transfer to hospital was mostly in vehicles other than ambulance., CONCLUSION: Neurotrauma in our study was mostly due to RTC and it is most common in young male students. Contributory factors were head on collision and overtaking.

98. Adeshina, A. M., et al. (2013). "Multimodal 3-D reconstruction of human anatomical structures using SurLens Visualization System." Interdisciplinary sciences, computational life sciences 5(1): 23-36.

In the medical diagnosis and treatment planning, radiologists and surgeons rely heavily on the slices produced by medical imaging devices. Unfortunately, these image scanners could only present the 3-D human anatomical structure in 2-D. Traditionally, this requires medical professional concerned to study and analyze the 2-D images based on their expert experience. This is tedious, time consuming and prone to error; expecially when certain features are occluding the desired region of interest. Reconstruction procedures was earlier proposed to handle such situation. However, 3-D reconstruction system requires high performance computation and longer processing time. Integrating efficient reconstruction system into clinical procedures involves high resulting cost. Previously, brain's blood vessels reconstruction with MRA was achieved using SurLens Visualization System. However, adapting such system to other image modalities, applicable to the entire human anatomical structures, would be a meaningful contribution towards achieving a resourceful system for medical diagnosis and disease therapy. This paper attempts to adapt SurLens to possible visualisation of abnormalities in human anatomical structures using CT and MR images. The study was evaluated with brain MR images from the department of Surgery, University of North Carolina, United States and CT abdominal pelvic, from the Swedish National Infrastructure for Computing. The MR images contain around 109 datasets each of T1-FLASH, T2-Weighted, DTI and T1-MPRAGE. Significantly, visualization of human anatomical structure was achieved without prior segmentation. SurLens was adapted to visualize and display abnormalities, such as an indication of walderstrom's macroglobulinemia, stroke and penetrating brain injury in the human brain using Magentic Resonance (MR) images. Moreover, possible abnormalities in

abdominal pelvic was also visualized using Computed Tomography (CT) slices. The study shows SurLens' functionality as a 3-D Multimodal Visualization System.

---

100. Adrie, C., et al. (2010). "Immune status and apoptosis activation during brain death." Shock (Augusta, Ga.) 33(4): 353-362.

The present study evaluates the role of the inflammatory status and apoptosis activation in the development of organ dysfunction after brain death using plasma assays and macroarray analysis on skeletal muscle biopsies to look for evidence of remote tissue damage in two intensive care units in France and one in Belgium. As controls, we used patients undergoing hip surgery and healthy volunteers. Causes of brain death in the 85 consecutive patients included in the study were cardiac arrest (n = 29; 34%), stroke (n = 42; 49%, with 38 patients having hemorrhagic stroke), and head injury (n = 14; 17%). Of the 85 patients, 45 donated 117 organs. Plasma endotoxin and cytokine levels indicated a marked systemic inflammatory response in brain-dead patients, which was strongest in the cardiac arrest group. Leukocyte dysfunction, as assessed by cytokines production in response to various stimuli, was noted in a subgroup of patients with brain death after stroke. Interestingly, skeletal muscle biopsies showed no increase in mRNAs for genes related to inflammation, whereas mRNAs for both antiapoptotic and proapoptotic genes were increased, the balance being in favor of apoptosis induction. The increased activation of the proapoptotic caspase 9 was further confirmed by Western blot. In conclusion, the presence of inflammation and apoptosis induction may explain the rapid organ dysfunction seen after brain death. Both abnormalities may play a role in organ dysfunction associated with brain death. However, the level of systemic inflammation or the presence of circulating endotoxin was not associated with lower graft survival.

---

101. Adua, S., et al. (2019). "MA09.06 Adaptive Mechanisms of Resistance to Targeted Therapy in EGFR Mutant Brain Metastasis." Journal of Thoracic Oncology 14(10): S283.

Background: A subset of non-small cell lung cancers (NSCLCs) can be effectively treated with EGFR tyrosine kinase inhibitors (TKIs). However, a significant proportion of patients with brain metastasis progress after front-line treatment, underscoring the central nervous system (CNS) as a unique sanctuary site for persistent disease. Herein, we performed an integrated examination of the cellular, pharmacological, and molecular causes of resistance to targeted therapies in brain metastases. Method: The efficacy of osimertinib, a brain penetrant third generation TKI, was studied in mice using EGFR mutant NSCLC models derived from cell lines or patient biopsies. Animals with multi-organ metastases were treated continuously until disease progression was detected in the brain parenchyma. We also developed an in situ transcriptomic approach, referred to as Brain Metastasis Xenograft-RNA Sequencing (BMX-seq), to distinguish the transcriptome of tumor versus stroma in vivo. Molecular and biological responses were integrated with pharmacological analysis of loco-regional distribution of osimertinib in and around brain lesions. Result: In EGFR mutant models with multi-organ metastases, extra-cranial tumors could be effectively controlled, while brain metastases eventually progress despite strong osimertinib penetrance into the normal and tumor bearing CNS. Importantly, tumor cells isolated from progressing brain metastases did not exhibit resistance in vitro. However, these cells exhibited an enhanced resistant capacity when transplanted into the brain, demonstrating that this resistant phenotype is selected for and that exposure to the brain is a requirement for drug resistance in vivo. BMX-seq reveals that the stroma of drug resistant brain metastasis is characterized by activation of innate pro-inflammatory pathways. Reciprocally, we identified stromal induced activation of cytoskeletal and interferon response genes in drug resistant tumor cells. Interestingly, several of these genes are induced

in situ independently of drug treatment, suggesting that the brain metastatic niche can precondition tumor cells for ensuing drug resistance. Finally, we demonstrate that inhibiting mediators of interferon and cystoskeletal signaling increases the sensitivity of brain metastasis to osimertinib in vivo. Conclusion: Although advances have been made in the brain penetrating abilities of targeted therapies, acquired resistance in this unique TME still develops. Our results suggest that adaptive molecular interactions within the brain TME preconditions metastatic cells for TKI resistance and that targeting such pathways in combination with osimertinib should be explored to treat NSCLC patients suffering from or at risk for brain relapse. Keywords: brain metastasis, Drug resistance, Osimertinib

---

102. Adua, S. J., et al. (2019). "Uncovering adaptive mechanisms of resistance to targeted therapy in brain metastasis." Cancer Research 79(13).

A subset of lung adenocarcinoma (LUAD) can be effectively treated with EGFR tyrosine kinase inhibitors (TKIs). However, the incidence of brain metastasis increases in patients that relapse after frontline treatment, underscoring the central nervous system (CNS) as a unique sanctuary site for persistent disease. We sought to perform an integrated examination of the cellular and molecular causes of resistance to targeted therapies in brain metastasis. Results The efficacy of osimertinib, a brain penetrant third generation TKI, was studied in mice using two different EGFR mutant LUAD models. In the H1975 (EGFR L858R/T790M) model of secondline osimertinib treatment, subcutaneous tumors achieved complete response rates while H1975 brain metastases continued to grow despite strong drug penetrance into the CNS. Similarly, in the PC9 BrM4 (EGFR ex19del) model of firstline osimertinib treatment, most responding animals developed osimertinib resistance preferentially in the brain following significant regression of multiorgan metastatic lesions. Importantly, tumor cells isolated from progressing brain metastases did not exhibit resistance in vitro. However, these cells exhibited significantly enhanced resistant capacity in comparison to controls when serially transplanted into the brain demonstrating both that this resistant phenotype is selected for and that exposure to the brain metastatic niche is a requirement for drug tolerance in vivo. We utilized our recently optimized transcriptomic approach, referred to as Brain Metastasis XenograftRNA Sequencing (BMXseq), to comprehensively distinguish the transcriptome of tumor versus stroma in intact drug resistant brain lesions. Accordingly, our analysis reveals that the stroma of drug resistant brain metastasis is characterized by activation of proinflammatory pathways implying that resistant cells induce and/or coopt stromal inflammatory responses for their own benefit. Reciprocally, we identified stromal induced alterations in the expression of cytoskeletal and interferon response genes in drug resistant tumor cells. Interestingly, most of these genes are induced by the brain tumor microenvironment (TME) independently of drug treatment suggesting that the brain metastatic niche can precondition tumor cells for ensuing drug resistance. Conclusions Though advances have been made in the brain penetrating abilities of targeted therapies, acquired resistance in this unique metastatic niche still develops. Our results suggest that specific interactions between the tumor cells and stromal cells are required for the manifestation of this adaptive resistant phenotype. Furthermore, transcriptomic profiling has revealed potential regulators and molecular drivers that mechanistically explain how the brain TME preconditions metastatic cells for resistance.

103. Adwanikar, H., et al. (2011). Traumatic brain injury in animal models and humans. 50: 237-265.

Clinical/behavioral measures have traditionally been used to assess neurologic outcomes after human traumatic brain injury (TBI) as well as in experimental models of TBI. In this chapter, we address the metrics to assess injury/recovery in human TBI and consider the determinants of outcome. Further, we describe the commonly used experimental rodent models of TBI and the behavioral assays employed in these models for three major categories of neurologic assessments: sensorimotor (aggregate and individual tests), cognitive (memory and avoidance paradigms), and affective (novelty, social interaction, and anxiety) behaviors. Finally, we discuss the issues underlying use of behavioral assays in successful translation of candidate therapeutics from experimental models to human TBI.

104. Aesch, B., et al. (2014). "Fatal gunshot wound to the head with lack of immediate incapacitation." The American journal of forensic medicine and pathology 35(2): 86-88.

Investigation of deaths caused by penetrating gunshot wounds to the head often raises the possibility of foul play. The forensic pathologist may be asked if the victim was able to perform certain acts after the gunshot, and how quickly this person might have become incapacitated. The possibility of a suicidal act can depend on these answers. We report the case of a 45-year-old woman whose body was found with a right temporal entrance wound. A shotgun was found 60 ft from the body location. The question of knowing if this woman had been able to shoot herself in the head and then walk a distance of 60 ft before dying was essential for the investigation, as suicide was the first hypothesis. The autopsy and a careful neuropathology investigation allowed to answer this question. In the literature, multiple publications report cases of victims who were able to act following penetrating ballistic head injury.

---

105. Afsar, M., et al. (2021). "Neuropsychological and Linguistic Outcomes after Gunshot Injury to Cerebellum: A Case Report." Indian Journal of Neurotrauma.

Craniocerebral gunshot injuries (CGIs) are highly fatal and mostly seen in the military settings. CGIs to the posterior cortical regions and cerebellum in civilian population are uncommon. Cerebellum once thought to be mediating the motor and vestibular functions is increasingly seen as an important structure for human cognition and affect. We present a case of a 53-year-old police inspector who sustained a gunshot injury in the suboccipital region with resulting damage to predominantly left cerebellum and right occipital lobe. Patient presented with complaints of neck pain, reduced clarity of speech, and mild forgetfulness for day-to-day affairs after 7 months of injury. A comprehensive neuropsychological assessment revealed impairments in motor speed, processing speed, sustained attention, executive functions (verbal fluency, working memory), and encoding component of memory functions. The speech-language assessment revealed mild dysarthria and mild word finding difficulties. His profile with mild to moderate deficits in neuropsychological and speech language functioning was partly congruent with the cerebellar cognitive affective syndrome or Schmahmann's syndrome. The spontaneous recovery and extent of damage to cerebellum may explain the milder form of the syndrome. The case highlights the need to routinely screen for cognitive-affective disturbances in patients with traumatic lesions to cerebellum.

107. Agarwal, A., et al. (2017). "INTRAOCULAR LENS SCAFFOLD TO PREVENT INTRAOCULAR FOREIGN BODY SLIPPAGE." Retinal cases & brief reports 11(1): 86-89.

PURPOSE: To report the application of intraocular lens (IOL) scaffold technique in intraocular foreign body (IOFB) removal., METHODS: Patient with IOFB in posterior segment is included. The IOFB is retrieved from the posterior segment (pars plana vitrectomy and exteriorization of the IOFB from the retinal surface using an intravitreal forceps via the posterior capsulotomy) and placed on the iris. A three-piece posterior chamber IOL is placed in the sulcus via the clear corneal incision. IOFB is then removed from the anterior chamber over the IOL by forceps., RESULTS: Metallic IOFB of 4 mm x 3 mm has been retrieved by IOL scaffold technique after rescuing it from the posterior segment. There has been no drop or slip of IOFB in the vitreous during removal. Posterior chamber IOL served as scaffold during IOFB removal from anterior chamber., CONCLUSION: The IOL scaffold maneuver has shown to prevent slippage by acting as a barrier between the IOFB and the vitreous.

108. Agarwal, P. K., et al. (1993). "Unusual orbital foreign bodies." Indian journal of ophthalmology 41(3): 125-127.

Retained intraorbital organic foreign bodies, particularly wooden, are commonly encountered in ophthalmologic practice. We treated two children who had sustained such injury while playing. They presented to us with non-healing sinus with purulent discharge. In one of the patients, X-rays and CT scan helped to clinch the diagnosis, whereas in the other patient diagnosis was possible by correlating history with clinical findings. Surgical exploration in both patients helped us to remove the foreign bodies. Surprisingly, both the foreign bodies were 7 cm long wooden pieces. We, however, caution that management of such cases should be conservative and that surgical exploration be done only in case of complication. From our experience, we recommend proper localisation by all possible means, blunt dissection, careful haemostasis coupled with excellent lighting and exposure in the atraumatic removal of intraorbital foreign bodies.

109. Agarwal, S., et al. (2020). "Allogenic Simple Limbal Epithelial Transplantation Versus Amniotic Membrane Grafting in the Early Management of Severe-Grade Ocular Chemical Injuries-A Retrospective Comparative Study." American journal of ophthalmology 217: 297-304.

PURPOSE: To compare outcomes of management in the early stage of severe chemical injury (grade 4 and worse; Dua classification) with amniotic membrane grafting (AMG) alone vs allogenic simple limbal epithelial transplantation (alloSLET)., DESIGN: Retrospective comparative interventional case series., METHODS: Retrospective comparative interventional series. Records of patients with severe ocular chemical injury who underwent AMG alone (between 2009 and 2013) vs alloSLET (between 2013 and 2017) were analyzed for grade of injury, time of and interventions for epithelial healing, ocular surface status post healing (grade of symblepharon, and limbal stem cell deficiency [LSCD]), and type of and need for interventions in the chronic stage., RESULTS: Among patients presenting in early stage of severe chemical injury, 38 eyes (median age 11 years) managed with AMG alone were compared with 39 eyes (median age 8 years) managed with alloSLET. The mean time of presentation post injury was 33.85 +/- 27.5 and 40.6 +/- 23.5 days in the AMG and alloSLET group, respectively. The rate of epithelial healing was faster in the alloSLET group and the difference was noted to be statistically significant (odds ratio [OR] 0.966, P = .001). Similarly, the lower occurrence of LSCD (OR 0.137, P = .004) and need for keratoplasty (OR 0.093, P = .003) favored alloSLET over AMG. Final best-corrected visual acuity of >20/200 was achieved in 39.4% and 53.8% in the AMG and alloSLET groups, respectively., CONCLUSION: AlloSLET helps in faster epithelialization of the surface, thus reducing the need for subsequent surgeries in the chronic stage and aiding faster visual rehabilitation. The outcomes of alloSLET appear superior to amniotic membrane grafting alone and should be considered in eyes with grade 4 and above (Dua classification) chemical injuries in the early stage.

110. Aggrawal, A., et al. (2015). "Nail injury to the brain obfuscated by a fall from height - homicide or suicide? a case report." Medicine, science, and the law 55(1): 40-43.

Penetrating head injuries caused by unconventional objects such as a nail generate speculation and doubt regarding the manner of infliction. We report a case of a 24-year-old woman alleged to have committed suicide by a fall from height. Autopsy revealed an unprecedented penetrating intracranial injury caused by a nail over the right temporal region, confounding the manner of death. The underlying intersecting pattern of fractures determined the chronological sequence of events. In this paper, we discuss the manner, incidence and pathology of nail injuries to the brain.

---

111. Aghabiklooei, A., et al. (2012). "Multiple nails in the brain: an unusual suicidal attempt." The American journal of forensic medicine and pathology 33(1): 88-89.

We describe dangerous multiple self-inflicted brain-penetrating injuries caused by a nail gun device after a suicidal attempt for the first time in Iran. At the first forensic visit, we could not explain the manner of injuries. The authors reviewed the literature on the topics, and clinical presentation, radiographic findings, and forensic medical records are discussed.

112. Agimi, Y., et al. (2021). "Estimates of Long-Term Disability Among US Service Members With Traumatic Brain Injuries." The Journal of head trauma rehabilitation 36(1): 1-9.

BACKGROUND: Traumatic brain injury (TBI) is a significant health issue in the US military. The purpose of this study was to estimate the probability of long-term disability among hospitalized service members (SMs) with TBIs, using the South Carolina Traumatic Brain Injury and Follow-up Registry (SCTBIFR) model developed on civilian hospitalized patients., METHODS: We identified military patients in military or civilian hospitals or theater level 3 to 5 military treatment facilities (MTFs) whose first TBI occurred between October 1, 2013, and September 30, 2015. TBI-related disability at 1-year post-hospital discharge was estimated using regression coefficients from the SCTBIFR., RESULTS: Among the identified 4877 SMs, an estimated 65.6% of SMs with severe TBI, 56.2% with penetrating TBI, 31.4% with moderate TBI, and 12.0% with mild TBI are predicted to develop long-term disability. TBI patients identified at theater level 4 and 5 MTFs had an average long-term disability rate of 56.9% and 61.1%, respectively. In total, we estimate that 25.2% of all SMs hospitalized with TBI will develop long-term disability., CONCLUSION: Applying SCTBIFR long-term probability estimates to US SMs with TBIs provides useful disability estimates to inform providers and health systems on the likelihood that particular subgroups of TBI patients will require continued support and long-term care.

113. Agner, C., et al. (2002). "Neurocognitive assessment before and after cranioplasty." Acta neurochirurgica 144(10): 1033-1040.

OBJECTIVE: This paper addresses the possible value of neurocognitive tests on the evaluation of patients before and after cranioplasty for large cranial defects., METHODS: In a single patient with a large corrected cranial defect a detailed neurocognitive analysis was performed utilizing the EXIT interview and Cognistat before and after surgery. Planning and development of the surgical prosthesis were based on the pre-operative reconstruction of the head CT and on pre-operative pictures of the patient. Xenon-CT anatomical and quantitative cerebral blood flow (CBF) analysis was performed before and periodically after cranioplasty., FINDINGS: A significant improvement in major cognitive functions was observed after surgery., INTERPRETATION: Cognistat is a detailed neuropsychological battery that permits a better assessment of patients in diverse neurological conditions. The EXIT interview gives a better rapid assessment of cognition not provided by other methods, such as the mini-mental status examination (MMSE). The utilization of these techniques permits a better understanding of long-term outcomes for patients with diverse neurological conditions, including post-cranioplasty patients.

---

114. Agrawal, A., et al. (2008). "Unusual mode of firearm injury from the recoiled rear end of a gun barrel." Singapore medical journal 49(9): e238-241.

Atypical gunshot wounds are caused by a diverse set of parameters relating to weapons and ammunition. We report a previously-unreported and atypical mode of gunshot wound produced by a detached rear end of the barrel of a gun following accidental gun fire, and discuss the difficulties in the management. A 36-year-old man presented to the emergency department with an alleged history of injury on the forehead with the rear end of a gun barrel following accidental gunfire while cleaning the nozzle. Since the time of injury, the patient was in an altered sensorium and had weakness on the right

side of the body. There was minimal but continuous bleeding from the wound, with extrusion of brain matter. Skull radiograph showed that the rear end of the barrel had entered the left frontal bone, with associated depressed fracture of the frontal bone. The patient underwent a bicoronal, bifrontal craniotomy with a T-shaped extension towards the barrel to facilitate the reflection of the scalp flap and to avoid any movement of the barrel as it might further injure the brain. Necrotic brain, dura and bone pieces were removed. The patient was doing well at follow-up except for mild residual motor deficits. This case illustrates that while working with limited facilities, particularly in underdeveloped countries, a careful clinical assessment, interpretation of available images and a judicious operative approach can help to save the patient.

115. Agrawal, A., et al. (2017). "Epidemiological characteristics affecting outcome in traumatic brain injury." JMS - Journal of Medical Society 31(1): 28-31.

Background: Traumatic brain injury (TBI) is affected by multiple injury factors. Geography and vehicle prone to the accident may have an important role on the outcome. Aims: This study aims to study the details of place and mechanism of injury and their effect on discharge outcome. Settings and Design: Prospective study. Methods: This is a prospective study where 337 patients diagnosed with TBI were selected from an emergency department, after obtaining their consent. The details of place and cause of injury data was recorded on standard proforma using FileMaker Pro Advanced 13 software. Statistical Analysis: The data were analyzed using Stats Direct version 3.0.150. Results: The study reports that age, gender, and severity of the injury as per Glasgow coma scale was significant with the outcome at discharge. Higher number of patients was from rural setup (72.6%). Roadside accidents account for about 56% of injuries. About 77% of injuries were due to accidents. Two-wheeler was cause for accidents in 54% of injuries. Mechanism of injury like motor vehicle accident, fall, blunt, and the penetrating injury was significant with discharge outcome. Conclusion: The study addresses that majority of TBI patients are from rural areas and injuries are due to accidents. Mechanism of injury has significance with discharge outcome.

116. Agrawal, A., et al. (2007). "Transorbital orbitocranial penetrating injury due to bicycle brake handle in a child." Pediatric neurosurgery 43(6): 498-500.

Transorbital orbitocranial penetrating injuries (TOPI) are relatively rare and can be caused by a variety of unusual objects. Diagnosis of TOPI should be based on a detailed history and evaluation of available investigations as the penetrating injury may be overlooked. In the present case, a child sustained a penetrating injury with the brake handle of a bicycle due to the accidental fall of the bicycle on him and was managed conservatively. Copyright (c) 2007 S. Karger AG, Basel.

---

117. Agrawal, A., et al. (2016). "Transorbital Orbitocranial Penetrating Injury with an Iron Rod." Craniomaxillofacial Trauma and Reconstruction 9(2): 145-148.

Transorbital orbitocranial penetrating injuries (TOPIs) are relatively rare, can be caused by high-speed projectile foreign bodies to low-energy trauma (which is rarer), and account for 24% of penetrating head injuries in adults and approximately 45% in children. We report an uncommon nonfatal case of TOPI where a 16-year-old male child sustained injury due to accidental penetration of metal bar into the forehead. A bicoronal flap was raised to remove the metal bar. The patient recovered well, had normal vision, and doing well at follow-up.

---

118. Agrillo, A., et al. (2006). "Complex-type penetrating injuries of craniomaxillofacial region." The Journal of craniofacial surgery 17(3): 442-446.

Craniofacial traumas are one of the most common clinical events of the 21st century. The possibility of associated injuries of the head and neck may also determine functional and cosmetic

problems in these patients. The most frequent pathologic conditions observed are contusions, lacerations, abrasions, avulsions, and the inclusion of foreign bodies. In particular, penetrating injuries represent a rare but complex variety of craniofacial trauma. Generally, the penetrating material is stiff enough to cross through different anatomic structures during a particularly violent collision caused by a road or work accident or during an attack. The therapeutic strategy adopted for this type of patient depends mainly on diagnostic procedures such as skull radiograms in different projections, computerized tomography, magnetic resonance imaging, and, occasionally, echotomography. However, on arrival at the emergency department, the clinical conditions of the patient will determine the type of investigation to be carried out. Last, to prevent any postoperative infections, wide spectrum antibiotic therapy is advisable. Ideally, imaging should be repeated postoperatively to confirm resolution of the initial clinical condition. In this article, the authors describe three unusual clinical cases of patients with penetrating injuries of the head and face together with the protocol adopted for treatment of such complex craniofacial injuries. The three cases described demonstrate that, despite the initial appearance of penetrating wounds, a correct diagnostic assessment followed by a suitable therapeutic protocol can reduce cosmetic and functional defects to a minimum.

119. Agüloğlu, B., et al. (2014). "Rare head and neck trauma due to construction nail: Case report." Akademik Acil Tip Olgu Sunumlari Dergisi 5(7): 203-205.

Introduction: Oropharyngeal penetrating trauma is encountered more often in children under the age of 5 due to lack of their selfprotection. Case Report: In this paper, a 2-year-old girl who had penetrating oropharyngeal trauma after falling on a construction nail was presented. As a consequence of the physical examination and radiological examination applied to the patient, it was seen that the foreign body reached the clivus in the base of the skull, through the nasopharynx, passing by the hard and soft palate junction. In the status of the patient, who was operated on, no additional clinical aspects or neurological or lack of visual activity was observed in the post-operative period. As there was no complication during the follow-ups, the patient was discharged with recommendations. Conclusion: Oropharyngeal penetrating trauma should be careful in terms of mortality and morbidity due to the proximity to vital organs.

120. Agyabeng-Dadzie, K., et al. (2020). "Antiplatelet Agent Reversal Is Unnecessary in Blunt Traumatic Brain Injury Patients Not Requiring Immediate Craniotomy." The American surgeon 86(7): 826-829.

BACKGROUND: The need to reverse the coagulation impairment caused by chronic antiplatelet agents in traumatic brain injury (TBI) patients with acute traumatic intracerebral hemorrhage (TICH) remains controversial. We sought to determine whether emergent platelet transfusion reduces the incidence of hemorrhage expansion, mortality, or need for neurosurgical intervention such as intracranial pressure (ICP) monitoring, burr holes, or craniotomy., METHODS: All adult blunt TICH patients (age >=16 years) over a 4-year period were retrospectively reviewed. Patients with penetrating TBI, blunt TBI without TICH on admission computed tomography (CT), receiving warfarin, not on antiplatelet agents, or requiring immediate operative intervention were excluded. Patients were divided into 2 groups depending on whether they received a platelet transfusion: reversal group (RV) versus no reversal group (NR). Patient outcomes were analyzed using Mann-Whitney U and Fisher's exact tests., RESULTS: 169 blunt TBI patients on chronic antiplatelet therapy were studied (102 RV group, 67 NR group). The groups were well matched with regard to age, Injury Severity Score, Abbreviated Injury Scale-head, Glasgow Coma Score, mechanism of injury, need for intubation, time to initial CT scan, and hospital length of stay. Immediate platelet transfusion did not alter the occurrence of TICH extension on follow-up CT (26% vs 21%, P = .71), TBI-specific mortality (9% vs 13%, P = .45), need for ICP monitor (2% vs 3%, P = 1.0), burr hole (1% vs 3%, P = .56), or craniotomy (1% vs 3%, P = .56)., DISCUSSION: Immediate platelet transfusion is unnecessary in blunt TBI patients on chronic antiplatelet therapy who do not require immediate craniotomy.

121. Aharonson-Daniel, L., et al. (2006). "Different AIS triplets: Different mortality predictions in identical ISS and NISS." The Journal of trauma 61(3): 711-717.

BACKGROUND: Previous studies demonstrated different mortality predictions for identical Injury Severity Scores (ISS) from different Abbreviated Injury Scale (AIS) triplets. This study elaborates in both scope and volume producing results of a larger magnitude, applicable to specific injury subgroups of blunt or penetrating, traumatic brain injury, various age groups, and replicated on NISS., METHODS: All patients hospitalized after trauma at 10 hospitals, with ISS/NISS (new ISS) generated by two AIS triplets, excluding patients with isolated minor or moderate injuries to a single body region were studied. Patients were separated into two groups based on the different triplets. Inpatient-mortality rates were calculated for each triplet group. Odds ratios were calculated to estimate the risk of dying in one triplet group as compared with the other. The chi test determined whether the difference in mortality rate between the two groups was significantly different. Differences were further explored for various subgroups., RESULTS: There were 35,827 patients who had ISS/NISS scores generated by two different AIS triplets. Significant differences in death rates were noted between triplet groups forming identical ISS/NISS. Odds ratio for being in the second group (always containing the higher AIS score) ranged from 2.3 to 7.4., CONCLUSIONS: ISS and NISS that are formed by different AIS triplets have significantly different inpatient-mortality rates. The triplet with the higher AIS score has higher inpatient-mortality rates, overall and in several sub-populations of varying vulnerability. The comparison of populations and the interpretation of ISS/NISS based outcome data should take this important information into account and the components of AIS triplets creating each ISS and NISS should be reported.

---

122. Aharonson-Daniel, L., et al. (2003). "Epidemiology of terror-related versus non-terror-related traumatic injury in children." Pediatrics 112(4): e280.

OBJECTIVE: In the past 2 years hundreds of children in Israel have been injured in terrorist attacks. There is a paucity of data on the epidemiology of terror-related trauma in the pediatric population and its effect on the health care system. The objective of this study was to review the accumulated Israeli experience with medical care to young victims of terrorism and to use the knowledge obtained to contribute to the preparedness of medical personnel for future events., METHODS: Data on all patients who were younger than 18 years and were hospitalized from October 1, 2000, to December 31, 2001, for injuries sustained in a terrorist attack were obtained from the Israel National Trauma Registry. The parameters evaluated were patient age and sex, diagnosis, type, mechanism and severity of injury, interhospital transfer, stay in intensive care unit, duration of hospitalization, and need for rehabilitation. Findings were compared with the general pediatric population hospitalized for non-terror-related trauma within the same time period., RESULTS: During the study period, 138 children were hospitalized for a terror-related injury and 8363 for a non-terror-related injury. The study group was significantly older (mean age: 12.3 years [standard deviation: 5.1] v 6.9 years [standard deviation: 5.3]) and sustained proportionately more penetrating injuries (54% [n = 74] vs 9% [n = 725]). Differences were also noted in the proportion of internal injuries to the torso (11% in the patients with terror-related trauma vs 4% in those with non-terror-related injuries), open wounds to the head (13% vs 6%), and critical injuries (Injury Severity Score of 25+; 25% vs 3%). The study group showed greater use of intensive care unit facilities (33% vs 8% in the comparison group), longer median hospitalization time (5 days vs 2 days), and greater need for rehabilitative care (17% vs 1%)., CONCLUSIONS: Terror-related injuries are more severe than non-terror-related injuries and increase the demand for acute care in children.

---

123. Ahlawat, A., et al. (2015). "Predictors of survival after civilian penetrating brain injuries: A two-center cohort study." Neurocritical care 23(1): S35.

Introduction Predictors of survival in penetrating brain injury are poorly defined. In blunt traumatic brain injury(bTBI), admission motor GCS(mGCS), pupillary reactivity, hypoxia, hypotension, and Marshall CT score are validated independent predictors of outcome. We aimed to identify predictors of survival after PBI at hospital discharge and 6-months post-injury at two Level-1 trauma centers. Methods A retrospective cohort of 413 PBI patients from Maryland Shock/Trauma Center (n=377) and University of Massachusetts Medical School (UMass;n=36) between 1/2000-4/2013 were analyzed. Significant variables identified in univariate analyses were added in a stepwise fashion into clinically meaningful multivariable models, and compared to a base model using validated predictors of bTBI. Results The cohort's mean age was 32.5 years, 87.4% were men, 61.5% of the Maryland cohort was black and 75% of the UMass cohort was Caucasian. Median admit GCS and Injury Severity Score (ISS) were 3 (Q1,Q3:3,12) and 26 (Q1,Q3:25,34) respectively. Independent predictors of survival identified in multivariate analysis were: mGCS-6(OR=92;95%CI 39.19-216.15), bilateral reactive pupils(OR=77.68;95%CI 35.08-172.01), female gender(OR=2.1;95%CI 1.17,3.79), lowerlSS(OR=0.95;95%CI 0.94-0.97), lack of self-inflicted injury(OR=3.01;95%CI 1.89-4.77), transferfrom OSH(OR=3.3;95%CI 1.92-5.66), lackof IVH(OR=8.93;95%CI 5.35-14.9), tangential bullet trajectory(OR=10.2;95%CI 4.22-24.76), absence of multiple intracranial injuries(OR=2.57;95%CI 1.17-5.67), open cistems(OR=41.84;95%CI 19.79-88.48), and lower INR(OR=0.61;95%CI 0.54-0.69). After adjusting for known bTBI predictors, independent predictors of survival in the base model were pupillary reactivity and mGCS(C-statistic 0.935). Parsimonious clinically meaningful models were subsequently formed and added to the base model: clinical model (BaseModel+ISS+self-inflicted injury+transfer+sex;C-statistic 0.96); radiological model (BaseModel+bullet trajectory+IVH+cisterns+multiple intracranial injuries;C-statistic 0.96); laboratory model (BaseModel+INR;C-statistic 0.955); combined clinical/laboratory model (BaseModel+INR+ISS+self-inflicted injury+transfer+sex;C-statistic 0.97). Conclusions Using a sizable two-center cohort, we identified independent predictors of survival after PBI. Compared to pupillary reactivity and mGCS, additional predictors minimally added to the base model's strength. Further validation is warranted as well as future studies aimed at identifying modifiable risk factors for poor outcome.

127. Ahmad, M., et al. (2008). "Two years review of facial fractures at a tertiary care Hospital in Islamabad, Pakistan." Journal of the Liaquat University of Medical and Health Sciences 7(1): 13-17.

OBJECTIVE: To present the experience of characteristics and management of facial fractures in a tertiary care Hospital in Islamabad, Pakistan. METHODS: Study was conducted in the department of Plastic Surgery at Pakistan Institute of Medical Sciences, Islamabad, Pakistan from January 2002 to December 2003. Only adult patients of either sex were included who presented with facial fractures. Patients below 12 years of age and those having only facial lacerations were excluded. In all cases, plain X-rays, OPG (Orthopantomogram), Water's view and CT scan (in more severe cases) were obtained. Majority of the patients was operated on routine operation days (Monday to Saturday). All other fractures were managed by Open Reduction Internal Fixation (ORIF) via intra-oral approach (gingivobuccal incision). Only those fractures were approached from the external wound when the

wound lied on the line of fracture. RESULTS: Total 133 fractures were noted in 96 patients. Most of the patients were males (76%) with a male to female ratio of 3.1:1. Mean age of the patients was 36.5 years (range 13 - 79 years). The commonest cause was road traffic accident (53.1%) followed by assault (21.9%). Mandible was the commonest facial bone to be involved (59.4%).. Various associated injuries were also noted in these patients with facial lacerations (29.9%) being the most common. Various treatment modalities were employed including Maxillo-Mandibular Fixation (n=37), lag screws (n=21), microplates (n=23). The most frequent complication was pain and or lower lip paraesthesia. CONCLUSION: Patients with these injuries must undergo early interventions including reduction and stabilization of fractures. Moreover, ORIF should also be undertaken wherever possible not through an external approach but the intraoral approach.

128. Ahmad, Z., et al. (2018). "Penetrating midface trauma-knife puncture with soft tissue injury." Laryngo- Rhino- Otologie 97: S218.

Fall-related injuries in the field of ear, nose and throat medicine are the third most frequent trauma causes across all sexes. With increasing age, there is a significant rise in fall accidents. We present a case of a 47-year-old patient with spinal muscular atrophy, who accidentally stabbed himself a knife in the face due to tripping. The ER Treatment consisted of a primary Body Check and then a second survey According to ATLS Guidelines followed by CT imaging of the head, neck and vessels. The knife could be traced entering on the left side below the zygomatic bone, running medial to the lower jaw and opening smaller mastoid cells on the left. Vascular injury to the large brain-supplying vessels was Ruled out. Subsequently, together with the colleagues of the Oral and Maxillofacial Surgery, surgical treatment of the patient was carried out. In the further course, the patient could be extubated and transferred to the peripheral ward and, after a further four days, discharged to outpatient follow-up. After discharge, the patient presented for follow-up in our outpatient consultation with a non-irritating scar and intact facial nerve on both sides. This case presentation represents an exceptional injury pattern due to a fall event with a neurological underlying disease. It is to be expected that tumbling accindents due to demographic change as well as the correlating systemic pre-existing diseases will increase. Penetrating injuries in the civilian environment are so far rare in our experience, but a rise is expected due to political and demographic change. Preclinical care with a wide indication for securing the airway, CT imaging, angio-CT and subsequent interdisciplinary care in a head and neck trauma center seem to us to be inevitable for impalement traumas.

130. Ahmadi, J., et al. (1985). "Evaluation of cerebrospinal fluid rhinorrhea by metrizamide computed tomographic cisternography." Neurosurgery 16(1): 54-60.

Seven interesting and instructive cases of cerebrospinal fluid rhinorrhea evaluated by metrizamide computed tomographic cisternography are presented. The rhinorrhea was spontaneous in three patients and was related to previous head trauma or surgical procedures in four patients. The anatomical site and the extent of the fistula were demonstrated precisely by directly showing metrizamide passing through the bony defect. A combination of bone dehiscence and metrizamide within the adjacent paranasal sinuses or the nasal cavity is also useful in localization. Distortion of the interhemispheric fissure, sylvian fissure, or basal sulci indicates the probability of brain herniation through the defect.

131. Ahmed, A., et al. (2015). "Using FDA approved human neural stem cells for repair in a penetrating TBI." Journal of neurosurgery 123(2): A538-A539.

Introduction: Penetrating traumatic brain injuries (PTBI) are associated with the worst outcomes with both high mortality and severe disability. No treatment strategies are available, but stem cell transplantations have emerged as putative therapeutic approaches. In this rodent study, we evaluated the engraftment of FDA approved human fetal neural stem cells (hNSC; Neuralstem Inc.) in a rat model of PTBI. Methods: 3 rat strains (Sprague-Dawley (SD), Fischer and Athymic SD) underwent a unilateral penetrating ballistic brain injury (PBBI). Immunosuppression was established before stereotactic injection of control or hNSCs into the PBBI penumbra. Animals were sacrificed at defined time points post-transplantation. Brains were sectioned and assessed for graft cell number, graft survival, maturation and potential tumor formation. Results: 8 weeks after transplantation, grafted cells could be detected in 100% SD, 80% Athymic and 50% Fischer rats. Robust engraftment of 15% of cells was observed in all three strains. No overgrowth of undifferentiated cells/teratomas was observed. The transplanted cells stained predominantly for neuronal rather than astrocytic markers. Immature neurons with simple processes as well as mature neurons with complex dendritic arborizations were observed projecting towards the PBBI lesion. The graft volume in SD rats and athymic rats was comparable. Conclusion: 1) Robust engraftment at 8 week post transplantation was observed; 2) No transplant derived tumors were seen; 3) Immunosuppressed SD rats had a preserved graft size, making them suitable for further studies. We conclude that PTBI may be treated with NSC transplants. We are currently determining whether transplantation results in functional improvement.

---

132. Ahmed, Z., et al. (2017). "The mysterious mediastinal mass." Journal of General Internal Medicine 32(2): S620.

LEARNING OBJECTIVE #1: Recognize atypical presentation of renal cell carcinoma. LEARNING OBJECTIVE #2: Distinguish renal cell carcinoma as a differential diagnosis for anterior mediastinal mass CASE: A 46-year-old male with past medical history significant for hypertension, multiple urinary tract infections and quadriplegia secondary to gunshot wound presented with palpitations, hiccups and unintentional weight loss. Physical exam was remarkable for tachycardia with irregularly irregular rhythm. Laboratory data was significant for hemoglobin of 9.7gm/dl, TSH <0.01IU/ml, T3> 20 pg/ml. Initial EKG demonstrated atrial fibrillation with rapid ventricular response. Chest x-ray was notable for right paratracheal mass. CT chest showed thyroid gland enlargement and right anterior mediastinal mass measuring 8.2 × 6.0 × 4.9cm. Thyroid ultrasound showed enlarged heterogeneous thyroid gland with increased vascularity. Patient was treated for new onset atrial fibrillation associated with hyperthyroidism. CT abdomen done for unexplained weight loss, revealed hypo-densities in bilateral kidneys. Biopsy of mediastinal mass showed renal cell carcinoma and the patient was referred to oncology for further management. IMPACT: Certain neoplasms are commonly found in the anterior mediastinum. This case is a reminder to expand the differential ofmediastinalmasses beyond the expected neoplasms. DISCUSSION: Mediastinal masses can be divided into three categories depending on their location: anterior, middle and posterior, with anterior mediastinal masses being the most common. These typically include neoplasms of thymus or thyroid, germ cell tumors (notably teratoma), lymphoma or hemangioma. Renal cell carcinoma (RCC) presents with a wide array of symptoms with most common presentation of flank pain, abdominal mass, hematuria and weight loss. Around 16% of RCC patients have advanced disease with metastasis at the time of presentation. Common sites of metastasis include lung, lymph node, liver, bone, and brain. Chest cavity involvement of renal cell carcinoma usually manifests as pulmonary parenchymal disease with or without hilar lymphadenopathy. Renal cell carcinoma manifesting as an anterior mediastinal mass is rare with only two reported cases. One third of patients with renal cell carcinoma do not have the typical triad of presentation. Incidental findings of renal cell carcinoma are now being increasingly reported. This case illustrates an unusual presentation of renal cell carcinoma. It highlights the need to broaden the differential diagnosis of anterior mediastinal masses and merit renal cell carcinoma as one of the differentials.

133. Aiyagari, V., et al. (2005). "Treatment of severe coagulopathy after gunshot injury to the head using recombinant activated factor VII." Journal of critical care 20(2): 176-179.

PURPOSE: Patients with severe penetrating head injury often have a coagulopathy that is difficult to correct. In this report, we describe 3 such patients who were treated with activated factor VII (FVIIa) to stop ongoing hemorrhage that was refractory to conventional treatment., SUBJECTS AND METHODS: We treated 3 patients with severe head injury secondary to gunshot wounds to the head. All 3 patients had ongoing bleeding secondary to a severe consumptive coagulopathy that was refractory to treatment with fresh frozen plasma, platelets, and cryoprecipitate. Recombinant FVIIa was then administered to achieve hemostasis., RESULTS: Administration of FVIIa (90-120 microg/kg) was successful in rapidly achieving hemostasis and correcting abnormal laboratory parameters indicative of coagulopathy in all patients. Although all 3 patients died, control of bleeding made organ donation possible in 2 patients., CONCLUSION: In patients with a severe head injury and coagulopathy, use of FVIIa may help in correction of coagulopathy and decrease transfusion requirements. In patients where ongoing bleeding precludes the declaration of brain death, the use of this agent might help in achieving hemodynamic stability and preserve the possibility of organ donation. The ethical implications of using FVIIa in this situation are discussed.

---

134. Ajtai, B. M., et al. (1997). "Capability for reactive gliosis develops prenatally in the diencephalon but not in the cortex of rats." Experimental neurology 146(1): 151-158.

In this study, the glial reactions to stab wounds were investigated on a large population of newborn (P0) and fetal rats, by the immunohistochemical staining of the glial fibrillary acidic protein. The lesions penetrated both the cortex and the diencephalon. The fetuses were lesioned in utero from the 17th embryonic day (E17) and were born on E22 or E23 in the natural way. In the cortex usually no reactive gliosis developed although definitive tissue destructions remained after the lesion. Weak and incomplete glial reactions were observed in a few cases of E20 or P0 lesions only. In the diencephalon, however, the same stabbings provoked massive glial reactions. The timing and the morphology of this reaction were similar to those found in adult animals. At E17 the lesion did not result in reactive gliosis even in the diencephalon. Our study highlights two phenomena: (i) depending on the brain area servere glial reactions can already follow fetal lesions, and (ii) the appearance of the capability for glial reactions may be a stage of the local tissue maturation in every brain area and cannot be considered as a function of brain development in general. Probably, the capability for glial reactions can take place only when certain histogenetic processes (e.g., cell migration, axon growth, apoptosis) have been at least mostly accomplished, but which of the local development events are the determining ones remains to be investigated.

135. Akbay, E., et al. (2013). "Orbitomaxillomandibular reconstruction with free osteomyocutaneous fibular flap and lower trapezius myocutaneous flap." The Journal of craniofacial surgery 24(4): e438-441.

Several types of flaps and techniques have been used in the reconstruction of maxillomandibular defects. Myocutaneous flaps of the fibula, the scapula, the rib, the iliac bone, the radial forearm, the rectus abdominis, the anterolateral thigh, the latissimus dorsi, and the pectoralis major have been used either alone or in combination for this purpose. The aim of the current study was to discuss a 17-year-old patient with a gunshot injury who underwent orbitomaxillomandibular bone reconstruction using free fibular graft shaped as 3 pieces and soft tissue reconstruction using lower trapezius myocutaneous flap in conjunction with the surgical approach used.

---

136. Akbik, O. S., et al. (2020). "Treatment of unusually located traumatic intracranial aneurysms and severe vasospasm following a gunshot wound to the head: A case report." Surgical neurology international 11(57).

Background: Traumatic intracranial aneurysms (TICAs) represent up to 1% of all intracranial aneurysms. They can be the result of non-penetrating and penetrating brain injury (PBI). Approximately 20% of TICA are caused by PBI. Endovascular treatments as well as surgical clipping are reported in the literature. Other vascular complications of PBI include vasospasm although the literature is lacking on this topic. Case Description: The authors present a unique case of multiple TICAs after a PBI in a 15-year-old patient who sustained a gunshot wound to the head. The patient sustained injury through the middle cranial fossa and was taken emergently for a right-sided decompressive hemicraniectomy. Diagnostic cerebral angiogram (DCA) identified multiple TICAs along the right internal carotid artery (ICA) terminus and right middle cerebral artery as well as severe vasospasm. The patient was taken for clipping of those aneurysms and intraoperative treatment of vasospasm. Intraoperative blood flow measurements were taken before and after administration of intracisternal papaverine and arterial soft tissue dissection showing a significant increase in blood flow and improvement of vasospasm. Conclusion: While the literature has shifted towards endovascular treatment for TICAs, surgery still offers a safe and efficacious treatment strategy especially when TICAs present at large vessel bifurcation points where parent vessel sacrifice and stent assisted coiling are less favorable strategies. Severe flow limiting vasospasm can be seen in post-traumatic setting specifically PBI. Vasospasm can be treated during open surgery with intracisternal papaverine and arterial soft dissection as confirmed in this case report with intraoperative micro-flow probe measurements.

137. Akdogan, O., et al. (2008). "Orbital foreign body penetrating from the cheek." The Journal of craniofacial surgery 19(2): 439-440.

This study emphasizes the importance of diagnostic first aid procedures to avoid the consequences of trauma due to foreign body. A 20-year-old man referred to our hospital with a history of having a sharp penetrating injury to his right eye. Computed tomography evaluation reported right globe perforation and intraorbital glass foreign body measuring 4 x 7 cm was removed. Perforated eye was repaired and traumatic cuts were sutured. Orbital and ocular injuries are common, and delays in management may lead to complication. A team approach is the best technique for these patients.

138. Akhlaghi, F., et al. (2019). "Prevalence of maxillofacial fractures and related factors: A five-year retrospective study." Trauma Monthly 24(4).

Objectives: The aim of the current study was to assess the prevalence and causes of maxillofacial fractures in a five-year period among patients referring to Taleghani Hospital, Tehran, Iran. Methods: This retrospective study was conducted on patients with maxillofacial fractures from the beginning of 2013 until the end of 2017. Demographic factors, fracture site, fracture type, the cause of fracture, and performed treatment were recorded. Results: There were 708 patients with maxillofacial fractures; most cases were in men (85.2%) and in the second and third decades of life (53.8%). The majority of the fractures were in the mandible with the incidence rate of 64.7%. In addition, the most causes of maxillofacial fractures were due to car accident (CA) (29.4%), motor vehicle accident (MVA) (28.7%), and falling down (FD) (21%). No significant difference was observed in the type of fracture between the sex and age groups ($P > 0.05$). Conclusions: Maxillofacial fractures were associated with serious health problems, specifically in young males following CA and MVA.

140. Akhter, N., et al. (2022). "Frequency of Intracranial Hemorrhages in Medico-Legal Death Cases." Pakistan Journal of Medical and Health Sciences 16(5): 727-729.

Objective: To analyze the occurrence of cerebral bleeding in medically assisted deaths. Study Design: Cross-sectional Place of Study: Department of Forensic Medicine & Toxicolgy, Peoples University of Medical & Health Sciences for Women (PUMHSW), SBA and Peoples Medical College Hospital (PMCH) Nawabshah, Sindh, Pakistan from 1st October 2021 to 31st March, 2022. Materials and Methods: For this research, 94 people were enrolled. After obtaining written permission, all of the patient's demographic information was gathered. Analysis of all patients' tissue specimens. Toxicology and alcohol testing were performed on the blood sample. All cases were evaluated using X-rays and autopsy were carried out for all of them. Decomposed remains were not included in our research. Results: Among 94 cases, there were 60 (63.8%) males and 30 (36.2%) females. Included patient had mean age 31.45±13.43 years and had mean BMI 22.19±20.48. Frequency of deaths with intracranial lesion was found in 14 (14.9%) cases. We found that frequency of traumatic cases were higher than that of non-traumatic (cerebro-vascular accidents). Frequency of intracranial lesions alone was found in 31 (32.9%) cases. Hemorrhages in the subarachnoid space were the most frequent intracranial pathology. The most prevalent cause of delayed death is pneumonia. Conclusion: The number of deaths that were caused by cerebral trauma was found to be very low in this research; nevertheless, the bulk of deaths were caused by injuries to other anatomical regions.

---

141. Akincioglu, D., et al. (2022). "Combat-related ocular trauma and visual outcomes during counter-terrorism urban warfare operations in Turkey." Turkiye'de meskun mahalde terorle mucadele esnasinda gorulen okuler travma olgulari ve gorsel sonuclari. 28(5): 648-653.

BACKGROUND: The study was to report the clinical features and post-operative outcomes in military personnel admitted to the Ocular Trauma Center of Gulhane Training and Research Hospital after sustaining combat injuries in urban warfare., METHODS: This is a retrospective, non-comparative, interventional case series analyzing Turkish military personnel transferred to our tertiary ocular trauma center from the warfare zone and combat support hospitals. Ocular injuries were subdivided into zones and ocular trauma classification., RESULTS: There were 103 combat ocular injuries in 74 military personnel. The average age was 27.31+/-4.64 years (range; 21-48 years), and all were men (100%). The average follow-up was 529.34+/-213.98 days (288-1464 days). There were 84 open-globe and 19 closed-globe injuries. Thirty-six (34.9%) had final vision of 20/40 or better. Pars plana vitrectomy was the most common surgery (79.6%). Five eyes underwent evisceration, and seven eyes developed phthisis bulbi. The globe survival rate was 88.3%. Zone III injuries (32.2%) were the most common cause of unfavorable visual outcomes, and most injuries were caused by improvised explosive devices (IEDs) (59.2%). These devices also had the worst impact on globe survival and visual improvement. These eyes had a higher likelihood ratio of requiring globe removal surgery or developing phthisis bulbi [odds ratio: 21.5 (95% CI: 1.23-373)]. Two eyes that underwent keratoprosthesis-assisted pars plana vitrectomy followed by penetrating keratoplasty (PKP) during the same session developed PKP failure while failure was not seen in any of the cases that underwent PKP in a later session., CONCLUSION: Ocular injuries related to IEDs had the most significant impact on both visual and anatomic prognoses, and globe survival was less likely in eyes with zone III trauma, in which intraocular foreign bodies penetrated the choroid. There is a higher pos-sibility of PKP failure if this procedure is performed during the same session as other ocular surgery.

---

142. Akkari, R. and E. Kyereme-Tuah (2019). "Russian roulette sparks fever and tachycardia." American Journal of Respiratory and Critical Care Medicine 199(9).

19 year old male presented with self-inflicted gunshot wound to the head during a game of Russian roulette. Entry wound through right temporal area and exited in left posterior orbital area. Brain imaging showed ballistic missile injury through the low anterior frontal lobe with comminuted fractures,

injury to the frontal lobe, pneumocephalus, and bilateral frontal subarachnoid and temporal hematoma, parafalcine subdural hematoma with 6 mm leftward shift. Despite maximum medical management patient continued to have intermittent elevated intracranial pressure (ICP) requiring 3 repeat separate craniotomies and pentobarbital. Neurological exam gradually improved from comatose state to alert and localized with RUE intermittently following commands. During hospitalization he started presenting episodic bouts of fever, diaphoresis, tachycardia, hypertension and tachypnea. These resolved with narcotics and would recur multiple times through the day. Paroxysmal sympathetic hyperactivity (PSH) is common in patients with severe traumatic brain injury (TBI)[1], hypoxia [2] as well as Subarachnoid hemorrhage (SAH)[3]. It is seen in 1/3 of patients with severe TBI and diffuse axonal injury, and other critical neurologic diseases [4]. The onset of symptoms can be as early as on 3rd-day post-TBI [5] or within the rehabilitation phase. PSH is more frequent in younger patients and is associated with prolonged duration of fever [4]. The clinical diagnosis encompasses at least four following features: fever, tachycardia, hypertension, tachypnea, hyperhidrosis and motor features of extensor or flexion posturing, and dystonia consisting of spasticity or hypertonia [1-3] occurring transiently without any other cause [4]. The pathophysiology is thought to be due to disinhibition of subcortical sympathoexcitatory structures [6]. The excitatory/inhibitory ratio model suggests disconnection of descending inhibitory pathways causing spinal circuit excitation; paroxysms resolve in response to the recovery of the inhibitory drivers [8]. PSH has been shown to respond to combined nonselective beta-blockers, that minimize episodes and opiate agonists that abort the episodes [1,7,8]. GABAergic agents, dopamine agonists, benzodiazepines, clonidine, and baclofen may also be helpful but with less consistent results [1]. Once dysautonomic manifestations dissipate, the treatment can be tapered. Awareness and early recognition of this rare diagnosis yet commonly seen complication in TBI patients are crucial. The treatment with morphine and propranolol during acute episodes did not cease symptoms, but adding Dilaudid, Neurontin, and Clonidine improved symptoms substantially. The patient remained alert, not oriented though following commands with his RUE, on a chronic ventilator with tracheostomy and eventually transferred to a long-term care facility.

---

143. Al Jishi, A., et al. (2012). "Therapeutic challenge of orbito-cranial penetrating injuries." Canadian Journal of Neurological Sciences 39(3): S47.

Background: Penetrating head injury (PHI) with retained foreign body are uncommon cause of traumatic brain injury, yet they present a therapeutic dilemma between risk of infection and the operative risk of significant hemorrhage and further damage, whenever orbitocranial neurovascular structures are involved. Method: Two cases of orbito-cranial PHI with retained wood are presented. Because of the nature of the retained object, a surgical removal was favored to decrease the risk of infection. The pre-operative evaluation, and imaging, the intra-operative anatomy and management, the postoperative outcome, and a review of the literature will be presented. Results: Although the foreign body penetrated the intracranial content from the orbit through the superior orbital fissure (SOF), the trajectory was different, and the surgical approach was extradural for one and intradural for the other. None developed intra- or postoperative hemorrhage or infection. However, both remained with some degree of impairment of ocular motility and vision. Conclusion: Retained wooden objects through the SOF pose a therapeutic challenge. A meticulous analysis of the imaging is crucial for adequate surgical planning in order to minimize the risk of complications.

144. Al Mulla, A., et al. (2001). "Fireworks injury: temporal bone penetration and a wooden intra-cranial foreign body." Journal of the Royal College of Surgeons of Edinburgh 46(4): 249-251.

We describe a case of a teenager sitting in a car, who was struck by a fireworks missile. The unusual presentation of a large wooden foreign body penetrating through the temporal bone and lodging in the brain is detailed. The management is discussed.

---

145. Al Nimer, F., et al. (2004). "MHC expression after human neural stem cell transplantation to brain contused rats." Neuroreport 15(12): 1871-1875.

Human neural stem cells survive and improve motor function after transplantation to the contused brain. However, the transplants might be rejected and that depends on the graft immunogenicity, the host immunological status and the immunosuppression strategy. We transplanted human neural stem cells to rats with brain contusion and analyzed the donor and host MHC antigen expression and the effect of a short-term immunosuppression with cyclosporine. In vitro human neural stem cells expressed only MHC-II antigens. This expression was down-regulated 6 weeks after transplantation. The host response was characterized by an increased MHC-II expression which was down-regulated by a longer term of immunosuppression. These findings are novel and necessary in order to understand the immunogenicity of human neural stem cell grafts.

146. Alabi, S. B., et al. (2012). "Palatal avulsion injury by a foreign body in a child." BMJ case reports 2012.

A 6-year-old girl who claimed to have fallen while playing with metal rod that resulted in palatal avulsion injuries was presented. Neither of the parents was around when the incidence happened. She was brought to the hospital because of pain, bleeding from the mouth, drooling of saliva mixed with blood and inability to feed or phonate appropriately. Examinations of the oral cavity revealed a triangular area of avulsion in the posterior aspect of the hard palate extending to the soft palate. She had examination under anaesthesia and wound repaired with 3-0 vicryl interrupted sutures after thorough wound debridement. She did well and was discharged from the clinic.

147. Alaca, R., et al. (2002). "Anterior hypopituitarism with unusual delayed onset of diabetes insipidus after penetrating head injury." American journal of physical medicine & rehabilitation 81(10): 788-791.

Neuroendocrine dysfunctions are among the various complications that occur after traumatic brain injury. We report a case of onset of diabetes insipidus during acute rehabilitation of a 20-yr-old patient with a traumatic brain injury caused by a gunshot wound. Our case is the latest onset of diabetes insipidus after traumatic brain injury that has been reported in the literature.

---

148. Alafaci, C., et al. (2010). "Penetrating head injury by a stone: case report and review of the literature." Clinical neurology and neurosurgery 112(9): 813-816.

Traumatic intracranial penetration of foreign objects of non-missile intracranial nature rarely occurs. Haemorrhages, major vascular injury and contusions can be causes of death in early stage, epileptic seizures and infections are possible complications in later stages. Complete excision of the foreign body should be performed. Possible dural and vascular injuries should be repaired during surgical treatment. In the present study, we report a rare case of traumatic intracranial stone as a foreign object. A brief review of the literature is presented.

---

149. Al-Afif, S., et al. (2017). "Severe Cerebral Complications Secondary to Perforation Injury of the Anterior Skull Base During Sinonasal Surgery: An Underappreciated Problem?" World neurosurgery 108: 783-790.

OBJECTIVE: Functional endonasal sinus surgery (FESS) is widely practiced and is considered a generally safe procedure. Skull base injuries occur in <1% of procedures and are typically associated with cerebrospinal fluid leaks. Rarely, skull base injuries might result in cerebral lesions. Here we present a series of 4 patients with iatrogenic perforating injuries of the anterior skull base and cerebral lesions after routine FESS., METHODS: Four patients with iatrogenic perforating cerebral lesions after routine FESS, performed at other institutions, were referred to a tertiary neurosurgery department. Within a 10-year period these procedures were performed in 3 patients as endoscopic FESS and as a

microscopic FESS in 1 patient., RESULTS: There were 3 men and 1 woman. Mean age at the time of surgery was 50 years. In 3 instances (in which an endoscope was used), the ear, nose, and throat physician had noted perforation of the skull base during surgery, but it went unnoticed in 1 patient operated with the microscope. Frontal lobe hematoma occurred in all patients, and in 3 of them cerebral infarction developed secondary to injury of branches of the anterior cerebral artery. Three patients developed acute hydrocephalus. Two had rapid global brain swelling and they succumbed within days. The other 2 patients survived without apparent neurological deficits., CONCLUSIONS: Cerebral lesions during FESS still occur in contemporary surgery and they are possibly underreported. Even with prompt conservative and surgical measures, these lesions may result in catastrophic outcome. Associated vascular injuries have a worse prognosis. The only risk factor associated with lethal outcome in our series was younger age.

---

150. Alagoz, F., et al. (2016). "A case of delayed carotid cavernous fistula after facial gunshot injury presented as loss of vision with symptom resolution after endovascular closure procedure." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES 22(2): 199-201.

Carotid cavernous fistulas (CCFs) are abnormal connections between the carotid artery and the cavernous sinus (CS), and can occur as a result of blunt and penetrating head injuries. While occurrence is rare, diagnosis can be made in the emergency department. Described in the present report is the case of a 26-year-old man who presented with complaints of pain, redness, blurred and loss of vision in the right eye, and swelling of the upper face due to a gunshot injury he had sustained 35 days prior.

---

151. Alain, J., et al. (2018). "Bilateral nail gun traumatic brain injury presents as intentional overdose: A case report." CJEM 20(5): 788-791.

This report describes a rare but life-threatening case of a suicide attempt initially considered as intentional overdose at the emergency department. Persistent altered mental status, despite normal toxicology investigations, led the attending team to order a head computed tomography scan, which revealed a bilateral penetrating nail gun injury with a right temporal hematoma for which a decompressive craniectomy was performed. Although voluntary intoxication is the most frequent form of suicide attempt, emergency physicians must be alert and maintain a broad differential diagnosis. Although rare, penetrating head injuries have increased in recent decades. As neurological symptoms can be minimal and penetration wounds small, this type of injury could potentially be overlooked.

153. Alam, D. S., et al. (2009). "The technical and anatomical aspects of the World's first near-total human face and maxilla transplant." Archives of facial plastic surgery 11(6): 369-377.

OBJECTIVE: To discuss the technical and anatomical analysis and design of an osteocutaneous allograft transplant incorporating the donor maxilla and the execution of the operative protocol during the transplant., METHODS: The Cleveland Clinic reported the world's first successful combined face and maxilla transplant in December 2008. Unlike the 3 prior face transplants, this surgical procedure was done as a salvage operation in a patient who had undergone 23 major reconstructive procedures. The additional complexity due to significant postoperative scarring and recipient vessel depletion presented a unique challenge in this case. The extensive 3-dimensional losses of facial structures in multiple tissue planes required a Le Fort III osteomyocutaneous allotransplant incorporating the donor maxilla., RESULTS: We report the first successful transfer of a complete bony framework and soft-tissue envelope. The allograft has shown excellent integration and no long-term rejection. The

traditional conception based on anatomical studies suggested that this transfer would require independent dissection of the internal maxillary vascular system. This was not required in our patient whose allograft was based solely on the facial arterial system and its arcades., CONCLUSIONS: Successful near-total face and maxilla allograft transplant can be accomplished based on the facial arterial system and its arcades. This presents a novel method for reconstructing massive facial injuries with significant involvement of the facial skeleton.

154. Alam, H. B., et al. (2008). "Putting life on hold-for how long? Profound hypothermic cardiopulmonary bypass in a Swine model of complex vascular injuries." The Journal of trauma 64(4): 912-922.

BACKGROUND: Rapid induction of profound hypothermia for emergency preservation and resuscitation can improve survival from uncontrolled lethal hemorrhage in large animal models. We have previously demonstrated that profound hypothermia (10 degrees C) must be induced rapidly (2 degrees C/min) and reversed gradually (0.5 degrees C/min) for best results. However, the maximum duration of hypothermic arrest in a clinically relevant trauma model remains unknown., METHODS: Uncontrolled lethal hemorrhage was induced in 22 swine by creating an iliac artery and vein injury, followed 30 minutes later (simulating transport time) by laceration of the descending thoracic aorta. Through a thoracotomy approach, a catheter was placed in the aorta, and cold organ preservation solution was infused using a roller pump to rapidly induce profound hypothermia (10 degrees C) which was maintained with low-flow cardiopulmonary bypass. Vascular injuries were repaired during the asanguinous hypothermic low flow period. Profound hypothermia was maintained (n = 10-12 per group) for either 60 minutes or 120 minutes. After repair of injuries, animals were rewarmed (0.5 degrees C/min) and resuscitated on cardiopulmonary bypass, and whole blood was infused during this period. Animals were monitored for 4 weeks for neurologic deficits, organ dysfunction, and postoperative complications., RESULTS: The 4-week survival rates in 60- and 120-minute groups were 92% and 50%, respectively ($p < 0.05$). The surviving animals were neurologically intact and had no long-term organ dysfunction, except for one animal in the 120-minute group. The animals subjected to 120 minutes of hypothermia had significantly worse lactic acidosis, displayed markedly slower recovery, and had significantly higher rates of postoperative complications, including late deaths because of infections., CONCLUSION: In a model of lethal injuries, rapid induction of profound hypothermia can prevent death. Profound hypothermia decreases but does not abolish metabolism. With current methods, the upper limit of hypothermic arrest in the setting of uncontrolled hemorrhage is 60 minutes.

---

155. Al-Anee, A. M., et al. (2018). "Mandibular war injuries caused by bullets and shell fragments: a comparative study." Oral and maxillofacial surgery 22(3): 303-307.

PURPOSE: Is to compare the patterns, severity, and management of the high- and low-velocity mandibular war injuries managed at Al Shaheed Gazi Al-Hariri Hospital in Baghdad Medical City, Iraq, during a 2-year period., METHODS: Forty-one patients with a history of mandibular war injuries treated by our maxillofacial team were reviewed during a period of 2 years (2015-2017). All patients were treated in the Maxillofacial Unit of the Hospital of Specialized Surgeries in Baghdad Medical City., RESULTS: A 2-year retrospective study evaluated 41 patients with mandibular war injuries with a total of 94 fractures (comminution represents 79.06% of the bullet injuries, while it is only 62.74% with IED injuries). Management of these injuries was varied according to the severity of the injuries and resources available. Close reduction was used in 72.72% of the linear fracture cases, whereas open technique was used in 56.6% of the comminuted fractures., CONCLUSIONS: Bullet injuries were associated with a higher number of mandibular comminuted fractures, in addition to more extensive bone loss. While shell injuries of IED (improvised explosive devices), on the other hand, were associated with higher infection rate and more postoperative complication.

---

156. Alar, T., et al. (2013). "Acute and delayed traumatic diaphragmatic ruptures presenting at the emergency service: What are we missing?" Hong Kong Journal of Emergency Medicine 20(3): 172-177.

Introduction: Diaphragmatic rupture is rarely a cause of death by itself. It is especially difficult to diagnose diaphragmatic ruptures in patients with unstable vital signs who present at the emergency service with concurrent chest, abdomen, and extremity injuries as a result of blunt trauma. We evaluated the diagnostic processes, clinical findings and treatment results of acute and delayed traumatic diaphragmatic ruptures (TDR) cases that presented at the emergency service. Methods: A total of 29 patients that underwent surgical treatment with a diagnosis of TDR among 1021 patients that presented at the Canakkale State Hospital Emergency Service with acute or delayed thoracoabdominal trauma were retrospectively investigated. The age, gender, trauma etiology, diagnosis duration, injury severity score (ISS), rupture location, accompanying organ injuries, operation type, inpatient duration, morbidity and mortality were recorded on prepared forms to analyse the cases. Results: The mean age of the 29 patients with TDR was 45.31 + 17.76 years with and 20 (69%) males and 9 (31%) females. The trauma was blunt in 22 (76%) and penetrating in 7 (24%) cases. The TDR was acute in 16 (55%) and delayed in 13 (45%) patients. The surgery for TDR treatment consisted of with thoracotomy in 16 (55%) patients, laparotomy in 11 (38%) patients and both thoracotomy and laparotomy in 2 (7%) cases. Mortality occurred in 3 (10%) patients that presented at the acute stage. Conclusions: The patients undergoing thoracoabdominal trauma, should be explained the probability, although low, of rupture of the diaphragm. These patients should be followed up and it should be emphasized that they should absolutely tell this trauma history to the physician who examines them when they present at the emergency service.

---

157. Al-Bahrani, A. Z., et al. (2006). "Acute pancreatitis: An under-recognized risk of percutaneous transhepatic distal biliary intervention." HPB 8(6): 446-450.

Objective: Percutaneous transhepatic biliary intervention (PTBI) plays an important role in the management of biliary obstruction, and this may be complicated by acute pancreatitis. The aim of this study was to assess the incidence of acute pancreatitis following PTBI. Patients and methods: Patients who underwent PTBI between January 1992 and December 2003 in a tertiary referral centre were identified from the hospital database. Patients who did not have their amylase measured post-procedure were excluded, as acute pancreatitis might have been missed. Acute pancreatitis was defined as hyperamylasaemia of three times or more above normal in association with abdominal pain. Results: Over a 12-year period, 331 patients underwent 613 procedures. Serum amylase was measured after 134 procedures (21.9%) and was elevated in 26 of those (19.4%). There was no difference in the frequency of hyperamylasaemia between proximal and distal PTBI (14/73 [19.2%] vs 12/61 [19.7%] procedures, p=NS). However, acute pancreatitis developed after 4 of 61 (6.6%) distal PTBI (stent, n=3; internal-external catheter insertion, n=1) but not after proximal PTBI (cholangiography or external drainage) (p=0.041). The attacks were mild in three of the four patients. No pancreatitis-related deaths occurred. Conclusion: The risk of acute pancreatitis after distal PTBI is under-recognized and should be considered as a consent issue in patients scheduled for distal PTBI and when post-procedure abdominal pain ensues.

---

158. AlBayar, A., et al. (2019). "Risk of Vertebral Artery Injury and Stroke Following Blunt and Penetrating Cervical Spine Trauma: A Retrospective Review of 729 Patients." World neurosurgery 130: e672-e679.

BACKGROUND: Cervical spine trauma (CST) may result in vertebral artery injury (VAI), increasing the risk of developing stroke. Stroke risk following CST is poorly reported., METHODS: In total, 729 patients with CST were retrospectively analyzed, including rates of VAI, age at injury, cause of injury, cardiovascular history, smoking history, substance abuse history, embolization therapy, and antiplatelet or anticoagulant therapy prior or after injury. VAIs were identified and graded following the Modified Denver Criteria for Blunt Cerebrovascular Injury using magnetic resonance angiography and

computed tomography angiography. Brain scans were reviewed for stroke rates and statistically significant variations., RESULTS: Thirty-three patients suffered penetrating trauma, whereas 696 patients experienced blunt trauma. In total, 81 patients met the criteria for analysis with confirmed VAI. VAI was more common in penetrating injury group compared with blunt injury group (64% vs. 9%, P < 0.0005). However, low-grade VAI (less than grade III) was more common in blunt injury group versus penetrating group (37% vs. 14%, P < 0.05). The frequency of posterior circulation strokes did not vary significantly between groups (26.3% vs. 13.8%, P = 0.21). Cardiovascular comorbidities were significantly more common in the blunt group (50%, P = 0.0001) compared with the penetrating group (0%)., CONCLUSIONS: VAI occurs with a high incidence in penetrating CST. Although stroke risk following penetrating and blunt CST did not vary significantly, they resulted in serious complications in a group of patients. Further study of this patient population is required to provide high-level, evidence-based preventions for VAI complications.

---

159. Alberth, B. and J. Damjanovich (1990). "[Complications of retrobulbar injections. Possibilities for prevention]." Komplikationen retrobulbarer Injektionen. Moglichkeiten der Beseitigung. 196(2): 92-93.

The authors advocate the use of a new needle developed specifically to avoid complications with retrobulbar injections. In cases with high myopia sonography is performed to determine whether the patient has a posterior staphyloma, which can aggravate the risk of injury. In such cases the retrobulbar injection is performed with the patient's gaze directed downward and outward.

160. Albertina, L., et al. (2022). "Low-dose levetiracetam versus phenytoin for early seizure prophylaxis after traumatic brain injury." Critical care medicine 50(1 SUPPL): 773.

INTRODUCTION: Brain Trauma Foundation Guidelines recommend phenytoin (PHE) for the prevention of early posttraumatic seizures (PTS). Levetiracetam (LEV) has gained popularity in recent years for this indication owing to its lack of serum drug monitoring, ease of administration, minimal drug interactions, and fewer reported adverse effects when compared to PHE. However, the effective dose of LEV remains unclear. The purpose of this study was to compare the incidence of early PTS in patients receiving either lowdose LEV (500 mg twice daily) or PHE for the first seven days after traumatic brain injury (TBI). METHODS: A retrospective chart review was conducted on adult TBI patients receiving either low-dose LEV or PHE for the prevention of early PTS between January 2016 and September 2020. TBI patients were identified using diagnosis-related group codes. RESULTS: 200 patients were evaluated with 100 patients in each group. Overall, most patients (98%) sustained blunt TBIs. The LEV cohort had a lower median Glasgow Coma Scale (GCS) score on admission (13 vs 15), in addition to a lower median best GCS score (14 vs 15) and worst GCS score (8 vs 13) within 24 hours of admission. The LEV group more frequently received hyperosmolar agents (47% vs 21%) and underwent neurosurgical intervention (35% vs 18%) when compared to the PHE group. The incidence of clinical seizures occurred in a fewer proportion of patients receiving LEV (1% vs 8%, p = 0.035). While there was an increased median intensive care unit (ICU) length of stay (LOS) in the LEV group (6 vs 3 days, p < 0.001), there was no significant difference in median hospital LOS between groups (7 vs 5 days, p = 0.067). CONCLUSIONS: Low-dose LEV demonstrated a similar rate of early PTS in comparison to PHE when used for the first seven days after TBI. Differences in ICU and hospital LOS were more likely attributable to the LEV cohort's severity of injury, as measured by lower median GCS scores within the first 24 hours of admission in addition to an increased need for hyperosmolar and neurosurgical intervention. Larger, prospective studies involving more patients with penetrating TBIs would be necessary in order to validate observations made in this study.

161. Albrecht, J. S., et al. (2018). "Association of Alcohol With Mortality After Traumatic Brain Injury." American journal of epidemiology 187(2): 233-241.

Although alcohol exposure results in reduced mortality after traumatic brain injury (TBI) in animal models, clinical trials based on proposed mechanisms have been disappointing and have reported conflicting results. Methodological issues common to many of these clinical studies may have contributed to the spurious results. Our objective was to evaluate the association between blood alcohol concentration (BAC) and in-hospital mortality after TBI, and overcome methodological problems of prior studies. We conducted a retrospective cohort study on individuals treated for isolated TBI (n = 1,084) at the R Adams Cowley Shock Trauma Center (Baltimore, Maryland) from 1997 to 2012. We excluded individuals with injury to other body regions and examined multiple cutpoints of BAC. Our primary outcome was in-hospital mortality. In adjusted logistic regression models, the upper level of each blood alcohol categorization from 0.10 g/dL (odds ratio = 0.63, 95% confidence interval: 0.40, 0.97) through 0.30 g/dL (odds ratio = 0.25, 95% confidence interval: 0.08, 0.84) was associated with reduced risk of mortality after TBI compared with individuals with undetectable BAC. In sensitivity analyses among individuals without penetrating brain injuries (95% firearm-related) (n = 899), the protective association was eliminated. This study provides evidence that the observed protective association between BAC and in-hospital mortality after TBI resulted from bias introduced by inclusion of penetrating injuries.

162. Al-Darazi, F. and S. Koshy (2016). "Reverse takotsubo cardiomyopathy in a young organ donor." Journal of the American College of Cardiology 67(13): 1063.

Background: Takotsubo cardiomyopathy (TCM) is caused by the significant production of catecholamines that lead to myocardial hypokinesis through cardiomyocytes toxicity and coronary microvascular dysfunction. We present an organ donor who developed reverse TCM (a variant of TCM) following major head trauma. Case: 22 year old healthy man who sustained a gunshot to the head causing brain death was considered for organ donation. His Troponin-I peaked at 15 (μg/L) and echocardiogram showed basal-mid wall hypokinesis with sparing of the mid ventricle to apex. Patient had no family history of cardiomyopathy or sudden cardiac death, and no history of substance abuse. The patient's heart was rejected for transplantation based on the echocardiogram findings. Cardiac autopsy showed multifocal single cell death with contraction band necrosis along with foci of neutrophilic infiltrate most consistent with catecholamine surge, and there was no evidence of epicardial coronary artery disease. Decision Making: The clinical presentation and the echocardiographic findings were commensurate with reverse TCM. Tissue pathology confirmed the diagnosis. This variant comprises 1% of TCM. Recovery is the rule (96%), commonly within the first four weeks. Reverse TCM tends to occur in younger people, higher level of troponin is reported, and is more common with brain injury. Left ventricular systolic dysfunction that develops after the acute neurologic event limits the use of the donor hearts, hence decreasing the pool of potential heart donor by 20% to 40% by most reports. However, this dysfunction may be reversible once the catecholamine surge subsides. If there are better prediction models to assess recovery and recurrence rates there is a potential that these hearts could be used for transplantation. Conclusions: We suggest that young healthy adults with TCM or its variants, and a clearly identified catecholamine mediated stressful event may still be considered for heart donation as recovery is a likely to happen. There is a need for a prediction model that incorporates demographic, anatomical and pathological data including tissue biopsy findings to better assess the probability of recovery and recurrence.

163. Aldekhayel, S., et al. (2014). "Evolving trends in the management of orbital floor fractures." The Journal of craniofacial surgery 25(1): 258-261.

BACKGROUND: The management of orbital floor fractures is diverse and continues to evolve. The purpose of the current study was to provide an updated summary of the literature, with a focus on interspecialty differences, and contrast that with current treatment strategies of actively practicing plastic

surgeons., METHODS: A survey was conducted of surgeons who currently manage orbital floor fractures. The results are summarized and compared with a 10-year literature review (2002-2012) of surgical approaches, indications and timing of surgery, and implant selection in various surgical disciplines. Inclusion criteria included studies in English language with 10 or more patients., RESULTS: The survey response rate was 56%, of which 86 surgeons were identified to currently manage orbit fractures. A third of participants reported they are less likely to operate on these fractures relative to earlier in their career. Six factors were found to have the greatest influence on surgeon's operative decision: enophthalmos, hypophthalmos, positive forced duction, defect size, motility restriction, and persistent diplopia. The most common preferred approach to the orbit is midlid/infraorbital (45%) followed by transconjunctival (31%) and subciliary (24%). Medpor and titanium are the most preferred implants (83%) compared with autologous bone (5%)., CONCLUSIONS: Significant interdisciplinary and intradisciplinary differences in the management of orbital fractures exist. The most significant trends are the growing popularity of alloplastic versus autogenous materials for orbital floor reconstruction and the fact that one-third of surgeons are more likely to opt for a nonoperative (conservative) approach compared with earlier in their careers.

---

164. Aldemir, M., et al. (2004). "Predicting factors for mortality in the penetrating abdominal trauma." Acta chirurgica Belgica 104(4): 429-434.

PURPOSE: penetrating abdominal trauma (PAT) is still a serious problem all over the world. This study was made to define and discuss the factors that could affect mortality in the PAT., METHODS: the records of 1048 patients hospitalized and operated for PAT at Dicle University Hospital (DUH) between January 1990 and December 2001 were retrospectively reviewed. Patients (n = 1048) were divided into two groups: "Healthy Group" (HG) (n = 942) and "Deathly Group" (DG) (n = 106). The epidemiological and clinical features were evaluated as probable risk factors for mortality. The risk factors for mortality were revealed using univariate and multivariate analyses., RESULTS: a total of 1048 patients [937 (89.4%) male, 111(10.6%) female] with PAT were included in this study. The mortality rate (22.5%) of female patients was significantly higher than (8.6%) that of male patients (p = 0.000). The mean age was 30.01+/-63.9 (14-74) years and 30+/-12.5(15-71) years in the HG and DG consecutively (p = 0.85). The average interval between injury and operation (IBIO) was 2.09+/-1.3 (0.5-3) and 6.9+/-11.4 (1-6.1) hours in the HG and DG respectively (p = 0.000). Presence of shock on admission (PSDA) was determined in 87 patients and in 96 patients in the HG and DG respectively (p = 0.000). The mortality rate (14.9%) in patients presenting gunshot wounds (GSW) was significantly higher than (2.7%) that of patients with stab wounds (SW) (p = 0.000). The average number of injured intraabdominal organs (NIAOI) was 1.98+/-1.08 (1-7) and 4.67+/-1.99 (1-13) in the HG and DG respectively (p = 0.000). Mortality rates were 72.7% in cardiac injury, 30% in great vessels injuries, 32.6% in cranial injury, and 21.5% in major extremity and pelvic injury (p = 0.000). The average penetrating abdominal trauma index (PATI) was 11.78+/-9.44 (1-58) and 46.24+/-22.18 (15-119) in the HG and DG respectively (p = 0.000). In multivariate analyses, female gender [Odds Ratio (OR) = 10.74, 95% Confidence Interval (CI) = 3.03-38.12, P = 0.000], the long IBIO (OR = 1.82, CI = 1.39-2.40, P = 0.000), PSDA (OR = 94.45, CI = 28.32-314.95, P = 0.000), presence of cranial injury (OR = 0.03, CI = 0.002-0.363, P = 0.006) and high PATI (OR = 1.14, CI = 1.09-1.19, P = 0.000), were found significantly important for mortality., CONCLUSION: we determined that conditions such as, female gender, long interval between injury and operation, presence of shock on admission, presence of cranial injury and high PATI were predicting factors for mortality in PAT.

165. Alderazi, Y. J., et al. (2015). "Endovascular therapy for cerebrovascular injuries after head and neck trauma." Trauma (United Kingdom) 17(4): 258-269.

Cerebrovascular injuries after blunt or penetrating head and neck trauma often lead to significant disability from ischemic stroke, hemorrhagic stroke and uncontrolled extracranial hemorrhage. Trauma causes carotid or vertebral dissection, occlusion, pseudoaneurysm, arteriovenous fistula, vessel

transection, traumatic epistaxis, venous sinus thrombosis and carotid cavernous fistula. The rapid development of neuroendovascular techniques over the past two decades has led to effective therapies for each of these injuries. Controlled lesion embolization may use coils, liquid embolics (onyx or n-butyl cyanoarcrylate), polyvinyl alcohol particles or detachable balloons; there is stent angioplasty with uncovered, overlapping and covered stents or mechanical thrombolysis using stent-retrievers or aspiration catheters and the use of balloon occlusion tests and supraselective angiography to delineate safety of vessel sacrifice and to diagnose occult lesions respectively. Furthermore, the proliferation of stroke centers has increased local availability of rapid neuroendovascular expertise at many major trauma centers. Neuroendovascular therapies are less invasive than surgery, can often preserve the injured parent vessels and aid in treating conditions where surgery may be limited. In the absence of randomized controlled trials we present a narrative review of current endovascular therapeutic applications for each of these injuries. This expands the therapies at trauma teams' disposal in the continued effort to control bleeding, reduce secondary injury and prevent disability after trauma. Further research is necessary to inform the role of endovascular techniques after trauma. In particular, comparative studies are necessary to quantify the risk and benefits in conditions where surgical options also exist.

166. Aldrich, E. F., et al. (1992). "Predictors of mortality in severely head-injured patients with civilian gunshot wounds: a report from the NIH Traumatic Coma Data Bank." Surgical neurology 38(6): 418-423.

Predictors of outcome were examined in this prospective study of 151 patients severely injured by civilian gunshot wounds. Of the 151 patients, 133 (88%) died. Of the 123 patients with an initial Glasgow Coma Scale score of 3-5, 116 (94%) died, whereas of the 20 with an initial Glasgow Coma Scale score of 6-8, 14 (70%) died. There were no good outcomes, and only three moderate recoveries in patients who had initial scores of 8 or less. In those patients who survived long enough for intracranial pressure monitoring, intracranial hypertension predicted a very poor outcome. Computed tomographic scan characteristics such as midline shift, compression or obliteration of the mesencephalic cisterns, the presence of subarachnoid blood, intraventricular hemorrhage, and the presence of hyperdense or mixed-density lesions greater than 15 mL, either bilateral or unilateral, were all associated with a poor outcome. However, neither the caliber of gun nor the distance of the gun from the head significantly affected the risk of dying.

---

167. Aldridge, P., et al. (2021). "Head home: implementation during COVID-19 pandemic." Emergency medicine journal : EMJ 38(9): 692-693.

BACKGROUND: Recent research suggests that between 20% and 50% of paediatric head injuries attending our emergency department (ED) could be safely discharged soon after triage, without the need for medical review, using a 'Head Injury Discharge At Triage' tool (HIDAT). We sought to implement this into clinical practice., METHODS: Paediatric ED triage staff underwent competency-based assessments for HIDAT with all head injury presentations 1 May to 31 October 2020 included in analysis. We determined which patients were discharged using the tool, which underwent CT of the brain and whether there was a clinically important traumatic brain injury or representation to the ED., RESULTS: Of the 1429 patients screened; 610 (43%) screened negative with 250 (18%) discharged by nursing staff. Of the entire cohort, 32 CTs were performed for head injury concerns (6 abnormal) with 1 CT performed in the HIDAT negative group (normal). Of those discharged using HIDAT, four reattended, two with vomiting (no imaging or admission) and two with minor scalp wound infections. Two patients who screened negative declined discharge under the policy with later medical discharge (no imaging or admission). Paediatric ED attendances were 29% lower than in 2018., CONCLUSION: We have successfully implemented HIDAT into local clinical practice. The number discharged (18%) is lower than originally described; this is likely multifactorial. The relationship between COVID-19 and paediatric ED attendances is unclear but decreased attendances suggest those for whom the tool was

originally designed are not attending ED and may be accessing other medical/non-medical resources.

168. Aldunate, D., et al. (2020). "10 Years of Implementation of the "Glasgow 7" Quality Guarantee Program in the Mendoza Central Hospital: Epidemiology and Evolution of Neurocrytic Patients." Transplantation proceedings 52(4): 1053-1055.

INTRODUCTION: In 2003, the Glasgow 7 Quality Guarantee Program was put into effect in Argentina with the objective of standardizing the donation and transplant process throughout the country, establishing the observation and registration of all neurocritical patients with a score on the Glasgow Coma Scale of 7 of 15 or less admitted to critical beds of selected establishments., MATERIALS AND METHODS: The following study is retrospective, observational, and cohort-based. It was developed in the Central Hospital of Mendoza, in the critical units, including guard, coronary, cardiovascular surgery recovery, and intensive care therapy. The inclusion criteria were admission to the institution with a score on the Glasgow Coma Scale of 7 or less with a structural cause of coma. Data collection was carried out in the national online database SINTRA., RESULTS: From January 1, 2008, to December 31, 2018, 1757 patients were enrolled at the Central Hospital of Mendoza, Argentina with Glasgow scores of 7 or less. The most frequent cause of coma was brain trauma (934 patients; 53%), followed by stroke (614 patients; 35%). Of those who scored 3 of 15 in the GCS upon admission, 65% progressed to brain death, whereas 72% of those who scored 7 were discharged. Of all these patients, 270 became donors, accounting for 43% of all brain deaths, whereas 187 had refused to become organ donors (30.6%). Of the total real donors, 55% were multiorganic (150 donors).

---

169. Alegro, J. V., et al. (2019). "Successful treatment of carbapenem-resistant klebsiella pneumoniae (CRKP) aortic valve endocarditis with ceftazidime-avibactam." Open forum infectious diseases 6: S110.

Background. The emergence of carbapenem-resistant Klebsiella pneumoniae (CR-Kp) presents significant clinical challenges with our limited antibiotic armamentarium. Infective endocarditis caused by CR-Kp is rare, with few cases reported in the literature. The use of the novel β-lactam/β-lactamase inhibitor combination ceftazidime- avibactam (CAZ-AVI) in this setting has only been described in one 2018 case in Italy. Guidance in how these novel antibiotics should be used becomes more prudent as the prevalence of complicated CR-Kp infections increases. Methods. A 51-year-old male with a past medical history of a gunshot wound to the neck, type 2 diabetes, and osteomyelitis status post right below-the-knee and left toe amputations presented to the emergency department with altered mental status and right upper extremity weakness. The patient's hospital course was complicated by hemorrhagic stroke, left above-the-knee amputation, and intraoperative cardiac arrest. Subsequently, blood cultures on hospital days 41 and 43 grew CR-Kp and a transthoracic echocardiogram (TTE) showed moderate to severe aortic regurgitation. Results. Antimicrobial therapy was changed from imipenem-cilastatin and colistin to CAZ-AVI and amikacin. The organism was found to be susceptible to CAZ-AVI and amikacin, intermediate to colistin, and resistant to all carbapenems. A transesophageal echocardiogram (TEE) confirmed the presence of a small mobile vegetation on the aortic valve with perforation and severe regurgitation. CAZ-AVI and amikacin were continued for two weeks, and then switched to CAZ-AVI and ertapenem for an additional four weeks. Follow-up blood cultures on and after day 44 were negative for CR-Kp. A TTE performed after therapy completion no longer demonstrated aortic regurgitation; however, the valves were poorly visualized. The patient then suffered anoxic brain injury after a second cardiac arrest, thought to be unrelated to endocarditis. The patient's family then decided on hospice care and the patient expired. Conclusion. We report the successful treatment of CR-Kp endocarditis with CAZ-AVI and amikacin for two weeks followed by CAZ-AVI and ertapenem for four weeks. This regimen can be a viable option for patients that present with this rare multidrug-resistant infection.

170. Aleksandrov, L. N., et al. (1970). "[Mechanism of gunshot wounds of the cranium and brain (experimental study)]." O mekhanizme ognestrel'nykh ranenii cherepa i golovnogo mozga (eksperimental'noe issledovanie) 104(5): 81-85.

---

171. Alessi, G., et al. (2002). "Home-made gun injury: spontaneous version and anterior migration of bullet." British journal of neurosurgery 16(4): 381-384.

We report a unique case of a self-inflicted brain injury using an ingenious home-made gun with spontaneous anterior migration of the intact bullet. On admission, the patient was fully conscious with no neurological deficits. Computed tomography (CT) confirmed a penetrating missile injury with transventricular across midline trajectory and multi-lobe injury with the bullet lodged in the occipital lobe. Serial CT revealed spontaneous version with anterior migration of the bullet from the occipital lobe to finally come to rest in the ipsilateral frontobasal region. The bullet was removed via a left supra-orbital craniotomy. The patient experienced good outcome. Home-made gun injuries, although uncommon today, represent a special form of missile injury with unique low velocity terminal ballistics. As these weapons are seen infrequently today, surgeons should be alerted to their existence as patients with this form of injury usually have a good prognosis if vital brain structures are spared.

---

172. Alexandrakis, G., et al. (1998). "An intraocular foreign body masquerading as idiopathic chronic iridocyclitis." Ophthalmic surgery and lasers 29(4): 336-337.

The authors report a case of presumed idiopathic chronic iridocyclitis in which an intraocular foreign body (IOFB) was finally identified. There was no history of prior eye trauma. Ophthalmologic and laboratory evaluations were inconclusive. Seven months following unsuccessful medical treatment of the iritis and given the patient's occupational history, a skull x-ray was performed followed by computed tomography of the orbits. A metallic IOFB was identified in the pars plicata and was surgically removed with resolution of the inflammation. The possibility of an IOFB should always be entertained in idiopathic iridocyclitis refractory to medical treatment, even when there is no history of ocular trauma.

---

173. Alexandrakis, G. and J. L. Davis (2000). "Intracranial penetrating orbital injury." Ophthalmic surgery and lasers 31(1): 61-63.

The authors report a case of double-penetrating injury of the globe with intracranial involvement from a pellet gun. A 16-year-old boy had a visual acuity of bare light perception in the left eye after being hit by a pellet. There was an inferior limbal entry site, dense hyphema, and no view of the fundus. Computed tomographic scan showed the pellet intracranially close to the left cavernous sinus. After neurosurgical clearance, the patient underwent primary closure of the corneoscleral entry site followed 3 weeks later by pars plana vitrectomy, lensectomy, and repair of a rhegmatogenous retinal detachment. At 12 months postoperatively, visual acuity was 20/300 and the retina was attached. Our case demonstrates the potential for significant visual recovery in some patients with a penetrating orbital injury and intracranial involvement. Complete radiographic evaluation with neurosurgical consultation is important in the management of these patients prior to ophthalmologic intervention with possible foreign body removal. There is a need for more public awareness regarding the potentially harmful effects of pellet guns.

174. Alexandru-Abrams, D., et al. (2019). "Scalp Intravenous Catheter Infiltration Leading to Subdural and Intraparenchymal Fluid Collection and Severe Neurologic Sequelae: A Case Report." The Permanente journal 23.

INTRODUCTION: Preterm infants require intravenous (IV) access for administration of medications, IV fluids, and parenteral nutrition. The scalp is a common site for obtaining IV access, and in children with hydrocephalus or wide fontanelles and sutures, there is a high probability of penetrating the meninges and brain matter with the scalp IV needle. If this penetration occurs and remains unnoticed, the contents of the IV infusion can infiltrate into the brain and cause severe brain damage., CASE PRESENTATION: A 3-day-old female neonate, born with myelomeningocele, was receiving total parenteral nutrition through a scalp-vein IV. She experienced a sudden increase in head circumference, a bulging fontanelle, and respiratory distress. Magnetic resonance images demonstrated subdural fluid collection, and the patient underwent emergency surgery. The dura, when opened, exuded milky-white fluid consistent in color with parenteral nutrition. Postoperative imaging showed a parenchymal abnormality caused by the intracranial and intraparenchymal infusion of parenteral nutrition. Four years later, the child had a shunt and had mild cognitive impairment., DISCUSSION: In cases of accidental intracranial administration of parenteral nutrition, we recommend that aggressive therapy be pursued to minimize the risks of developing comorbidities such as meningitis and to allow for maximal functional recovery.

---

175. Alexopoulos, G., et al. (2020). "Ballistic lobar trajectory outcomes in civilian firearm penetrating brain injury." Journal of neurosurgery: 1-10.

OBJECTIVE: Penetrating brain injury (PBI) is the most lethal of all firearm injuries, with reported survival rates of less than 20%. The projectile trajectory (PT) has been shown to impact mortality, but the significant lobar tracks have not been defined. The aim of this retrospective case-control study was to test for associations between distinct ballistic trajectories, missile types, and patient outcomes., METHODS: A total of 243 patients who presented with a PBI to the Saint Louis University emergency department from 2008 through 2019 were identified from the hospital registry. Conventional CT scans combined with 3D CT reconstructions and medical records were reviewed for each patient to identify distinct PTs., RESULTS: A total of 65 ballistic lobar trajectories were identified. Multivariable regression models were used, and the results were compared with those in the literature. Penetrating and perforating types of PBI associated with bitemporal (t-statistic = -2.283, $p = 0.023$) or frontal-to-contralateral parietal (t-statistic = -2.311, $p = 0.025$) projectile paths were universally found to be fatal. In the group in which the Glasgow Coma Scale (GCS) score at presentation was lower than 8, a favorable penetrating missile trajectory was one that involved a single frontal lobe (adjusted OR 0.02 [95% CI 0.00-0.38], $p = 0.022$) or parietal lobe (adjusted OR 0.15 [95% CI 0.02-0.97], $p = 0.048$). Expanding or fragmenting types of projectiles carry higher mortality rates (OR 2.53 [95% CI 1.32-4.83], $p < 0.001$) than do nondeformable missiles. Patient age was not associated with worse outcomes when controlled by other significant predictive factors., CONCLUSIONS: Patients with penetrating or perforating types of PBI associated with bitemporal or frontal-to-contralateral parietal PTs should be considered as potential donor candidates. Trauma patients with penetrating missile trajectories involving a single frontal or parietal lobe should be considered for early neurosurgical intervention, especially in the circumstances of a low GCS score (< 8). Surgeons should not base their decision-making solely on advanced patient age to defer further treatment. Patients with PBIs caused by nondeformable types of projectiles can survive multiple simultaneous intracranial missile trajectories.

---

176. Algattas, H. N., et al. (2021). "Impact of Coronavirus Disease 2019 Shutdown on Neurotrauma Volume in Pennsylvania." World neurosurgery 151: e178-e184.

OBJECTIVE: The 2020 coronavirus disease 2019 (COVID-19) pandemic resulted in state-specific quarantine protocols and introduced the concept of social distancing into modern parlance. We assess the impact of the COVID-19 pandemic on neurotrauma presentations in the first 3 months after shutdown throughout Pennsylvania., METHODS: The Pennsylvania Trauma Systems Foundation was queried for registry data from the Pennsylvania Trauma Outcomes Study between March 12 and June 5 in each year from 2017 to 2020., RESULTS: After the COVID-19 shutdown, there was a 27% reduction

in neurotrauma volume, from 2680 cases in 2017 to 2018 cases in 2020, and a 28.8% reduction in traumatic brain injury volume. There was no significant difference in neurotrauma phenotype incurred relative to total cases. Injury mechanism was less likely to be motor vehicle collision and more likely caused by falls, gunshot wound, and recreational vehicle accidents ($P < 0.05$). Location of injury was less likely on roads and public locations and more likely at indoor private locations ($P < 0.05$). The proportion of patients with neurotrauma with blood alcohol concentration >0.08 g/dL was reduced in 2020 (11.4% vs. 9.0%; $P < 0.05$). Mortality was higher during 2020 compared with pre-COVID years (7.7% vs. 6.4%; $P < 0.05$)., CONCLUSIONS: During statewide shutdown, neurotrauma volume and alcohol-related trauma decreased and low-impact traumas and gunshot wounds increased, with a shift toward injuries occurring in private, indoor locations. These changes increased mortality. However, there was not a change in the types of injuries sustained.

177. Al-Ghamdi, A., et al. (2007). "Primary pediatric keratoplasty: indications, graft survival, and visual outcome." Journal of AAPOS : the official publication of the American Association for Pediatric Ophthalmology and Strabismus 11(1): 41-47.

BACKGROUND: Penetrating keratoplasty in children has been documented to have a higher rate of graft failure and a worse visual prognosis than adult keratoplasty., METHODS: We undertook a retrospective review of all cases of primary penetrating keratoplasty performed in children 12 years of age or younger at the King Khaled Eye Specialist Hospital between January 1, 1990, and December 31, 2003., RESULTS: One hundred sixty-five primary penetrating keratoplasties were performed in 134 children during the study interval. The surgical indications were congenital opacities in 130 eyes (78.8%), acquired, traumatic opacities in 18 eyes (10.9%), and acquired, nontraumatic opacities in 17 eyes (10.3%). Among congenital opacities, 35 cases were caused by congenital hereditary endothelial dystrophy (CHED). The median follow-up for 73 grafts (44.2%) that remained clear was 50 months (range, 12-50 months), whereas the median follow-up for 92 grafts (55.8%) that failed was 6 months (range, 1-54 months). Kaplan-Meier graft survival was significantly higher at all postoperative intervals in eyes with CHED than for other surgical indications ($p < 0.001$). Eyes with CHED were significantly more likely to achieve ambulatory vision or vision >20/200 than eyes with other indications ($p < 0.001$)., CONCLUSIONS: Pediatric keratoplasty was associated with an excellent prognosis for graft survival in eyes with CHED and a fair prognosis for graft survival in eyes with non-CHED congenital opacities and acquired opacities. The best visual prognosis was obtained in eyes with CHED and the worst prognosis was for non-CHED congenital opacities.

178. Alhillo, H. T., et al. (2018). "Direct head injury caused by a tear gas cartridge. Questions on safety: A case report from Iraq and review of the literature." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia 56: 179-182.

INTRODUCTION AND BACKGROUND: Primary injuries from tear gas weapons include injuries to the visual and respiratory systems and skin. However, few studies have reported direct mechanical brain injuries from tear gas weapons., CASE REPORT: A 27-year-old male presented to the emergency department of a neurosurgery teaching hospital in Baghdad, Iraq, with a penetrating head injury of unknown source., DISCUSSION: Tear gas weapons are considered safe, but tear gas exposure causes severe complications. Traumatic brain injuries as a direct effect of tear gas bombs are rarely reported in the literature. Tear gas cartridge injuries should be managed in the same manner as any penetrating brain injury, with appropriate neuromonitoring. This monitoring is crucial for the detection and prevention of secondary brain insults., CONCLUSION: Emergency medicine specialists and neurosurgeons should be aware that tear gas weapons are not always safe, and they should anticipate chemical, thermal and mechanical side effects of tear gas weapons. The literature and our results suggest that these weapons should not be considered civil and harmless.

179. Ali, A. S., et al. (2013). "Clinico-imaging and EEG characteristics of intractable epilepsy following closed head injury." Epilepsia 54: 132-133.

Purpose: Post traumatic epilepsy (PTE) is seen in 2-20% following head trauma. Risk factors include injury severity, depressed skull fracture, intracranial hematoma, penetrating trauma, coma >24 h, early post traumatic seizures, focal EEG and neuroimaging abnormalities. However, not much data is available in such patients with intractable seizures following closed head injury (CHI). Method: Consecutive patients with intractable (seizure freedom <1 year in spite of treatment with at least two AEDs) PTE following closed head injury were selected from our Epilepsy Clinic over past 1 year. Their demographic, clinico-imaging and EEG data were reviewed and correlated. Results: Eleven patients (five males & six females) with mean age (±SD) 22 (±9) years presented with intractable epilepsy of 29 (±33) months average duration, fulfilling the methodology. Age of CHI was 37.4 (±33.6) months with time to onset of seizures as 17.3 (±14.2) months following the injury. Etiologies of CHI were Motor Vehicle Accident in eight and fall in three patients. All but two patients had either physical or cognitive sequeale following CHI. Neuroimaging showed lesions in all, with multi-lobar involvement in 8/12 (66.6%) patients. The EEG revealed epileptogenic abnormalities in 9/12 (75%) that were multifocal in 6/9 patients. Conclusion: All patients with intractable PTE following CHI revealed MRI abnormality and three quarter had epileptogenic abnormalities on EEG. Two-thirds of the patients had Motor Vehicle Accident as the etiology in our cohort.

180. Ali, D., et al. (2021). "CD300f immune receptor inhibition induce exacerbation of penetrating cortical injury." Glia 69(SUPPL 1): E196-E197.

Immune receptors play a critical role in regulating immune and inflammatory processes in the central nervous system (CNS). CD300f is of particular interest given its capacity to transmit activating and inhibitory signals. We previously demonstrated that the ligands of CD300f are present in the normal CNS and that the overexpression of CD300f has a neuroprotective role after an acute excitotoxic brain injury. In order to study its biological function, we used rCD300f-Fc, a fusion protein that interrupts the endogen interaction between CD300f receptor-ligands, and CD300f KO animals, both in vitro as well as in vivo. In vitro, in co-cultures of hippocampal neurons and mixed glia, we observed that the fusion protein induced a dose-dependent neuronal death. This neuronal death was dependent on glia, because no cell death was detected in enriched hippocampal neuronal cultures treated with CD300f-Fc. Moreover, we observed that conditioned medium of co-cultures of hippocampal neurons and mixed glia treated whit rCD300f-Fc induced neuronal death in enriched neuronal cultures, however conditioned medium by mixed glia treated whit rCD300f-Fc did not. In accordance with the in vitro results, in vivo studies, performed by injecting rCD300f-Fc into rat or mouse neocortex, showed an increased lesioned areaas observed by Nissl stain or an increased neuronal loss as observed by direct counting of YFP+ neurons in Thy1-YFP-H mice. Many of the ligands of CD300f, such as phosphatidylserine, sphingomyelin or lipoproteins, are shared with TREM2 immune receptor. To address the question of whether the effects of CD300f-Fc could be mediated by the inhibition of TREM2, CD300f KO mice were injected intracortically with rCD300f-Fc or control IgG. As expected, no effect was observed by CD300f-Fc injection in CD300f KO mice when compared to control IgG injection, suggesting that the fusion protein is acting by inhibiting the endogenous CD300f receptor. In conclusion, taken together, these data suggests that CD300f is involved in the maintenance of CNS homeostasis after an in vivo penetrating brain injury, and that microglial CD300f inhibition may alter microglial phenotype generating a neurotoxic microenvironment.

181. Ali, M., et al. (2012). "An unusual cause of traumatic brain injury in Khyber Pakhtunkhwa: A case report." JPMI - Journal of Postgraduate Medical Institute 26(3): 343-346.

Penetrating head injuries can be the result of numerous intentional or unintentional events, including missile wounds, stab wounds, motor vehicle and occupational accidents (nails, iron rods) or assaults (screw-drivers). Penetrating head injuries caused by screw-drivers constitute only a small part of the total number of traumatic head injuries seen in casualty. We report a case of neuro-trauma who was operated in our institution. A 25 years gentleman presented in casualty on with a screw-driver penetrating into the skull, as an unusual case of violence.

182. Ali, Q. M., et al. (1994). "Patterns of skull base fracture: a three-dimensional computed tomographic study." Neuroradiology 36(8): 622-624.

Three-dimensional (3D) computed tomographic (CT) reconstructions were studied retrospectively in 14 patients with skull base fractures. Our aim was to assess the clarity of visualisation and pattern of these fractures. The reformations were obtained from 3 mm thick two-dimensional (2D) CT images. The 2D data stored on optical discs were retrieved and reformatted using the scanner's software. The 3D technique could demonstrate the presence of fractures as well as 2D images. It was of special value in defining the depth and extent of fractures in the floor of the cranial fossae. Undisplaced and displaced fractures could both be demonstrated. Fractures in the anterior fossa run diagonally towards the midline and then cross the cribriform plate of the ethmoid bone. Fractures of the middle fossa run obliquely anteroposterior. Fractures in the lamina papyracea and cribriform plate were difficult to reconstruct due to the thinness of these bones and threshold definitions. The volume of the 3D block determines the angles suitable for viewing the fractures. In spite of present technical difficulties, the 3D images are of greater anatomical and diagnostic value, particularly in anterior fossa fractures. There is no additional radiation risk to the patient, since reconstructions are made from routine 2D images.

183. Alio, J. L., et al. (2013). "Autologous fibrin membrane combined with solid platelet-rich plasma in the management of perforated corneal ulcers: a pilot study." JAMA ophthalmology 131(6): 745-751.

IMPORTANCE: The combined use of autologous fibrin membrane and the eye platelet-rich plasma (E-PRP) clot could be considered as a new surgical alternative for the closure of corneal perforations., OBJECTIVE: To evaluate the use of autologous solid platelet-rich plasma in combination with an autologous fibrin membrane as a surgical alternative for wound closure in perforated corneal ulcers., DESIGN: Both the fibrin membrane and the E-PRP clot were prepared with the patient's own blood just before the operation. Nylon stitches were used to fixate the fibrin membrane to the conjunctiva and then the E-PRP clot was placed over the corneal perforation, underneath the fibrin membrane. A temporal partial tarsorrhaphy was performed at the end of the procedure. We conducted postoperative monitoring for 3 months. SETTING Vissum Corporacion Oftalmologica, Alicante, Spain., PARTICIPANTS: Eleven patients with perforated corneal ulcers., INTERVENTION: Surgical alternative for the closure of corneal perforation., MAIN OUTCOMES AND MEASURES: Corneal biomicroscopy, fluorescein test, digital tonometry., RESULTS: In all cases the corneal perforation was sealed. The fibrin membrane was present over the corneal surface for the first 3 to 5 days and then gradually disappeared. No evidence of infection or inflammation was detected. Digital tonometry confirmed acceptable levels of ocular tonus in all cases from day 2 after the operation. No patients reported pain, discomfort, or other symptoms, and no complications were observed. After 3 months' follow-up, there was no evidence of relapses or perforations. Corneal grafting was eventually performed in 7 of the 11 cases., CONCLUSIONS AND RELEVANCE: The combined use of autologous fibrin membrane and E-PRP clot is a safe and effective surgical alternative for the closure of corneal perforations. This technique can be considered as a temporary measure until the condition of the cornea permits definite intervention.

184. Aljuboori, Z., et al. (2022). "A case series of crossbow injury to the head highlighting the importance of an interdisciplinary management approach." Surgical neurology international 13: 60.

BACKGROUND: Penetrating crossbow head injuries are rare with no clear consensus regarding the optimal management paradigm for such injuries. We present three cases of crossbow injury to the head, with emphasis on the need for a comprehensive multidisciplinary management plan., CASE DESCRIPTION: Three cases are presented of patients presenting with self-inflicted penetrating crossbow to head injuries. All three patients presented with intact neurological exam. A comprehensive multidisciplinary plan was created for all three cases with subsequent successful removal of the arrows. All three patients were discharged home with modified Rankin scale score of <2., CONCLUSION: Penetrating crossbow brain injuries are rare and require complex management. A comprehensive management strategy is necessary to manage these injuries. Moreover, careful consideration of factors such as the arrow trajectory, complexity of the injuries, and availability of the required expertise is important to increase the chances of success.

185. Aljuboori, Z., et al. (2020). "Endovascular Treatment of a Traumatic Middle Cerebral Artery Pseudoaneurysm with the Pipeline Flex Embolization Device." World neurosurgery 133: 201-204.

OBJECTIVE: Traumatic pseudoaneurysms of the proximal middle cerebral artery (MCA) segments are challenging to treat. We describe the management of traumatic internal carotid artery and MCA pseudoaneurysms with flow diversion., CASE DESCRIPTION: A 19-year-old man had sustained a gunshot wound to the head. Delayed digital subtraction angiography showed de novo formation of the left internal carotid artery ophthalmic segment and left MCA M2 segment pseudoaneurysms. We had initially performed coil embolization of the left MCA pseudoaneurysm. However, it had recurred 2 weeks later. We treated both pseudoaneurysms with flow diversion using the Pipeline Flex embolization device. The patient has continued with dual antiplatelet therapy of aspirin and ticagrelor. Follow-up digital subtraction angiography at 6 months showed complete obliteration of both pseudoaneurysms with patent parent vessels. The patient remained neurologically intact., CONCLUSIONS: Flow diversion can be an efficacious treatment of traumatic MCA pseudoaneurysms in appropriately selected cases. The risks versus benefits of dual antiplatelet therapy must be weighed in trauma settings.

186. Aljuboori, Z., et al. (2020). "The utility of repeat computed tomography angiogram after blunt cerebrovascular injury." Journal of neurointerventional surgery 12: A94.

Introduction Blunt cerebrovascular injury (BCVI) can lead to thromboembolic events. The necessity of short-term repeat vascular imaging after the initial diagnosis is controversial. The aim of this retrospective cohort study is to assess the utility of short-interval computed tomography angiography (CTA) after an initial diagnosis of BCVI. Methods We retrospectively reviewed consecutive patients with BCVI managed at the University of Louisville from 2016-2019 who underwent short-term (1-3 weeks) repeat CTA after initial diagnosis. The exclusion criteria were age <18 years, penetrating injury, and previous neck irradiation. We collected baseline data and performed logistic regression analysis to identify predictors of BCVI imaging outcomes. Results The study cohort comprised 38 patients (68% male) with a mean age of 45 years. Motor vehicle accident (79%) was the most common mechanism of injury, and 89% had cervical spine fractures. Unilateral VA and grade I dissection were the most common findings on initial CTA were a unilateral VA dissection (66%) that was Biffl grade I (36%). Antiplatelet therapy or anticoagulation was administered to 82% of patients after the initial diagnosis (table 1). Shift analysis showed a significant improvement in Biffl grades on repeat CTA (p=0.0001) (figure 1). Biffl grades I injuries were more likely to improve (relative risk ratio [RRR]=3.6, CI 95% (1.02-13.1),p=0.04), whereas grade IV injuries were more likely to be stable (RRR=33, CI 95% (2.9-374), p=0.005). Ten BCVIs (26%) completely resolved on repeat imaging (table 2). The rates of early (<2 weeks) and delayed (2 weeks to 3 months) ischemia were 5% and 0%, respectively. Endovascular stenting was performed in 8%. Conclusion Short-term repeat non-invasive vascular imaging can help to identify the evolution of BCVI. Repeat vascular imaging at short intervals

can help to identify patients who may require endovascular intervention, but additional studies are necessary to clarify its role in the management of BCVI. (Figure Presented).

---

187. Aljuboori, Z., et al. (2020). "The Utility of Repeat Computed Tomography Angiogram After Blunt Cerebrovascular Injury." Clinical neurosurgery 67(SUPPL 1): 96-97.

INTRODUCTION: Blunt cerebrovascular injury (BCVI) can lead to thromboembolic events. The necessity of short-term repeat vascular imaging after the initial diagnosis is controversial. The aim of this retrospective cohort study is to assess the utility of short-interval computed tomography angiography (CTA) after an initial diagnosis of BCVI. METHODS: We retrospectively reviewed consecutive patients with BCVI managed at the University of Louisville from 2016-2019 who underwent short-term (1-3 weeks) repeat CTA after initial diagnosis. The exclusion criteria were age < 18 years, penetrating injury, and previous neck irradiation. We collected baseline data and performed logistic regression analysis to identify predictors of BCVI imaging outcomes. RESULTS: The study cohort comprised 38 patients (68% male) with a mean age of 45 years. Motor vehicle accident (79%) was the most common mechanism of injury, and 89% had cervical spine fractures. Unilateral VA and grade I dissection were the most common findings on initial CTA were a unilateral VA dissection (66%) that was Biffl grade I (36%). Antiplatelet therapy or anticoagulation was administered to 82% of patients after the initial diagnosis. Shift analysis showed a significant improvement in Biffl grades on repeat CTA (P = .0001). Biffl grades I injuries were more likely to improve (relative risk ratio [RRR] = 3.6, CI 95% (1.02-13.1), P = .04), whereas grade IV injuries were more likely to be stable (RRR = 33, CI 95% (2.9-374), P = .005). Ten BCVIs (26%) completely resolved on repeat imaging. The rates of early (<2 weeks) and delayed (2 weeks to 3 months) ischemia were 5% and 0%, respectively. Endovascular stenting was performed in 8%. Imaging outcomes of vascular injuries Number of patients Second CTA Third CTA Total 38 16 Normalized 9 (24%) 1 (6%) Improved 2 (5%) 6 (38%) Stable 14 (37%) 9 (56%)Worse 13 (34%) 0% Abbreviations: CTA; computed tomography angiogram. CONCLUSION: Short-term repeat non-invasive vascular imaging can help to identify the evolution of BCVI. Repeat vascular imaging at short intervals can help to identify patients who may require endovascular intervention, but additional studies are necessary to clarify its role in the management of BCVI.

188. Alkadhimi, A., et al. (2017). "Frontal lobe abscess due to orbital roof blow out fracture." International journal of oral and maxillofacial surgery 46: 74.

Background: A medically fit and well 34-year-old female patient initially presented to the emergency department at Queens Medical Centre following an accident in which she fell from her bike and hit the left orbit with handlebar. Plain film radiographs (OM10o and 30o) showed no evidence of any facial fractures. Clinically, she had no functional problems apart from diplopia on lateral gaze associated with left eye. A two-week review was planned by ophthalmology. Objectives: Patient attended eye causality department 7 days after the initial trauma complaining of ongoing restriction of movement. Ophthalmological examination revealed restricted ocular motility and diplopia on all directions of gaze particularly downwards. Methods: Acomputed tomography (CT) scan performed to investigate the cause of restriction revealed an orbital roof fracture. Following discussion with neurosurgery a magnetic resonance imaging (MRI) was arranged to exclude abscess. Findings: CT showed blowout fracture through the superamedial left orbital cavity with displaced fragments projected 2 cminto the left frontal lobe. Subsequent MRI scan showed abscess formation around the left frontal lobe. The patient had urgent bifrontal craniotomy and drainage of the abscess. Due to risk of infection, no roof repair was performed. Conclusion: This case emphasised the importance of multidisciplinary approach in trauma cases; in this scenario the patient was managed by the maxillofacial surgical team, neurosurgery and ophthalmology. This case also highlights the need for consideration of mechanism of injury in light of clinical findings. A penetrating injury should always make the surgeon consider and exclude underlying bony injury.

189. Alkan, A., et al. (2002). "Early MRI findings in stab wound of the cervical spine: two case reports." Neuroradiology 44(1): 64-66.

MR imaging was found to be the most sensitive modality for the detection of spinal cord abnormalities in the acutely injured spine. Although it is reported that traumatic pneumomyelogram indicates a base-of-skull or middle cranial fossa fracture and is almost certainly associated with intracranial subarachnoid air, early MR imaging may demonstrate subarachnoid air in penetrating trauma of the spinal cord without head injury. We report two cervical-spine stab-wound cases, one of which had subarachnoid air on early MR findings.

191. Allaire, M. T. and M. H. Manhein (2008). "Suicide by blasting caps: a case study of rare cranial trauma." Journal of forensic sciences 53(6): 1313-1315.

Suicide is a deliberate act of ending one's life. Suicide by use of any explosive device, when not involved in a terrorist act, is quite rare in occurrence when compared with other methods routinely utilized. In this paper, we present to the medicolegal community a case of an adult male who committed suicide with blasting caps and the subsequent extensive damage to the cranial hard tissue. Although the cause and manner of death were relatively straightforward, consultation with forensic anthropologists was requested for an anthropological trauma assessment of the highly fragmented skull. After the skull was cleaned and reconstructed, the analysis revealed similarities between blasting cap trauma to the head and high velocity gunshot trauma to the head. Therefore, in a case where some evidence may have been removed or destroyed, forensic analysis involving trauma of this magnitude could result in a misinterpretation of the true mechanism responsible for the osseous damage. In this case, cooperation among the law enforcement agency, coroner's investigators, the forensic pathologist, and forensic anthropologists provided a comprehensive death case analysis.

---

192. Allais, L., et al. (2021). "Emergent bilateral hemicraniectomy in the setting of delayed diagnosis of traumatic brain injury." Journal of neurosurgical anesthesiology 33(4): 413.

Traumatic brain injuries (TBI) cause a large burden of ED visits and deaths.1 Intracranial hypertension (ICH) is a consequence of severe TBI. When medical management of ICH fails, decompressive craniotomy becomes necessary to mitigate brain swelling and herniation.2 Unfortunately, TBIs can be difficult to detect early, leading to delayed care. Furthermore, when the brain undergoes significant trauma, a catecholamine surge can lead to cardiac collapse. We present a severe TBI masked by a Glasgow Coma Scale (GCS) of 15, requiring emergent bilateral craniectomies, complicated by intraoperative catastrophic cardiovascular events. Case Summary: Patient is a 49 year old man who arrived after witnessed gunshot wounds to the head. He was awake, able to speak coherently, moving all extremities, with a head wound thought to be a bullet “graze injury.” Head CT revealed a bullet tract from left parietal tissues to the right temporal lobe, holohemispheric bleeds, pneumocephalus and edema. His care was elevated to involve Neurosurgery and Anesthesiology. The patient became progressively hypertensive, developed rightward gaze deviation, left sided motor deficits as his neurological status quickly declined, He was intubated with the head of bed at 30°, hyperventilated, and moved to the OR. He received Mannitol, 23% saline, and Levetiracetam. The Catastrophic Brain Injury protocol was started. He remained hypertensive during the early operative course. As hemorrhages were evacuated, he required a Phenylephrine infusion and PRBCs to maintain adequate cerebral perfusion. During flap closure, the patient developed profound bradycardia and hypotension. Carotid pulse could not be identified until after receiving 0.2 mg of epinephrine. Additional vasoactive medications were given during similar episodes of abrupt profound lability during which the surgical team appreciated

continued herniation with closure. Due to complications of continued hemodynamic lability, global autonomic dysregulation, and poor neurologic exam, the decision for compassionate extubation was made POD 12. Discussion: Missed diagnosis of TBI increases morbidity and mortality. This patient's initial presentation may have led to a delay in escalation of care. In spite of initial high GCS, a witnessed firearm attack should trigger expedited management of presumed TBI. Time to craniectomy might have been shorter, improving brain preservation.3,4 High GCS on presentation can be a positive prognostic factor with timely intervention.5 Expediting tertiary care regardless of GCS may be protective. Initially hypertensive, the patient became suddenly hypotensive and bradycardic. Similar to the myocardial "stunning" in subarachnoid hemorrhages,6 this was possibly catecholamine-mediated, worsened by early brainstem herniation. His catecholamine reserves were likely exhausted after a massive surge, demonstrated by response only to exogenous catecholamines. Furthermore, the cardiomyopathy induced by adrenergic cascade can in of itself be a threat by provoking abrupt and cataclysmic arrhythmias refractory to chemical support.

---

193. Allareddy, V., et al. (2014). "Emergency department visits with facial fractures among children and adolescents: an analysis of profile and predictors of causes of injuries." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons 72(9): 1756-1765.

PURPOSE: The objectives of this study were to provide nationally representative estimates of hospital-based emergency department (ED) visits for facial fractures in children and adolescents, examine the burden associated with such visits, identify common types of facial fracture, and examine the role of patient-related demographic factors on the causes of facial fractures., MATERIALS AND METHODS: The Nationwide Emergency Department Sample for 2008 to 2010 was used. All ED visits with a diagnosis of facial fractures in those no older than 21 years were selected. Demographic characteristics, types of facial fracture, causes of injuries, and hospital charges were examined., RESULTS: During the study period, 336,124 ED visits were for facial fractures in those no older than 21 years. Late adolescents (18 to 21 yr old) and middle adolescents (15 to 17 yr old) comprised 45.6% and 26.6% of all ED visits, respectively. Male patients comprised 74.7% of ED visits. The most common facial fractures were those of the nasal bones and mandible. Younger children were more likely to have falls, pedal cycle accidents, pedestrian accidents, and transport accidents, whereas older groups were more likely to have firearm injuries, motor vehicle traffic accidents, and assaults ($P < .05$). Female patients were more likely to have falls, motor vehicle traffic accidents, and transport accidents, whereas male patients were more likely to have firearm injuries, pedal cycle accidents, and assaults ($P < .05$). Those residing at low annual income household levels were at a high risk for having firearm injuries, motor vehicle traffic accidents, and transport accidents ($P < .05$)., CONCLUSIONS: Late adolescents, middle adolescents, and male patients comprise a significant proportion of these ED visits. Age, gender, and household income levels are significantly associated with the causes of facial fracture injuries.

194. Allareddy, V., et al. (2014). "Impact of facial fractures and intracranial injuries on hospitalization outcomes following firearm injuries." JAMA otolaryngology-- head & neck surgery 140(4): 303-311.

IMPORTANCE: Firearm injuries (FAIs) play a major role in unintentional injuries, suicides, and homicides. It is important that policy makers, public health authorities, physicians, and the public are kept abreast of current trends in FAIs so that preventive programs can be tailored to the needs of cohorts that are at highest risk for such injuries., OBJECTIVES: To provide nationally representative longitudinal estimates of outcomes associated with hospitalizations attributed to FAIs in all age groups in the United States during the years 2003 to 2010; to obtain prevalence estimates of skull and/or facial fractures and intracranial injuries among those hospitalized owing to firearm injuries; and to examine the association between the occurrence of skull and/or facial fractures and/or intracranial injuries and in-

hospital mortality., DESIGN, SETTING, AND PARTICIPANTS: In this retrospective analysis of the largest all-payer hospitalization data set in the United States, we evaluate a Nationwide Inpatient Sample of patients hospitalized for FAIs during the years 2003 to 2010., EXPOSURES: Face and/or skull fracture and/or intracranial injuries due to firearm injuries., MAIN OUTCOMES AND MEASURES: The main outcome of interest was in-hospital mortality. The primary independent variables included occurrence of face and/or skull fracture and/or intracranial injuries. RESULTS During the study period, 252,181 visits were attributed to FAIs. Adolescents and young adults accounted for nearly 80% of all hospitalizations, with more than half of these in the 18- to 29-year-old, high-risk group. Male patients consistently accounted for 89% of the hospitalizations. The uninsured population accounted for nearly a third of hospitalizations. A total of 214,221 FAI hospitalizations did not involve facial and/or skull fractures or intracranial injuries; 13,090 involved a facial and/or skull fracture without a concomitant intracranial injury; 20,453 involved an intracranial injury without a concomitant facial and/or skull fracture; and 4417 involved both a facial and/or skull fracture and intracranial injury. Those with intracranial injuries without concomitant facial and/or skull fractures (odds ratio [OR], 58.40; 95% CI, 50.08-68.11) (P < .001) and those with both facial and/or skull fractures and intracranial injuries (OR, 17.45; 95% CI, 13.98-21.79) (P < .001) were associated with higher odds of in-hospital mortality than those without these injuries. Teaching hospitals were associated with higher odds of in-hospital mortality than nonteaching hospitals (OR, 1.31; 95% CI, 1.14-1.49) (P < .001). Teaching hospitals also tended to treat a higher proportion of complex cases. The uninsured had higher odds of in-hospital mortality than those with private insurance (OR, 1.55; 95% CI, 1.35-1.78)., CONCLUSIONS: AND RELEVANCE Occurrence of intracranial injuries was an independent risk factor for poor outcomes. Teaching hospitals had higher mortality rates but also treated more complex cases than nonteaching hospitals.

---

195. Allareddy, V., et al. (2016). "Firearm injuries in children in the USA: A persistent, pervasive, public health issue!" Critical care medicine 44(12): 200.

Learning Objectives: Firearm injuries (FAI) play a major role in intentional as well as unintentional injuries in children and are a major cause of morbidity and mortality. Current national estimates and trends of FAI in children are unknown. We sought to characterize FAI in children requiring emergency department(ED) visit. Further, we sought to identify the predictors of mortality in this cohort. Methods: We performed a retrospective analysis of the Nationwide Emergency Department Sample (years 2008 to 2013), the largest all-payer ED database in the United States. All children aged <18years who visited the ED due to FAI were identified using the external cause of injury codes. Available modes of FAI (accidental vs non-accidental) and resulting types of injuries were assessed. Outcomes included in-hospital mortality (IHM), hospital charges (HC) and Length of stay (LOS). A multivariable logistic regression analysis adjusted for a multitude of patient and hospital level characteristics was used to identify the predictors of mortality in the ED and following hospitalization. Results: Over a 6y period, a total of 49,061 children visited the ED due to FAI in the USA. Of these 16,247(33%) were admitted to the same hospital. The mean age was 14.5y and males accounted for 85% of visits. Outcomes include: Mean ED HC ($4615), mean inpatient HC ($89,859) and mean LOS (6.2days). 1752 patients died in the ED, while 1119 died following hospitalization. Major modes of FAI included accidental (37%), assault (46%), legal intervention (1.7%) and suicide/ self-inflicted(2.6%). Predictors of increased risk of mortality (Odds ratios, 95% CI, p value) included younger(0-9y) age (1.7{1.1-2.5},0.01); uninsured(2.4{1.8-3.3},<0.01); mode of FAI-accidental (4.1{1.4-12.2},0.01), assault(5.2{1.7-16},<0.01) or self-inflicted(15.3{4.7-49.7},<0.01); and those with intracranial injuries(18.4{13.2-25.6),<0.01). Conclusions: Nearly 22 children visit ED every day due to FAI. Adolescents, males and those without insurance or from lower income group are the high risk cohorts. FAI in children are no longer rare tragedies!.

---

196. Allareddy, V., et al. (2016). "Is it time for code GSW (gunshot wound)? 194 adult ED visits a day!" Critical care medicine 44(12): 203.

Learning Objectives: Firearm injuries (FAIs) play a major role in suicides, homicides and unintentional injuries. It is important that policy makers, physicians and the public are kept abreast of current trends in FAIs so that preventive programs can be tailored to the needs of cohorts that are at highest risk for such injuries. We sought to characterize FAI in adults requiring emergency department(ED) visit. Further, we sought to identify the predictors of mortality in this cohort. Methods: We performed a retrospective analysis of the NEDS (years 2008 to 2013), the largest all-payer ED database in the USA. All patients aged >18years who visited the ED due to FAI were identified. Available modes of FAI (accidental vs non-accidental) and resulting types of injuries were assessed. Outcomes included in-hospital mortality (IHM), hospital charges (HC) and Length of stay (LOS). A multivariable logistic regression analysis adjusted for a multitude of patient and hospital level characteristics was used to identify the predictors of mortality in the ED and following hospitalization. Results: Over a 6y period a total of 423,624 adults visited the ED due to FAI. Of these 154,399(36.4%) were admitted to the same hospital. Characteristics included: mean age of 32y (18-30y accounted for 57.5%), males (89%), low income (48.3%) and uninsured (44.9%). Outcomes include: Mean ED HC ($5,192), mean inpatient HC ($103,765) and meanLOS (7.2days). 22,998 patients died in the ED, while 13,363 died following hospitalization. Major modes of FAI included accidental (33.5%), assault (47.2%), legal intervention (2.6%) and suicide/self-inflicted(6.9%). Predictors of increased risk of mortality (OR's, 95% CI, p value) included the uninsured(1.9{1.7-2.1},<0.01); self-inflicted FAI (2.3{1.2-4.4},0.01); and those with intracranial injuries(15.3{13.8-16.9),<0.01), crushing/internal injury(4.1{3.6-4.6},<0.01) or open injury to head/neck/ trunk(2.2{2-2.5},<0.01). Conclusions: 194 adults visit ED every day due to FAI. 1 in 12 exposed to FAI died. Young adults, males, the uninsured, and those from lower income were the high risk cohorts. FAI are common occurrences in USA.

197. Allen, I. V., et al. (1983). "An ultrastructural study of experimental high velocity penetrating head injury." Acta neuropathologica 59(4): 277-282.

Experimental high velocity missile brain injury in the rhesus monkey produces widespread swelling of perivascular astrocytes within 30 min of injury. Possible mechanisms for this lesion include a direct effect of force, chemical mediation secondary to the extravasation of blood, alterations in the permeability of the blood brain barrier and ischaemia. The implications of this findings for the function of the blood brain barrier, for neurotransmission and for neuronal survival are discussed.

198. Allison, R. Z., et al. (2017). "Derivation of a Predictive Score for Hemorrhagic Progression of Cerebral Contusions in Moderate and Severe Traumatic Brain Injury." Neurocritical care 26(1): 80-86.

BACKGROUNDS: After traumatic brain injury (TBI), hemorrhagic progression of contusions (HPCs) occurs frequently. However, there is no established predictive score to identify high-risk patients for HPC., METHODS: Consecutive patients who were hospitalized (2008-2013) with non-penetrating moderate or severe TBI were studied. The primary outcome was HPC, defined by both a relative increase in contusion volume by >=30 % and an absolute increase by >=10 mL on serial imaging. Logistic regression models were created to identify independent risk factors for HPC. The HPC Score was then derived based on the final model., RESULTS: Among a total of 286 eligible patients, 61 (21 %) patients developed HPC. On univariate analyses, HPC was associated with older age, higher initial blood pressure, antiplatelet medications, anticoagulants, subarachnoid hemorrhage (SAH) subdural hematoma (SDH), skull fracture, frontal contusion, larger contusion volume, and shorter interval from injury to initial CT. In the final model, SAH (OR 6.33, 95 % CI, 1.80-22.23), SDH (OR 3.46, 95 % CI, 1.39-8.63), and skull fracture (OR 2.67, 95 % CI, 1.28-5.58) were associated with HPC. Based on these factors, the HPC Score was derived (SAH = 2 points, SDH = 1 point, and skull fracture = 1 point). This score had an area under the receiver operating curve of 0.77. Patients with a score of 0-2 had a 4.0 % incidence of HPC, while patients with a score of 3-4 had a 34.6 % incidence of HPC., CONCLUSIONS:

A simple HPC Score was developed for early risk stratification of HPC in patients with moderate or severe TBI.

199. Allison, R. Z., et al. (2014). "Risk factors for delayed intraparenchymal hematoma enlargement after moderate and severe traumatic brain injury using multivariable regression modeling." Neurocritical care 21(1): S136.

Introduction After traumatic brain injury (TBI), delayed enlargement of intraparenchymal hematomas (IPH) has been reported in up to 40% of patients but predictive models for IPH enlargement have not been developed. Methods The trauma database from the only American College of Surgeons verified trauma center in Hawaii was queried to identify consecutive patients admitted for non-penetrating moderate and severe TBI from 2008-2013. Retrospective chart review was undertaken to collect additional variables. IPH volume was estimated using the ABC/2 method. The primary outcome was IPH enlargement by ≥10 mL on serial imaging. Chi-square and ANOVA were used to identify factors associated with IPH enlargement ($p< 0.1$) which were then included in a multivariable logistic regression model. Results 419 patients were screened, of whom 286 had repeat imaging and were included in the analyses. Mean age was 47.6±26.7 years, 70.6% were male, 38.8% were Asian, 29.7% were Native Hawaiian or Pacific Islander, and 25.2% were white. Mechanism of injury was fall in 48.3%, motor vehicle crash in 25.2%, and assault in 15.0%. In-hospital mortality was 20.6%. Sixty-one patients (21.3%) had delayed IPH enlargement, which was symptomatic in 52% of cases. On univariable analyses, IPH enlargement was associated with older age, higher initial systolic blood pressure, anti-platelet medications, anticoagulants, subarachnoid hemorrhage (SAH), subdural hematoma (SDH), skull fracture, frontal contusion, and shorter interval from injury to initial CT. Packed red blood cells (pRBC) transfusion was protective. In a stepwise logistic regression model, SAH (OR 6.33), SDH (OR 3.46), skull fracture (OR 2.67), and pRBC transfusion (OR 0.31) were independently associated with IPH enlargement ($p< 0.05$). Conclusions We identified risk factors for delayed IPH enlargement after moderate and severe non-penetrating TBI. These factors could be used to identify patients at high risk for IPH enlargement who require closer clinical and radiographic monitoring and may benefit from investigational treatments.

200. Allon, G., et al. (2016). "The role of computed tomography in the immediate workup of open globe injury." European journal of ophthalmology 26(5): 503-504.

PURPOSE: Immediate primary closure is indicated in cases of traumatic open globe injury. Orbital computed tomography (CT) is performed prior to primary closure in order to rule out possible intraocular foreign bodies (IOFB) and/or damage to adjacent extraocular as well as intraocular structures. The aim of the present study is to evaluate the yield of orbital CT scan in immediate clinical decision-making in cases of open globe injury., METHODS: All cases of open globe injury treated in our institute during a 10-year period were reviewed. All underwent a CT scan before any surgical intervention, regardless of trauma severity. The influence of the CT scan results on decisions regarding the immediate treatment of the open globe injury was analyzed., RESULTS: A total of 125 cases of open globe injury were included in the present study. In none of these cases did the CT scan results have any influence on immediate treatment. The CT scan results did influence decisions that were made after the immediate operative stage., CONCLUSIONS: Computed tomography scan has limited value in immediate clinical decision-making in cases of open globe injury scheduled for primary closure. While not crucial prior to the initial procedure, it is of value in managing the case during the following few days as well as later on. This study suggests that a CT scan performed after the initial globe exploration and suturing procedure is a valid alternative to stalling the definite globe suturing process until a CT scan is obtained and interpreted.

---

201. Allred, D., et al. (2014). "Anoxic brain injury and emerging consciousness in a lightning strike victim: A case report." Archives of physical medicine and rehabilitation 95(10): e56-e57.

Objective: N/A Design: Case Report Setting: South Texas Veterans Health Care System, San Antonio, TX. Participants: Army service member struck by lightning who sustained an anoxic brain injury, hemorrhagic contusion of left frontal lobe, burns of 14% total body surface area requiring surgical allografting and epithelial corneal defects of right eye. Acute hospital course complicated further by stress-induced cardiomyopathy, pulmonary embolism, rhabdomyolysis, AKI, SIADH, dysautonomia, pneumonia and respiratory failure with prolonged intubation and tracheostomy, and dysphagia with gastrostomy tube placement. At the onset of his rehabilitation, his Rancho Los Amigos (RANCHO) cognitive functioning level was II. Interventions: The patient was enrolled in the Veterans Health Administration emerging consciousness program (VHA-ECP) which involves a highly functional interdisciplinary rehabilitation team with treatment focus on detailed environmental regulation, direct stimulation interventions, mobility and positioning programs and management of medical comorbidities and traumatic brain injury-related sequalae. Main Outcome Measure(s): Overall improvement in alertness and cognition measured by the Rancho Los Amigos cognitive functioning scale, neuropsychiatric testing and gains achieved in activities of daily living (ADLs) measured by functional independence measure (FIM) scoring. Results: Upon completing the 90-day VHA-ECP, patient had improved his cognitive function and level of alertness to a RANCHO V and was able to be subsequently enrolled into a traditional acute inpatient rehabilitation program. Conclusions: This case report illustrates the efficacy of the VHA-ECP in an anoxic brain injury patient, which is different than the more typical traumatic brain injuries of blast or penetrating trauma.

204. Almogy, G., et al. (2005). "Can external signs of trauma guide management?: Lessons learned from suicide bombing attacks in Israel." Archives of surgery (Chicago, Ill. : 1960) 140(4): 390-393.

BACKGROUND: Following a suicide bombing attack, scores of victims suffering from a combination of blast injury, penetrating injury, and burns are brought to local hospitals., OBJECTIVE: To identify external signs of trauma that would assist medical crews in recognizing blast lung injury (BLI) and effectively triaging salvageable and nonsalvageable victims., DESIGN: Retrospective analysis of all 15 suicide bombing attacks that occurred in Israel from April 1994 to August 1997., SETTING: National survey., PATIENTS: One hundred fifty-three victims died and 798 were injured as a result of 15 attacks. Medical records were reviewed for external signs of trauma, such as burns and penetrating injuries, and the presence of BLI. Main Outcome Measure The odds ratio for BLI and death., RESULTS: Three settings were targeted: buses, semiconfined spaces, and open spaces. Sixty survivors (7.5%) suffered from BLI, which was more common in buses (37 of 260) than semiconfined spaces (14 of 279) and open spaces (9 of 259) (P<.001). Victims with BLI were more likely to suffer from penetrating injury to the head or torso, burns covering more than 10% of the body surface area, and skull fractures (odds ratios, 4, 11.6, and 55.8, respectively; P<.001). Victims who died at the scene were more likely to suffer from burns, open fractures, and amputations in comparison with survivors (odds ratios, 6.5, 18.6, and 50.1, respectively; P<.001)., CONCLUSIONS: Following a suicide bombing attack, external signs of trauma should be used to triage victims to the appropriate level of care both at the scene and in the hospital. Triage of salvageable and nonsalvageable victims should take into account the presence of amputations, burns, and open fractures.

---

205. Almogy, G., et al. (2006). "Suicide bombing attacks: Can external signs predict internal injuries?" Annals of surgery 243(4): 541-546.

OBJECTIVE: To report the distribution and types of injuries in victims of suicide bombing attacks and to identify external signs that would guide triage and initial management., SUMMARY BACKGROUND DATA: There is a need for information on the degree to which external injuries indicate internal injuries requiring emergency triage., METHODS: The medical charts and the trauma registry database of all patients who were admitted to the Hadassah Hospital in Jerusalem from August 2001 to August 2004 following a suicide bombing attack were reviewed and analyzed for injury characteristics, number of body areas injured, presence of blast lung injury (BLI), and need for therapeutic laparotomy. Logistic analysis was performed to identify predictors of BLI and intra-abdominal injury., RESULTS: The study population consisted of 154 patients who were injured as a result of 17 attacks. Twenty-eight patients suffered from BLI (18.2%) and 13 patients (8.4%) underwent therapeutic laparotomy. Patients with penetrating head injury and those with > or =4 body areas injured were significantly more likely to suffer from BLI (odds ratio, 3.47 and 4.12, respectively, $P < 0.05$). Patients with penetrating torso injury and those with > or =4 body areas injured were significantly more likely to suffer from intra-abdominal injury (odds ratio, 22.27 and 4.89, respectively, $P < 0.05$)., CONCLUSION: Easily recognizable external signs of trauma can be used to predict the occurrence of BLI and intra-abdominal injury. The importance of these signs needs to be incorporated into triage protocols and used to direct victims to the appropriate level of care both from the scene and in the hospital.

206. Almojuela, A., et al. (2022). "Vasospasm following low-velocity penetrating pediatric intracranial trauma." Journal of medical case reports 16(1): 48.

BACKGROUND: BB guns or non-powder guns created in the modern era are able to reach exceedingly fast velocities as a result of advances in compressed-gas technology. While missile penetrating trauma has been well documented in neurosurgical literature, penetrating intracranial injury secondary to non-powder guns, along with their associated complications and treatments, is not well described, and even less so in the pediatric population., CASE PRESENTATION: Here, we describe an unusual case of a 6-year-old Indigenous child who was accidentally shot with a BB gun to the head. He subsequently developed delayed acute right-sided weakness due to symptomatic vasospasm. His symptoms resolved following hypertensive therapy, balloon angioplasty intervention, and intra-arterial milrinone therapy., CONCLUSIONS: This case highlights the unique complication of delayed symptomatic vasospasm in a child following a non-missile intracranial penetrating injury. Intracranial vasospasm needs to be considered in the presence of delayed neurological deficit given its potential reversibility. This case also emphasizes the importance of gun safety and education when handling and storing these potential weapons around children.

207. Almuqamam, M., et al. (2022). "Therapeutic intensity and treatment of hyperthermia in severe traumatic brain injury." Critical care medicine 50(1 SUPPL): 791.

INTRODUCTION: Severe acute traumatic brain injury (sTBI) is a leading cause of pediatric morbidity and mortality. There are no known effective primary therapies for sTBI and management thus centers on the prevention of secondary brain injury. Fever is both a well-established complication of sTBI and known to potentiate secondary injury. We aimed to describe the incidence, duration, severity, and management of fever in children with sTBI. METHODS: This is a retrospective observational study performed at a level one pediatric trauma center. We reviewed relevant data over the first 72 hours of PICU admission in all sTBI patients (presenting GCS ≤8). Collected data included demographic information, timing of the first temperature ≥38.0°C, total duration of temperature ≥38.0°C, maximum temperature, and the timing of all therapies aimed at either fever prevention or reduction. Data are presented using descriptive statistics. RESULTS: Thirty-five patients with sTBI were included (71%

male; median age 4, IQR 0.88-11.0 years). The etiologies of TBI included motor vehicle accident (13/35, 37%), nonaccidental head trauma (11/35, 31%), fall (6/35, 17%), and gunshot wounds (5/35, 14%). 62% of patients developed fever in the first 72 hours of hospitalization with a median time of 5.78 (IQR 3.19 - 13.09) hours to the first fever following PICU admission and a duration of the first fever of 120 (IQR 60 - 285) minutes. The median total duration of hyperthermia ≥38.0°C in the first 72 hours of PICU admission was 256 (IQR 76 - 495) minutes. Tylenol was prescribed to 66% of patients with a fever, a cooling blanket to 11%, and any other therapy aimed at temperature regulation to 3%. The median time from the first fever to the prescription of the first therapy aimed at prevention or management of hyperthermia was 1.22 (IQR -0.27 - 6.39) hours and was started after the first fever in 68% of patients. CONCLUSIONS: Despite the well-described implications of fever in sTBI, it occurs with a high frequency in the clinical management of sTBI. Therapies aimed at prevention or treatment of fever commonly occurs after the start of the first fever and is a potentially modifiable risk factor for worse patient outcomes.

208. Alnaousf, E., et al. (2010). "Penetrating cranio-cerebral injury - An unusual assault with a long iron bar." Kuwait Medical Journal 42(4): 304-306.

Violent penetrating head injury is rare but it is a significant cause of morbidity in children. We report a case of a 12-year-old boy who sustained a penetrating skull injury at the right parietal bone following an assault with a long curved iron bar.

---

209. Al-Omaishi, L., et al. (2013). "Difficulties with recruitment of traumatically brain injured patients for a prospective post-traumatic epilepsy study." Epilepsy Currents 13: 182-183.

Rationale: Traumatic Brain Injury (TBI) is a well-known risk factor for post-traumatic epilepsy (PTE), especially among survivors of penetrating head injuries such as gun shot wounds (GSW), assaults, and blast injuries. We sought to enroll new civilian TBI patients into a prospective study designed to predict the onset of PTE through computerized analysis of electroenchalography (EEG) and microRNA biomarkers with a target enrollment of 90 patients. One critical component of a prospective study such as this is a reasonable expectation of enrollment and an understanding as to why a majority of TBI patients are poor study subjects. Methods: This is an ongoing study. We screened all new TBI patients upon admission as a Level 1 trauma to St. Joseph's Hospital and Medical Center (SJHMC) beginning October 16, 2011. Criteria for enrollment included moderate to severe penetrating or closed head injuries (initial Glasgow Coma Score (GCS) <13), with no previous diagnosis of epilepsy, and not participating in another clinical trial. If the patient was unable to sign for him or herself, families were approached with information about the study and the legally authorized representative was asked to sign for consent. Results: To date (6/15/12) 111 patients who came through SJHMC as a Level 1 trauma patient who had sustained moderate to severe TBI (mean age: 38, GCS at admission: 7.1, mean lowest GCS: 5.7) have been screened for enrollment. Of these, 85 patients were ineligible for study for a variety of reasons; 33 died from their injuries (mean time from injury to death = 6.4 days), 13 lived far from the Phoenix Metropolis and would be unable to return, 10 were not interested, 8 were chronic alcoholics, 7 had a history of seizure disorders, 4 were polysubstance abuse users with suicidal ideologies, and 12 were rejected for other reasons. Of the 26 enrolled, 3 died from their injuries, 5 suffered acute traumatic seizures (but have not yet developed PTE) and 5 were withdrawn. This means only 12.6% of all moderate to severe Level 1 TBI patients are active study participants. Mechanisms of injury were as follow: motor vehicle collision (30), auto vs. pedestrian (20), GSW (14), motorcycle crash (14), assault (11), fall (10), ATV accident (8), and other (4). Alcohol was a factor in 60% of all injuries; 36% of patients were positive for other substances including but not limited to cocaine, marijuana, and opiates, and amphetamines. Conclusions: Prospective clinical studies of PTE after TBI which require long-term follow-up are difficult. Our experience has been that only 1 of 8 such patients (12.6%) could be enrolled and continuously followed over six or more months. This experience should be considered when

planning a long term follow-up study of moderate to severe TBI patients with either penetrating or closed head injuries.

210. Alonso, N., et al. (2016). "Pseudoaneurysm of the internal maxillary artery: A case report of facial trauma and recurrent bleeding." International journal of surgery case reports 21: 63-66.

Introduction Pseudoaneurysms occur when there is a partial disruption in the wall of a blood vessel, causing a hematoma that is either contained by the vessel adventitia or the perivascular soft tissue. Presentation of case A 32-year-old male presented to the emergency department presented with comminuted fractures in the left zygoma, ethmoids, and the right ramus of the mandible following a gunshot wound. The patient underwent open reduction of his fractures and the patient was discharged on the eighth day after the trauma. Thirteen days after the discharge and 21 days after the gunshot wound, the patient returned to the ER due to heavy nasopharyngeal bleeding that compromised the patency of the patient's airways and caused hemodynamic instability. Arteriography of the facial blood vessels revealed a pseudoaneurysm of the maxillary artery. Endovascular embolization with a synthetic embolic agent resulted in adequate hemostasis, and nine days after embolization the patient was discharged. Discussion The diagnosis of pseudoaneurysm is suggested by history and physical examination, and confirmed by one of several imaging methods, such as CT scan with contrast. Progressive enlargement of the lesion may lead to several complications, including rupture of the aneurysm and hemorrhage, compression of adjacent nerves, or release of embolic thrombi. Conclusion This case reports the long-term follow up and natural history of a patient with a post-traumatic pseudoaneurysm of the internal maxillary artery and the successful use of endovascular embolization to treat the lesion.

212. Alper, M., et al. (1998). "Gunshot wounds of the face in attempted suicide patients." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons 56(8): 930-934.

PURPOSE: The purpose of this retrospective study was to evaluate the functional and cosmetic results of the treatment of gunshot wounds associated with attempted suicide that resulted in facial injury., PATIENTS AND METHODS: The records of 12 patients with facial injury resulting from gunshot wounds with a suicidal origin, who were hospitalized and treated at Ege University Hospital, Department of Plastic and Reconstructive Surgery, were reviewed., RESULTS: All injuries were limited to the head and neck region; in only one patient did intracranial penetration occur. Mandibular fractures were detected in all cases. Fractures of the maxilla were present in 11 patients. Eight patients suffered from zygomatic fractures. Perforating ocular trauma was present in two cases. Soft tissue repair was performed by primary closure, local flaps, or skin grafts, and rigid fixation was used for fractures. Procedures such as distant flaps or bone grafting were left for delayed reconstruction., CONCLUSION: Only 3 of 12 patients returned for follow-up and reconstruction. It was therefore concluded that relatives of these patients believe that the repair of such deformities, even if it is a functional deformity, is not necessary. Thus, in such cases, one should do as much reconstruction as possible at the primary surgical intervention.

213. Alqadri, S. L., et al. (2016). "Vasopressin bolus protocol compared to desmopressin (DDAVP) for managing acute, post-operative central diabetes insipidus." Neurocritical care 25(1): S275.

Introduction: Management of post-operative central diabetes insipidus (DI) is focused on replacing urine output with free water. This may not always be sufficient, and desmopressin (DDAVP) is needed. The use of DDAVP, however, is known to cause profound changes in sodium particularly if

the triphasic response post-pituitary surgery is occurring. Herein, we report a case using a dilute vasopressin bolus protocol in managing hypovolemia in acute, post-operative, central DI. Methods: Case report comparing two protocols for DI management. Statistical analysis was performed on serum sodium, urine specific gravity, and urine output using student t-test. P<0.05 was considered significant. Results: Patient is a 16-year-old male admitted to the neurosciences intensive care unit (NSICU) after bifrontal decompressive craniotomy for severe traumatic brain injury from self-inflicted gunshot wound. Immediately post-operatively, he developed increased urine output. He arrived to NSICU hypovolemic (3.4 liters negative in three hours) and hypernatremic (148meq/L). He was resuscitated with intravenous fluids including a dilute vasopressin bolus protocol. This protocol consisted of 1 unit of vasopressin in 1 liter of 0.45% normal saline. This was given in boluses based on the formula: urine output minus one hundred. At the start of this protocol, the serum sodium was 148 and one-hour urine output was 1 liter. This protocol was continued for 48 hours. Endocrinology was consulted and recommended changing to DDAVP. Serum sodium was 149[NP1] and one-hour urine output 320 cc prior to first dose of DDAVP. Comparing the bolus protocol to the DDAVP protocol, the average sodium was 143.8+3.2 and 149.6+3.2 meq/L (p=0.0001), average urine output was 433.2+354.4 and 422.3+276.0 cc/hr (p=0.90), and average specific gravity was 1.019+0.009 and 1.016+0.01, respectively (p=0.42). Conclusions: A protocol using dilute vasopressin bolus is an alternative for managing acute, central DI post-operatively, particularly with acute hypovolemia. Additional studies are needed to address its efficacy in a larger sample.

214. Alrajhi, K., et al. (2010). "MINOR and minimal head injuries in patients on warfarin." Canadian Journal of Emergency Medicine 12(3): 253-254.

Introduction: There is currendy very little evidence to guide physicians on how to manage emergency patients who sustain a minor or minimal head injury (HI) while on warfarin. The objective of this study was to determine the incidence of intracranial bleeding (ICB) in andcoagulated patients with minor (initial GCS of 13-15 with witnessed loss of consciousness [LOC]/confusion or amnesia) and minimal (no LOC/amnesia/confusion) His and the association of ICB to clinical features, and international normalized ratio (INR) level. Methods: Historical cohort study of all adult patients who presented to 2 tertiary care EDs over 2 years with minor or minimal His, identified through the National Ambulatory Care Reporting System database, while on warfarin with INRs of 1.5 or greater. Exclusions included penetrating injuries, new focal neurologic deficits and previous brain surgery. Our structured data collection tool included 25 variables from history, physical exam, CT, surgical interventions, return visits and death. Our outcome, ICB, included any type of bleed within the cranium, and was determined by either 1) CT during initial ED visit, or 2) CT during a subsequent ED visit at any of the 4 regional hospitals within 2 weeks of the initial visit. Results: We identified 176 patients, of which 60.2% were female, mean age was 79.0 (range 25-100) years and mean EMR was 2.5 (range 1.5- 8.2). A total of 157 patients (89.2%) had CT scans and 28 (15.9%) had ICB. Comparing the group with ICB to the group with no ICB there was no significant difference in INR levels (mean 2.53 v. 2.45, p = 0.5), respectively, while LOC correlated with higher incidence of ICB (28.6% v. 10.8%, p < 0.05), respectively. Incidence of ICB was 21.9% in the minor HI group versus 4.8% in the minimal group. Conclusion: The incidence of ICB in patients on warfarin is considerable. LOC was associated with higher rates of ICB. This study supports a low threshold for ordering a CT scan for patients with minor or minimal head injuries who are on warfarin.

---

215. Alrajhi, K. N., et al. (2015). "Intracranial bleeds after minor and minimal head injury in patients on warfarin." The Journal of emergency medicine 48(2): 137-142.

BACKGROUND: There is little evidence to guide physicians on management of patients who sustain head injuries while on warfarin., OBJECTIVES: Our objective was to determine the rate of intracranial bleeding in anticoagulated patients with minor and minimal head injuries and the association with clinical features and international normalized ratio (INR)., METHODS: We conducted a historical

cohort study of adult patients, taking warfarin, at two tertiary care emergency departments over 2 years with minor (Glasgow Coma Score 13-15, with loss of consciousness, amnesia, or confusion) or minimal (Glasgow Coma Score 15 without loss of consciousness, amnesia, or confusion) head injuries. Patients with penetrating injuries, INR < 1.5, or a new focal neurological deficit were excluded. Our outcome, intracranial bleeding, was determined by the radiologist's final computed tomography (CT) report for imaging performed within 2 weeks., RESULTS: There were 176 patients enrolled, of which 157 (89.2%) had CT and 28 (15.9%) had intracranial bleeding. Comparing patients with and without intracranial bleeding found no significant differences in INR, and loss of consciousness was associated with higher rate of intracranial bleeding. The rate of intracranial bleeding in the minor and minimal head injury groups was 21.9% and 4.8%, respectively., CONCLUSIONS: The rate of intracranial bleeding in patients on warfarin is considerable. Loss of consciousness is associated with high rates of intracranial bleeding. This study supports a low threshold for ordering CT scans for anticoagulated patients with head injuries.

217. Al-Schameri, A. R., et al. (2016). "Middle cerebral artery aneurysm surgery after stent misplacement: A case report." Interventional neuroradiology : journal of peritherapeutic neuroradiology, surgical procedures and related neurosciences 22(1): 49-52.

Stent misplacement during endovascular treatment of middle cerebral artery (MCA) aneurysms can cause challenges and be problematic, if clipping becomes necessary. This article reports on a 56-year-old woman with an unruptured, multi-lobulated MCA aneurysm, whom primarily refused surgery; therefore, she was scheduled for stent-assisted coiling. After successful deployment of the stent, it unfortunately then became snagged by the microcatheter and was pulled backwards. The subsequent surgical procedure (i.e. clipping of the MCA aneurysm) was challenging, due to the position of the dislodged stent. Such as misplacement of the stent is rarely documented: It resulted in the difficult handling of a MCA aneurysm. Aneurysms of the MCA should primarily be considered for surgical clipping. In conclusion, an increased risk for eventual surgery should be considered, in cases where endovascular treatments with stents are performed.

---

218. Alt, K. W. (2016). "The grimace of battle-a mass grave from the thirty years' war: Dental, forensic and social aspects in the lives of soldiers." Acta Stomatologica Croatica 50(2): 188.

The Thirty Years' War (1618-1648) was one of the most destructive conflicts in the European history. Violence, famine and diseases significantly decreased the European population. In November 1632 a small town in today's Central Germany, was the setting of one of the greatest and bloodiest combats: the great Battle of Lützen. General Wallenstein and the Swedish King Gustav II Adolf were the most prominent actors on the battlefield, the latter was mortally wounded. More than 6.000 soldiers lost their lives, and-after looting-the dead bodies were buried in numerous mass graves. In summer 2011 archaeologists discovered one of these mass graves at the edge of Lützen. The complete grave was recovered en bloc and the skeletons were detailed analyzed in situ, accompanied by methods such as isotopic analyses (C/N, Sr/O), medical imaging techniques (Xray, CT, DVT) and histology. The grave contained the skeletal remains of 47 men with an age at death range from about 15 to 45 years; most of the men were 20-30 years old. One major intention was the reconstruction of the nature of violence in which these men died on the battlefield. Among numerous perimortem injuries a high number of cranial gunshot wounds were found. This kind of death and the caliber of the lead bullets helped to reconstruct the course of the combat, particularly in the area the soldiers died. Healed injuries, such as fractures of the upper and lower limbs or blunt and sharp force trauma to the cranium, provide information about healing conditions and insufficient medical treatment. Poor hygiene and long lasting deprivations have left osteological traces as well and reflects the adverse living conditions during wartime.

219. Al-Thobity, A. M., et al. (2014). "Zygomatic implants as a rehabilitation approach for a severely deficient maxilla." The International journal of oral & maxillofacial implants 29(6): e283-289.

A gunshot injury is one of the main trauma injuries that affect the head and neck region. Severe esthetic, functional, and psychologic deficiencies are consequences of gunshot injuries. The use of implants anchored in the zygomatic bone has been advocated as an approach to the prosthetic rehabilitation of a severely deficient maxilla. This approach provides the patient with an immediate, high-quality, esthetic, and functional complete fixed prosthesis and eliminates the need for bone grafting. In this case report, a patient with a severely deficient maxilla caused by a gunshot injury was rehabilitated by placement of four zygomatic and two pterygomaxillary implants, which were immediately loaded with a complete fixed all-acrylic resin interim prosthesis. The definitive CM Prosthesis (CM Prosthetics) was constructed using computer-aided design/computer-assisted manufacture (CAD/CAM) technology.

221. Altintas, M., et al. (1998). "Eye socket reconstruction with the prefabricated temporal island flap." Plastic and reconstructive surgery 102(4): 980-987.

Insufficiency of tissues and progressive contraction usually restrict the application of prosthetic devices in anophthalmic eye sockets. To achieve a successful reconstruction, the plastic surgeon has to form a socket that has proper dimensions and is completely covered by a well vascularized epithelial surface. Eye socket reconstruction with free skin, mucous membrane, or dermis-fat grafts usually remains unsatisfactory in severe cases. We have used a prefabricated temporal island flap to solve this difficult problem since 1983. In this method, a full-thickness skin graft is applied over the temporal fascia to create a prefabricated island flap based on the superficial temporal vessels. This flap is transposed into the eye socket 3 weeks later. Some modifications in flap design have been done to get better fitting of the prosthesis since that time. Thirty-three patients with constricted eye sockets that could not use prosthetic devices were treated with prefabricated temporal island flaps since 1983. The follow-up period was between 1 and 13 years. Eye sockets with adequate size and volume were created in all patients, and the results were successful. This method prevented secondary graft shrinkage, and the prefabricated island flaps preserved their dome shape during the follow-up period. We believe this method is a useful one in the treatment of the contracted socket.

222. Alvarez, J. A., et al. (1999). "Delayed rupture of traumatic intracranial pseudoaneurysm in a child following gunshot wound to the head." The Journal of cranio-maxillofacial trauma 5(4): 39-44.

BACKGROUND AND OBJECTIVES: Traumatic intracranial aneurysms (TICAs) are highly unstable lesions that may rupture within minutes after formation or remain quiescent for several weeks and manifest with delayed hemorrhage and neurologic deterioration. Mortality following a rupture may be 30% to 40%. Among all cerebral aneurysms, the incidence of TICAs is less than 1%; 20% to 30% of TICAs occur in children., METHODS AND MATERIALS: A child with a low-caliber craniocerebral gunshot wound deteriorated neurologically 12 days after the initial injury and emergency evacuation of an intracranial hematoma. A new massive left frontal hematoma was discovered, caused by the rupture of an unsuspected left pericallosal artery pseudoaneurysm. The new hematoma was evacuated, and the aneurysm was trapped using microsurgical techniques., RESULTS AND/OR CONCLUSIONS: A high index of suspicion should be maintained for delayed pseudoaneurysm genesis and rupture. A cerebral arteriogram should be obtained when significant subarachnoid hemorrhage or intraparenchymal

hematomas are present, when missiles traverse major arteries, or when the pterional or cranioorbitofacial regions are violated. Treatment should be prompt.

223. Alvarez, M. N., et al. (2013). "Flow diverting stents as exclusive treatment of a traumatic carotid cavernous fistula complicated by a wide-neck fusiform aneurysm." Journal of Vascular and Interventional Radiology 24(1): 145.e149-145e110.

Purpose: High flow direct carotid cavernous fistulas (CCF) are an infrequent complication from blunt or penetrating trauma to the basilar skull, which are now treated endovascularly with the objective of eliminating the fistula while preserving patency of the internal carotid artery (ICA). To our knowledge the use of a flow diverting stent as sole therapy for a CCF has been described only once in the literature. We present a traumatic high flow direct CCF complicated by a wide-neck dissecting distal ICA aneurysm treated exclusively with flow diverting stents. Materials and Methods: 21 year-old female was the driver in a high speed motor vehicle rollover, suffering multiple facial bone, sphenoid and basilar skull fractures. Initial angiography revealed a small dissection of the cavernous segment of the left ICA and a direct CCF with early and abnormal drainage into the ipsalateral cavernous sinus, superior and inferior ophthalmic veins and petrosal sinuses. The patient returned to the angio suite fourteen days later for anticipated endovascular repair with detachable coils. The diagnostic angiogram demonstrated a 1.5 x 1.2 x 1.0 cm lobulated and fusiform aneurysm arising from the dissected segment of the cavernous segment of the distal left ICA with a neck of approximately 11 mm as well as continued filling of the cavernous andpetrosal sinuses and ophthalmic veins. The patient was treated five days later by telescoping two Pipeline embolization devices (PED) within the cavernous segment of distal ICA. Post stent deployment angio- gram demonstrated stagnant flow within the aneurysm and cessation of the flow within the cavernous sinus and petrosal sinuses. Results: Approximately ten months after intervention the patient returned for a follow-up diagnostic angiogram. Cerebral injection of the left ICA demonstrated normal contour of the reconstructed cavernous segment of the ICA and normal antegrade flow into the ipsilateral anterior and middle cerebral arteries. There was no evidence of residual aneurysm and no abnormal filling of the ophthalmic veins and cavernous and petrosal sinuses. Conclusion: We present a unique case of a CCF complicated by a dissecting, wide- neck fusiform aneurysm. While there are several recent reports in the literature reporting the successful treatment of these types of aneurysms with flow diverting stents, there has only been one published case of a CCF treated solely with a flow diverting stent. The PED allowed reconstruction of the distal ICA and the telescoping of two devices supplemented coverage across the vascular defect eliminating the fistula and diminishing intra-aneurysmal flow. Followup angiogram performed ten months later demonstrated normal flow dynamics, a completely thrombosed aneurysm and resolution of the fistula. Thus, flow diverting stents may provide a safe, durable and effective alternative to the treatment of complicated CCFs.

---

225. Alves, J. L., et al. (2012). "Temporal gunshot injuries - about 3 different cases and review of the literature." Sinapse 12(1): 45-51.

Background: Although rare, penetrating temporal bone trauma by gunshot injury has a tremendous potential impact in terms of mortality and morbidity. As one of the most complex anatomical regions in the cranium and intracranial compartments, multiple clinical and radiological presentations should be expected, implying different management strategies, by specialized teams, and expecting several possible outcomes. Methods and results The authors report on three Traumatic Brain Injury patients with this particular sub-type of injury, different particularities and management, followed by a brief review on the subject. The preferred surgical and medical strategies are presented and

balanced against the relevant literature. Conclusion A crucial and necessary interdisciplinary approach is clearly the only valid option for an optimal treatment and followup of this type of patients suffering this complex traumatic injury.

226. Alves, O. L., et al. (2003). "Evaluation of topiramate neuroprotective effect in severe TBI using microdialysis." Annals of the New York Academy of Sciences 993: 25-53.

Despite recent advances in our understanding of human traumatic brain injury (TBI) pathophysiology, we still need effective neuroprotective agents. The lack of rigorous drug pharmacokinetic studies in the "living" brain is an important cause of neuroprotection trials failure in human TBI research. In the past, several drugs have been labeled as inefficient, and even withdrawn from expensive trials, without knowing their actual penetration in the traumatized human brain. The injured brain is characterized by an increased diffusion distance, due to edema, and reduced blood flow that modulates drug transport across the blood-brain barrier (BBB). In the study reported in this paper, we used cerebral microdialysis to provide a safe and efficient tool for continuous in vivo evaluation of bioavailability and pharmacologic efficacy of topiramate, a glutamate release inhibitor. Topiramate crossed the BBB in neuroprotective concentrations, and showed a lowering effect on glutamate levels, thereby modifying the natural history of glutamate release after TBI. The use of cerebral microdialysis in phase II drug studies will allow the detection of the appropriate therapeutic window and dosage for the neuroprotective agent. This strategy represents a clear improvement compared to traditional clinical trial design, and will reduce the trial costs.

227. Alvis-Miranda, H. R., et al. (2015). "Management of Craniocerebral Gunshot Injuries: A Review." Korean journal of neurotrauma 11(2): 35-43.

Craniocerebral gunshot injuries (CGI) are increasingly encountered by neurosurgeons in civilian and urban settings. Unfortunately this is a prevalent condition in developing countries, with major armed conflicts which is not very likely to achieve a high rate of prevention. Management goals should focus on early aggressive, vigorous resuscitation and correction of coagulopathy; those with stable vital signs undergo brain computed tomography scan. Neuroimaging is vital for surgical purposes, especially for determine type surgery, size and location of the approach, route of extraction of the foreign body; however not always surgical management is indicated, there is also the not uncommon decision to choose non-surgical management. The treatment consist of immediate life salvage, through control of persistent bleeding and cerebral decompression; prevention of infection, through extensive debridement of all contaminated, macerated or ischemic tissues; preservation of nervous tissue, through preventing meningocerebral scars; and restoration of anatomic structures through the hermetic seal of dura and scalp. There have been few recent studies involving penetrating craniocerebral injuries, and most studies have been restricted to small numbers of patients; classic studies in military and civil environment have identified that this is a highly lethal or devastating violent condition, able to leave marked consequences for the affected individual, the family and the health system itself. Various measures have been aimed to lower the incidence of CGI, especially in civilians. It is necessarily urgent to promote research in a neurocritical topic such as CGI, looking impact positively the quality of life for those who survive.

229. Amadasi, A., et al. (2015). "Assets and pitfalls of chemical and microscopic analyses on gunshot residues in skeletonized bodies: a report of five cases." International journal of legal medicine 129(4): 819-824.

In case of gunshot wounds, forensic anthropologists and pathologists have many tools at hand, and the assistance that chemical and microscopic investigations can provide in such scenarios is often valuable and crucial. However, the results of such analyses in the search of gunshot residues (GSR) ought not to be acritically considered. We report five cases where chemical (sodium rhodizonate) and microscopic (scanning electron microscopy-energy dispersive X-ray spectroscopy (SEM-EDX)) analyses were performed for the search of GSR. Four cases concerned the forensic field and analyses on buried, charred, or submerged remains, whereas one case concerned the historical remains of a soldier of the First World War. In every case, the search for GSR with these techniques showed their persistence even after long periods and preservation in peculiar environments. However, chemical analyses provided their contribution, but in two cases, anthropological analyses provided crucial and solving results. The five cases show the indisputable usefulness of chemical and microscopic analyses in the search of GSR in gunshot wounds and especially how such residues may survive in time and in adverse environmental conditions. However, experts should always be dubious about some pitfalls (such as contamination) one can frequently find in these scenarios.

230. Amaefule, K. E., et al. (2019). "Trauma intensive care in a terror-ravaged, resource-constrained setting: Are we prepared for the emerging challenge?" African Journal of Emergency Medicine 9: S32-S37.

Introduction: Trauma in developing countries has been on the increase, a situation perpetuated by rising road traffic collisions, terrorism and firearms proliferation. Some of the victims of trauma are left with life threatening conditions requiring urgent surgical intervention and/or intensive care. The objectives of this study were to determine the pattern of major trauma needing intensive care in the region, and to determine the outcome of major trauma admitted to intensive care unit. Methods: A six-year retrospective cohort study of trauma patients needing intensive care, set in the Intensive Care Unit of Ahmadu Bello University Teaching Hospital, Zaria, North-West Nigeria. Subjects were major trauma patients admitted into the intensive care unit of the institution, identified via an admission register kept in the unit. The main outcomes measured were length of stay and mortality. Results: Trauma admissions represented 25.1% of the all intensive care admissions. Severe traumatic brain injury accounted for 32.1% of the trauma admissions, while burns accounted for 23.2%. Of the injuries, 15.5% were sustained in bomb blasts, and 8.3% were firearm injuries. The majority of the patients stayed for no more than seven days from admission. Burns patients had the worst outcomes, with 82.1% mortality. Conclusion: Major trauma contributes significantly to local intensive care admissions, with terrorism-related trauma now an emerging challenging cause of major trauma in our region. The observed poor outcomes in this study are a reflection of the quality of available intensive care, and lends credence to the concept of appropriately resourced, specialised intensive care units for optimisation of care.

231. Amano, K. and S. Kamano (1982). "Cerebellar abscess due to penetrating orbital wound." Journal of computer assisted tomography 6(6): 1163-1166.

A cerebellar abscess developed in a child with a penetrating transorbital wound extending deep into the cerebellum. The computed tomographic (CT) scans at first demonstrated the image of the residual foreign body as a sharp, low density track. This changed to high density with suggestion of granulation along the lesion. The cerebellar abscess developed at the tip of the track with CT ring enhancement. Antibiotic treatment reduced the size and density of the abscess.

232. Amano, Y., et al. (2022). "Multiple Brain Metastases in a Patient with ROS1 Fusion-Positive Lung Adenocarcinoma as a Disease Flare due to Crizotinib Cessation Caused by Disseminated Aseptic Inflammation from Crizotinib-Associated Renal Cysts: A Case Report." Case Reports in Oncology 15(1): 338-344.

Rapid tumor growth after cessation of molecularly targeted drugs, called "disease flare,"may occur and affect the prognosis of lung cancer. However, this phenomenon has never been reported in ROS proto-oncogene 1 (ROS1) fusion-positive lung adenocarcinoma. Herein, we report a disease flare in a patient with ROS1 fusion-positive lung adenocarcinoma. A 60-year-old female was diagnosed with stage IVA ROS1 fusion-positive lung adenocarcinoma via bronchoscopy. Although crizotinib, an ROS1 tyrosine kinase inhibitor, achieved a partial response, a mass lesion appeared in the patient's right kidney 12 months after starting crizotinib, which was diagnosed pathologically as crizotinib-associated renal cysts (CARCs). Given that readministration of crizotinib repeatedly induced CARC-like aseptic inflammation that appeared to be disseminated around surgical site, crizotinib treatment had to be abandoned. Around 25 days after crizotinib cessation, she was referred to the emergency department with a convulsive seizure and hemiparesis due to new, rapidly growing brain metastases. Whole-brain irradiation and administration of another ROS1 tyrosine kinase inhibitor, entrectinib, markedly ameliorated the metastases and improved hemiparesis. This has been the first report of a disease flare after crizotinib cessation due to CARCs in a patient with ROS1 fusion-positive lung adenocarcinoma. Attention should be paid to disease flare, especially in the brain, when molecularly targeted medication is stopped due to adverse events in ROS1 fusion-positive lung adenocarcinoma. Switching to drugs that penetrate the blood-brain barrier could overcome disease flare in the brain.

---

233. Amaolo, M., et al. (2002). "Cranial gunshot: Revised concepts on bullets, therapeutic management and revision of literature." Prensa Medica Argentina 89(10): 860-872.

The gunshot wounds constitute the majority of penetrating injuries to the head. In patients under 45 years old they are a cause of brain death in 35% of cases, and 65% die in the place that the event takes place before receiving any medical attention. Nowadays, these lesions are arising in frequency because of maybe the facility to obtain firearms in the civil ambit and to the continuous armored events all around the world. That demands interests in order to improve the ballistics knowledge and apply it to surgical techniques in the gunshot wounds to the head.

234. Amaral, M. B. F., et al. (2017). "Facial fractures caused by less-lethal rubber bullet weapons: case series report and literature review." Oral and maxillofacial surgery 21(3): 357-361.

PURPOSE: The present study aims to describe three cases of patients inflicted by rubber bullets with severe facial fractures., METHODS: In addition, a review of English-language literature involving facial fractures by rubber bullets from 1975 to 2016 was performed., RESULTS: This current study demonstrated that the use of the LLRBW is unsafety even when applied by police enforcements exclusively., CONCLUSIONS: Management of facial fractures caused by LLRBW is done in a usual manner with closed or open reduction associated with bone mini-plates or reconstruction plates when indicated. Special initial wound care should be done to avoid secondary infection and additional procedures.

---

235. Amat, J. A., et al. (1996). "Phenotypic diversity and kinetics of proliferating microglia and astrocytes following cortical stab wounds." Glia 16(4): 368-382.

Brain injury induces reactive gliosis, characterized by increased expression of glial fibrillary acidic protein (GFAP), astrocyte hypertrophy, and hyperplasia of astrocytes and microglia. One hypothesis tested in this study was whether ganglioside GD3+ glial precursor cells would contribute to macroglial proliferation following injury. Adult rats received a cortical stab wound. Proliferating cells were identified by immunostaining for proliferating cell nuclear antigen (PCNA) and by [3H]-thymidine autoradiography, and cell phenotypes by immunocytochemical staining for GD3, GFAP, ED1 (for reactive microglia) and for Bandeiraea Simplicifolia isolectin-B4 binding (all microglia). Animals were labeled with thymidine at 1,2,3, and 4 days postlesion (dpl) and sacrificed at various times thereafter. Proliferating cells of each phenotype were quantified. A dramatic upregulation of GD3 on ramified

microglia was seen in the ipsilateral hemisphere by 2 dpl. Proliferating cells consisted of microglia and fewer astrocytes. Microglia proliferated maximally at 2-3 dpl and one third to one half were GD3+. Astrocytes proliferated maximally at 3-4 dpl, and some were also GD3+. Both ramified and ameboid forms of microglia proliferated and by 4 dpl all GD3+ microglia were ED1+ and vice versa. In the contralateral cortex microglia expressed neither GD3 nor ED1. Thus they acquired these antigens when activated. Neither microglia nor astrocytes that were thymidine-labeled at 2, 3, or 4 dpl changed in number in subsequent days. Most thymidine+ astrocytes were large GFAP+ reactive cells that clearly arose from pre-existing astrocytes, not from GD3+ glial precursors. In this model of injury microglia proliferate earlier and to a much greater extent than astrocytes, they can divide when in ramified form, and GD3 is up-regulated in most reactive microglia and in a subset of reactive astrocytes. We also conclude that microglial proliferation precedes proliferation of invading blood-borne macrophages.

236. Amato, A., et al. (2011). "Isoelectic electroencephalogram (eeg) with bithalamic injury and hyperdynamic cerebral blood flow: A case study." Neurocritical care 15(1): S260.

Introduction Electroencephalography (EEG) is a non-invasive neurophysiological test used to evaluate the electrical activity of the cerebral cortex. In the ICU, it is widely used to evaluate for subclinical seizure activity and as an adjunct to verify the diagnosis of brain death. We present the case of a patient with severe, penetrating traumatic brain injury who had clinical and sonographic evidence of cerebral blood flow while showing no evidence of electrical activity. Methods A 17 year old male was admitted to our NeuroICU after sustaining a gunshot wound to the head. At presentation, the patient had a Glasgow Coma Scale (GCS) of 4 (E1M2V1) with bilateral fixed pupils and bilateral extensor posturing. Head CT imaging showed a large right temporal lobe contusion and 9mm of right-to-left subfalcine herniation prompting an emergent decompressive hemicraniectomy. Results Post-operatively, the patient remained comatose (GCS 4) with extensor posturing. Continuous EEG was performed that showed severe diffuse slowing. However, shortly after recording had begun, spontaneous electrical activity was no longer present. Transcranial doppler ultrasound performed simultaneously showed global hyperdynamic cerebral blood flow. Follow-up imaging revealed extensive hypodensities in the frontal lobes and thalami. Over the next 4 days, the patient's condition worsened and he progressed to clinical brain death. Conclusions We present this unique case of an isoelectric EEG in the absence of clinical signs of brain death. We believe the patient's bithalamic injury contributed to the lack of spontaneous electrical activity through the loss of thalamocortical inputs in the setting of severe bilateral hemispheric injury. We also present this case to highlight the limitations of EEG as a confirmatory test for brain death in the ICU.

---

237. Ambrosi, P. B., et al. (2012). "Prognostic factors in civilian gunshot wounds to the head: a series of 110 surgical patients and brief literature review." Neurosurgical review 35(3): 429-426.

This study was carried out to evaluate the early results and the prognostic factors affecting the outcome during the in-hospital stay of 110 patients with civilian gunshot wounds to the head admitted at the Hospital of Restauracao, Recife, Brazil. Penetrating injury (66%) was the most prevalent type of wound encountered in the present series. Twelve of the 110 (10.9%) patients presented a unilateral dilated pupil at the admission. Motor impairment was present in 24/110 (21.8%) patients. Intracerebral hematoma was present in 36/110 (32.7%) and there were 15/110 (13%) patients with cerebrospinal fluid fistula. Eleven of 110 patients developed meningitis and in 9/110 intracranial abscesses occurred. Nine of 110 patients developed deep venous thrombosis, 11/110 had urinary infection, and coagulopathy was detected in 8/110. Following the surgical procedure, 27/110 (24.5%) patients died during their hospital stay. When the two groups, survivors and non-survivors, were compared, there were significant statistical differences and the univariate analysis identified five preoperative predictors of a poor outcome following surgery: age over 40 years (odds ratios (OR) 5.4, 95% CI 1.73-16.82); presence of unilateral pupil dilatation (OR 5.5, 95% CI 1.641-18.13); low (<=8) Glasgow coma score on admission (OR 6.50, 95% CI 2.27-18.60), presence of intracranial hematoma (OR 3.0, 95% CI 1.21-7.34), and

respiratory infection (OR 4.8, 95% CI 1.75-13.47). Thus, (a) age of the patient (juvenile/young age), (b) high preoperative Glasgow coma score, (c) lack of pupil abnormalities, and (d) absence of intracerebral hematoma are predictors of a good prognosis.

238. Ameen, A. A. (1984). "The management of acute craniocerebral injuries caused by missiles: analysis of 110 consecutive penetrating wounds of the brain from Basrah." Injury 16(2): 88-90.

Penetrating missile injuries of the head comprised 3.4 per cent of the missile injuries admitted to our hospital directly or transferred from nearby hospitals. Those who died accounted for approximately 70 per cent of the total deaths in hospital from missiles. The immediate treatment is presented and the results are evaluated in 110 consecutive cases. The points emphasized are, first, that less than rapid evacuation selects those patients who are probably going to survive anyway; second, that bullet wounds of the head are nearly always fatal, especially if inflicted by high-velocity weapons; and, third, that the operation should include wide exposure of the injured site with thorough excision of the wound track and watertight closure of the dura.

243. Amene, C., et al. (2013). "Outcomes of middle fossa skull base defects repaired using a novel combination of materials." Journal of Neurological Surgery, Part B: Skull Base 74.

Introduction: Defects in the middle cranial fossa result in cerebrospinal fluid (CSF) leaks that can present a daunting challenge to skull base surgeons, both in diagnosis and treatment. Defects may arise spontaneously or may be acquired after trauma or surgical manipulations. Persistent leaks require surgical intervention to avoid possibly fatal complications including meningitis and brain herniation. Secondary to the variability in techniques and materials used for repair, outcome analysis has yielded mixed results in the literature. The objective of this study was to evaluate the safety and durability of the authors' repair technique using a combination of three synthetic materials. Methods: We performed a retrospective case review of patients treated for CSF leaks between January 2009 and September 2012. Inclusion criteria for the study were: neuroimaging-documented temporal bone defect, gross CSF otorrhea, and symptoms consistent with CSF leak. Ten patients were found to have been treated surgically for middle fossa CSF leaks. Hydroxyapatite cement, collagen-based dural substitute matrix, and polyethylene glycol hydrogel sealant were used in all patients for the repair. Results: Of the 10 cases that met the inclusion criteria, four were spontaneous defects and six were acquired (one penetrating traumatic brain injury, five with previous surgical procedures). CSF otorrhea was present in nine patients (90%), and hearing loss was present in five (50%). One patient presented with rhinorrhea. Nine cases were repaired via the middle fossa approach, and one case was repaired through a combined

middle fossa/transmastoid approach. In all patients, the CSF leaks were successfully repaired using all three synthetic agents with an inlay/onlay technique. The repair was supplemented by autologous graft (temporalis muscle, fascia, or pericranium) in seven cases. Mean follow-up duration was 59.1 weeks (range, 1-180 weeks). In one patient, an epidural hematoma developed at the operative site on postoperative day 7, and in another patient a superficial wound dehiscence occurred on postoperative day 48. There was no evidence of wound infections, neurovascular damage, or CSF leakage requiring reoperation during the follow-up period. Conclusions: The middle fossa approach using a combination of hydroxyapatite cement, collagen-based dural substitute matrix, and polyethylene glycol hydrogel sealant is a safe, effective method for repairing middle fossa CSF leaks. A multilayered closure remains an important aspect to these closures.

244. Amer, H., et al. (2018). "Mayo Clinic's first face transplant: 17 months on." American Journal of Transplantation 18: 761.

Mayo Clinic established a reconstructive transplant program as an extension of clinical practice in 2010. A 31-year-old Caucasian male had significant functional limitations and disfigurement despite multiple conventional reconstructive procedures following a self-infl icted gunshot to the face. These limited his social interactions and potential for career advancement due to inability to pass fitting of required safety equipment. He was referred for transplant 7 years after his injury and was listed for transplant after 2 1/2 years of evaluation, education, psychosocial assessment and follow-up. The surgical team rehearsed the planned surgery over 50 Saturdays in the anatomy lab. Guides developed by Medical Modeling using 3D CT reconstruction aided bone cuts. The patient received a blood group compatible, negative flow cross match, no DSA transplant. Donor and recipient were EBV negative but CMV mismatched (D+/R-). The graft consisted of all facial tissues from below the eyelids including maxilla, mandible and upper and lower teeth. Immunosuppression consisted of anti-thymocyte globulin (ATG) induction and a triple immunosuppressive regimen consisting of tacrolimus, mycophenolate mofetil, and corticosteroids. The patient recovered well from surgery. The aesthetic result was deemed good by the patient “better than I expected”. He regained his sense of smell, the ability to chew food (prior to the transplant he had only two molar teeth with significant microstomia). Gradually nerve regeneration progressed with the ability to smile and coapt his lips. Nasal breathing was also possible. One VCA Banff grade two rejection occurred on day 57-post transplant. This was successfully treated with a course of pulse corticosteroids. Seven months after transplant asymptomatic primary CMV infection was detected on surveillance. A short course of valganciclovir controlled the infection. One year after transplant two-point discrimination was 5 mm. Surveillance biopsy showed no inflammation and no donor specific antibodies were detected. Seventeen months from transplant renal function remains preserved and functional recovery continues with the patient progressing in his chosen career and social integration.

---

245. Amer, H., et al. (2018). "Mayo clinic's first face transplant: One year outcome." Transplantation 102(7): S433.

In June 2016, we performed the first face transplant at Mayo Clinic. Mayo Clinic established a reconstructive transplant program as an extension of clinical practice in 2010. A 31-year-old Caucasian male had significant functional limitations and disfigurement despite multiple conventional reconstructive procedures following a self-inflicted gunshot to the face. These limited his social interactions and potential for career advancement. He was referred for transplant 7 years after his injury. He was listed for transplant after 2 1/2 years of evaluation, education, psychosocial assessment and follow-up. The surgical team rehearsed the planned surgery over 50 Saturdays in the cadaver lab. Guides developed by Medical Modeling using 3D CT reconstruction aided bone cuts. He received a blood group compatible, negative flow crossmatch, no DSA transplant. Donor and recipient were EBV negative. Donor was CMV positive and the recipient negative. The graft consisted of all facial tissues from below the eyelids including maxilla, mandible and teeth. Immunosuppression consisted of anti-thymocyte

globulin (ATG) induction and a triple immunosuppressive regimen consisting of tacrolimus, mycophenolate mofetil, and corticosteroids. The patient recovered well from surgery. The aesthetic result was deemed excellent by the patient better than I expected. He regained his sense of smell, the ability to chew food (prior to the transplant he had only two molar teeth with significant microstomia. Gradually nerve regeneration progressed with the ability to smile and coapt his lips. Nasal breathing was also possible. One VCA Banff grade two rejection occurred on day 57-post transplant. This was successfully treated with a course of pulse corticosteroids. Seven months after transplant valganciclovir prophylaxis was discontinued due to leucopenia. Asymptomatic primary CMV infection was detected on surveillance. A combination of viral markers and virus specific immune monitoring was used to tailor therapy. A short course of valganciclovir controlled the infection and the patient developed humoral and cellular virus specific monitoring. One year after transplant two-point discrimination was 5 mm. Renal function was preserved and functional recovery continues.

---

246. Amin, D., et al. (2021). "Incidence of Gunshot Wounds to Head and Neck Increased during COVID-19 Pandemic." Journal of oral and maxillofacial surgery 79(10): e15.

Purpose: COVID-19 was declared a pandemic by the World Health Organization on March 2020. Since then, there was an increase in the number of firearm purchases. The purpose of this study was to investigate whether the incidence of gunshot wounds (GSWs) to the head and neck increased during the COVID-19 pandemic. Materials and methods: This cross-sectional study reviewed patients in the Trauma Registry at Grady Memorial Hospital (GMH) in Atlanta, GA. Patients were included if they: 1) sustained GSW to head and neck, 2) activated the Trauma Registry, and 3) were treated at GMH. Patients were stratified according to date of injury into 1 distinct time period: 1) March 13 to August 13, 2019 (i.e., before the COVID-19 pandemic, BC19) or 2) March 13 to August 13, 2020 (i.e., during initial 6 months of the COVID-19 pandemic, C19) (Figure 1). March 13 was chosen because COVID-19 was announced as a national emergency on that date. The research team collected patient demographics, distressed communities index (DCI), social history, and etiology of GSW. Details regarding extent of GSW injury (i.e., isolated soft tissue, bony, other locations of injuries) were recorded. Injury severity was described using the following variables: status of patient and Glasgow Coma scale (GCS) on arrival to GMH, cardiopulmonary resuscitation (CPR) in Emergency Department (ED), diagnosis of shock on admission, disposition from ED, ICU length of stay (LOS), total days on mechanical ventilator (MV), hospital LOS, and hospital discharge status. Descriptive statistics were performed. Univariate and bivariate analysis were performed. The Chi-squared test was used for categorical variables. Statistical significance was P <.05. Results: During the study period, 948 patients sustained GSW. Of them, 215 patients had GSWs to head and neck. The BC19 group had 96 patients (78 males) with a mean age of 31.5 years old (range 7-82). The C19 group had 119 patients (101 males) with an average age 32.7 years (range 14-82). Overall, there was a 10.4% increase in incidence of GSW to head and neck during C-19 (Figure 2). The data showed that alcohol abuse was associated with an increase in GSW to the head and neck (P <.0001). The mean DCI for C19 group was lower than BC19 by 8%, meaning that the distress to the population was decreased. GSW to base of skull occurred 34.5% more often during C19 (P =.002), and intracranial injuries occurred 26% more often during BC19 (P =.03). In the BC19 group, 85.4% of the patients arrived alive to GMH, compared to 16% in C19 group. Patients had shock on admission (BC-19; n = 22, 22.9 %, C-19; n = 24, 20.2%). Researchers found that the status on arrival to ED (i.e., alive) was statistically significant (P <.0001). Outcomes data: Researchers found a 10.4% increase in the incidence of GSWs to the head and neck during C-19. Specifically, the peak incidence occurred during May, June, and July, with 25 cases per month (Figure 2). The peak in incidence was parallel with the shelter-in-place order in the state of GA that was issued on April 3, 2020. The finding is consistent with previous studies that showed an increase in gun violence during the COVID-19 pandemic. Conclusion: In conclusion, understanding the underlying causes for the increase in GSW to the head and neck during the COVID-19 pandemic is imperative for implementing gun violence prevention programs. Health system leaders should develop partnerships that embrace medical professional organization support to proactively reduce firearm-related injury during periods of social isolation.

247. Amin, D., et al. (2021). "Frequency of Firearm Injuries to Head and Neck Increased During Covid-19 Pandemic." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons 79(11): 2299-2305.

PURPOSE: During coronavirus disease-19 (COVID-19) pandemic, hospitals faced challenges which were different than previous years. The purpose this study was to report frequency of firearm injuries (FI) to head and neck during the COVID-19 pandemic., MATERIALS AND METHODS: This cross-sectional study reviewed patients in the Trauma Registry at Grady Memorial Hospital (GMH) in Atlanta, GA. Patients were included if they sustained FI to head and neck, were listed in TR, and were treated at GMH. Patients were stratified according to date of injury into 1) before COVID-19 pandemic, (BC19) or 2) during initial 5 months of COVID-19 pandemic, (C19). Variables were patient demographics, illegal substance use, etiology, place of injury, distressed communities index, location of injury, Glasgow Coma scale on arrival, cardiopulmonary resuscitation in Emergency Department (ED), shock on admission, disposition from ED, length of stay, days on mechanical ventilation and discharge status. Descriptive, univariate, and bivariate analysis were completed. Chi square test was used for categorical variables. Statistical significance was $P < .05$., RESULTS: There were 215 patients who met inclusion criteria. There were 96 patients (78 males) with a mean age of 31.5 years old during BC19. There were 119 patients (101 males) with a mean age 32.7 years old during C19. There was a 10.4% increase in FI to head and neck during COVID-19. Our data showed that alcohol use was associated with FI during C19 ($P<= .0001$). FI to base of skull occurred 34.5% more often during C19 ($P = .002$). Cranial injuries occurred 26% more often during BC19 ($P = .03$). During BC19, 85.4% of the patients arrived alive to GMH, but only 16% arrived alive during C19 ($P <= .0001$)., CONCLUSIONS: There were more FI to head and neck during COVID-10 pandemic than during the previous time period.

248. Amini, A., et al. (2006). "Remote cerebellar hemorrhage." AJNR. American journal of neuroradiology 27(2): 387-390.

Remote cerebellar hemorrhage (RCH) is a rare but benign, self-limited complication of supratentorial craniotomies that, to the best of our knowledge, has not been described in the imaging literature. RCH can be an unexpected finding on routine postoperative imaging studies and should not be mistaken for more ominous causes of bleeding such as coagulopathy, hemorrhagic infarction, or cortical vein occlusion. Cerebellar hemorrhage in the typical setting can be identified as RCH and does not require more extensive or invasive evaluation.

249. Amirjamshidi, A., et al. (2000). "Traumatic aneurysms and arteriovenous fistulas of the extracranial vessels in war injuries." Surgical neurology 53(2): 136-145.

BACKGROUND: Extracranial vessel injuries are potentially devastating complications of penetrating head and neck wounds associated with war conflicts. These vasculopathies may be occlusive or they may lead to formation of traumatic aneurysms (TA) and arteriovenous fistulae (AVF). Even though these penetrating injuries are usually clinically silent and often appear only as small superficial wounds, they may lead to catastrophic hemorrhage or vascular insult. In this study, we attempted to elucidate signs, symptoms and circumstances present in these victims who are at risk of harboring an occult vasculopathy, excluding the occlusive ones and concentrating primarily on TAs and AVFs., MATERIALS AND METHODS: In a prospective study conducted during 8 years of war between Iran and Iraq, we encountered 13 cases of traumatic vasculopathies of the extracranial carotid and vertebral arteries. The type and number of injuries were: carotid-jugular fistula (CJF) 3, carotid trunk or branch aneurysm (CA) 2, superficial temporal artery aneurysm (STA) 3, vertebral artery aneurysm (VA) 2, vertebral arteriovenous fistula (VAVF) 1, ophthalmic artery aneurysm (Oph. An.) 1, and lingual artery

aneurysm (Lin. An.) 1. Angiography was performed between the 5th and 30th day after the injury and surgical intervention was performed in all cases., RESULTS: The Glasgow outcome scale (GOS) score was 13-15 in all victims at the time of discharge from the base hospital without any additional neurological deficit. The follow-up period varied from 5 to 8 years in all cases in whom no further morbidity or mortality occurred. Single photon emission computed tomography was the noninvasive tool used for measurement of cerebral blood flow in the cases in which a major vessel ligation was performed; no remarkable change in cerebral blood flow was noted., CONCLUSION: Early recognition of stigmas suggesting possible formation of extracranial traumatic vasculopathies such as TAs or AVFs in the difficult situation of war frontier hospitals should be highlighted for attending physicians or younger neurosurgeons. Performing angiography promptly in suspected cases can pick up such traumatic vascular lesions earlier. Using simpler surgical techniques in situations in which more sophisticated endovascular equipment is unavailable can be life-saving for these usually young victims.

---

250. Amirjamshidi, A., et al. (2003). "Minimal debridement or simple wound closure as the only surgical treatment in war victims with low-velocity penetrating head injuries. Indications and management protocol based upon more than 8 years follow-up of 99 cases from Iran-Iraq conflict." Surgical neurology 60(2): 105-101.

BACKGROUND: During military conflicts, surviving victims traditionally underwent large enough craniectomy or craniotomy to achieve extensive debridement of the in-driven bone, shell fragments, and debris. Meanwhile, the completely as well as the partially devitalized adjacent brain tissue would also be debrided. This might have led to additional neurologic deficit or lesser degree of recovery of functions., METHOD: We studied the efficacy and safety of much more limited or even absence of surgical intervention in a selected group of wartime head-wounded patients. Among 1,150 war victims with penetrating head wounds referred to two major centers affiliated with Tehran University of Medical Sciences during the 8-year period spanning the Iran-Iraq conflict, there were 191 head-wounded patients who underwent either no surgical intervention or a very limited debridement. We have attempted to follow up as closely as possible for more than 8 years. Ninety-nine of them fulfilled the criteria to be included in this series. Close follow-up for development of cerebral infections, functional recovery, or development of new neurologic deficits and epilepsy were performed. At least 3 contrast-enhanced CT scans were taken for each patient. All patients were victims of the battle-field areas with low- to moderate-velocity missile or shell fragment injury. The Glasgow Coma Scale (GCS) scores of the patients were between 8-14 when visited by the first attending neurosurgery staff. The factors considered to be effective in the outcome analysis were the entry point, the number of the in-driven bone fragments, the retained shell fragments, the brain compartments affected, and the paranasal sinus or skull base involvement with or without cerebrospinal fluid (CSF) fistula., RESULTS: There were 13 unilobar, 44 bilobar, 4 trilobar, 38 transventricular, and 3 skull base lesions. The number of retained metal fragments varied between 1 to 6. The number of retained bone fragments varied between 1 to 5 in 73 victims and more than five chips in other cases. The outcome was good (back to work) in 90 patients and poor (severely disabled) in 4. Five patients died because of severity of brain damage and meningitis. The effect of the different enumerated variables upon the outcome was measured using chi(2) and Fisher exact test, which was nonsignificant for all of the variables except for the orbitofacial entry point of injury ($p = 0.00006$)., CONCLUSION: This study seems to indicate that not only is reoperation for retained bone or shell fragments unnecessary, but surgeons having modern neuroradiological instruments available to detect the proper explanation for changes in GCS of the patients may decide not to proceed with any surgical intervention in a good number of patients. As a result of the "no surgical treatment protocol," one can preserve cerebral tissue without exposing the patient to undue risk of seizures, infection, or death by leaving behind some or all the in-driven bone and shell fragments.

---

251. Amirjamshidi, A., et al. (1997). "Air-gun pellet injuries to the head and neck." Surgical neurology 47(4): 331-338.

BACKGROUND: Air-gun pellet injuries (AgPI) of the central nervous system (CNS) are rare but catastrophic events. They occur mostly in children and young adults. The entrance is usually either through the orbit or through the neck and the entry wound is so small that it may be disregarded on physical examination in the emergency room. Early recognition and correct management of the possible complications of AgPIs is important and may prevent a poor outcome. METHODS We intend to present our experience with 16 cases of AgPIs of the head and neck referred to the department of neurosurgery during the last 15 years. The characteristic findings on physical examination of the cases and the imaging studies performed are described. Special management undertaken for the rare complications are mentioned and a short literature review is performed on each entity. RESULTS All our cases happened in the first and second decades of life and only in boys playing with toy guns. There were 12 head and face and four neck wounds. Damaged globe that had to be exenterated was the earliest complication, handled by ophthalmologists (four cases). Cerebrospinal fluid (CSF) leakage, meningitis, brain abscess formation, development of traumatic aneurysm (TA), carotid-cavernous sinus fistula (CCF), wandering intracerebral and intraventricular pellet, and splitting of the pellet after striking hard bone were the complications noted. In addition to plain X-ray films, computed tomography (CT) scanning and angiography were diagnostic procedures of choice. CONCLUSIONS The present series of patients is the largest collection of AgPIs to the head and neck reported in the literature in which nearly all the possible complications of such injuries have been reviewed. Early recognition and awareness of the possible cumbersome complications of such a minor penetrating wound can prevent major catastrophies in this young group of victims.

252. Amirjamshidi, A., et al. (2009). "Attempting homicide by inserting sewing needle into the brain Report of 6 cases and review of literature." Surgical neurology 72(6): 635-641.

BACKGROUND AND OBJECTIVES: Child abuse with sewing needle is a rare but well-known homicide attempt threatening the life of victims. Information about diagnosis and treatment of such cases either in the acute or chronic phases is lacking and ambiguous in the literature. This study intends to report the experience of 6 victims of homicide attempt who presented to the authors in different decades of life and were managed in different ways. This may deliver some evidences to the literature regarding management of further cases encountered by neurosurgeons., MATERIAL AND METHODS: The authors had the chance of managing 6 patients referred to their trauma center harboring one or more sewing needles within their cranium. There were 3 male and 3 female patients, with 2 patients in their first decade of life, and the others, each in either decade of life. The youngest was 6, and the eldest 51 year old. The elder patients were having vague headaches, for which a plain skull x-ray or CT of the brain lead to the diagnosis of persisting intracranial foreign bodies. Chronic headache was the main complaint of the patients. Four patients underwent surgical removal of the sewing needle, and 2 are being followed., RESULTS: Among the 4 patients who underwent surgery, 1 died after a short period of 'akinetic mutism.' Headache and limb paresthesia improved 6 months after the operation in 2 cases, and the other 1 remained unchanged. The cases under observation have been doing well. Biochemical analysis of the rusted needle showed a composite of oxidant form of some of the elements of needle such as Fe, Mn, and Cr., CONCLUSION: In spite of standard algorithms proposed for management of penetrating head wounds, selection of the best treatment in the victims harboring sewing needles in their brain needs close cooperation between neurosurgeons, pediatricians, psychiatrists, and social workers. Furthermore, there is no absolute indication for removing sewing intracranial needles detected in the later decades of life.

253. Amirjamshidi, A., et al. (1996). "Traumatic aneurysms and arteriovenous fistulas of intracranial vessels associated with penetrating head injuries occurring during war: principles and pitfalls in

diagnosis and management. A survey of 31 cases and review of the literature." Journal of neurosurgery 84(5): 769-780.

In the early days of the war between Iran and Iraq, reports of the sudden deaths of soldiers who previously had survived a penetrating head injury suggested the possibility that a late complication, traumatic aneurysm (TA), could be the cause of this catastrophe. In response, the authors planned a prospective study to perform cerebral angiography in victims with penetrating head traumas, especially in those who had artillery shells or bone fragments passing through areas of dense vasculature. Thirty-one TAs and arteriovenous fistulas were documented. Not all of the lesions, however, were deemed appropriate for surgical intervention. Six aneurysms (19.4%) healed spontaneously and shrank or disappeared on repeated serial angiograms. The authors present their cases and discuss the incidence of TAs, their natural course and behavior, and the special problems encountered in managing these interesting and potentially fatal complications of penetrating head injuries.

254. Ammar, M. A. and N. S. Hussein (2018). "Using propranolol in traumatic brain injury to reduce sympathetic storm phenomenon: A prospective randomized clinical trial." Saudi Journal of Anaesthesia 12(4): 521-528.

Background: Traumatic brain injury (TBI) correlated with increased sympathetic activity on the expense of parasympathetic system due to loss of cortical control after brain injury. Manifestations of sympathetic storm include tachycardia, hypertension, tachypnea, and hyperthermia. The neuroprotective effects via reducing cerebral metabolism and lowering O2 and glucose consumption are the targets early after trauma. Beta-blockers reduce sympathetic activity. Objectives: We suppose that using propranolol blunts the sympathetic storming phenomenon as it is a nonselective β inhibitor and has a lipophilic property to steadily penetrate blood-brain barrier. Patients and Methods: Sixty patients allocated randomly into two groups, each consisting of 30 patients. Group A started propranolol and Group B received placebo within first 24 h. Primary outcome was catecholamine levels on day 7, and the secondary outcomes were physiological measures (heart rate [HR], respiratory rate [RR], mean arterial blood pressure [MABP], temperature, random blood sugar, and follow-up Glasgow coma score [GCS] and sedation score). Results: Analysis of outcomes demonstrated that Group A tended to have lower catecholamine levels in comparison to Group B in day 7 (norepinephrine 206.87 ± 44.44 vs. 529.33 ± 42.99 pg/ml, P = <0.001), epinephrine level (69.00 ± 8.66 vs. 190.73 ± 16.48 pg/ml, P < 0.001), and dopamine level (32.90 ± 4.57 vs. 78.00 ± 3.48 pg/ml P < 0.001). GCS of the patients in Group A improved and was statistically significant compared to Group B in day 7 (13 vs. 10, P = 0.006), with percent change interquartile range (20.0 vs. 8.33, P = 0.006). Regarding hemodynamic parameters between the two groups MABP, HR, RR, and temperature, there was no statistically significant difference on day 1, while on day 7, there is high statistical significance and significant percent change (P < 0.001). Conclusion: Early usage of propranolol after TBI controls hemodynamics and blood sugar with decreased catecholamine levels correlated with the improvement of GCS.

---

255. Ammaturo, C., et al. (2001). "[Non-surgical treatment of liver trauma]." Il trattamento non operatorio dei traumi epatici. 53(2): 181-187.

The aim of the study was to assess the role of non-operative treatment in haemodynamically stable patients with liver trauma. Over the period from 1996 to July 2000, out of a total of 2,048 patients with abdominal trauma, 124 open and 1,924 closed, we observed 77 hepatic lesions, consisting of 55 closed traumas and 22 penetrating traumas. Non-operative treatment was implemented in 18 patients (32.7%) with closed liver traumas. In addition to serial clinical examinations of the abdomen, the patients receiving non-operative treatment were submitted to thorough haemodynamic monitoring and complete blood counts in the intensive care unit. After an abdominal CT scan at entry, patients were submitted to abdominal ultrasonography 6, 12 and 24 hours after admission. Only two patients required transfusions, one presenting a pelvic fracture and the other a triple fracture of the femur, tibia and fibula. There was no mortality. A biloma was present in one case, successfully treated by means of a US-guided

drainage puncture. It is patients with major cranial traumas that pose most problems for conservative treatment. Fifty percent of non-therapeutic laparotomies in our series were performed in patients with severe cranial traumas. It is precisely in these patients that an improvement in diagnostic capability is most desirable.

256. Amole, O., et al. (2017). "A 14-Year Review of Craniomaxillofacial Gunshot Wounds in a Resource-Limited Setting." Craniomaxillofacial Trauma and Reconstruction 10(2): 130-137.

This study analyzed the prevalence, clinical characteristics, and management of civilian-type craniomaxillofacial gunshot wounds (CGSWs) seen over a 14-year period in a Northern Nigerian teaching hospital. A retrospective study of all hospital records relating to CGSWs from January 2000 to December 2013 was conducted to determine the prevalence of CGSWs. Information retrieved included site of injury, type of projectile, management protocol, as well as duration of hospitalization. A total of 46 admissions for CGSWs were recorded during the period under review from a total of 2,228 maxillofacial admissions. This gave a prevalence of 2.1% for CGSWs (95% confidence interval = 1.56-2.81). Sex distribution was 14.3:1 (M:F) with overall mean age of 32.9 ± 8.4 years. Average length of hospitalization was 17.7 (±15.56) days. Management of CGSWs consisted of emergency care, preliminary intervention, definitive reconstruction, revisions, and rehabilitation. Conclusively, analysis of the yearly incidence of CGSWs showed that the incidence and severity increased within the past 2 years under review (18 cases, 39.13%; χ 2 trend = 7.7, p = 0.006). This period was noted to correspond with heightened violence within the region mostly due to the acts of unknown gunmen and insurgents.

257. Ampanozi, G., et al. (2010). "Virtopsy: CT and MR imaging of a fatal head injury caused by a hatchet: A case report." Legal medicine (Tokyo, Japan) 12(5): 238-241.

Hatchet blows to the human skull often cause fatal injuries. We present a case of homicide by hatchet blow that underwent CT, MRI, and autopsy examination. Skull fragmentation, fracture lines, and brain injuries were demonstrated prior to autopsy. Many of the hatchet-specific characteristics (flaking, crushing, shattering, and fracture lines) described in literature were observed in the post-mortem imaging of this case.

258. Anderova, M., et al. (2004). "Voltage-dependent potassium currents in hypertrophied rat astrocytes after a cortical stab wound." Glia 48(4): 311-326.

Changes in the membrane properties of reactive astrocytes in gliotic cortex induced by a stab wound were studied in brain slices of 21-28-day-old rats, using the patch-clamp technique and were correlated with changes in resting extracellular K+ concentration ([K+]e) measured in vivo using K+-selective microelectrodes. Based on K+ current expression, three types of astrocytes were identified in gliotic cortex: A1 astrocytes expressing a time- and voltage-independent K+ current component and additional inwardly rectifying K+ currents (K(IR)); A2 astrocytes expressing a time- and voltage-independent K+ current component and additional delayed outwardly rectifying K+ currents (K(DR)); and complex astrocytes expressing K(DR), K(IR), and A-type K+ (K(A)) currents and Na+ currents (I(Na)). Nestin/bromodeoxyuridine (BrdU)-negative A1 astrocytes were found further than approximately 100 microm from the stab wound and showed an upregulation of K(IR) currents within the first day post-injury (PI), correlating with an increased resting [K+]e. Their number declined from 62% of total astrocytes in control rats to 41% in rats at 7 days PI. Nestin/BrdU-positive A2 astrocytes were found only within a distance of approximately 100 microm from the stab wound and, in comparison to those in control rats, showed an upregulation of K(DR) currents. Their number increased from 8% of the total number of astrocytes in control rats to 39% 7 days PI. Both A1 and A2 astrocytes showed hypertrophied processes and increased GFAP staining, but an examination of cell morphology revealed greater changes in the surface/volume ratio in A2 astrocytes than in A1 astrocytes. Complex astrocytes did not display a hypertophied morphology; K(IR) currents in these cells were upregulated

within 1 day PI, while the K(DR), K(A), and I(Na) currents were increased only 6 h PI. We conclude that two electrophysiologically, immunohistochemically, and morphologically distinct types of hypertrophied astrocytes are present at the site of a stab wound, depending on the distance from the lesion, and may have different functions in ionic homeostasis and/or regeneration. 260. Anderson, R. and J. Montero (2014). "Utilization of seizure prophylaxis in traumatic brain injury (TBI) patients." Critical care medicine 42(12): A1626.

Learning Objectives: There is a high risk in development of seizures after a traumatic brain injury (TBI). Seizures are classified as early, within seven days of injury, or late, more than seven days. Incidence of early and late seizures ranges from 4-25% and 9-42%, respectively. Risk factors for seizures include subdural, epidural or intracerebral hematoma, depressed skull fracture, cortical contusion, penetrating head wound, initial Glasgow Coma Score <10, or occurrence of seizure within 24h. Seizures in acute period can be detrimental due to elevations in intracranial pressure, blood pressure changes, alterations in oxygen delivery, and excessive neurotransmitter release. Prophylaxis is recommended seven days post injury to decrease early seizures and is not recommended for preventing late seizures. This evaluation assesses the utilization of seizure prophylaxis after a TBI at a Level II Trauma Center. Methods: Patients admitted to the trauma service with an acute TBI between January 2012 and June 2014 and started on an anticonvulsant for seizure prophylaxis within 24 hours of admission were identified. Demographic data, including type of TBI, hospital length of stay, and disposition were evaluated. Descriptive data was used to evaluate the anticonvulsant agent utilized, the duration of therapy, and if therapy was continued upon discharge. Results: Preliminary results include 28 patients receiving seizure prophylaxis after TBI. Majority were male (89%) with median age of 45 (18-84). Levetiracetam was most commonly used (79%), with the remaining receiving phenytoin. Levetiracetam was frequently dosed 500mg q12h with no loading dose. Median duration of prophylaxis was 7 (3-30) days. Five patients were discharged home on prophylaxis; two were appropriate to complete a total of 7 days. One person on levetiracetam developed seizures and switched to phenytoin. Conclusions: Preliminary results suggest that levetiracetam is commonly utilized for seizure prophylaxis in TBI patients. Duration of prophylaxis appears to be appropriate at our institution. Further evaluation into appropriate initiation is needed.

---

261. Anderson, S. A. and P. G. Story (1996). "Case study of an orbital screwdriver injury." Journal of ophthalmic nursing & technology 15(3): 103-104.

1. A man struck himself in the right eye with a screwdriver. The initial diagnosis was probable medial wall fracture with medial rectus entrapment, but a forced auction test result was negative and the initial x-ray study of the orbit and sinuses was within normal limits. The patient was treated with topical antibiotics and observed closely. Subsequent exams revealed a complete, isolated right gaze palsy. 2. An axial computed tomography scan of the orbit revealed an area of a probable hematoma overlying the lateral rectus muscle. There was also a fracture of the greater wing of the spheroid. 3. One month after the injury, the patient had complete, spontaneous clearing of the diplopia and lateral gaze palsy. The patient has had no residual effects 3 years later. This care reinforces the idea that injuries such as this should be treated symptomatically and observed.

262. Ando, T., et al. (2011). "Comparison of therapeutic effects between pulsed and continuous wave 810-nm wavelength laser irradiation for traumatic brain injury in mice." PloS one 6(10): e26212.

BACKGROUND AND OBJECTIVE: Transcranial low-level laser therapy (LLLT) using near-infrared light can efficiently penetrate through the scalp and skull and could allow non-invasive treatment for traumatic brain injury (TBI). In the present study, we compared the therapeutic effect using 810-nm wavelength laser light in continuous and pulsed wave modes in a mouse model of TBI., STUDY DESIGN/MATERIALS AND METHODS: TBI was induced by a controlled cortical-impact device and 4-hours post-TBI 1-group received a sham treatment and 3-groups received a single exposure to transcranial LLLT, either continuous wave or pulsed at 10-Hz or 100-Hz with a 50% duty cycle. An 810-nm Ga-Al-As diode laser delivered a spot with diameter of 1-cm onto the injured head with a power density of 50-mW/cm(2) for 12-minutes giving a fluence of 36-J/cm(2). Neurological severity score (NSS) and body weight were measured up to 4 weeks. Mice were sacrificed at 2, 15 and 28 days post-TBI and the lesion size was histologically analyzed. The quantity of ATP production in the brain tissue was determined immediately after laser irradiation. We examined the role of LLLT on the psychological state of the mice at 1 day and 4 weeks after TBI using tail suspension test and forced swim test., RESULTS: The 810-nm laser pulsed at 10-Hz was the most effective judged by improvement in NSS and body weight although the other laser regimens were also effective. The brain lesion volume of mice treated with 10-Hz pulsed-laser irradiation was significantly lower than control group at 15-days and 4-weeks post-TBI. Moreover, we found an antidepressant effect of LLLT at 4-weeks as shown by forced swim and tail suspension tests., CONCLUSION: The therapeutic effect of LLLT for TBI with an 810-nm laser was more effective at 10-Hz pulse frequency than at CW and 100-Hz. This finding may provide a new insight into biological mechanisms of LLLT.

263. Andrade, G. C. d., et al. (2004). "[Penetrating brain injury due to a large asbestos fragment treated by decompressive craniectomy: case report]." Lesao cerebral penetrante por grande fragmento de fibra de amianto tratada por craniectomia descompressiva: relato de caso. 62(4): 1104-1107.

We report the case of a 22-year-old man victim of penetrating brain injury due to a 15 x 12 asbestos fragment and a successfully treatment via decompressive craniectomy. Unlike gunshot wounds to the head, penetrating brain injury from low energy objects are unusual. Most cases reported involve cranio-orbitary injuries as well as self inflicted lesions in mentally ill patients. The reported case is noteworthy due to the large dimensions of the foreign body, the treatment via decompressive craniectomy and the good patient functional outcome.

265. Andreu, M., et al. (2022). "Assessing fetal human neural stem cells tumorigenicity potential in athymic rats with penetrating traumatic brain injury (pTBI)." Brain research 1791: 148002.

Traumatic brain injuries (TBI) often produce disability in survivors due to unresolved inflammation and progressive neurodegeneration. The central nervous system in mammals is incapable of self-repair. Two decades of preclinical studies and clinical trials have provided insights into TBI pathophysiology that could be utilized to develop clinically relevant therapy. Our laboratory recently reported efficacy of clinical trial grade fetal human neural stem cells (hNSCs) in immunosuppressed rats with penetrating traumatic brain injury (pTBI). Next, in compliance with the United States Food and Drug Administration (USFDA) guidance, this study explores safety by assessing the tumorigenicity potential of intracranial hNSC transplants in athymic rats with pTBI. First, the maximum tolerated dose (MTD) was determined. Then, forty athymic pTBI rats were randomized to either: Group A. pTBI + vehicle or Group B. pTBI + hNSCs at MTD one week after injury with 6-months survival, sufficient time to uncover transplant associated tumorigenicity. A board-certified Pathologist examined hematoxylin-eosin (H&E), Ki67 immunostained brain and spinal cord, serial sections along with several abnormal peripheral masses for evidence of lesion, transplant, and oncogenesis. There was no evidence

of transplant derived tumors or oncogenic tissue necrosis. Consistent with athymic literature, the lesion remained unchanged even after robust hNSC engraftment. This safety study supports the conclusion that hNSCs are safe for transplantation in pTBI. The differences in lesion expansion between immunosuppressed and athymic rats in the presence of hNSCs suggests an unexpected role for thymus derived cells in resolution of trauma induced inflammation.

---

266. Andrews, B. T. (1989). "Treatment of acute traumatic internal carotid artery occlusion with extracranial-to-intracranial arterial bypass: case report." Neurosurgery 25(1): 90-92.

Ligation of the cervical internal carotid artery resulted in an acute neurological deficit in the dominant hemisphere of a 35-year-old man who suffered a penetrating injury to the neck. Regional cerebral hypoperfusion was suspected because the ischemic symptoms occurred while the patient was fully heparinized. Immediate institution of a barbiturate coma, volume expansion, and placement of a high-flow extracranial-intracranial arterial bypass graft led to rapid recovery of hemispheric function. High-flow extracranial-intracranial bypass grafts appear to be indicated for the treatment of symptomatic cerebral ischemia in selected cases of acute ligation or occlusion of the extracranial carotid artery.

---

267. Andrews, B. T., et al. (2016). "Orbit fractures: Identifying patient factors indicating high risk for ocular and periocular injury." The Laryngoscope 126 Suppl 4: S5-11.

OBJECTIVES/HYPOTHESIS: Maxillofacial trauma frequently involves the bony orbit that surrounds the ocular globe. Concomitant globe injury is a concern whenever orbit trauma occurs and in severe cases can occasionally result in vision loss. The mechanism of injury, physical exam findings, and radiographic imaging can provide useful information concerning the severity of the injury and concerns for vision loss. Using these three tools, it is hypothesized that the patient's history, physical exam, and radiographic findings can identify high-risk maxillofacial trauma patients with concomitant ocular injury. Identification of high risk patients who require comprehensive ophthalmologic evaluation may alter management and possibly preserve or restore vision., STUDY DESIGN: A retrospective clinical chart review was performed at a tertiary academic medical center., METHODS: Subjects were identified using the institutional trauma registry. Data collected included subject demographics, patient medical records and notes, ophthalmologic testing, and radiographic imaging. The incidence of orbit fracture and concomitant ocular injury associated with the mechanism of injury, physical exam findings, and radiographic imaging was determined. Statistical analysis was performed using a chi-square and Fisher exact test., RESULTS: In this study, 279 subjects with orbit fractures were identified and the incidence of concomitant ocular injury was 27.6% (77 of 279). Mechanism of injury was statistically associated with an increased risk of ocular injury (P = 0.0340), with penetrating trauma being the most likely etiology. The physical exam findings of visual acuity and an afferent pupillary defect were statistically associated with ocular injury (P = 0.0029 and 0.0001, respectively). Depth of orbit fracture on radiographic imaging was statistically associated with ocular injury (P = 0.0024), with fractures extending to the posterior third of the orbit being most likely to have associated ocular injury., CONCLUSION: Maxillofacial trauma patients with orbit fractures and concomitant ocular injury occur in more than one in four patients. Comprehensive ophthalmologic evaluation is recommended for all patients who sustain an orbit fracture. Subjects with a penetrating trauma mechanism of injury, physical exam findings of visual acuity deficits and an afferent pupillary defect, and radiographic imaging demonstrating fracture depth involvement of the posterior orbit are at highest risk for vision loss and warrant specific concern for ocular injury assessment., LEVEL OF EVIDENCE: IV.

268. Andrews, M., et al. (2021). "Sleep and Tau Pathology in Vietnam War Veterans with Preclinical and Prodromal Alzheimer's Disease." Journal of Alzheimer's Disease Reports 5(1): 41-48.

Background: The increasing prevalence of Alzheimer's disease (AD) and lack of effective medications has led to a need to identify modifiable risk factors as targets for interventions. Objective: In this cross-sectional study, we sought to determine whether worse sleep quality is associated with increased pathological tau, and whether this relationship is affected by amyloid pathology. Methods: 66 male participants underwent Florbetapir (AV45) positron emission tomography (PET) and Flortaucipir (FTP) PET and completed the Pittsburgh Sleep Quality Index questionnaire (PSQI) as part of the Department of Defense Alzheimer's Disease Neuroimaging Initiative, a multicenter study collecting data from Vietnam War veterans, some of whom have a history of post-traumatic stress disorder, or non-penetrating traumatic brain injury. AV45 PET was used to determine the presence of significant amyloid pathology. We used regression models to determine the effects of amyloid pathology and PSQI on tau deposition in brain regions associated with Braak stages. Results: Among the 66 participants, 14 individuals were amyloid positive (21%) and 52 were amyloid negative (79%). In regions associated with Braak stages III-IV, there was a significant interaction of amyloid status on PSQI (β=0.04, p=0.003) with higher PSQI correlating with higher FTP SUVr in amyloid-positive individuals only (β=0.031, p=0.005). Conclusion: Our study found that an AD profile of tau deposition was associated with an interaction between self-reported sleep quality and amyloid pathology such that worse self-reported sleep was related to higher tau in regions usually associated with AD progression, but only in individuals with high cerebral amyloid deposition.

269. Ang, B. T., et al. (2009). "Drosophila parkin mutants exhibit increased neuronal cell death following traumatic brain injury." Journal of neurotrauma 26(8): A8.

Parkin, a Parkinson's disease (PD)-linked gene product, is widely expressed throughout the brain and is commonly regarded to be a broad-spectrum neuro-protectant. De-regulation of parkin expression has thus also been implicated in stroke-induced neuronal death. Parkin apparently protects neurons against oxidative stress-mediated death by preserving proteasome and mitochondrial functions. Given this, it is tempting to propose that parkin may have a role in trauma-induced central nervous system injury. To address this, we utilized a model of penetrating traumatic brain injury (TBI) in Drosophila where age-matched control flies or flies either over-expressing parkin or ablated of endogenous parkin expression were subjected to a cranial puncture wound. Whilst Parkin-overexpressing flies did not show increased survival over control flies, parkin null flies exhibited significantly increased mortality, especially during the first two hours following the injury. Immunohistochemistry analysis upon injured wild-type flies and flies specifically designed to eludcidate regions of neuronal apoptosis, revealed marked neuronal death in the injured fly brains, which takes place at the injury site and also at distant locations. Our preliminary results therefore suggest a role for parkin in TBI and also outline the utility of drosophila for TBI studies. Experiments are currently underway to determine if heightened oxidative stress contributed by the loss of parkin function underlies the enhanced sensitivity of parkin null flies towards TBI-induced death.

270. Angel, M. F., et al. (1992). "The serratus anterior free tissue transfer for craniofacial reconstruction." The Journal of craniofacial surgery 3(4): 207-212.

The serratus anterior muscle was used as a free tissue transfer to reconstruct complex craniofacial defects in 5 patients. Serratus anterior muscle alone and serratus anterior muscle with rib were the transfers made. All flaps survived and scapular winging did not occur. The serratus anterior muscle has several advantages for the reconstruction of medium-sized craniofacial defects. Because of its position, a two-team approach is possible. It has a consistent pedicle anatomy and low donor site morbidity. It has a large caliber vessel and a long pedicle. When compared with the commonly employed rectus abdominis flap for moderate-sized defects, the serratus muscle offers greater versatility in design and has the option of incorporating bone and innervated muscle without increasing significant donor site morbidity.

271. Anglin, D., et al. (1998). "Intracranial hemorrhage associated with tangential gunshot wounds to the head." Academic emergency medicine : official journal of the Society for Academic Emergency Medicine 5(7): 672-678.

UNLABELLED: Tangential gunshot wounds (TGSWs) to the head are gunshot wounds in which the bullet or bullet fragments do not penetrate the inner table of the skull., OBJECTIVES: To determine the occurrence of intracranial hemorrhage (ICH) associated with TGSW to the head and to assess the ability of selected clinical criteria to predict ICH in this patient population., METHODS: A retrospective chart review of patients diagnosed as having TGSWs to the head presenting to the ED of Los Angeles County + University of Southern California Medical Center from October 1, 1993, to May 31, 1996., RESULTS: Four hundred twenty patients with gunshot wounds to the head presented to the ED. CT confirmed the diagnosis of TGSWs in 154 patients (36.7%). Head CT of patients with TGSWs revealed 25 (16.2%) skull fractures and 37 (24.0%) ICHs. Fourteen (56.0%) skull fractures were depressed. Of patients with a CT-documented TGSW to the head, 23 (16.1%) had a history of a loss of consciousness (LOC), 129 (84.3%) had a normal neurologic examination in the ED, 17 (11.1%) had a Glasgow Coma Scale score (GCS) < 15, and 75 (48.7%) had retained extracranial bullets or bullet fragments. Of all patients with TGSWs to the head, 113 had a GCS of 15 with no LOC and a normal neurologic examination, with 17 of these 113 patients (15.0%) having ICH. One patient died while hospitalized. Fifty-six (36.6%) patients were released home directly from the ED. Five clinical criteria (history of LOC, GCS < 15 on ED presentation, skull fracture, location of TGSW on the skull, and presence of extracranial bullet fragments) were examined to determine their ability to predict ICH. None of these criteria either alone or in combination were adequately predictive of ICH., CONCLUSION: In this series, 1 in 4 patients with a TGSW to the head had an ICH. All patients with TGSWs to the head should undergo head CT to rule out depressed skull fractures and ICH.

272. Ankichetty, S. P., et al. (2011). "Occult chiari malformation: A rare presentation." Canadian Journal of Anesthesia 58: S80.

Purpose: To present a case of occult Chiari type I malformation after subarachnoid block in a patient who underwent total knee replacement. Clinical Features: Patient was consented. A 60 year old ASA III female was scheduled for left total knee replacement. Her past history was significant for morbid obesity, asthma and hypertension. Subarachnoid block using 27G Whitacre spinal needle was performed. She had an uneventful surgery. In the PACU, she was drowsy but arousable with stable hemodynamics. However, two hours later, she had intermittent apnoeic episodes and desaturation to 90% with 60% oxygen. Blood gas analysis showed respiratory acidosis. She was intubated and lungs were ventilated and transferred to ICU and weaned in ICU over next 36 hours. Post extubation , she had difficulty of swallowing, visual disturbance of left eye and syncope while coughing. Ophthalmologist, neurologist and otolaryngologist opinion was seaked and could not find the exact cause. MRI showed Chiari I malformation with 17mm cerebellar tonsillar herniation below the foramen magnum and compression of medulla without hydrocephalus. Her symptoms resolved over a week by conservative management and advised surgery. She had an uneventful posterior fossa decompression for Chiari I malformation after 6 months subsequently. Chiari I malformation is a maldevelopment of the hindbrain characterised by cerebellar tonsillar herniation of atleast 3 to 5 mm below foramen magnum. These patients are usually symptomatic when herniation > 5mm and definitely >12 mm. There are case reports of successful epidural labour analgesia in patients with chiari malformation. There is also a report of occult chiari malformation presented as quadriplegia in a patient who had dural tear secondary to gun shot wound. Lumbar puncture and external lumbar drainage, lumbo-peritoneal shunts have precipitated tonsillar herniation and death in patients with known chiari malformation. Our patient presented late with symptoms of difficulty of swallowing despite herniation of 17mm probably due to slow leak of CSF through puncture site and subsequent changes in cranio-caudal CSF flow dynamics. Conclusion: This is the only report of occult chiari malformation with dysphagia, visual disturbance and syncope in the post operative period after spinal anesthesia. (Figure Presented).

273. Ankrah, N.-K., et al. (2020). "Effect of Chronic Alcoholism on Traumatic Intracranial Hemorrhage." World neurosurgery 144: e421-e427.

BACKGROUND: Traumatic intracranial hemorrhage (TICH) is one of the commonest indications for neurosurgical consultation after trauma. Worsening neurologic examination results, size of initial TICH, presence of displaced skull fracture, and concomitant anticoagulant use at the time of injury drive the recommendations for repeat computed tomography of head (RCTH), to assess for stability of intracranial hemorrhage. Chronic alcohol use is not generally considered an indication for repeat head computed tomography (CT)., METHODS: A retrospective study of 423 patients with TICH with normal admission platelet (PLT) counts was reviewed for this study, taken as a subset of 1330 patients with TICH admitted to Lahey Hospital and Medical Center over a 3-year period. Of these 423 patients, 330 were classified as nonalcoholics and 93 were classified as alcoholics, based on whether alcohol use disorder was documented in the patient's medical record, present before injury. The normal PLT level was defined as >=100,000 mu/L. Patients were excluded from review if they had comorbid conditions that could cause PLT dysfunction or coagulopathy. Continuous and categorical variables were compared using independent t test and chi2, respectively. Binary logistic regression was used to predict outcome: stable versus worsening of TICH on RCTH. Statistical analysis was conducted using SPSS version 25., RESULTS: The mean age of the nonalcoholic and alcoholic cohorts were 71.9 years and 54.8 years, respectively. A significantly higher percentage of alcoholics were male. There was a statistically significant difference (chi2 = 8.14; P < 0.004) in radiologic progression of TICH between the 2 groups, with the alcoholics having a worsening RCTH 16.1% of the time compared with only 6.7% in nonalcoholics. Chronic alcohol use was an independent predictor of radiologic progression in patients with normal PLT level (odds ratio, 2.69; confidence interval, 1.34-5.43; P < 0.006)., CONCLUSIONS: Chronic alcohol use was an independent predictor of radiologic progression of TICH in the setting of normal PLT level. Modification of this risk of progression with transfusion of fresh PLTs in chronic alcoholic patients with TICH needs to be investigated in a prospective trial.

Head injury causes more deaths and disabilities than any other neurologic cause in individuals under age 50. Skull fractures can tear the arteries and veins that supply the meninges (the protective membrane covering the brain), causing hemorrhage or intracranial pressure from the rapidly expanding mass of clotted blood. Meningitis-causing bacteria can be introduced via the small openings caused by

skull fracture. Even closed head injuries (head injuries that do not result in displaced skull fractures) can cause bruising and tearing of brain tissue. In the medical management of patients with head injuries, family and friends can play a key role in post-treatment observation.

279. Anonymous (1998). "Practice parameter: antiepileptic drug treatment of posttraumatic seizures. Brain Injury Special Interest Group of the American Academy of Physical Medicine and Rehabilitation." Archives of physical medicine and rehabilitation 79(5): 594-597.

The practice of antiepileptic drug (AED) prophylaxis for posttraumatic seizures (PTS) is common, although results of clinical trials raise questions regarding the benefits of such treatment. A subcommittee of the Brain Injury Special Interest Group of the American Academy of Physical Medicine and Rehabilitation was impaneled to review published literature regarding AED prophylaxis of PTS and formulate recommendations in the form of a practice parameter. The subcommittee presents the following recommendations: (1) Treatment standard: Prophylactic use of phenytoin (PHT), carbamazepine (CBZ), sodium valproate (VPA), or phenobarbital (PB) is not recommended for preventing late PTS, defined as seizures that occur after 1 week of injury, in the patient in whom there has been no history of seizures following a nonpenetrating traumatic brain injury (TBI). (2) It is recommended as a treatment option that PHT, PB, and CBZ may be used to prevent early PTS in patients at high risk for seizures following TBI. (3) Prophylactic use of PHT, CBZ, VPA, or PB is not recommended for preventing late PTS following penetrating TBI.

281. Anonymous (2001). "Fluid Resuscitation in Pre-Hospital Trauma Care: a consensus view." Journal of the Royal Army Medical Corps 147(2): 147-152.

Fluid administration for trauma in the pre-hospital environment is a challenging and controversial area. There is not yet any equivocal answer which can be supported by clear unanswerable evidence. Nevertheless, a careful reading of what evidence is available does allow some provisional conclusions to be drawn. We believe that the following represent the best possible current expert consensus on pre-hospital fluids in trauma. As future evidence brings clarity to this area, these guidelines can be modified, and further consensus statements will be issued taking into account such information. When treating trauma victims in the pre-hospital arena: Cannulation should take place en route where possible Only two attempts at cannulation should be made Transfer should not be delayed by attempts to obtain intravenous access Entrapped patients require cannulation at the scene Normal saline is recommended as a suitable fluid for administration to trauma patients Boluses of 250 ml fluid may be titrated against the presence or absence of a radial pulse (caveats; penetrating torso injury, head injury, infants).

287. Anonymous (2011). "[Forensic medical assessment of injuries to the human body and clothes caused by a crossbow arrow]." Sudebno-meditsinskaia ekspertiza 54(3): 32-35.

Analysis of the data published in the special literature revealed the lack of information for the objective comprehensive forensic medical evaluation of injuries to the human body and clothes caused by the arrows from different models of crossbows. Morphological characteristics of injuries were shown to strongly depend on the design features of the arrows. This fact can be used to differentiate between injuries inflicted by crossbow arrows and other types of missile weapons.

290. Ansari, S. A. and A. M. Panezai (1998). "Penetrating craniocerebral injuries: an escalating problem in Pakistan." British journal of neurosurgery 12(4): 340-343.

We carried out a prospective study on patients admitted to busy neurosurgical units in Karachi and Quetta with penetrating craniocerebral injuries. Of the 100 patients, 52 died and 48 survived in spite of aggressive surgical management. Maximum mortality was in patients with Glasgow Coma Score (GCS) below 5. A delay of 6 h, delay in interhospital transfers, and limited post operative aggressive management led to further secondary insults to the brain contributing to a poorer outcome. A review of current literature on pathophysiology and management is included and the importance of prehospital optimum care, and early transfer to the neurosurgical centre are emphasized. Since only two of the 35 patients with a GCS of less than five survived, with severe disabilities, utilizing resources in third world countries on the management of craniocerebral penetrating injuries in patients with a GCS less than 5 is questioned especially when organ donation is not possible.

291. Anthony, J. P., et al. (1997). "The free fibula bone graft for salvaging failed mandibular reconstructions." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons 55(12): 1417-1412.

PURPOSE: The purpose of this study was to determine the efficacy of vascularized free fibula bone grafts for mandibular salvage reconstruction., PATIENTS AND METHODS: Seven patients had

fibula grafts after failed attempts at mandibular reconstruction. The prior attempts involved 20 operative procedures. Four of the seven patients (57%) had a history of radiation to the affected mandible. Bony defects averaged 10.2 cm (range, 4.5 to 24 cm), and the associated soft tissue defects averaged 6 x 12 cm. Average follow-up was 16 months. Cosmetic (facial symmetry) and functional (speech quality, oral continence, deglutition, donor site morbidity, dental rehabilitation) results were evaluated by questionnaire and clinical examinations., RESULTS: Soft tissue coverage and mandibular restoration were successful in all patients, and flap survival was 100%. Five of the seven patients (70%) achieved good or excellent functional results, and five of seven (70%) achieved good or excellent esthetic results. Complications were minimal, and the average hospital stay was 14 days., CONCLUSIONS: When the initial attempt at mandibular reconstruction is unsuccessful, mandibular function and esthetics can be salvaged with reliable vascularized soft tissue and bone flaps. As long as appropriate flap options are considered and the patient is medically stable, successful mandibular reconstruction should be achievable despite the number or cause of prior failed attempts.

292. Antic, B., et al. (1999). "[Secondary neurosurgical management of craniocerebral war injuries]." Sekundarno neurohirursko zbrinjavanje ratnih kraniocerebralnih povreda. 56(1): 9-13.

In Belgrade Military Medical Academy 88 males and 1 female (aged 13-55, average 28.6 years) with war craniocerebral injuries (CCI) were secondarily neurosurgically treated from October 1991 trough December 1992. Primary neurosurgical management of these patients was performed in war hospitals in former Yugoslavia. Out of 89 patients, 78 had penetrating, and 11 closed CCI. Out of 55 patients with penetrating CCI who underwent surgery, intracranial debridement was performed in 34 patients. All patients with severe CCI (GCS = 3-8) were severely by disabled or died, and in the majority of patients with minor CCI (GCS = 13-15) the outcome was good ($p < 0.01$). Statistical analysis showed no significant correlation between the extent of cerebral lesion and the outcome of penetrating CCI ($p > 0.05$). Eight (10.3%) patients with penetrating CCI died. The outcome of war CCI mostly depended on the severity of injury.

293. Antonyshyn, O. M., et al. (1993). "Reconstruction of composite facial defects: the combined application of multiple reconstructive modalities." Canadian journal of surgery. Journal canadien de chirurgie 36(5): 441-452.

OBJECTIVE: To describe the combined use of craniofacial skeletal reconstruction, tissue expansion and microvascular free tissue transfer in the repair of major composite facial defects., DESIGN: Case series with an integrated team approach., SETTING: Craniofacial unit, university teaching hospital., PATIENTS: Three cases were selected to best illustrate the combined use of the three modalities in reconstruction of acute traumatic, congenital and post-traumatic facial defects. A 15-year-old boy had a shotgun wound to the face; a 23-year-old man had Treacher Collins syndrome; and a 55-year-old woman had a post-traumatic composite defect of the central midface., INTERVENTIONS: Preoperatively, complete neurologic, ophthalmologic and dental examinations, anthropometric analysis, prosthodontic assessment, computed tomography and computer graphics. Operatively, craniofacial exposure followed established surgical principles. Skeletal reconstruction was performed to provide accurate positioning of bony segments and three-dimensional stability. Bone grafting was used when necessary to restore bony continuity and increase stability. Tissue expansion was used to provide more locally available tissue for wound closure and resurfacing composite defects. Microsurgical free tissue transfer was used to provide functional replacement of deficient tissues., RESULTS: The results of the modalities used for reconstruction of these composite facial defects are illustrated for each case described., CONCLUSIONS: The use of multiple modalities, including craniofacial skeletal reconstruction, tissue expansion and free tissue transfer, allow the surgeon to address the specific functional and anatomical requirements associated with composite facial defects that are characterized by a combined deficiency of multiple tissues in the craniofacial region.

294. Anwar, D. R., et al. (2015). "Mode of injury and mortality following traumatic paediatric head injury in a single centre series of 309 patients." European Journal of Paediatric Neurology 19: S70-S71.

Objective: Paediatric traumatic brain injury (TBI) remains the leading cause of death in children aged >1 year. In the USA Trauma Bank, Haider found similar mortality for pedestrians and motor vehicle crashes (MVC), higher than falls, but four times the mortality for gunshot wounds. However, there are few European studies, data on outcome in survivors is limited and any relationship between mode of injury and CT findings has received little attention. Methods: This was a retrospective review of all severe TBI admitted to a single European centre over 14 years. Demographics, mechanism of injury, and CT data were collected. Outcome was scored using the King's Outcome Scale for Children with Head Injury (KOSCHI)and logistic regression analysis with death as the outcome was conducted in 309 consecutive children <18 years. Results: 10 children were non-accidentally injured (NAI), 107 had fallen, 83 were pedestrians, 43 were in a MVC, 33 were riding a bike and 17 were struck by an object. CT scan was more likely to be normal after a fall (41%) compared with 29% of pedestrians, 26% of MVC victims and 8% of cyclists. Twentyone (7%) died; mortality was lower (3%) in those who had fallen compared with rates for MVC (7%), pedestrians (10%) and cyclists (10%) and NAI (20%). Acute subdural haemorrage on initial CT was the most common finding associated with death (14%). Outcome in survivors was also related to mode of injury ($p<0.001$), with children who fell more likely to be discharged with no or minimal sequelae (KOSCHI grade 5a or b). Conclusion: Despite differences in aetiology of TBI between Europe and the US, with no gunshot wounds in our series, we also found that mortality is higher in pedestrians and cyclists and in NAI than following falls. Neuroimaging was often normal and outcome good after falls.

295. Aouinti, I., et al. (2014). "Vancomycin therapeutic drug monitoring in cerebrospinal fluid." Therapie 69(6): 529-530.

Vancomycin penetrates poorly through the blood-brain barrier. Determination of vancomycin concentration in plasma is recommended. In contrast, its determination in cerebrospinal fluid (CSF) is rarely performed. We report the case of a 74-year-old man with post traumatic meningitis with vancomycin concentration measured in CSF.

---

296. Aoun, S. G., et al. (2018). "Osteodiskitis of Lumbar Spine Due to Migrated Fractured Inferior Vena Cava Filter." World neurosurgery 113: 298-303.

BACKGROUND: Venous thromboembolism can be a significant cause of morbidity in the trauma population. Medical and surgical specialties have been pushing the indication for prophylactic filter placement., CASE DESCRIPTION: A 36-year-old man presented with axial lower back pain with a radicular right L2 component after lifting a heavy object. He had a history of penetrating brain trauma 3 years prior, with placement of a prophylactic inferior vena cava filter. His radiograph, computed tomography, and magnetic resonance imaging of the lumbar spine showed fracture of his filter, with migration of the fractured fragment through the inferior vena cava and into the L2-L3 disk space, and surrounding bony lysis and severe osteodiskitis. He was treated medically with intravenous and then oral antibiotics and improved clinically and radiographically., CONCLUSIONS: Conservative use of filter devices and early retrieval once their indication expires are paramount to avoid unnecessary complications.

297. Apaydin, A., et al. (2015). "Management of self-inflicted gunshot (pellet) wounds of the jaws with Le fort I osteotomy followed by implant insertion and prosthetic rehabilitation." International journal of oral and maxillofacial surgery 44: e188.

Background: Gunshot injuries to maxillofacial complex can result from suicide, rarely patients can survive. Those wounds can result in devastating functional and aesthetic consequences because of the missing hard and soft tissues. Objective: We would like to present the treatment of a case who had self-inflicted injury with severe tissue loss.A43-year-old man was sent to our clinic from the Plastic Surgery Department 4 months after his initial admission with several scar formations in soft tissues, a missing left eye and a smashed mandible which had been reconstructed. Half of the tongue, floor of the mouth and most of the maxilla were destroyed on the left side. The fractures of the right maxilla had healed in a retruded position; the vertical height of the face was shortened, resulting in a cross bite, causing a deviation to right. We advanced the maxilla with Le fort I osteotomy to establish the vertical dimension with the aid of the upper and lower molars. Dental and orthodontic implants, an obturator prosthesis to the maxilla and an implant-supported prosthesis to the mandible were applied. We achieved the restoration of function and emotional comfort to the patient. Findings and conclusions: Management of gunshot wounds of the maxillofacial region represents formidable challenge to the surgeon. The type and severity of the injury and success of the treatment depend on the gun type, projectile velocity and tissue resistance. The most difficult problems are secondary infection, severe deformity and tissue volume loss.

---

299. Appelbaum, R. D., et al. (2022). "Penetrating brain injury with hypopituitarism." Trauma case reports 38: 100628.

A 34-year-old healthy male presented as a trauma activation after sustaining a gunshot wound to his face. CT head imaging was suggestive of a ballistic fragment adjacent to a posterior wall sphenoid sinus fracture with likely a small volume of adjacent blood products. He was ultimately diagnosed with hypopituitarism which included central diabetes insipidus, central hypothyroid, and adrenocorticotropic hormone deficiency secondary to cortisol deficiency. This case illustrates the spectrum of endocrine dysfunction that can occur with skull base injuries, and the appropriate pituitary-function screening and treatment that should be performed if there is clinical concern. Early recognition and prompt treatment of pituitary insufficiency can facilitate overall rehabilitation after TBI.

300. Appleby, J., et al. (2015). "Perimortem trauma in King Richard III: a skeletal analysis." Lancet (London, England) 385(9964): 253-259.

BACKGROUND: Richard III was the last king of England to die in battle, but how he died is unknown. On Sept 4, 2012, a skeleton was excavated in Leicester that was identified as Richard. We investigated the trauma to the skeleton with modern forensic techniques, such as conventional CT and micro-CT scanning, to characterise the injuries and establish the probable cause of death., METHODS: We assessed age and sex through direct analysis of the skeleton and from CT images. All bones were examined under direct light and multi-spectral illumination. We then scanned the skeleton with whole-body post-mortem CT. We subsequently examined bones with identified injuries with micro-CT. We deemed that trauma was perimortem when we recorded no evidence of healing and when breakage characteristics were typical of fresh bone. We used previous data to identify the weapons responsible for the recorded injuries., FINDINGS: The skeleton was that of an adult man with a gracile build and severe scoliosis of the thoracic spine. Standard anthropological age estimation techniques based on dry bone analysis gave an age range between 20s and 30s. Standard post-mortem CT methods were used to assess rib end morphology, auricular surfaces, pubic symphyseal face, and cranial sutures, to produce a multifactorial narrower age range estimation of 30-34 years. We identified nine perimortem injuries to the skull and two to the postcranial skeleton. We identified no healed injuries. The injuries were consistent with those created by weapons from the later medieval period. We could not identify the

specific order of the injuries, because they were all distinct, with no overlapping wounds. Three of the injuries-two to the inferior cranium and one to the pelvis-could have been fatal., INTERPRETATION: The wounds to the skull suggest that Richard was not wearing a helmet, although the absence of defensive wounds on his arms and hands suggests he was still otherwise armoured. Therefore, the potentially fatal pelvis injury was probably received post mortem, meaning that the most likely injuries to have caused his death are the two to the inferior cranium., FUNDING: The University of Leicester.

301. Applegate, L. J., et al. (1990). "Traumatic pseudoaneurysm of the cervical carotid artery: the value of arteriography." Neurosurgery 26(2): 312-315.

A patient who sustained a gunshot wound to the neck and subsequent blunt trauma is presented. No angiogram was performed after the initial injury. Subsequently, the patient developed a cerebral embolus from a thrombus dislodged from a pseudoaneurysm of the cervical carotid artery, resulting in complete occlusion of the distal internal carotid artery. After antiplatelet therapy, the distal internal carotid artery recanalized, and the pseudoaneurysm occluded spontaneously. We stress the need for the use of arteriography in the initial evaluation of penetrating injuries to the neck and the utility of repeated arteriograms for further treatment planning as these traumatic lesions can change with time.

302. Apriawan, T., et al. (2021). "Three-dimensional (3D)-printed model reconstruction in pre-operative planning for wooden penetrating brain injury." Bioprinting 24.

Objective: The advancements in technology have made the use of three-dimensional printed model reconstruction in neurosurgery receive special attention due to its role in the process of decision-making and pre-operative planning. Penetrating brain injuries (PBI) have a high risk of damage to the complex intracranial neurovascular structures. Due to its difficulty, 3D-printed model reconstruction could help neurosurgeons in the decision making of PBI surgery strategy. Methods: The authors reported of an 18-year-old male carpenter who was referred to the hospital due to a wooden PBI. We performed computed tomography (CT) scan, CT angiography (CTA), magnetic resonance venography (MRV) and magnetic resonance angiography (MRA). We then performed segmentations and integrations of the digital imaging and communications in medicine (DICOM) data. The digital reconstruction was then used for 3D printing, and the printed model was used for the foreign object extraction simulation for pre-operative planning. Results: There were no intra- and post-operative neurovascular complications after the craniotomy and wooden foreign body extraction procedure. Conclusion: This method was beneficial since it enhances the anatomical visualization of the location and trajectory of the foreign body. Moreover, the printed model allows for a more direct and realistic simulation for the foreign body extraction procedure.

303. Apuzzo, M. L., et al. (1982). "Transcallosal, interfornicial approaches for lesions affecting the third ventricle: surgical considerations and consequences." Neurosurgery 10(5): 547-554.

A group of 11 patients with a variety of lesions affecting the 3rd ventricle have been treated using a direct transcallosal interfornicial approach to the region. In 3 patients, no attendant hydrocephalus was present. In an effort to minimize potential cortical injury related to the approach, we studied the venous anatomy in the region of the coronal suture. Based on this study, appropriate flap placement and interhemispheric entry points were defined. Although no lasting, clinically apparent morbidity was observed in any of the 11 cases, we performed more sophisticated studies of the interhemispheric transfer of somesthetic and perceptual motor tasks, as well as psychometric testing related to parameters of intelligence and memory, 3 to 8 months postoperatively in 6 cases. The results and clinical material indicate that this surgical technique is a safe, feasible alternative in the management of a wide spectrum of pathological lesions within this region. A transcallosal, interfornicial approach offers excellent visualization of the entire 3rd ventricle without the dependence on hydrocephalus or an

extensive extra-axial mass to enhance the exposure. With proper planning and technique, it may be accomplished with a minimum of physiological consequence.

304. Aras, M., et al. (2014). "Being a neighbor to Syria: a retrospective analysis of patients brought to our clinic for cranial gunshot wounds in the Syrian civil war." Clinical neurology and neurosurgery 125: 222-228.

OBJECTIVE: Toward the end of 2010, the Arab spring, the waves of revolutionary demonstrations and protests influenced also Syria, where violent clashes turned into a civil war. Hundreds of thousands of people became refugees. The use of excessive force unfortunately culminated in numerous deaths and injuries in many cities. Being the closest city to Aleppo, Damascus and Homs, the biggest cities of Syria, Antioch/Hatay has been the city where initial emergency treatments were performed. For this reason, we examined and retrospectively analyzed the medical records of the patients treated in the clinics of our hospital due to cranial gunshot wounds during the war., MATERIAL AND METHODS: The medical records of 186 patients who were injured in the Syrian War and brought to, followed up and treated in the Neurosurgery Clinic of Mustafa Kemal University, Faculty of Medicine in Hatay, a Turkish city on the Syrian border, between April 2011 and June 2013., RESULTS: A total of 186 patients were evaluated in a period of more than 2 years. Of all 91.4% of the patients were adults (male/female: 152/18) and 8.6% of them were pediatric patients (male/female: 14/2). The average age of the patients was 31 years, with an age range of between 2 months and 67 years. According to Glasgow coma score (GCS) of the patients at the time of admission, GCS was 3 in 32 patients (17.2%), between 4 and 7 in 70 patients (37.6%), and between 8 and 15 in 84 patients (45.1%). We observed that the patients with GCS of 4-7 had a significantly lower mortality among the 56 patients treated surgically compared with the 14 patients treated medically., DISCUSSION: Cranial gunshot wounds are responsible for high mortality and morbidity. A multiplicity of factors plays a role on morbidity and mortality. These are the duration of transport, the injury pattern, the velocities of the weapons used, and the Glasgow Coma Scales of the patients at the time of admission., CONCLUSION: The authors recommend that the patients with cranial gunshot wounds who has GCS of 4-7 should be aggressively treated including surgery as well. We do not recommend surgical treatment for patients with GCS of 3. All our experiences show that treatment of gunshot wounds will continue to be a matter of debate, about which there is more to learn. The data presented in this study will once again demonstrate the seriousness of the event, and will, perhaps, contribute to the peace negotiations to end the war.

305. Aravapalli, A., et al. (2009). "Cerebral fat embolism and the "starfield" pattern: A case report." Cases journal 2(11).

Nearly all long-bone fractures are accompanied by some form of fat embolism. The rare complication of clinically significant fat embolism syndrome, however, occurs in only 0.9-2.2% of cases. The clinical triad of fat embolism syndrome consists of respiratory distress, altered mental status, and petechial rash. Cerebral fat embolism causes the neurologic involvement seen in fat embolism syndrome. A 19-year-old African-American male was admitted with gunshot wounds to his right hand and right knee. He had diffuse hyperactive deep tendon reflexes, bilateral ankle clonus and decerebrate posturing with a Glasgow Coma Scale (GCS) score of 4T. Subsequent MRI of the brain showed innumerable punctate areas of restricted diffusion consistent with "starfield" pattern. On a 10-week follow up he has a normal neurological examination and he is discharged home. Despite the severity of the neurologic insult upon initial presentation, the majority of case reports on cerebral fat embolism illustrate that cerebral dysfunction associated with cerebral fat embolism is reversible. When neurologic deterioration occurs in the non-head trauma patient, then a systemic cause such as fat emboli should be considered. We describe a patient with non-head trauma who demonstrated the classic "starfield" pattern on diffusion-weighted MRI imaging.

---

306. Arbour, R. B. (2013). "Early metabolic/cellular-level resuscitation following terminal brain stem herniation: implications for organ transplantation." AACN advanced critical care 24(1): 59-78.

Patients with terminal brain stem herniation experience global physiological consequences and represent a challenging population in critical care practice as a result of multiple factors. The first factor is severe depression of consciousness, with resulting compromise in airway stability and lung ventilation. Second, with increasing severity of brain trauma, progressive brain edema, mass effect, herniation syndromes, and subsequent distortion/displacement of the brain stem follow. Third, with progression of intracranial pathophysiology to terminal brain stem herniation, multisystem consequences occur, including dysfunction of the hypothalamic-pituitary axis, depletion of stress hormones, and decreased thyroid hormone bioavailability as well as biphasic cardiovascular state. Cardiovascular dysfunction in phase 1 is a hyperdynamic and hypertensive state characterized by elevated systemic vascular resistance and cardiac contractility. Cardiovascular dysfunction in phase 2 is a hypotensive state characterized by decreased systemic vascular resistance and tissue perfusion. Rapid changes along the continuum of hyperperfusion versus hypoperfusion increase risk of end-organ damage, specifically pulmonary dysfunction from hemodynamic stress and high-flow states as well as ischemic changes consequent to low-flow states. A pronounced inflammatory state occurs, affecting pulmonary function and gas exchange and contributing to hemodynamic instability as a result of additional vasodilatation. Coagulopathy also occurs as a result of consumption of clotting factors as well as dilution of clotting factors and platelets consequent to aggressive crystalloid administration. Each consequence of terminal brain stem injury complicates clinical management within this patient demographic. In general, these multisystem consequences are managed with mechanism-based interventions within the context of caring for the donor's organs (liver, kidneys, heart, etc.) after death by neurological criteria. These processes begin far earlier in the continuum of injury, at the moment of terminal brain stem herniation. As such, aggressive, mechanism-based care, including hormonal replacement therapy, becomes clinically appropriate before formal brain death declaration to support cardiopulmonary stability following terminal brain stem herniation.

---

307. Arbour, R. B. (2013). "Traumatic brain injury: pathophysiology, monitoring, and mechanism-based care." Critical care nursing clinics of North America 25(2): 297-319.

Traumatic brain injury, which may be blunt or penetrating, begins altering intracranial physiology at the moment of impact as primary brain trauma. This article differentiates blunt versus penetrating brain trauma, primary versus secondary brain injury, and subsequent intracranial pathophysiology. Discussion and case study correlate intracranial pathophysiology and multisystem influences on evolving brain injury with mechanism-based interventions to modulate brain components (brain, blood, and cerebrospinal fluid volumes). The discussion also explores the effects of controlled ventilation, cardiopulmonary physiology, and global physiologic state on secondary injury, control of intracranial pressure, and recovery.

308. Arciniegas, D. B., et al. (2011). "Mini-mental state exam and frontal assessment battery scores predict inpatient rehabilitation outcomes after traumatic brain injury." Journal of Neuropsychiatry and Clinical Neurosciences 23(2): 1.

Background: Physicians are often called upon to opine on the relationship between early posttraumatic cognitive impairments and inpatient rehabilitation outcomes. The value of commonly used bedside cognitive assessments, including the Mini-Mental State Exam (MMSE) and Frontal Assessment Battery (FAB), for this purpose remains under-explored in this population. Objective: To evaluate the MMSE and FAB, independently and combined, as predictors of: 1) rehabilitation length of stay (RLOS); 2) Functional Independence Measure (FIM) score proximate to neuropsychiatric consultation; and 3) discharge FIM score. Methods: Medical records of 83 inpatients consecutively evaluated on a brain injury rehabilitation unit were retrospectively reviewed. Inclusion criteria were: TBI (non-penetrating)

by American Congress of Rehabilitation Medicine criteria; age 20-89 years; primary language English; non-aphasic; neuroimaging demonstrating intracranial abnormality consistent with TBI. Data extracted from records of eligible subjects included: demographic information; TBI mechanism; MMSE, FAB, and FIM scores; and RLOS. Multiple regression modeling was used to investigate the proportion of variance in FIM scores and RLOS accounted for by MMSE and/or FAB Z-scores. Results: Fifty-five subjects were included. MMSE and FAB Z-scores independently predict RLOS and FIM at consultation and discharge. The combination of these measures accounted for a greater proportion of variance in all models than did either measure alone. Conclusions: Normatively interpreted MMSE and/or FAB scores inform usefully on duration of inpatient rehabilitation hospitalization as well as functional status proximate to consultation and inpatient rehabilitation discharge. Prospective study of these measures as predictors of short- and long-term rehabilitation outcomes in this population is warranted.

---

309. Arciniegas, D. B., et al. (2012). "Norm-adjusted mini-mental state examination and frontal assessment battery scores predict inpatient rehabilitation outcomes after traumatic brain injury." Brain injury 26(4-5): 709-710.

Objectives: Physicians and psychologists are often called upon to evaluate persons with early posttraumatic cognitive impairments and to predict inpatient rehabilitation outcomes. The value of 'bedside' cognitive assessments that are commonly used for similar purposes by these clinicians in other contexts, including the Mini-Mental State Examination (MMSE) and Frontal Assessment Battery (FAB), remains underexplored in this population. This study sought to evaluate MMSE and FAB performance among persons receiving inpatient rehabilitation after TBI, and to test the hypotheses that MMSE and FAB Z-scores, independently and in combination, predict: 1) rehabilitation length of stay (RLOS); 2) total Functional Independence Measure (FIM) score proximate to neuropsychiatric consultation; and 3) discharge FIM score. Methods: Medical records of 83 English-speaking, non-aphasic, adults with non-penetrating TBI and abnormal intracranial neuroimaging consecutively admitted to an inpatient rehabilitation unit were reviewed. Demographic information, TBI characteristics, MMSE, FAB, and FIM scores, and RLOS were extracted from the medical record. Multiple regression modeling was used to estimate the proportion of variance in FIM scores and RLOS accounted for by MMSE and/or FAB Z-scores. Results: Fifty-five subjects (42 men, 13 women), age 46.5±17.4 years with 13.5±2.3 years of education and admitted to inpatient rehabilitation 21.7±19.9 days post-TBI, met study eligibility criteria. The MMSE and FAB were administered approximately six days after inpatient rehabilitation admission. Total FIM scores at admission, consultation, and rehabilitation discharge were 54.5±18.2, 69.2±24.0, and 102.2±17.6, respectively. Raw MMSE and FAB scores were Z-transformed (to adjust for age- and education-effects) using previously published population norms for these measures. MMSE and FAB Z-scores were -2.6±2.8 and -5.6±4.1, respectively. MMSE and FAB Z-scores independently predicted RLOS (both $R^2=0.19$ and $p<0.002$) as well as total FIM score at consultation ($R^2=0.48$, $p<0.001$ and $R^2=0.28$, $p<0.001$, respectively) and rehabilitation discharge ($R^2=0.08$, $p<0.04$ and $R^2=0.09$, $p<0.03$, respectively). The combination of MMSE and FAB Z-scores accounted for a greater proportion of variance in RLOS ($R^2=0.25$, $p<.001$), total FIM score at consultation ($R^2=0.53$, $p<0.001$), and total FIM score at rehabilitation discharge ($R^2=0.12$, $p<.0.04$) than did either measure alone. Conclusions: Normatively interpreted MMSE and/or FAB scores inform on duration of inpatient rehabilitation hospitalization as well as functional status proximate to consultation and inpatient rehabilitation discharge. These findings offer preliminary support for the use of the MMSE and FAB as elements of the 'bedside' cognitive assessment of persons receiving inpatient rehabilitation following TBI. While retrospective analysis is a limitation of the present study, the derivation of these data from a typical inpatient brain injury rehabilitation clinical practice increases their translational immediacy. Prospective study is needed to investigate further the value of Z-transformed MMSE and FAB scores as predictors of rehabilitation outcomes among persons with TBI.

---

310. Arciniegas, D. B., et al. (2012). "Clock drawing performance predicts inpatient rehabilitation outcomes after traumatic brain injury." Brain injury 26(4-5): 748-749.

Objectives: Clock drawing is a widely used, timeefficient, easily performed 'bedside' cognitive assessment. However, the value of clock drawing tests as assessments of cognitive impairments in the early period following traumatic brain injury (TBI) and as predictors of rehabilitation outcome is underexplored. This study addressed this issue by evaluating clock drawing performance among persons receiving inpatient rehabilitation after TBI and by testing the hypotheses that Clock Drawing Interpretation Scale scores predict: 1) total Functional Independence Measure (FIM) score proximate to neuropsychiatric consultation; 2) discharge total FIM score; 3) FIM efficiency; and 4) rehabilitation length of stay (RLOS). Methods: Medical records of 83 English-speaking, non-aphasic, adults with non-penetrating TBI and abnormal intracranial neuroimaging consecutively admitted to an inpatient rehabilitation unit were reviewed. Demographic information, TBI characteristics, clock drawings, FIM scores, and RLOS were extracted from the medical record. One investigator scored clock drawings using Mendez' (1992) 20- point Clock Drawing Interpretation Scale (CDIS); a blinded subset were rescored three years later in order to establish test-retest reliability. FIM efficiency was calculated as: ([discharge total FIM score] - [admission total FIM score]) 7 RLOS. Multiple regression modeling was used to investigate the proportion of variance in FIM scores, FIM efficiency, and RLOS accounted for by CDIS score, controlling for the effects of age. Results: Forty-five subjects (35 men, 10 women), age 47.1±17.8 years with 13.8±2.3 years of education and admitted to inpatient rehabilitation 22.2±20.4 days post-TBI, met study inclusion criteria. Testretest reliability of CDIS scores was r=0.95. CDIS scores were normally distributed (13.4±5.6, range 2-20, Kolmogorov-Smirnov d=0.19, p=NS), and were correlated with age (r=-0.41, p<0.005) but not education. After controlling for age, CDIS score predicted total FIM score at consultation (adjusted R2=0.31, p<0.001) and discharge (adjusted R2=0.19, p<0.005), as well as rehabilitation length of stay (adjusted R2=0.22, p<0.002). The combination of CDIS score and age predicted total FIM efficiency (adjusted R2=0.10, p<0.05); CDIS score contributed more strongly (β=0.30, p=0.06) than did age (β=-0.13, p=0.42). Conclusions: Clock drawing was scored easily and consistently using the CDIS, which yielded a normally distributed score set. CDIS scores predicted functional status and length of inpatient rehabilitation hospitalization and contributed to prediction of the efficiency of functional recovery. The CDIS focuses on the contribution of frontally-mediated cognition to clock drawing performance, a characteristic that appears to influence strongly its prediction of inpatient rehabilitation outcomes. The present findings suggest that standardized administration of the clock drawing test and CDIS scoring may contribute usefully to the assessment of persons receiving inpatient rehabilitation after TBI and inform rehabilitation outcome expectations. Prospective study of clock drawing using CDIS in this population is warranted.

A 90-year-old woman presented with an accidental maxillofacial-clival penetrating injury with a butcher's knife, with its tip reaching the immediate proximity of the basilar artery. The knife was removed at surgery, with no untoward sequelae.

---

312. Ardill, W. and S. Gidado (2003). "Penetrating head wound: a remarkable case." Surgical neurology 60(2): 120-123.

BACKGROUND: The modern management of penetrating head injuries is generally considered a neurosurgical specialty that relies heavily on the use of sequential imaging techniques, an ever-changing armamentarium of sophisticated antibiotics and specific neurosurgical operative skills. Unfortunately these optimal therapeutic components are frequently not available to patients injured in underdeveloped countries., METHODS: An unusual case of a young patient suffering a penetrating brain wound and undergoing delayed treatment in an African mission hospital is reviewed., RESULTS: A functional but neurologically impaired outcome resulted from limited surgical debridement and short-

term broad-spectrum antibiotic administration., CONCLUSIONS: The multiple exigencies of surgical practice in an underdeveloped African nation do not preclude successful management of penetrating head trauma.

313. Ardissino, M., et al. (2019). "Decompressive craniectomy in paediatric traumatic brain injury: a systematic review of current evidence." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery 35(2): 209-216.

INTRODUCTION: Paediatric traumatic brain injury (pTBI) is one of the most frequent neurological presentations encountered in emergency departments worldwide. Every year, more than 200,000 American children suffer pTBIs, many of which lead to long-term damage., OBJECTIVES: We aim to review the existing evidence on the efficacy of the decompressive craniectomy (DC) in controlling intracranial pressure (ICP) and improving long-term outcomes in children with pTBI., METHODS: A comprehensive search of the MEDLINE and EMBASE databases led to the screening of 212 studies, 12 of which satisfied inclusion criteria. Data extracted included the number and ages of patients, Glasgow Coma Scale scores at presentation, treatment protocols and short- and long-term outcomes., RESULTS: Each of the nine studies including ICP as an outcome reported that it was successfully controlled by DC. The 6-12 month outcome scores of patients undergoing DC were positive, or superior to those of medically treated groups in nine of 11 studies. Mortality was compared in only two studies, and was lower in the DC group in both.Very few studies are currently available investigating short- and long-term outcomes in children with TBI undergoing DC., CONCLUSION: The currently available evidence may support a beneficial role of DC in controlling ICP and improving long-term outcomes.

314. Arendall, R. E. and A. M. Meirowsky (1983). "Air sinus wounds: an analysis of 163 consecutive cases incurred in the Korean War, 1950-1952." Neurosurgery 13(4): 377-380.

Review of 1105 records patients with penetrating craniocerebral injuries incurred in the Korean War revealed 163 cases with air sinus wounds, an incidence of 14.8%. The characteristics of these wounds and their surgical management have been described. Foremost among the complications of air sinus wounds are the development of a cerebrospinal fluid fistula and the occurrence of posttraumatic infection. Prompt and radical debridement with exenteration of the affected sinus and watertight closure of the dura mater represent the key to the reduction of complications when dealing with penetrating wounds involving the air sinuses.

315. Ares, W. J., et al. (2019). "A comparison of digital subtraction angiography and computed tomography angiography for the diagnosis of penetrating cerebrovascular injury." Neurosurgical focus 47(5): E16.

OBJECTIVE: Penetrating cerebrovascular injury (PCVI) is a subset of traumatic brain injury (TBI) comprising a broad spectrum of cerebrovascular pathology, including traumatic pseudoaneurysms, direct arterial injury, venous sinus stenosis or occlusion, and traumatic dural arteriovenous fistulas. These can result in immediate or delayed vascular injury and consequent neurological morbidity. Current TBI guidelines recommend cerebrovascular imaging for detection, but there is no consensus on the optimum modality. The aim of this retrospective cohort study was to compare CT angiography (CTA) and digital subtraction angiography (DSA) for the diagnosis of PCVI., METHODS: The records of all patients presenting to two level I trauma centers in the United States between January 2010 and July 2016 with penetrating head or neck trauma were reviewed. Only those who had undergone both CTA and DSA were included. Clinical and neuroimaging data were collected, and PCVIs were stratified using a modified Biffl grading scheme. DSA and CTA results were then compared., RESULTS: Of 312 patients with penetrating trauma over the study period, 56 patients (91% male, mean age 32 years) with PCVI met inclusion criteria and constituted the study cohort. The mechanism of injury was a gunshot

wound in 86% (48/56) of patients. Twenty-four (43%) patients had sustained an angiographically confirmed arterial or venous injury. Compared with DSA as the gold standard, CTA had a sensitivity and specificity of 72% and 63%, respectively, for identifying PCVI. CTA had a positive predictive value of 61% and negative predictive value of 70%. Seven patients (13%) required immediate endovascular treatment of PCVI; in 3 (43%) of these patients, the injury was not identified on CTA. Twenty-two patients (39%) underwent delayed DSA an average of 25 days after injury; 2 (9%) of these patients were found to harbor new pathological conditions requiring treatment., CONCLUSIONS: In this retrospective analysis of PCVI at two large trauma centers, CTA demonstrated low sensitivity, specificity, and positive and negative predictive values for the diagnosis of PCVI. These findings suggest that DSA provides better accuracy than CTA in the diagnosis of both immediate and delayed PCVI and should be considered for patients experiencing penetrating head or neck trauma.

316. Arffa, R. C., et al. (1985). "Keratometric and refractive results of pediatric epikeratophakia." Archives of ophthalmology (Chicago, Ill. : 1960) 103(11): 1656-1659.

Keratometric and refractive results of pediatric epikeratophakia showed that patients under 1 year of age had steeper corneas preoperatively and required more correction, as estimated by the Sanders-Retzlaff-Kraff regression formula. The average spherical equivalent of refractive error six months postoperatively was +6.92 +/- 4.67 diopters in patients under 1 year, and -0.72 +/- 4.22 D in patients over 1 year. Three of 14 younger patients and 35 of 54 older patients were within 3 D of emmetropia. Since March 1982, significant undercorrection has occurred only in patients 6 months old or younger. Younger children achieved an average of 46% of the predicted change in corneal curvature, while older children achieved 85%. Also, the Sanders-Retzlaff-Kraff formula may be inaccurate in estimating powers for younger children. Therefore, we recommend at this time that epikeratophakia be used as a secondary procedure in neonates with congenital cataracts.

319. Arici, L., et al. (2012). "Penetrating head trauma with four nails: an extremely rare case." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES 18(3): 265-267.

We present a rare case of self-inflicted penetrating head trauma by a 34-year-old male who hammered four nails into his own head; he had been diagnosed with schizophrenia seven years before. On the physical examination, four nails were observed in the hairy scalp that had been driven into the cranium in the right temporal and parietal areas of the head. No cerebrospinal fluid fistulas were present.

On the neurological examination, no motor or sensory deficits were present. The Glasgow Coma Scale was 15. On direct skull X-ray and cranial computerized tomography (CT), the nails were seen to be approximately 10 cm long and extending in various directions. No injury was observed in the main vasculature on CT angiography. Under general anesthesia, two nails in the right temporal area were removed by extraction, and the other two nails in the right parietal area were removed through a mini craniotomy. In areas such as the temporal area where the bone is thin, nails can be removed by extraction. However, in areas like the parietal bone where the bone is thick, removal of the nails using this method may not always be possible.

---

320. Arienta, C., et al. (1997). "Management of head-injured patients in the emergency department: a practical protocol." Surgical neurology 48(3): 213-219.

BACKGROUND: The management of head-injured patients admitted to emergency departments is not standardized., METHODS: The authors performed a retrospective analysis of 10,000 head-injured patients admitted to the Emergency Department of our hospital in a 21-month period and, on the basis of a statistical correlation between each clinical parameter (symptoms and signs upon arrival at the hospital or risk factors) and the presence of intracranial lesions, they propose a practical protocol in an attempt to avoid the overuse or radiologic examinations and yet identify patients with possible life-threatening complications., RESULTS: On the basis of this correlation the patients have been divided into four groups. In the first group (called group alpha) are patients with: no history of loss of consciousness, no vomiting or amnesia, a normal neurologic examination, and minimal if any subgaleal swelling. They can be released into the care of relatives who are given a special instruction sheet (X rays unnecessary). No patient in group alpha had complications of any kind. The second group (group beta) is made up of patients with at least one of the following features: transient loss of consciousness, post-traumatic amnesia, a single episode of vomiting or significant subgaleal swelling. They undergo a computed tomography (CT) scan and if this is normal, only a short period of observation is needed. If CT scan is not available, the skull is X rayed and, if this X ray is negative, the patient is sent home with the warning sheet after an observation period. If a fracture is found, CT scan should be performed promptly. No patient in group beta with normal skull X rays developed intracranial lesions. The third group (group gamma) contains patients with at least one of the following symptoms: impaired consciousness, repeated episodes of vomiting, neurologic deficits, otorrhagia, otorrhea, rhinorrea, signs of basal skull fracture, seizures, penetrating or perforating wounds, lack of cooperation for varying reasons, patients who have undergone previous intracranial operations or been affected by coagulopathy or submitted to anticoagulant therapy, and finally, epileptic or alcoholic patients. They receive a CT scan immediately and, if necessary, again prior to discharge. Six patients in group gamma with GCS = 15 upon admission were operated on for intracranial hematoma. The fourth group (group delta) is composed of comatose patients. Immediately following resuscitation maneuvers and prior to any surgical intervention, they undergo a CT scan. A linear association between the severity groups and the presence of intracranial lesions has been demonstrated., CONCLUSIONS: The present protocol stresses the importance of the patient's clinical and anamnestic evaluation upon arrival in the Emergency Department, especially in minor head injuries.

321. Arif, S. H., et al. (2016). "Attempted Suicide with Needle Penetration through Cranial Defect: A Rare Case Report." Indian Journal of Neurotrauma 13(2): 104-106.

Intracranial foreign bodies are usually secondary to penetrating injuries through the orbit, ear, or cranial bones. Nails, knives, screwdrivers, sewing needles, bullets, and shrapnel have been described related to penetrating brain injury (PBI). The majority of deaths from trauma reflect unintentional accidents, but a significant minority follow suicide and even a smaller proportion (less than 10%) reflect homicide. Self-inflicted injuries among psychiatric patients are not uncommon. We report a rare case of a 35-year-old woman who tried to commit suicide by inserting a needle in her brain through cranial defect. Needle was removed and patient recovered uneventfully. Awareness of the psychological

condition and suicide precautionary measures should be kept in mind in all cases of self-inflicted PBI patients.

---

322. Arifin, M. Z., et al. (2012). "Penetrating skull fracture by a wooden object: Management dilemmas and literature review." Asian journal of neurosurgery 7(3): 131-134.

Most penetrating skull injuries are caused by gun shot wounds or missiles. The compound depressed skull fracture represents an acute neurosurgical emergency. Management and diagnosis of such cases have been described, but its occurence following a fall onto a piece of wood is quite unusual. A 75-year-old female fell onto a piece of wood that penetrated her skull on the left frontal region and was treated in our department. The patient had no neurological deficits during presentation. She was managed surgically and removal of the wooden object was performed to prevent early or late infection complications. Wooden foreign bodies often pose a different set of challenges as far as penetrating injuries to the brain are concerned. Radiological difficulties and increased rates of infection due to its porous nature make these types of injuries particularly interesting. Their early diagnosis and appropriate treatment can minimize the risk of complications.

323. Arkin, M. S., et al. (1996). "Anterior chiasmal optic nerve avulsion." AJNR. American journal of neuroradiology 17(9): 1777-1781.

In a case of traumatic avulsion of the optic nerve at the anterior chiasm, MR imaging provided highly specific images of the injury site, including the absence of the optic nerve within the optic canal and the point of transection at the anterior portion of the chiasm. This was confirmed clinically and histopathologically. MR imaging should be considered in cases of suspected chiasmal injury.

325. Armonda, R., et al. (2011). "Specific clinical applications of transcranial doppler ultrasound for patients with wartime traumatic brain injury." Journal of neurotrauma 28(6): A5.

Traumatic brain injury (TBI) is associated with the severest casualties from Operation Iraqi Freedom (OIF) and Operation Enduring Freedom (OEF). From Oct. 1, 2008 AMEDD TBI program initiated transcranial Doppler (TCD) ultrasound service for TBI patients who were presented for care at the National Naval Medical Center and at the Walter Reed Army Medical Center. MATERIAL & METHODS: Eighty five patients (3 females) aged 18 to 40 years (mean 25.9 years) who had suffered wartime TBI injuries (with Glasgow Coma Scale scores ranging from 3 to 15) were investigated with daily TCD studies. A total of 505 TCD studies (mean 6.4 tests/patient, ranged from 1 to 30) were made after admission. There were 28 (33%) patients after explosive blast injury, 23 patients (27%) after GSW and 34 (40%) after other causes of TBI (closed, penetrating, MVA, falls, etc). Comprehensive TCD protocol and well published diagnostic criteria for vasospasm and abnormally high intracranial pressure (ICP) applied in all cases. RESULTS: The TCD signs of mild, moderate and severe vasospasm were observed in 29 (34.1%), 16 (18.8%) and 10 (11.7%) of patients, respectively. The TCD signs of intracranial hypertension were recorded in 56 (65.8%) patients. Abnormally high CBFV's without TCD signs of vasospasm and abnormally low CBFV's were recorded in 8 (9.4%) and 12 (14.1%) of all patients, respectively. Five patients (5.8%) underwent transluminal angioplasty for post-traumatic vasospasm treatment. CONCLUSION: These findings demonstrate that delayed cerebral arterial spasm is a frequent complication of combat TBI and that the severity of spasm is comparable to that seen in aneurysmal SAH. In addition, TCD provided valuable information about the presence of abnormally high ICP. Because vasospasm and intracranial hypertension represent significant events in a high

proportion of patients after wartime TBI, close daily TCD monitoring is recommended for the management of such patients.

326. Arnold, P. G. and G. B. Irons (1981). "One-stage reconstruction of massive craniofacial defect with gastroomental free flap." Annals of plastic surgery 6(1): 26-33.

A large craniofacial defect resulting from a close-range shotgun blast is described. It involves the left hemimandible, the left maxilla, the hard palate with nasal support, the roof of the left orbit, and the left side of the oral lining. The defect was reconstructed using autogenous ribs for the facial skeleton. The remainder of the defect was repaired with a composite free tissue transfer of gastric wall and greater omentum on the right gastroepiploic vessels. The gastric wall was used to reconstruct the oral mucosa, the omentum was packed around the bone grafts for nourishment, and a split-thickness skin graft was placed on the outside surface. The technical aspects of the procedure are described and a two-year follow-up presented.

---

327. Aromatario, M., et al. (2016). "Weapon identification using antemortem CT with 3D reconstruction, is it always possible?--A report in a case of facial blunt and sharp injuries using an ashtray." Legal medicine (Tokyo, Japan) 18: 1-6.

An interesting case of homicide involving the use of a heavy glass ashtray is described. The victim, a 81-years-old woman, has survived for few days and died in hospital. The external examination of the victim showed extensive blunt and sharp facial injuries and defense injuries on both the hands. The autopsy examination showed numerous tears on the face, as well as multiple fractures of the facial bones. Computer tomography scan, with 3D reconstruction, performed in hospital before death, was used to identify the weapon used for the crime. In recent years new diagnostics tools such as computer tomography has been widely used, especially in cases involving sharp and blunt forces. Computer tomography has proven to be very valuable in analyzing fractures of the cranial teca for forensic purpose, in particular antemortem computer tomography with 3D reconstruction is becoming an important tool in the process of weapon identification, thanks to the possibility to identify and make comparison between the shape of the object used to commit the crime, the injury and the objects found during the investigations. No previous reports on the use of this technique, for the weapon identification process, in cases of isolated facial fractures were described. We report a case in which, despite the correct use of this technique, it was not possible for the forensic pathologist to identify the weapon used to commit the crime. Authors wants to highlight the limits encountered in the use of computer tomography with 3D reconstruction as a tool for weapon identification when facial fractures occurred.

---

328. Arora, M. M., et al. (2008). "Analysis of non enemy action deaths in counter insurgency operations through mortuary services." Medical Journal Armed Forces India 64(2): 104-107.

Background: Regional Trauma Centre in the northern India receives the mortal remains of all fallen soldiers for embalming. Non enemy action deaths during counter insurgency operations (CI Ops) were analysed for planning preventive measures. Methods: Mortal remains received for embalming from Jan 1999 to Dec 2006 were analysed with respect to mode of injury, causation, body parts involved, fatality, seasonal variation and changing trends. Result: Accidents accounted for 3.02 deaths per thousand troops and environmental factors were responsible for 1.14 deaths per thousand troops deployed. Accidental deaths peaked in 2000, declined in 2001 and then remained more or less static. Of the accidental deaths, 88 % were brought in dead and 12% died after reaching hospital. Road traffic accidents were the major killers accounting for 48.2 %, followed by accidental discharge of weapon 35.5 %. The latter is showing a rising trend from 8 % of total accidents in 2001 to 65 % in 2005 and 51 % in 2006 ($p < .01$). Most (49.7 %) of the deaths were below 25 years of age. Proportion of persons below 25 years was more in fatalities due to accidental gunshot wound. Amongst the road traffic accidents, 40%

died of head injury and 51.2 % due to multiple injuries. When deaths occurred due to accidental discharge of own weapon, 36.4 % had brain injury and 22% heart injury. Of the environmental fatalities all but one were brought in dead. Majority were due to avalanches and landslides (51.2 %), followed by earthquake (22.4 %), lightning (12.8 %), high altitude pulmonary oedema (10.4 %) and hypothermia (3.2 %). Most of the deaths due to avalanches occurred in February while all deaths due to earthquake were in October 2005. Of the deaths due to lightning, 75 % occurred in April and May. Conclusion: Prevention of death caused by road traffic accidents, accidental discharge of weapon, avalanches and lightning will conserve manpower and add to operational preparedness.

---

329. Arora, M. M., et al. (2009). "Pattern of fatal injuries in counter terrorist operations: An innovative analysis through embalming services." Medical Journal Armed Forces India 65(2): 103-107.

Background: Mortal remains of the soldiers killed in counter-terrorist operations in Kashmir valley are sent to their home after undergoing mandatory embalming. Methods: Injuries on the mortal remains of the soldiers killed in counter terrorist operations between Jan 1999 to Dec 2006 were analysed with respect to the agent, mode of injury, age, rank structure, body parts involved, seasonal variations and changing trends. Fatalities consequent to enemy action across line of control and fatalities of Kargil war were also analysed for comparison. Statistical analysis was done using chi square test for difference in proportions. Result: Over the study period, terrorist induced injuries accounted for 8.16 deaths per thousand troops deployed whereas enemy action from across the line of control accounted for 0.63 deaths per thousand. Terrorist induced fatalities peaked in 2001 and thereafter revealed a declining trend ('p' < 0.001). Fatalities due to enemy action across line of control declined to zero since 25 Nov 2003 consequent to effective ceasefire. Of the total fatalities, 89.5% were killed in action (KIA) while 10.5% died of their wounds after reaching the hospital. Fatality to total injured ratio peaked to 29% in 2001 and than stabilized to about 23%. Mean KIA to total casualty ratio was 21%. The rank structure of the fatalities was officers 8.6%, JCOs 7.3%, and Other Ranks 84.1%. Most of the soldiers died young, 51% being below 25 years of age. Out of the terrorist induced fatalities, 78.2% died of gunshot wounds and 21.5% by splinters and improvised explosive devices (IED). The ratio was reversed in enemy induced fatalities and in Kargil war. Fatalities peaked during June to November and declined in winters. Body region wise, 23.4% of all deaths were due to head injury, 8.4% due to neck and maxillofacial injury, 18.4% due to injury to lungs and 11% due to heart injury. Most frequent target of the fatal bullet was brain (25.4%), closely followed by lungs (22.5%) and heart (12.3%). When soldier died of splinters/IED, multiple body parts were injured in 57.5%, brain in 17.3%, face & neck in 3.5%, heart in 6.6%, lungs in 5.3%, abdomen in 3.5% and limbs in 5.8%. Fatality due to head and heart injury peaked in 2001, while multiple injuries peaked in 2000, declined in 2001 and peaked again in 2004 and 2005 ('p' < 0.001). In fatalities of Kargil war, chest injuries were less but multiple injuries were more. Conclusion: Most of the fatalities were due to gunshot wounds selectively aimed at head, face, neck and thorax. Therefore, a lightweight flexible and effective bulletproof protection for this area will conserve manpower.

330. Arora, R., et al. (2017). "Preliminary results from the comparison of simple limbal epithelial transplantation with conjunctival limbal autologous transplantation in severe unilateral chronic ocular burns." Indian journal of ophthalmology 65(1): 35-40.

PURPOSE: To compare the safety, efficacy, and clinical outcomes of simple limbal epithelial transplantation (SLET) with conjunctival-limbal autologous transplantation (CLAU) in severe unilateral ocular chemical burns., MATERIALS AND METHODS: Twenty patients of unilateral chronic ocular burns with more than 270degree limbal stem cell deficiency and a healthy fellow eye were divided into two groups - ten patients of Group A underwent SLET while ten patients of Group B were operated for CLAU. Patients were followed up for 6 months and assessed for a stable epithelialized ocular surface, extent of reduction in vascularization and forniceal reconstruction, improvement in corneal clarity and visual acuity., RESULTS: A stable epithelialized corneal surface was obtained in all patients, with a

significant reduction in the mean clock hours of vascularization in both the groups (P < 0.001). The mean symblepharon score showed a statistically significant reduction from 1.80 +/- 1.14 to 0.30 +/- 0.63 in Group A and 1.70 +/- 1.06 to 0.15 +/- 0.24 in Group B at 6 months. Corneal clarity, as well as best-corrected visual acuity, showed a statistically significant improvement in both the groups., CONCLUSION: Both the procedures, SLET and CLAU, were equally effective in achieving a stable ocular surface, forniceal reconstruction, and regression of corneal vascularization. The requirement of minimal donor tissue in SLET makes it a preferred option over CLAU in cases of uniocular chronic ocular burns.

331. Arosarena, O. A., et al. (2009). "Maxillofacial injuries and violence against women." Archives of facial plastic surgery 11(1): 48-52.

OBJECTIVE: To determine if patterns of facial injuries differed between those of female assault victims with maxillofacial injuries and those of female patients with maxillofacial injuries from other causes., METHODS: We reviewed the medical and dental records of 326 adult female facial trauma patients treated by otolaryngologists and oral/maxillofacial surgeons at the University of Kentucky Medical Center. Information abstracted included date of injury, dates of presentation for medical attention, mechanism(s) of injury, diagnoses, and treatments., RESULTS: While victims of intimate partner violence were more likely to have zygomatic complex fractures, orbital blow-out fractures, and intracranial injuries than were other patients with facial trauma, women assaulted by unknown or unidentified assailants were more likely to have mandible fractures (P = .004)., CONCLUSION: These results in conjunction with other presenting circumstances, such as delay in presentation, can assist the surgeon treating patients with maxillofacial injury in recognizing interpersonal violence against women.

---

332. Arosemena, M. A., et al. (2018). "Thyroid storm triggered by strangulation in a patient with underlying undiagnosed graves' disease." Endocrine Reviews 39(2).

Background: Thyroid storm is a life-threatening syndrome characterized by end-organ compromise. Presenting symptoms include tachycardia, high-output heart failure, agitation, altered mental status, fever, and respiratory distress. Thyroid storm may be precipitated by an acute event, such as thyroid surgery, infection or parturition. Blunt force, penetrating trauma, and suicide attempt by hanging have also been reported in the literature as causes of thyrotoxicosis resulting in thyroid storm. Strangulation is a not a well-known precipitant of thyroid storm. (1) Clinical Case: A 32-year-old African American female presented to the emergency department with shortness of breath after being sexually assaulted and strangulated. On arrival to the Emergency Department she was tachycardic, tachypneic and hypoxemic. On physical exam, proptosis and soft tissue swelling of the neck were noted. Chest x-ray revealed predominantly right-sided pulmonary opacities, suggestive of pulmonary edema (Figure 1). She was placed on non-invasive mechanical ventilation and later on required intubation. Her temperature reached 40.6°C and remained elevated despite acetaminophen and ice packs. Over the hospitalization she developed multi organ dysfunction and distributive shock requiring vasopressor support. Blood and tracheal aspirate cultures were sent with no evidence of microorganism growth. She remained unresponsive off sedation, so MRI brain was performed, showing no abnormalities. Thyroid function revealed fT4: 5.66 ng/dl (normal range, 0.93 - 1.70), T3: 309.9 ng/dl (80-200 ng/dL) and TSH <0.005 mcIU/mL (0.270 - 4.200 mcIU/mL) (Figure 2). A Burch- Wartofsky score was calculated: 75, highly suggestive of thyroid storm. She was started on treatment according to American Thyroid Association guidelines. Two days after treatment, thyroid hormones decreased significantly with T3 149.4 ng/dl and fT4 2.54 ng/dl. Additionally, her temperature, heart rate, pulmonary edema, and mental status gradually improved. On day ten, after five days of normal thyroid hormones, methimazole dose was decreased, hydrocortisone was discontinued, and propranolol was titrated off. She was extubated and safely left the Intensive Care Unit. Conclusion: This is the second reported case of thyroid storm secondary to manual strangulation and the first report of strangulation unmasking a previously undiagnosed Graves' disease. This case reveals how strangulation can produce severe thyroid injury and

subsequent thyroid storm and the importance of having high degree clinical suspicion for early diagnosis and decrease mortality.

334. Arslan, E. D., et al. (2015). "Assessment of traumatic deaths in a level one trauma center in Ankara, Turkey." European journal of trauma and emergency surgery : official publication of the European Trauma Society 41(3): 319-323.

Trauma management shows significant progress in last decades. Determining the time and place of deaths indicate where to focus to improve our knowledge about trauma. We conducted this retrospective study from data of trauma victims who were brought to a major tertiary hospital which is a level one trauma center in Ankara, Turkey, and died even if during transport or in the hospital between 1 March 2010 and 1 March 2013. The patients' demographic characteristics, trauma mechanisms, time frames and causes of deaths determined by physicians were recorded. Traumas were grouped as "high energy trauma" (HET) and "low energy trauma" (LET). Falls from ground level were defined as LET. 209 traumatic deaths due to trauma or trauma-related conditions were found in the study period. 161 of 209 (78 %) patients suffered from HET. Motor vehicle collisions (MVC) (56 %) were the most common mechanism of trauma followed by burns (16 %), falls (11 %), gunshots (9 %) and stabs (6 %) in this group and traumatic brain injuries (TBI) (41 %) were the most common cause of death followed by circulatory collapse (22 %) and multi-organ failure (20 %). 36 % of deaths occurred before arrival at hospital, 25 % in the first 24 h of admission, 18 % between 2nd and 7th day and 21 % after first week. Trimodal distribution of traumatic deaths was not valid for all types of injuries and the most important factor to decrease traumatic deaths is still prevention. Also we have to keep on searching to improve our knowledge about trauma management.

---

335. Arslan, M., et al. (2012). "Transorbital orbitocranial penetrating injury caused by a metal bar." Journal of neurosciences in rural practice 3(2): 178-181.

Transorbital intracranial injury is uncommon, representing 0.04% of penetrating head trauma with a high mortality rate. Orbital penetrating injuries may cause severe brain injury if the cranium is entered, typically via the orbital roof, the superior orbital fissure, or the optic canal. A 13-year-old male sustained a severe brain injury due to penetration of the right orbit with an iron bar. The bar entered the inferiomedial aspect of the orbit and emerged from the left occipital bone. Neurological examination revealed deep coma (GCS: E1M2V1) with fixed, dilated, and non-reactive pupils. The bar followed an intracranial trajectory, through the third ventricle and suprasellar cistern. The patient underwent an immediate exploration with removal of the bar. Unfortunately, he died 10 days postoperatively due to severe diencephalic injury with brainstem herniation. In this case report, we discuss the radiologic diagnosis and surgical management of transorbital orbitocranial injury by foreign body penetration.

336. Arslan, M., et al. (2012). "Spontaneous migration of a retained bullet within the brain: a case report." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES 18(5): 449-452.

Gunshot injury to the head is usually mortal, and spontaneous migration of a retained bullet is rare. We report the case of a 23-year-old man with a spontaneously migrated bullet within the brain. Cranial computerized tomography (CT) indicated that the bullet was lodged deeply in the left parietal region. The patient was conscious and had right homonymous hemianopsia. The bullet was close to the vital structures and deep-seated; therefore, surgical intervention was not considered. Two months after the injury, repeat CT revealed that the bullet had migrated posteriorly and caudally due to gravitational

factors. Management of the retained bullet was controversial. Removal of a deep-seated bullet may cause additional neurological deficit, but migration of a retained bullet may cause damage to vital structures, producing significant neurological damage. We proposed that the bullet in the brain should be removed if it could be reasonably accessed without causing additional neurological damage.

337. Arslantas, A., et al. (2001). "Inadvertent insertion of a nasogastric tube in a patient with head trauma." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery 17(1-2): 112-114.

This is a report of a 3-year-old boy with intracranial penetration of a nasogastric tube causing brain damage in the left frontal lobe. A computed tomography (CT) showed passage of the nasogastric tube via a fracture of the cribriform plate into the intracranial cavity. The tube was manually removed under antibiotic prophylaxis. The patient then underwent dural repair for rinorrhoea and was discharged in good health.

---

338. Arum, A., et al. (2018). "[A foreign object in the frontal lobe]." Ugeskrift for laeger 180(23).

In this case report a 77-year-old male tumbled in his lavatory and hit his head against a toilet roll holder. The holder penetrated his eye and orbita and left a 0.5 x 1 cm cylindrical piece of plastic inside his frontal lobe. He was admitted at a neurosurgical department, where the foreign object was removed. In this report, we summarise some of the basic principles of handling patients with a penetrating brain trauma, including risk of infection, control of bleeding and technical considerations before surgically removing a foreign object.

339. Arunkumar, M. J., et al. (1999). "Penetrating intracranial wooden object: case report and review of CT morphology, complications, and management." Surgical neurology 51(6): 617-620.

BACKGROUND: Penetrating intracranial wooden fragments after vehicular accidents are uncommon. The CT morphology, complications, and management in such cases are quite variable., CASE REPORT: A 27-year-old male was seen with a "twig" from a tree embedded firmly just below the right medial canthus after a motorcycle accident. Diagnosis of intracranial penetrating wooden object was made on CT scanning. The wooden stick, which had splintered into two, was extricated through a craniotomy in two operative sessions. However the patient succumbed to septicemia and meningitis on the twelfth day after the accident., CONCLUSIONS: The need for prompt extrication of these objects and the causes of high mortality in this condition are discussed. The importance of imaging the intracranial compartment in injuries involving the periorbital region is emphasized.

340. Arunkumar, P., et al. (2015). "Determined to Die! Ability to Act Following Multiple Self-inflicted Gunshot Wounds to the Head. The Cook County Office of Medical Examiner Experience (2005-2012) and Review of Literature." Journal of forensic sciences 60(5): 1373-1379.

Cases of multiple (considered 2+) self-inflicted gunshot wounds are a rarity and require careful examination of the scene of occurrence; thorough consideration of the decedent's psychiatric, medical, and social histories; and accurate postmortem documentation of the gunshot wounds. We present a series of four cases of multiple self-inflicted gunshot wounds to the head from the Cook County Medical Examiner's Office between 2005 and 2012 including the first case report of suicide involving eight gunshot wounds to the head. In addition, a review of the literature concerning multiple self-inflicted gunshot wounds to the head is performed. The majority of reported cases document two gunshot entrance wound defects. Temporal regions are the most common affected regions (especially the right and left temples). Determining the capability to act following a gunshot wound to the head is necessary in crime scene reconstruction and in differentiation between homicide and suicide.

---

342. Aryan, H. E., et al. (2005). "Gunshot wounds to the head: gang- and non-gang-related injuries and outcomes." Brain injury 19(7): 505-510.

PRIMARY OBJECTIVE: This study examined the differences between gang and non-gang-related incidents of penetrative missile injuries in terms of demographics, motivation, intra-cranial pathology, transit time, injury time and clinical outcome., RESEARCH DESIGN: Retrospective and prospective chart review., METHODS AND PROCEDURES: Between 1985-1992, 349 patients with penetrating missile injuries to the brain presenting to LAC-USC were studied., EXPERIMENTAL INTERVENTIONS: Inclusion criteria were implemented to keep the cohort as homogenous as possible. Patients excluded were those with multiple gunshot wounds, non-penetrating gunshot wounds to the head, systemic injuries and cases in which the motivation for the incident was unknown., MAIN OUTCOMES AND RESULTS: Gang-related shooting slightly out-numbered non-gang-related incidents. Demographic analysis showed both a male and Hispanic predominance for both gang- and non-gang-related victims and significant differences in gender, race and age. Occipital entrance sites were more common in the gang-related vs temporal entrance sites in the non-gang-related. Mean transit time to the emergency department for gang-related shootings was less than non-gang-related shootings (24.4 vs 27.8 minutes). Most shooting incidents took place between 6pm and 3am. No difference between survival and outcome was noted between gang and non-gang victims., CONCLUSIONS: Significant differences were found between gang- and non-gang-related shooting victims in terms of demographics, entrance site and transit time. No difference was found between injury time, survival and outcome between gang and non-gang populations.

---

343. Asahi, S. and M. Kagawa (1985). "[Penetration of cefotaxime into human cerebrospinal fluid]." The Japanese journal of antibiotics 38(6): 1680-1684.

The penetration of cefotaxime (CTX) into the cerebrospinal fluid (CSF) was monitored to evaluate the prophylactic efficacy of the drug against post-craniotomy infections. Doses ranged from 1 to 2 g were administered to patients with subarachnoid hemorrhage due to the rupture of cerebral aneurysm, traumatic cerebral contusion, or subdural edema accompanied by intracerebral hemorrhage, by intravenous drip infusion over a period of 30 or 60 minutes. CTX readily entered the CSF with concentrations exceeding MICs against the major pathogens occurring after craniotomy. CTX proved to be effective in the prevention of post-craniotomy infections in noninflammatory situations, especially after surgery in the case of cerebral traumas or subarachnoid hemorrhage.

344. Asal, N., et al. (2019). "Olfactory Fossa and New Angle Measurements: Lateral Lamella-Cribriform Plate Angle." The Journal of craniofacial surgery 30(6): 1911-1914.

OBJECTIVES: The authors investigated the olfactory fossa (OF) in patients with unilateral nasal septal deviation (NSD) and presented the lateral lamella-cribriform plate angle (LLCPA)., METHODS: Paranasal sinus computed tomography images of 300 adult subjects with unilateral NSD (111 males, 189 females) were evaluated retrospectively. Septal deviation angle (SDA), Keros Classification, OF depth and width, LLCPA; and orbital plate and cribriform plate (OPCP) distance were measured., RESULTS: The OF depth values (ipsilateral, contralateral) were found as Keros III >Keros II >Keros I (Padjusted <0.0175). The OF width values (ipsilateral) were detected as Keros I >Keros II and Keros I >Keros III (Padjusted <0.0175). In patients with higher SDA values, ipsilateral OF depth values decreased (P <0.05). The LLCPA and OPCP values were higher in Keros I and lower in Keros III (P

<0.05)., CONCLUSION: In patients with lower LLCPA and OPCP, endoscopic sinus surgery will be more dangerous for trauma to lateral lamella and intracranial penetration.

---

345. Asano, K., et al. (2018). "Prototype screwdriver stopper to avoid intracranial penetration injury." Neurosurgical review 41(3): 895-898.

Screwdriver slipping from the tapping screw head (screwdriver slip) represents a very dangerous situation that leads to the risk of entry into the intracranial operation field. We have developed a screwdriver stopper device to attach to the top of the screwdriver in order to prevent intracranial penetration injuries. We performed 48 craniotomies in our institute. The instrument is made from clear acrylic with a central hole (diameter, 3 mm). We checked the number of screwdriver slip events, as a precursor to intracranial penetration injury, in screwdrivers from five different companies, and compared the results. We used 496 tapping screws in 512 tightening procedures. Although screwdriver slip occurred at an overall rate of 17/512(3.3%), we completely avoided serious intracranial penetration injuries. No significant differences in rates of screwdriver slip were seen between the five companies (chi2 test, p = 0.997). Screwdriver slip is a precursor to intracranial penetration injury, but cannot be avoided with cross-type screwdrivers. Many neurosurgeons may be operating without knowledge of the potential risk of intracranial penetration injury. The screwdriver stopper described herein may prove extremely useful for preventing intracranial penetration injuries during neurological surgery.

346. Asatryan, A. A., et al. (2010). "Improved method of primary cranioplasty using autologous bone crumbs." New Armenian Medical Journal 4(3): 38.

Introduction: Surgical procedures performed due to craniocerebral trauma (CCT) often result in skull defects, which afterwards cause functional-morphological changes of CNS and pose risk for unprotected brain. The advantages of primary and early cranioplasty are permanently stated in the literature. For primary plastic of skull defect the autologous bone crumbs are used in the Surb Astvatsamayr Medical Center for approximately 25 years. The objective of this study was to increase the effectiveness of the method. Material and Methods. During 2005-2009 the primary cranioplasty was performed in 126 children at the ages from 1 month to 17 years. There were 26 closed and 71 depressed skull fractures, from which 31 injuries were penetrating. Mild brain contusion was in 30 cases, moderate in 29 cases and severe in 7. In 39 cases fractures were located in two or more bones of the skull (more often temporal, parietal and occipital bones), in the rest cases injury was located in the right parietal region. Intracranial acute hemorrhages were diagnosed in 29 patients (26 epidural and 3 subdural hemorrhages). Results and discussion: Since 2005 brain computed tomography (CT) has been used as an additional diagnostic method of CCT, which allows describing precisely the nature, volume and locations of intracranial changes, thus making planning and performance of the surgical procedure more effective. Having initial information about the location of fractures and hematoma made possible to perform intracranial procedures (removal of contusion and hematoma) using bone plastic or two separate bone resection entries (windows) by leaving 1 cm width bone bridge between them. It allowed keeping natural vault of skull curvature and at the same time to overcome some small skull defects using autolplastic method. This modification was used among 9 patients in our Clinic. In all cases the complete regeneration of bone defect and better plastic results were achieved. Conclusion: Having pre-surgical CT results of brain injury gives opportunity to use improved method of cranioplasty more widely and improve treatment outcomes.

347. Ascanio, L. C., et al. (2019). "Distal Parent Vessel Occlusion of 2 Superior Cerebellar Artery Fusiform Aneurysms: Report of 2 Cases and Literature Review." World Neurosurgery: X 3.

Background: Fusiform superior cerebellar artery (SCA) aneurysms are rare, and their management represents a technical challenge. In complex aneurysms, endovascular parent vessel occlusion of the SCA may be a treatment option. Here, we present 2 cases of fusiform SCA aneurysms,

1 ruptured and 1 unruptured, as well as our institution's management with parent vessel occlusion. We also provide a review of the literature. Cases Description: Case 1: A 42-year-old male was transferred from an outside hospital with subarachnoid hemorrhage. On admission, the patient had a Glasgow Coma Scale score of 8, a Hunt and Hess grade 4, and a Fisher grade 4. A diagnostic angiogram demonstrated a right SCA fusiform lesion with proximal and distal dilatations of 1.45 mm and 5.35 mm long, respectively, likely representing a single dissecting pseudoaneurysm. The distal dilatation was coiled, resulting in parent vessel occlusion. The patient recovered clinically and was discharged in stable condition. Case 2: A 27-year-old female was transferred from an outside hospital due to a brainstem stroke. A diagnostic angiogram revealed an S2/S3 segment left SCA fusiform lesion, likely representing a dissecting aneurysm. The patient was neurologically intact at admission and managed conservatively. At the 2-month follow-up angiogram, the dissection had extended along the length of the SCA. Consequently, the patient underwent coil embolization of the distal left SCA. At the 6-month follow-up, the vessel remained obliterated and the patient's neurologic status had improved. Conclusions: Endovascular coil embolization of fusiform SCA aneurysms offers a reasonable and safe treatment approach.

---

348. Aseeva, K. S., et al. (2014). "Rare case of stroke, caused by bullet." Cerebrovascular Diseases 37: 386.

Background: Among the determined etiologies of the ischemic stroke there is quite rare cause - bullet embolism. There are a few cases with bullet embolism described, approximately 200 cases all over the world. Case description: 13 year-old patient R.A. was admitted to an accident and emergency department. His mother stated, that two days ago, her son had a pneumatic gunshot to the chest, and she took out the bullet, then her son's BP fell to the 70/40. They referred to hospital, where he was examined by a surgeon, underwent chest X-ray (NIL) and primary surgical treatment of the wound on the chest and was let home. The next day the boy experienced severe headache, weakness and absence of any active movements in left extremities, somnolency and vomit for three times. On general examination - in the heart area on the chest there was a skin defect of 0,5∗0,5 sm size. Neurological examination revealed left hemiplegia and hemihypestesia, torpor. Investigations: Routine analyses were NIL. Head CT showed ischemic area 4,7∗ 1,8∗4,7 sm on the right, 'Hyperdense right MCA' sign, foreign body of the pyramid of right temporal bone. Cranium X-ray confirmed the foreign body to be a bullet. On the ECG was sinus arrhythmia with heart rate of 72-107 per minute. Ultrasound of the head and neck vessels showed the occlusion on the internal carotid artery on the right at the siphon level, and occlusion of the right MCA on the M1 and M2 levels. CT angiography of the head showed right inner carotid artery, right MCA thrombosis. Chest CT displayed wound channel going inside of the pericardium with no signs of excess liquid, contusion of lungular segments. Conclusion: This case presentation shows that even asymptomatic gunshot may cause delayed embolism of different vessels, including cerebral arteries and may lead to serious consequences, not depending on the patient's age.

---

349. Aseri, S., et al. (2016). "A rare case of low pressure headache secondary to spontaneous intracranial hypotension treated with epidural blood patch." Regional Anesthesia and Pain Medicine 41(2).

Introduction Spontaneous intracranial hypotension is a rare disorder that may have a varied presentation. This leads to a delay in the diagnosis and treatment. The recent advances in the radiological techniques have made it possible to diagnose the entity with a greater confidence. Due to the paucity of cases there is no controlled study to determine the best method of treatment. Therefore it is important that every case is reported and an inference is made regarding the presentation, diagnosis and method of treatment. We have had one such case of spontaneous intracranial hypotension. A 71 years old male patient was referred by General Practitioner to neurologist at the Walton Centre for Neurology and Neurosurgery with six weeks history of headache. He was seen by neurologist and had a CT scan and was referred to Neurosurgeon. Neurosurgeon reviewed him and an MR Scan was done and based on MR finding patient was referred to Department of Pain Medicine for intervention. Results/Case

report History: Patient was complaining of 6 weeks history of Headache, throbbing type, associated with tinnitus. It was positional headache, worse on standing and eased by sitting and lying down. Aggravating factors were coughing, sneezing and running. Associated with Nausea and dizziness. Examination: Occipital headache, no neck stiffness, no other neurological impairment. Investigations: CT SCAN: bilateral chronic subdural heamatoma, (no aneurysm or malformation seen) MR SCAN: meningeal thickening (? Subdural collection) and Slumping of midbrain and feature of chronic intracranial hypotension. e/o subdural collection (? SDH) Diagnosis: Chronic low pressure headache secondary to spontaneous intracranial hypotension Treatment: Epidural blood patch was done in theatre under complete aseptic precaution and epidurogram was done to confirm needle epidural space. 30ml of patients autologas blood was injected into epidural space. Patient had immediate relief of headache at rest and relief of Headache while sneezing & coughing after 24 hrs of blood patch. Discussion In spontaneous intracranial hypotension there is often the absence of definitive cause like history of dural puncture or penetrating trauma. The cardinal signs and symptoms are orthostatic headache which is increased in the upright position and decreases at recumbent position(1) and low CSF pressure Other atypical cases have been reported with no postural headache, normal CSF pressure (2) and normal cranial MRI(3). A German neurologist called Schaltenbrand introduced the term 'aliquorrea' to describe spontaneous intracranial hypotension in the absence of any precipitating factors like dural puncture or trauma (4). However Henry Woltman of The Mayo clinic described in 1940 that frontal or occipital headache comes on when the patient is up and leaves when the patient lies down(5). This headaches affect women more than men and typically occur in the middle age but can also affect children and the elderly(6). The incidence is roughly 5 per 100,000. Generally the spontaneous intracranial hypotension occurs due to leak from the spinal cord and there is CSF in the dural sac. There may be a weakness in the meninges that lead to a tear and CSF leak. There have also been accounts of fragile arachnoid cysts. (Figure presented).

350. Asfar, S. N., et al. (1995). "The ICU outcome of head injury in Basrah, Iraq." Journal of Neurological and Orthopaedic Medicine and Surgery 16(4): 237-241.

A prospective study was carried out on 60 acutely head-injured patients admitted to the Intensive Care Unit at Basrah Teaching Hospital, Basrah, Iraq. The study assessed parameters that may affect the outcome of the patients, including age, sex, time and mode of injury, clinical state on admission, and management. Of the 60 patients, including age, sex, time and mode of injury, clinical state on admission, and management. Of the 60 patients, 22 died, 7 had some degree of disability, and 31 recovered fully. Significantly good results were obtained in younger age groups of either sex, in those received within the first 4 hours following injury, in those who sustained shell and gunshot wounds, and in those who experienced a fall from height, in those with Glasgow Coma Scale of 11-15, in those with depressed fracture with or without penetrating injury in comparison with basilar fracture, and in those with intracerebral hematoma in contrast with acute subdural hematoma. The most common cause of death was intracranial hematoma.

---

351. Ashraf, M. F., et al. (2020). "Frequency of intracranial hemorrhages in medicolegal death cases: A cross sectional study." Pakistan Journal of Medical and Health Sciences 14(4): 949-951.

Aim: To examine the frequency of intracranial hemorrhages in medicolegal death cases. Study Design: Cross-sectional Place and duration of study: Department of Forensic Medicine & Toxicology and Department of Radiology, Khawaja Muhammad Safdar Medical College Sialkot from 1st January 2019 to 30th June 2020. Methodology: Total one hundred and ten patients were enrolled which include, dead bodies directly landing in dead house for postmortem or after death in wards for autopsy. Patient's complete demographics were recorded. Histopathology performed by tissue specimens of patients in which it is required. Blood sample was taken for alcohol and toxicological analysis. Cases were examined by using X-rays, CT Scans and MRI (where needed) complete autopsies were carried out. The decomposed bodies were excluded. Results: Mean age of patients was 33.18±16.68 with BMI

23.52±17.65. Intracranial lesions accounted for 12.68% of the total deaths. Mostly patients aged >23-35 were mainly affected by intracranial lesions. Percentage of traumatic (road traffic accidents) cases were greater than non-traumatic (cerebro-vascular accidents). Ratio of males was excess than that of females. Intracranial lesions separate were seen in 29(26.36%) patients. Subarachnoid hemorrhages were the commonest intracranial lesions. Pneumonia represents the commonest complication in delayed death. Conclusion: Intracranial cause of death was minimum in number but they showed majority of sharing injuries in other anatomical sites.

352. Asimi, N., et al. (2013). "Penetrating vascular trauma resulting in bullet emboli: A case report, literature review, and recommendations." Chest 144(4).

INTRODUCTION: Although rare a bullet embolism following a penetrating vascular trauma requires a thorough investigation and timely diagnosis and management 1,2. Embolization of the heart is quite infrequent and usually involves the right heart and pulmonary vasculature 2. We present a unique case of a bullet migration from the carotid sinus to pulmonary vascular bed. CASE PRESENTATION: A 25 year-old male trauma patient with a gunshot wound to the left face of unknown gun at unknown range was brought in to our Trauma Center. Glasgow Coma Scale (GCS) on arrival was 3T. Computer tomography (CT) imaging was consistent with bullet fragment in the right superior aspect of the posterior fossa just under the tentorum. The patient was stabilized and right lateral ventricular external drain was placed. Follow up CT (4hours after the initial one) was significant for increased edema, phenumocephalus, and absence of previously noted bullet fragment. A new stable metallic density within the heart silhouette was noted on a portable chest x-ray (CXR) approximately 5 hours later. Follow up CT (done 3 hours later) was significant for a 5mm metallic foreign body within vascular bed of partially collapsed left lower lung field just posterior to the heart. Given the patient's critical and unstable neurological condition cardiothoracic surgery service recommended to continue broad spectrum antibiotics and to re-evaluate the bullet after patient stabilizes or in case the bullet dislodges or becomes symptomatic. Within 48 hours of admission, the patient was transferred to a highly specialized neurological center. At the time of transfer there were no complications associated with the bullet embolus. DISCUSSION: The diagnostic and therapeutic management of penetrating injuries of the great vessels, particularly involving projectile embolization, continue to be controversial 2, 3. The lack of experience and centralized body of evidence contributes to the difference in recommendation for diagnosis and management. CONCLUSIONS: Undoubtedly there is a need for evidence based guidelines to aid trauma surgeons in recognition, diagnosis and management of bullet emboli. Furthermore, establishing risk stratification and timetable of embolization would be of great value in treating penetrating vascular injuries with fragment migration.

353. Asiminei, A. G., et al. (2010). "In vivo assessment of brain motion and deformation patterns by magnetic resonance imaging and its implication for cerebral contusion pathogenesis research." Brain injury 24(3): 253.

Objectives: Among all types of injuries worldwide, Brain Injury is the most likely to result in death or permanent disability. This indicates a critical need for more effective ways of understanding the mechanisms of TBI (traumatic Brain Injury) in order to prevent brain injuries. Previous studies indicate the relative brain-skull motion as a determinant factor in the occurrence of TBI, particularly for closed brain injuries without skull fractures. Although relative brain motion has been studied for decades, the patterns of relative brain motion with respect to the skull are not yet thoroughly understood. This study further investigates brain motion patterns in humans under quasistatic loading conditions using experimental Magnetic Resonance Imaging (MRI). Method: 15 human volunteers with different age were scanned in four different head positions (left lateral, right lateral, prone and supine) with a resolution of 1.1 pixels/mm and using a 3 Tesla MRI scanner. Image analysis and segmentation were performed using MimicsTM . Pair-wise comparison (prone vs. supine and left vs. right) of the obtained 3D models was performed for each volunteer by subjecting the skull models to a global registration

process and alignment using 3-maticTM . The whole brain motion, the regional brain motion patterns and the regions where brain deformation is dominant were analyzed using the Focus Inspection 4.8 software. Results: Head movement in the coronal plane determines a whole brain translation in the coronal plane with a slight rotation in the axial plane with maximum amplitudes between 2.01mm and 5.67mm. Head rotation in the sagittal plane leads to a whole brain rotation in the same plane with individual maximum amplitudes between 2.65mm and 12.02mm. These maximum amplitudes were seen at the inferolateral and medial cortex of the frontal and temporal lobes. For the lateral ventricles displacement, individual maximum values varied between 1.19mm and 3.44mm for lateral head movement and between 0.01mm and 6.38mm for prone-supine head movement. In general, higher displacement amplitudes were observed for the older volunteers. Beside head displacement, also brain deformation was observed, again being most pronounced for prone-supine head movement. Conclusions: The relative brain-skull movement is most pronounced at the orbital gyri, the lateral aspect of the frontal lobes and at the inferolateraland medial aspect of the temporal lobes. More important brain displacement and deformation occur in prone-supine head movement. The present study provides a possible etiology for the frontal and temporal lobes as being predilection sites for cerebral contusions. The results have also implications for the use of navigation in brain surgery, radiation therapy and for brain cine-MRI modalities.

354. Aslan, S., et al. (2006). "Air guns: toys or weapons?" The American journal of forensic medicine and pathology 27(3): 260-262.

Air guns and blank guns may appear relatively harmless at first glance, but they are, in fact, potentially destructive, even lethal, weapons. Approximately 2 to 2.5 million nonpowder firearms are sold annually, and again approximately 12.9 per 100,000 population are treated for such injuries in hospital emergency departments each year in the United States. Unfortunately, these guns are considered to be a toy for children. Therefore, incidents of air gun injuries are gradually increasing. Although such injuries may initially be considered trivial, it may signify severe internal tissue pathologies. These apparently trivial injuries may have catastrophic consequences if unnoticed. In this study, we report 4 cases with head injury due to a shot by these guns. The cases indicate that these people had used the guns belonging to their parents for the purpose of suicide. The cases also show that these machines are not innocent.

---

355. Assaf, A. A. (1985). "Traumatic retinal detachment." The Journal of trauma 25(11): 1085-1089.

Six hundred forty-three patients had retinal detachment surgery during 81/2 years; 17.6% were under the age of 30 years. Analysis of this group of patients showed that males were more commonly affected than females (68%). Trauma was the most frequent cause, reported in 40% of cases. Dialysis was the commonest retinal break, occurring in 51% of patients, and 73% of these occurred in the inferior temporal quadrant. In patients with a history of trauma, the type of the retinal break produced and operative success was related to the severity of ocular damage, with more successful outcomes in nontraumatic cases and fewer of these in cases of ocular perforation.

356. Assiri, Z. A., et al. (2020). "Retrospective radiological evaluation to study the prevalence and pattern of maxillofacial fracture among Military personal at Prince Sultan Military Medical City [PSMMC], Riyadh: An institutional study." Saudi Dental Journal 32(5): 242-249.

Purpose: The aim of the present study was to analyze the prevalence, causes, and patterns of maxillofacial fractures retrospectively in patients who were treated at Prince Sultan Military Medical City, Riyadh, Saudi Arabia. Methods: Patients′ medical records were reviewed from 2005 to 2014. Patient′s age, gender, cause, and the pattern of maxillofacial fractures were studied. Associated body injuries were also recorded. Results: Out of 263 patients, 207 (78.7%) were male and 56 (21.3%) were female. The age range was from 3 to 67 yr with a mean age of 26.21 yr. Road traffic accidents 236

(89.8%) were the most commonly reported cause of maxillofacial fractures, followed by falls 14 (5.3%), assaults 4 (1.5%), gunshot 3 (1.1%), and sport accidents 2 (0.8%). Most of the cases of maxillary fracture were Le Fort II 27 (36.5%), followed by LeFort I 23 (31.1%), LeFort III 20 (27.0%) and palatal fractures 4 (5.4%). Of the mandibular fractures, parasymphysis fractures constituted 61 (27.4%), body 50 (22.4%), condyle 45 (20.2%), angle 40 (17.9%), symphysis 16 (7.2%), ramus 7 (3.1%) and coronoid 4 (1.8%). Zygomatic complex fractures 110 (94.8%) were the most commonly reported fractures in the mid and upper facial region. Other facial fractures included orbital floor 61 (97.0%), naso-orbito-ethmoidal 18 (19.8%), and frontal 12 (13.2%). Conclusion: Road traffic accidents were the most common cause of maxillofacial fractures. Spreading awareness among young drivers regarding road safety regulations is highly recommended.

357. Astarci, P., et al. (2009). "Endovascular treatment of acute aortic isthmic rupture: concerning midterm results." Annals of vascular surgery 23(5): 634-638.

BACKGROUND: We evaluated midterm results of endovascular management of traumatic aortic isthmic ruptures., METHODS: Between 2001 and 2008, 10 patients (seven males, mean age 38 years) underwent endovascular treatment of an acute aortic rupture. Eight procedures were emergent, with four cases of hemodynamic instability with Glasgow scores of 3, 5, and 7. Associated traumas were severe brain, liver, and pelvic bone injuries. All procedures were performed with transoesophageal echocardiography monitoring. We used two AneuRx and nine Medtronic Talent or Valiant stent grafts., RESULTS: All patients survived their traumatic isthmic rupture. In nine patients, stent-graft deployment was successful. One patient experienced a distal migration needing a laparotomy and deployment of an additional new thoracic stent graft. The mean intensive care unit stay was 48 hr (range 24-168). The mean hospital stay was 11 days (range 8-43). All patients were controlled clinically and by contrast computed tomography (CT) according to the EUROSTAR protocol. There were no endoleaks, stent graft-related complications, or late deaths during a mean follow-up of 49 months. The control CT showed a lack of apposition of the proximal part of the stent graft at the inner curve of the aortic arch in three patients., CONCLUSION: The midterm results of endovascular treatment of acute traumatic aortic isthmic rupture are encouraging and compare favorably to the surgical approach. Late follow-up is required to exclude possible stent-graft complications, especially in young patients with angulated aortic arches.

358. Atabey, C. and T. Ersoy (2012). "An unusual penetrating craniocerebral injury due to landmine explosion: a case report." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES 18(2): 181-184.

Penetrating landmine injuries are the unavoidable consequences of military conflicts. They are potentially life-threatening. The mortality rates in the literature range from 23% to 92% and are considerably higher in patients admitted with poor neurologic state. Penetrating craniocerebral injuries require early surgical management designated to prevent infection and remove foreign objects, necrotic tissue and complicating blood clots, as well as to minimalize post-traumatic sequelae. We report herein an interesting case of penetrating intracerebral injury with giant shrapnel due to landmine in a 20-year-old young man.

---

359. Atac, K., et al. (2004). "Foot drop due to cranial gunshot wound." Military medicine 169(7): 568-569.

OBJECTIVE: We present a case of foot drop from hemorrhagic contusion after cranial gunshot, which has never been reported., METHODS: A 21-year-old man was admitted with inability of dorsiflexion 1 day after a tangential gunshot wound of the scalp. The scalp skin was cut by the rifle bullet. He had foot drop and his neurological examination was normal except for weakness at dorsiflexion of the right foot. Pathological reflexes and sensation failure were not detected. T1- and T2-

weighted magnetic resonance images showed hyperintense contusion at the right superior frontal gyrus and mild subdural hemorrhage. Peripheral nervous system examination was electrophysiologically normal. Motor-evoked potentials showed the location of the lesion at the motor cortex because no electrical record was obtained from the right anterior tibial and extensor digitorum brevis muscles, and there was a normal record on the left. Six months later, the patient's neurological examination was uneventful., CONCLUSION: When a cranial gunshot wound injury victim presents with foot drop, the central causes should be included in the differential diagnosis list.

360. Atalar, M. H., et al. (2007). "[Diffuse cerebrovascular air embolism on CT secondary to cardiopulmonary resuscitation]." Kardiyopulmoner resusitasyon sonrasi BT'de saptanan difuz serebrovaskuler hava embolizmi. 13(4): 319-321.

Air embolism is known to be a complicating factor in several clinical settings, including thoracic, cardiovascular and neurosurgical operations, central line placement, penetrating thoracic and cranial trauma and haemodialysis. Computed tomography (CT) is useful for showing cerebral air embolism. However, CT demonstration of massive air in all of the major cerebral arteries is extremely rare. In this report, we present a 45-year-old woman with cerebrovascular pneumoangiogram on postmortem CT examination after an unsuccessful posttraumatic cardiopulmonary resuscitation and discuss the possible mechanisms of pneumoangiogram.

---

361. Atawneh, A. F. (1974). "Injuries of the common and internal carotid arteries." Journal of the Kuwait Medical Association 8(1): 41-48.

Indirect injuries to the carotid arteries without penetrating wounds in the neck are less well recognized than those with penetrating wounds. The vessels of the neck are vulnerable to traumatic injury because of their close proximity to the skin and lack of bony protection. The effects of carotid obstruction may be falsely attributed to direct injury to the brain. Intimal tear (leading to thrombosis) is the most frequently encountered lesion. This is due either to a direct blow to the artery or to severe stretching i.e., sudden stretching and rebound causing intimal trauma. The media also may be torn but not the adventitia. Most of these lesions are at or near the bifurcation; a striking number are between the bifurcation of the artery and the base of the skull. Half of the patients have bruises or abrasions to the skin of the neck. In the early cases the diagnosis was only made at autopsy.

---

362. Atia, A., et al. (2021). "Distribution of wounding patterns in casualties from mass shooting events." Trauma (United Kingdom).

Introduction: The incidence and severity of public mass shootings, and mass casualty incidents (MCI), continues to rise. Understanding the wounding pattern and incidence of potentially preventable death after these incidents is key not only to Health System and Trauma Center emergency response planning but also to community outreach and initial emergency interventions. Methods: A retrospective study of autopsy reports after events with at least 10 fatalities exclusive of the assailants identified via the Federal Bureau of Investigation database from 1 January 1999 to 31 December 2020 was performed. Sites of injury, identification of weaponry, and identification of potentially survivable wounds were compiled. Results: Nine events including 203 victims were reviewed. Overall, 56% of gunshots were to the head/neck/face; 37% were to the chest; 43% were to the abdomen/torso/back; 31% were to the lower extremity; and 36% were to the upper extremity. On average, there were 29 fatalities per event. Conclusion: Emergency response disaster care strategy should focus on immediate point of care at the site of wounding by both the civilian population and medical personnel, as well as rapid extrication of victims for definitive medical care. Review of these autopsy results indicates exsanguination, often treatable, is the primary cause of death—supporting community education efforts in hemorrhage control. The location of the wounding patterns seen in this study warrants primary integration of

craniomaxillofacial, orthopedic trauma, neurotrauma, and surgical critical care/trauma surgical specialists into the initial response team for MCI.

363. Atreya, A., et al. (2016). "Pressure cooker - A potential hazard in domestic setting." Kathmandu University Medical Journal 14(54): 181-183.

Pressure cooker is an integral part of Asian kitchen, and is frequently used in Nepal. Steam under pressure generated while cooking has high boiling point and great penetrating power. The use of pressure cooker in kitchen is associated with unintentional injuries that mostly include pressure cooker burns. In rare instances the pressure cooker may accidently explode and may cause serious injuries. The same mechanism is used in making explosive device for mass homicides. An unusual case of penetrating facial injury sustained in a pressure cooker explosion in a domestic setting is reported along with a brief review of literature on pressure cooker explosions.

365. Atwood, R. E., et al. (2020). "Levetiracetam Is Safe and Effective for Post-Traumatic Seizure Prophylaxis for Combat-Related Traumatic Brain Injury: A Retrospective Cohort Study." Journal of the American College of Surgeons 231(4): S175.

Introduction: Post-traumatic seizure prophylaxis is recommended in patients with traumatic brain injury (TBI) at high risk for post-traumatic seizures, but there is no consensus on the optimal pharmacologic therapy. Levetiracetam is frequently used for seizure prophylaxis in combat-related TBI, but its efficacy and safety in this patient population have not yet been described. Methods: A retrospective cohort of 687 consecutive casualties (Caring for Combat Casualties Database) transferred to the continental US from October 2010 to December 2015 was analyzed; 71 patients with combat-related injuries and radiographic evidence of depressed skull fractures or intracranial hemorrhage were included. Data collection included demographics and injury characteristics including initial Glasgow Coma Score (GCS), CT findings, interventions, and 6-month Glasgow Outcome Score (GOS). Results: All patients in this cohort were male, with an average age of 25 (median 24; interquartile range [IQR] 4.5) and average Injury Severity Score (ISS) of 28 (median 27; 15). The most common mechanism of injury was explosive blasts (76%). Penetrating TBI was common (51%). Most patients (87%) received levetiracetam for seizure prophylaxis, with 2.8% receiving phenytoin. The remaining 13% were cleared by neurosurgery for no prophylaxis. Two patients developed seizures while on seizure prophylaxis (2.8%). Both of these patients suffered transcranial gunshot wounds and ultimately died. No serious adverse effects were attributed to levetiracetam. Conclusion: Levetiracetam appears to be a safe and effective medication for post-traumatic seizure prophylaxis in Caring for Combat Casualties patients. The rate of post-traumatic seizures in combat-related TBI on appropriate prophylaxis is low.

---

366. Augustin, A., et al. (2021). "A case of an unusual penetrating brain injury." British Journal of Surgery 108(SUPPL 6): vi88.

Introduction: Penetrating brain injuries (PBI) are less common than closed head traumas. Interest in frontal lobe injuries dates back to 1848's famous Phineas Gage incident. Here, we report a case of a construction worker, who showed a remarkable neuropsychiatric outcome following a workplace accident. Case Presentation: 45year old gentleman came with complaint of a foreign body accidentally lodged in his forehead. He had no neurological deficits or CSF leak. X-ray revealed that a 5.5cm metallic screw was penetrating his skull, headfirst; CT revealed that approximately 3cm of the screw was in the frontal sinus. He was given antiepileptics and antibiotics prophylactically. Surgically the screw was removed by raising a bone flap and mobilizing the screw carefully by cutting the dura and

adequate irrigation, causing minimal damage to the brain parenchyma. The dural deficits were repaired and the frontal sinus was canalized, then a drain was placed, and the patient was shifted to ICU for postoperative monitoring. Discussion: It is important to prognosticate PBI as they can have neurological deficits that may be lifelong. Understanding the mechanism of injury, aggressive medical management and immediate surgical intervention may lead to improved outcomes. A foreign object of the size of 5.5cm, completely penetrating the skull would have otherwise resulted in extensive parenchymal damage. Literature suggests that no two people have an identical frontal sinus. In our patient the size the frontal sinus has served the purpose of protection against PBI and has resulted in minimal parenchymal injury (of only about 1cm).

---

367. Auh, Y. H., et al. (1980). "The excessively small ventricle on cranial computed tomography: clinical correlation in 75 patients." The Journal of computed tomography 4(4): 325-329.

Excessively small ventricle (ESV) was demonstrated in 75 (8.3%) of 9,000 patients over 15 years of age examined by cranial computed tomography (CT). The patients had no other CT abnormality except for ESV. Detailed retrospective analysis of clinical records of these 75 patients revealed four major groups of patients: 1) those with seizures (24%); 2) those with headaches (24%); 3) those with acute non-penetrating head trauma (21.5%); and 4) those with benign increased intracranial pressure (8%). The remaining patients (22.5%) had a variety of cerebral derangements.

368. Aulino, J. M., et al. (2005). "Temporal lobe intraparenchymal retained foreign body from remote orbital trauma." AJNR. American journal of neuroradiology 26(7): 1855-1857.

We present the case of a 35-year-old man with a new onset of seizure disorder who was found to harbor an intraparenchymal retained foreign body related to remote orbital trauma. Imaging revealed a rim-enhancing anterior medial temporal lobe mass. Histologic evaluation of the resected mass showed evidence of acute and chronic inflammation with associated foreign material. The patient described a "bar fight" 16 years previously in which he received a blow to the orbit with a pool cue stick. The diagnosis of a foreign body reaction should be considered when an intraparenchymal mass is identified in this location.

369. Aurangzeb, A., et al. (2011). "Predisposing factors, clinical presentation and outcome of repeated aspiration in cerebral abscess through a drainage tube in situ." Journal of Ayub Medical College, Abbottabad : JAMC 23(4): 58-60.

BACKGROUND: Cerebral abscess is a serious and life threatening complication of several diseases. Aspiration of the abscess cavity versus excision of capsule are still in debate for the capsulated, large, superficially located abscesses especially in patients with poor surgical fitness. The objective of this study was to look for the clinical presentation and outcome of patients with repeated aspiration in cerebral abscess through a drainage tube in situ., METHODS: This prospective study was conducted in Department of Neurosurgery, Ayub Medical College, Abbottabad from Jan 2010 to Jun 2011. Twenty-three patients with age ranges 6-21 years who had large, solitary, capsulated, superficially located abscesses, were included in this study. These patients had poor American Society of Anaesthesiologists (ASA) grading (grade III and IV). After thorough clinical examination and workup, patients were subjected to operative procedure. The procedure included placement of 8 size nasogastric tube in the abscess cavity through a single burr hole. Under strict aseptic conditions, repeated aspiration of pus was done through the drain daily for 2-4 days consecutively at intervals of 24 hours. The demographic data. predisposing factors, clinical presentation, and outcome of patients with repeated aspiration through drain placed in abscess cavity were recorded. Postoperatively, gadolinium enhanced CT-scan was done twice in the first month at the span of two weeks each, later on monthly for next 3 months. The CT-scans were reviewed for recurrence or any other possible intracranial complications. Patients were followed for duration of 3 to 6 months., RESULTS: The predisposing factors found were congenital

heart disease in 7 (30.4%) patients, spread of contagious infections like mastoiditis/Chronic suppurative ottitis media in 5 (21.7%) patients, sinusitis in 2 (8.6%) patients, meningitis in 5 (21.7%) patients, septicemia in 3 (13.7%) patients, and penetrating cranial injury in 1 (4.34%) patients. In 16 (69.5%) patients presenting complaints were headache and vomiting, altered sensorium in 8 (34.7%) patients, hemiparesis in 9 (39.1) patients, aphasia in 3 (13.1%) patients, papillodema in 2 (8.7%) patients, and seizures in 1 (4.34%) patients. The abscess resolved in 19 (82%) of patients, recurrence occurred in 2 (8.7%) of patients, and death occurred in 2 (8.7%)., CONCLUSION: Cerebral abscess is a life threatening condition requiring aggressive management measures. Aspiration of cerebral abscess with repeated aspiration through a drainage tube is a life saving in patients with poor ASA grade with low recurrence of abscess formation and low mortality.

---

371. Austin, A. E., et al. (2013). "Multiple injuries in suicide simulating homicide: report of three cases." Journal of forensic and legal medicine 20(6): 601-604.

Multiple inflicted injuries in traumatic deaths usually indicate homicide. Three cases are reported where homicide was initially suspected due to findings at the death scene and the apparent nature of the injuries however, after investigation, involvement of any other individuals in the deaths could be excluded. Case 1: A 52-year-old male was found with multiple stab wounds. At autopsy, 36 stab wounds were identified, the majority of which were superficial. Only two stab wounds had penetrated deeply. Case 2: A 19-year-old female was found with three gunshot entry wounds to the right temple and a .22 calibre automatic rifle resting across her lap. Case 3: A 47-year-old female was found with numerous haematomas and three deep head wounds in keeping with trauma from impact with a blunt object. A high level of clozapine was detected on toxicological analysis of blood and a history of schizophrenia was reported. Although multiple self-inflicted wounds are most often caused by sharp objects such as knives, on occasion multiple gunshot wounds and rarely, blunt trauma may also be encountered. Careful integration of scene and autopsy findings may be required to avoid misinterpretation of the circumstances and manner of death.

---

372. Austin, A. E., et al. (2012). "Head impalement - An unusual form of suicide." Journal of forensic and legal medicine 19(5): 264-266.

An 80-year-old man with pancreatic adenocarcinoma and depression was found with his head impaled on a bolt that had been screwed into a hole that had been drilled in the floor of a shed at his home address. Once the bolt was in place the decedent had winched a heavy weight above it, using a pulley that he had attached to the metal roof frame, and the front fork of a bicycle frame. The latter had been bolted to a nearby work bench as a winching device. After the weight had been positioned, he had placed his head over the bolt and cut the rope with a kitchen knife. The impact of the falling weight had forced his head onto the bolt with penetration of the cranial cavity. The complexity of the design of the suicide apparatus is exceedingly rare in our experience and the time taken to set up the device indicated that there had been a considerable degree of premeditation. The finding of complex apparatus at a death scene may provide useful information in ascertaining the manner of death and also in providing some indication as to the decedent's level of determination to succeed.

---

373. Austin, A. E., et al. (2012). "Recent firing range suicides in South Australia." Journal of forensic sciences 57(6): 1495-1496.

Two cases are reported from South Australia, where deaths occurred that were due to single self-inflicted gunshot wounds to the head in individuals who were visiting indoor firearm ranges. Case 1: A 54-year-old man visiting an indoor firing range placed a .357 magnum handgun to his head and fired one shot. Case 2: A 23-year-old woman who was being instructed in firearm usage at an indoor firing range placed a 9 mm handgun to her head and fired one shot. In both cases, deaths were due to cerebral laceration with skull fracture. Firing ranges may be utilized by individuals who are seeking weapons for suicide attempts, and suicide may be successfully undertaken at such locations even while a victim is under direct supervision. In jurisdictions, where firearm ownership is strictly legislated, it may be that clubs can inadvertently provide access to firearms for this type of activity.

374. Autelitano, L., et al. (2008). "Ossification of vascular pedicle in fibular free flaps: a report of four cases." International journal of oral and maxillofacial surgery 37(7): 669-671.

The fibular free flap is the most widely used flap for jaw reconstruction. Flap contouring requires removal of bone excess in the proximal segment by a subperiosteal dissection, preserving vascular connections between the pedicle and the bone and leaving well vascularized periosteum attached to the vascular pedicle. Among about 100 reconstructions with fibular flaps, 4 cases were observed of abnormal ossification along the vascular pedicle. Periosteum preserves its osteogenic capability after transposition, especially in a revascularized flap; this characteristic, together with the direct contact with the bone, allows the possibility of new bone formation along the pedicle. It would appear necessary to change the technique of reducing fibular excess, with removal of periosteum together with the bone, in order to avoid the complication described.

375. Avecillas-Chasin, J. M., et al. (2014). "Surgical management of chronic traumatic pseudomeningocele of the craniocervical junction: case report." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery 30(6): 1125-1128.

PURPOSE: Chronic traumatic pseudomeningocele (PM) is a rare complication of gunshot injuries of the craniocervical junction in pediatric patients. Impairment of the CSF dynamics may cause severe symptoms and should be treated., METHODS: We report the case of a 6-year-old girl who was accidentally shot in the neck during tribal clashes. On being admitted, she was neurologically intact with cerebrospinal fluid (CSF) leakage through the wounds. She underwent primary closure of the wounds in a rural medical facility. After two episodes of meningitis, CSF leakage resolved spontaneously. Nine months later, the patient was presented with a disfiguring mass growing in the posterior neck, severe headaches, and constitutional symptoms such as loss of appetite and a failure to thrive., RESULTS: Neurosurgical intervention was performed with the patient in the prone position. Occipital pericranium graft was used to repair the defect, and the cavity of the PM was obliterated with muscle layers. The patient's symptoms improved at 1 year follow-up without PM recurrence., CONCLUSION: This is a rare presentation of gunshot injuries in an environment with limited neurosurgical resources. Restoring the normal pattern of CSF circulation should be the aim of any neurosurgical intervention.

376. Avery, N. C. and T. Cheak (1998). "Treatment of cranial vault fractures: recent trends toward a more conservative approach." The Journal of cranio-maxillofacial trauma 4(3): 42-48.

A number of aspects in historical teaching regarding the indications for operative treatment of fractures of the cranial vault have been recently challenged. Several contemporary studies have reported excellent results by employing a more conservative approach regarding the treatment of displaced fractures of the skull. Improvements in the diagnosis of injuries by computerized tomography (CT) scanning, antibiotic therapy, and the ability to rapidly transfer patients to neurosurgical care have allowed neurosurgeons to treat many of these injuries outside the operating room with local irrigation, debridement, and simple closure of the wound. Cosmetic deformities of the skull are one of the few

absolute indications for surgical therapy. This article reviews the recent literature regarding skull fractures of the cranial vault and discusses the indications for surgical therapy in these patients and cases where a more conservative approach may be utilized.

---

377. Aveta, A. and P. Casati (2008). "Soft tissue injuries of the face: early aesthetic reconstruction in polytrauma patients." Annali italiani di chirurgia 79(6): 415-417.

Facial injuries are often accompanied by soft tissue injuries. The complexity of these injuries is represented by the potential for loss of relationships between the functional and the aesthetic subunits of the head. Most reviews of craniofacial trauma have concentrated on fractures. With this article, we want to emphasize the importance of early aesthetic reconstruction of the face in polytrauma patients. We present 13 patients with soft tissue injuries of the face, treated in our emergency department in the 'day one surgery", without "second look"procedures. The final result always restored a sense of normalcy to the face. The face is the first most visible part of the human anatomy, so, in emergency, surgeons must pay special attention also to the reconstruction of the face, in polytrauma patients.

---

378. Avila, R., et al. (2017). "Acute kidney injury in critical trauma patients: Incidence and clinical outcomes." Intensive Care Medicine Experimental 5(2).

INTRODUCTION. Many factors are involved in the prognosis of trauma patients. Acute kidney injury (AKI) is one of the most threatening complications because of its high association with bad outcomes, increasing morbid mortality, length of stay in ICU (LOS) and higher treatment costs.These patients are exposed to multiple injuries such as shock, rhabdomyolysis, abdominal hypertension and administration of IV contrast, which make them vulnerable to developing AKI. In this study we describe the incidence and outcomes of patients with trauma related AKI who were managed in the Trauma Intensive Care Unit. OBJECTIVES. To identify the incidence and outcomes of patients with trauma related acute kidney injury (AKI), as defined by KDIGO criteria, at a single level I trauma center in Santa Fe, Argentina. METHODS. We performed a retrospective study of 611 trauma patients admitted to the Hospital Cullen intensive care unit from January 2014 to January 2016. The trauma unit database (Hardinero Q) was used to retrieve patient data for this analysis. We collected patient demographics: age, sex and injury severity score (ISS). We conducted multivariable logistic regression to identity independent predictors for AKI and mortality. In the mortality prediction model we evaluated the following risk factors: age, mechanism of injury (blunt vs. penetrating) or traumatic brain injury (TBI), BMI, hematocrit on admission and AKI. RESULTS. The overall incidence of AKI was 19.5% (n = 119), ICU LOS in non AKI 14 days vs 21 days in AKI. Mean ISS was 23 and mean age was 37 (SD 15.2) in the AKI group. Overall mortality in the AKI group was 71% (n = 85) but was significantly lower in the non AKI group (71% versus 27% P < 0.00001). AKI was an independent predictor of mortality (OR 11,6 95% CI 4.51-29.82). Hematocrit on admission was an independent risk factor for AKI. Forty-one patients (36%) required renal replacement therapy. CONCLUSIONS. Our findings are similar to other studies where AKI in trauma patients was an independent risk factor for mortality and LOS ICU. Renal replacement therapy treatment is high in this group and represents a significant health care cost burden.

379. Avlonitis, V. S., et al. (2003). "Pulmonary transplantation: the role of brain death in donor lung injury." Transplantation 75(12): 1928-1933.

The paucity of suitable lung donors and the high early mortality as the result of primary graft failure remain major challenges in pulmonary transplantation. There is evidence that the lung is injured in the donor by the process of brain death and often is made unusable or fails posttransplantation after amplification of the injury by the process of ischemia-reperfusion. An understanding of the mechanism of donor lung injury could lead to the development of new treatment strategies for the donor to reduce lung injury, increase the number of donors with acceptable lungs, and improve the results of transplantation. The pathophysiology of brain death is complex and involves sympathetic,

hemodynamic, and inflammatory mechanisms that can injure the lung. The literature is reviewed, and these mechanisms are discussed together with their possible interrelations.

380. Avrahami, E., et al. (1986). "Computerized tomographic demonstration of intraorbital bone fragments caused by penetrating trauma." Ophthalmic surgery 17(1): 41-43.

Three patients with fragments of bones lodged in the orbit from apparently non-penetrating trauma, associated with cranio-cerebral injury, are reported. In all three cases the initial symptoms and signs of intraorbital or retrobulbar injury were minimal. The bone fragments were not demonstrable on plain x-ray films of the skull but were clearly shown on computerized tomographic (CT) scans of the orbit. They could easily have been overlooked had reliance been placed on plain x-ray films alone. In patients with suspected non-penetrating orbital trauma, axial and coronal CT views of the orbit are recommended.

381. Awad, A. H., et al. (2000). "Recognized globe perforation during strabismus surgery: incidence, risk factors, and sequelae." Journal of AAPOS : the official publication of the American Association for Pediatric Ophthalmology and Strabismus 4(3): 150-153.

BACKGROUND: Inadvertent perforation of the globe is a well-recognized complication of extraocular muscle surgery. We evaluated the incidence, risk factors, and sequelae of this complication at our institution., METHODS: Medical records of patients who underwent extraocular muscle surgery at King Khaled Eye Specialist Hospital, Saudi Arabia, between September 1983 and April 1997, were reviewed for the occurrence of globe perforation. We documented preoperative visual acuity and refraction, surgical procedure, how the perforation occurred, and immediate management, as well as the sequelae of the perforation, its management, and final outcome., RESULTS: Recognized perforations occurred in 15 of 4886 procedures, for an overall incidence rate of 3/1000. Perforations were 3 times more common in myopic eyes (>-6.00 D, P =.05) and 2 times more common in eyes with previous extraocular muscle surgery. Perforations occurred during muscle reattachment (5 cases), placement of traction sutures at the limbus (4 cases with transient hyphema), muscle disinsertion (3 cases), and placement of sutures at the muscle insertion before disinsertion (3 cases). One patient had a large scleral laceration with uveal prolapse, necessitating scleral patch graft at the time of surgery, and later had retinal detachment surgery with loss of 2 lines of visual acuity. Endophthalmitis, cataract, glaucoma, and phthisis bulbi were not encountered in our review., CONCLUSION: The current incidence of globe perforation is low and only rarely associated with serious sequelae.

382. Awadalkreem, F., et al. (2020). "Prosthetic rehabilitation of maxillary and mandibular gunshot defects with fixed basal implant-supported prostheses: A 5-year follow-up case report." International journal of surgery case reports 68: 27-31.

Introduction: Gunshot injuries to the oral maxillofacial region have serious aesthetic and functional consequences. Presentation of case: A 32-year-old male patient presented with a marginal mandibular resection owing to a gunshot wound. A clinical examination revealed destroyed crowns in teeth 12, 11, and 21; extraction in teeth 13, 22, 24, 31, 32-45; a fracture in tooth 38; and severe pain. Further, he had multiple submental scars and a completely obliterated sulcus. Consequently, a multidisciplinary team was formed who devised the following treatment plan: stage 1, root canal treatment for the maxillary anterior teeth, followed by crown construction and transitional mandibular removable partial denture construction, and stage 2, placement of immediately loaded basal implant definitive prostheses supported by 6 corticobasal screw implants. After 5 years of use, the patient presented with excellent peri-implant soft tissue health, prosthesis stability, and great improvements in aesthetics and function. The patient was highly satisfied with the treatment and restoration of his quality of life. Discussion: Accurate treatment planning is vital for managing complicated cases, including gunshot defect cases, and should involve the selection of the most suitable reconstructive technique with

lower susceptible complication rates and high success rates. The described treatment eliminates the need for bone grafting, reduces treatment duration, and involves fixed prosthesis placement. Conclusion: To our knowledge, this is the first report on basal implant-based full-mouth rehabilitation in a gunshot mandibular defect patient. The fixed hybrid basal implant-supported prosthesis produced highly acceptable aesthetic and phonetic results and greatly improved the patient's life.

---

383. Awasthi, D., et al. (1991). "Coagulation changes after an experimental missile wound to the brain in the cat." Surgical neurology 36(6): 441-446.

Platelet studies (total number and platelet aggregation) and coagulation assays (fibrinogen, factor VIII, and anti-thrombin III) were performed on systemic arterial blood of four control and four experimental adult cats that sustained a penetrating missile injury to the brain. Among the brain-wounded, a significant decrease in the total number of platelets and aggregates occurred 120 minutes after injury. Fibrinogen levels decreased significantly in the brain-wounded animals by 240 minutes after injury and continued declining until the end of the 6-hour experiment. No significant changes occurred in factor VIII and antithrombin III levels in wounded as compared with control animals. These results indicate that blood coagulation factors are altered following a missile wound to the brain. These alterations may, occasionally, lead to clinically manifested bleeding disorders, specifically disseminated intravascular coagulation. Thus, early analysis and control of the coagulation system in the brain-wounded patient should be considered to prevent and treat bleeding disorders in the setting of penetrating head injury.

---

384. Awori, J., et al. (2017). "Penetrating Head Injury by a Nail Gun: Case Report, Review of the Literature, and Management Considerations." Journal of stroke and cerebrovascular diseases : the official journal of National Stroke Association 26(8): e143-e149.

Our objective is to discuss penetrating head injuries (PHIs) which, although rare, lead to considerable morbidity and mortality. One of the most significant culprits of PHI is the nail gun, which was introduced in 1959 and has gained substantial popularity. We describe our successful strategy for removing an 8-cm nail that penetrated through the orbit and middle cranial fossa, with the tip lodged within the posterior fossa. Vascular imaging and balloon test occlusion are imperative in circumstances where vessel sacrifice is necessary. In addition, positioning of balloons within large vessels that are in close proximity to the penetrating object is necessary to control bleeding that may occur during removal of the object. It is of paramount importance to have a multidisciplinary team participating in the management and eventual removal of foreign objects within the intracranial compartment. Included is a review of the literature and a discussion on management approaches to such injuries.

386. Aycart, M. A., et al. (2016). "A Retrospective Analysis of Secondary Revisions after Face Transplantation: Assessment of Outcomes, Safety, and Feasibility." Plastic and reconstructive surgery 138(4): 690e-701e.

BACKGROUND: Face transplantation has emerged as a viable option for certain patients in the treatment of devastating facial injuries. However, as with autologous free tissue transfer, the need for secondary revisions in face transplantation also exists. The authors' group has quantified the number of revision operations in their cohort and has assessed the rationale, safety, and outcomes of posttransplantation revisions., METHODS: A retrospective analysis of prospectively collected data of the authors' seven face transplants was performed from April of 2009 to July of 2015. The patients'

medical records, preoperative facial defects, and all operative reports (index and secondary revisions) were critically reviewed., RESULTS: The average number of revision procedures was 2.6 per patient (range, zero to five procedures). The median time interval from face transplantation to revision surgery was 5 months (range, 1 to 10 months). Most interventions consisted of debulking of the allograft, superficial musculoaponeurotic system plication and suspension, and local tissue rearrangement. There were no major infections, allograft skin flap loss, or necrosis. One patient suffered a postoperative complication after autologous fat grafting in the form of acute rejection that resolved with pulse steroids., CONCLUSIONS: Secondary revisions after face transplantation are necessary components of care, as they are after most conventional free tissue transfers. Secondary revisions after face transplantation at the authors' institution have addressed both aesthetic and functional reconstructive needs, and these procedures have proven to be safe in the context of maintenance immunosuppression. Patient and procedure selection along with timing are essential to ensure patient safety, optimal function, and aesthetic outcomes., CLINICAL QUESTION/LEVEL OF EVIDENCE: Therapeutic, V.

387. Aydin, S. (2019). "Intracranial Penetrating Trauma Caused by Fishing Sinker." World neurosurgery 129: 237-240.

BACKGROUND: Intracranial penetrating traumas (IPTs) are rarely encountered in neurosurgery practice. Here, we report the case of a patient with orbital and cranial trauma caused by an unexpected object., CASE DESCRIPTION: A 37-year-old male presenting with a right orbital penetrating injury was referred to our emergency department. Neurologic examination of the patient revealed right periorbital ecchymosis, a dilated and fixed right pupil, and right hemiparesis. Cranial computed tomography showed fractures of the right orbital medial wall and the anterior skull base, as well as bifrontal and left parietal intracerebral hemorrhage accompanied by a metallic foreign body artifact. Emergency left frontoparietal decompressive craniectomy was performed, and the foreign body, identified as a fishing sinker, was removed. No additional postoperative complications were observed, and cranioplasty was performed 6 months postoperatively., CONCLUSIONS: IPTs have high morbidity and mortality rates. Early surgical intervention is often the first treatment option. Intracranial injury caused by a fishing sinker is an extremely rare low-energy intracranial penetrating trauma, and in the literature, this is the first reported case in which the patient survived.

---

388. Aydin, S., et al. (2010). "The association of mobile medical team involvement on on-scene times and mortality in trauma patients." The Journal of trauma 69(3): 589-594.

OBJECTIVES: Mobile medical teams (MMTs) provide specialized care on-scene with the purpose to improve outcome. However, this additional care could prolong the on-scene time (OST), which is related to mortality. The purpose of this study was to assess the effects of MMT involvement on the mortality rate and on the OST, in a Dutch consecutive cohort of Level I trauma patients., METHODS: All patients who required presentation in the trauma resuscitation room in an urban Level I trauma center were included in this prospective study during the period of November 2005 till November 2007. For data collection, we used both pre- and in-hospital registration systems. Outcome measures were 30-day mortality and OST., RESULTS: In total, 1,054 patients were analyzed. In 172 (16%) patients, the MMT was involved. Mortality was significantly higher in the MMT group compared with patients treated without MMT involvement; 9.9% versus 2.7%, respectively ($p < 0.001$). Significantly higher Injury Severity Scores, intervention rates, and a significantly lower Triage Revised Trauma Score were found in patients treated by MMT. After adjustment for patient and injury characteristics, no association could be found between MMT involvement and higher mortality (95% CI, 0.581-3.979; $p = 0.394$). In patients with severe traumatic brain injury (GCS score <= 8) in whom a MMT was involved, the mortality was 25.5%, compared with 32.7% in those without MMT involvement ($p = 0.442$). The mean OST was prolonged (2.7 minutes) when MMT was involved (26.1 vs. 23.4 minutes; $p = 0.003$)., CONCLUSIONS: In this study, OSTs were long compared with PHTLS

recommendations. MMT involvement slightly prolonged the OST. Trauma patients with MMT involvement had a high mortality, but after correction for patient and injury characteristics, the mortality rate did not significantly differ from patients without MMT involvement.

390. Ayoub, A. F. and J. Rowson (2003). "Comparative assessment of two methods used for interdental immobilization." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery 31(3): 159-161.

AIM: This investigation was carried out to compare Dimac wires with arch bars for interdental immobilization., MATERIAL AND METHODS: The assessment was conducted on 50 patients who had mandibular fractures and in whom intermaxillary fixation was required as a part of the treatment. The time required for applying each method of fixation, the needle-stick injuries that occurred during their application, and the periodontal damage that followed interdental immobilization was investigated., RESULTS: The mean time required for the application of Dimac wires was significantly less than that required for arch bars. The needle-stick injuries were significantly less with Dimac wires. Patients reported difficulty with oral hygiene with arch bars in place. This was associated with periodontal damage following removal of fixation., CONCLUSION: Dimac wires is safer to use and less traumatic to the periodontium

391. Azad, T. D. (2021). "Opinion & Special Articles: Shared Decision-Making During the COVID-19 Pandemic: Three Bullets in 3 Hemispheres." Neurology 96(20): e2558-e2560.

Patients with traumatic brain injury may be dependent on the decision-making of their families. Restrictive visitation policies implemented during the coronavirus disease 2019 (COVID-19) pandemic disproportionately affect these patients and their families. This narrative aims to illustrate this phenomenon and catalyze discussions regarding the need for careful evaluation of restrictive family visitation policies and exceptions that may be required for patients with brain injuries.

---

392. Azarpira, N., et al. (2013). "Penetrating knife injury to the temporal lobe: A case report." Neurosurgery Quarterly 23(1): 64-65.

We present the case of a traumatic brain and artery injury with complete occlusion of this vessel in a 28-year-old man due to a penetrating stab wound to the brain. His initial Glasgow Coma Score was 14/15. The initial computed tomography scan showed that the knife had passed through the medial part of the left temporal lobe with midline shift. He was managed aggressively with surgery and made an excellent recovery. The cerebral angiography performed after 2 months revealed dissection of the internal carotid. In this report, we emphasize on performing an angiogram to exclude intracranial vascular lesion in similar situations.

393. Azevedo, B. E. C. D., et al. (2022). "Prognosis in Traumatic Brain Injury." Brazilian Neurosurgery 41(2): E108-E136.

Objective To characterize the profile of TBI victims who required neurosurgical approach in two reference hospitals in the metropolitan area of Florianópolis, state of Santa Catarina, Brazil, and to identify the prognostic increase in the Pupil Reactivity Score when subtracted from the Glasgow Coma Score, found in the Glasgow-P. Additionally, to present demographic, etiological, clinical, and tomographic data, and associate them with the outcome of death. Methods Medical record data and

computed tomography (CT) scans of patients with TBI undergoing neurosurgical procedures from January 2014 to April 2019, at 2 reference hospitals in the metropolitan area of Florianópolis, state of Santa Catarina, Brazil - Hospital Regional de São José Dr. Homero de Miranda Gomes (HRSJ-HMG, in the Portuguese acronym) and Hospital Governador Celso Ramos (HGCR, in the Portuguese acronym). Results The results of the 318 cases studied indicated that the male gender predominated (87.7%). The most affected age group was between 35 and 65 years old (47.5%). The main cause was motorcycle accidents (26.1%), followed by a fall from a height (16.4%). Most patients required admission to the intensive care unit (ICU) (85.8%), with an average duration of 13 days. The average total hospital stay was 28 days. Most cases needed external ventricular drain (EVD) (64.8%). The predominant tomographic classification was Marshall II (43.4%), followed by Marshall IV (26.1%). Most patients presented with extra-axial hematoma (64.2%), with subdural hematoma (SDH) being the most frequent (45%). Most patients presented with sequelae at hospital discharge (43.4%). Conclusion There was no clinically relevant increase between the Glasgow and Glasgow-P scores for the tested outcomes (need for decompressive craniectomy, midline shift, presence of basal cisterns obliteration, need for ICU admission, and death).

394. Azevedo-Filho, H., et al. (2010). "Prognostic factors in civilian gunshot wounds to the head: A serie of 110 cases." Brain injury 24(3): 280.

Objectives: Despite advances in neurosurgery, the surgical management of civilian gunshot wounds to the head (GWH) has remained a controversial issue, especially concerning the prognostic factors regarding outcome. This study was carried out to focus on the prognostic factors affecting the outcome until discharge. Method: 110 patients with GWH were studied between January 2002 and March 2005 in Recife, Brazil. Results: The most prevalent type of wound was the penetrating injury (74.5%). Twelve out 110 (10.9%) patients presented a dilated pupil. Motor impairment was present in 24/110 (21.8%) patients. Intraaxial hematoma was present in 36/110 (32.7%) patients. There were 15/110 cases (13%) of CSF fistulae. Eleven patients developed meningitis and in nine cases intracranial abscess occurred. Nine cases presented venous thrombosis, 11 urinary infection and 8 coagulopathy. Following the surgical procedure, 27/110 (24.5%) patients died during their hospital stay. Univariate analysis identified five preoperative predictors of poor outcome following GW H surgery: age over 40 years (OR 5.4, 95% CI 1.73-16.82); presence of unilateral pupil dilatation (OR 5.5, 95% CI 1.641-18.13); low (≤8) GCS on admission (OR 6.50, 95% CI 2.27-18.60) or GCS<15 (OR 10.7, 95% CI 1.70-65.76), presence of intracranial hematoma (OR 2.69, 95% CI 1.11- 6.57), and respiratory infection (OR 4.8, 95% CI 1.75-13.47). Conclusions: When the two groups - survivors and nonsurvivors - were compared, there were significant statistical differences with respect to the age of the patient, GCS on admission, pupil size, presence of intracranial hematoma, CSF fistula and respiratory distress/pneumonia.

---

395. Aziz, H., et al. (2013). "Prothrombin complex concentrate effectively treats coagulopathy in patients with lethal brain injuries and increases organ donation." Journal of Surgical Research 179(2).

Introduction: Coagulopathy is a defined barrier for organ donation in patients with lethal traumatic brain injuries. There are many ways to treat coagulopathy, but the effectiveness of Prothrombin Complex Concentrate (PCC) in the reversal of coagulopathy to facilitate organ donation is not well described. The purpose of this study was to document our experience with the use of Prothrombin Complex Concentrate (PCC) to facilitate organ donation in patients with lethal traumatic brain injuries. Methods: We performed a 4 year (2008-2011) retrospective analysis of all patients with devastating gunshot wounds to the head. The data was analyzed for demographics, parameters for coagulopathy, change in International Normalized ratio (INR), and subsequent organ donation. Coagulopathy was defined as INR >1.5. Primary endpoint of the study was organ donation. Results: 88 patients with lethal traumatic brain injury were identified from the trauma registry of which13 were coagulopathic at the time of admission (Mean INR of 2.3 +0.8). Ten patients (10/13) received PCC for

reversal of coagulopathy. Mean INR before PCC administration was 2.06+0.37 and 1.36 +0.42 after administration (p-<0.006). Correction of coagulopathy was attained in 70 % (7/10) patients. Of these 7 patients; consent for donation was obtained in 6 patients and resulted in 19 solid organs being procured. The cost of PCC per patient averaged $1,022 ±$544. Conclusions: PCC effectively reveres coagulopathy associated with lethal traumatic brain injury and enabled patients to proceed to organ donation. Though various methodologies exist for the treatment of coagulopathy to facilitate organ donation; PCC provides for a cost effective therapy for reversal of coagulopathy in patients with lethal traumatic brain injuries. (Table Presented).

396. Azzi, A. J., et al. (2019). "Transcranial Blade Injuries and Principles of Their Safe Extraction." The Journal of craniofacial surgery 30(3): e228-e231.

Retained cranial blade injuries are uncommon events lacking standardized recommendations for appropriate surgical extraction. The authors present a case of a 30-year-old male who sustained a penetrating blade injury of the left orbit with intracranial extension through the skull base into the temporal lobe. The patient walked to the emergency room and remained alert. Clinically, the patient had only a small laceration of the left upper eyelid with no gross visual impairment. The radiological investigation confirmed the presence of a knife blade in the orbit. Intraoperative management included an intracranial approach and an extracranial craniofacial dissection for blade visualization and soft tissue protection, globe protection and to avoid any major bleeding. A thorough review of the penetrating cranial injuries literature is presented and a trauma management algorithm is offered for the care of similar injuries.

397. Baba, M., et al. (1982). "[Penetrating transorbital intracranial foreign body]." No shinkei geka. Neurological surgery 10(8): 869-874.

About a month prior to admission to our hospital, a 25-year-old man had a quarrel with his friend and was stabbed in his left eye with a cracked bottle of beer. He underwent emergency operation for the injured left eye. Subsequently he was admitted to an ophthalmological ward in our hospital for plastic surgery of an artificial eye. An intracranial foreign body was pointed out, and he was soon transferred to our neurosurgical ward. Plain x-ray films and tomograms of the skull and CT scan showed a foreign body at medial portion of the left superior orbital fissure. Carotid angiography revealed no significant implication of the cerebral vessels. As there was a strong suspicion of cerebral contusion or liquorrhea, a pterional craniotomy was so designed as to do removal of thie foreign body and repair of the dura mater in one stage. The post-operative couse was uneventful without liquorrhea or miningitis. It was emphasized that pterional approach used by Hamby (1970) for surgery of malignant exophthalmos was useful and felicitious in this case. It was additionally reported that cerebrospinal orbitorrhea observed in this case was rare and it might be the third case in the literature.

398. Bababeygy, S. R. and A. A. Sadun (2013). "Bilateral oedipism." Ophthalmic plastic and reconstructive surgery 29(1): e11-12.

A 20-year-old woman presented with self-inflicted pencil wounds to her bilateral orbits. CT angiography revealed penetration of pencils through optic canals into temporal lobes. Examination revealed bilateral no light perception, fixed dilated pupils, complete ptosis, and complete ophthalmoplegia. The patient was admitted to the psychiatric ward and her vision and cranial nerve deficits did not improve.

399. Babakhanian, R. V., et al. (1994). "[The possibility of inflicting injuries by shots from a gas weapon at close range]." O vozmozhnosti prichineniia povrezhdenii pri vystrelakh iz gazovogo oruzhiia s blozkogo rasstoianiia. 37(4): 5-7.

Two cases from practical forensic medical expert evaluation are presented, connected with injuries inflicted by point-blank shots from gas pistols of 8 and 9 mm caliber. These two examples demonstrate the difficulties in expert evaluation, which are explained by the absence of scientifically-based methodology. The authors emphasize the necessity of comprehensive studies in this field to develop methods for the differential diagnosis of injuries inflicted by gas weapons and those inflicted by blank cartridge gunshots.

400. Babar, S., et al. (2016). "The Role of 320 Slice CT Angiography in Predicting Vascular Trauma." Journal of the College of Physicians and Surgeons--Pakistan : JCPSP 26(1): 23-26.

OBJECTIVE: To determine the accuracy of multidetector CT angiography (MDCT angiography) as initial diagnostic technique in depicting and characterizing post traumatic vascular injuries, looking for additional injuries and confirming the findings with intervention and follow-up., STUDY DESIGN: Descriptive analytical study., PLACE AND DURATION OF STUDY: Department of Radiology, Shifa International Hospital, Islamabad, from June 2010 to October 2013., METHODOLOGY: Patients who underwent MDCT angiography for clinically suspected post traumatic vascular injury were included. All MDCT angiographies were performed on 320 slice CT (Aquilion OneTM) and were reviewed by two independent consultant radiologists. The sites of injury were intracranial, neck and maxillofacial, chest, abdomen and extremities. The presence and characteristics of vascular injuries were confirmed by post-operative findings or digital subtraction angiography (DSA). Sensitivity and specificity was calculated., RESULTS: The age of the patients ranged from 7 to 90 years with 94% (48) males and 6% (3) females. Blunt trauma was commoner than penetrating trauma. The site of injury in majority was extremities. Majority of patients had post-traumatic pseudoaneurysm formation followed by arterial occlusion, thrombosis, active extravasation, spasm, arteriovenous malformation and combination injuries. Twenty-one (41%) patients were reported as having vascular injury and confirmed by surgery or DSA. Fifteen (29.5%) patients were reported as normal and had no intervention on follow-up. The sensitivity and specificity of MDCT angiography was found as 100% and 88%, NPV of 100%, PPV of 94% and accuracy of 96%., CONCLUSION: MDCT angiography can be reliably used as an initial diagnostic technique for the evaluation and characterization of post-traumatic vascular injuries.

401. Babl, F. E., et al. (2017). "Diagnostic accuracy of the nexus II head injury clinical decision rule in children. a predict prospective cohort study." Archives of disease in childhood 102: A115.

Aims Clinical decision rules (CDRs) can be applied in Emergency Departments (EDs) to optimise the use of computed tomography (CT) in children with head trauma. The National Emergency XRadiography Utilisation Study II (NEXUS II) CDR, as amended for children, has not been externally validated in a large paediatric cohort. The objective of this study was to conduct a multicentre external validation of the NEXUS II CDR in children. Methods We performed a prospective observational study of patients<18 years presenting with head trauma of any severity to 10 Australian/New Zealand EDs. In a planned secondary analysis we assessed the performance of the NEXUS II CDR for its diagnostic accuracy (with 95% confidence intervals (CI)) in predicting clinically important intracranial injury (ICI) as identified in CT scans performed in ED. Results Of 20 137 total patients, we excluded 28 with suspected penetrating injury. Median age was 4.2 years. CTs were obtained in ED for 1962 (9.8%), of whom 377 (19.2%) had a clinically important ICI as defined by NEXUS II. 74 (19.6%) of these patients underwent neurosurgery. Sensitivity for clinically important ICI based on the NEXUS II CDR was 373/377 (98.9%; 97.3%-99.7%) and specificity 156/1585 (9.8%; 8.4%-11.4%). Positive and negative predictive values were respectively 373/1802 (20.7%; 18.8%-22.6%) and 156/160 (97.5%; 93.7%-99.3%). Of the 18 147 children who did not have a CT scan 49.5% had at least one NEXUS II risk criterion. Conclusions NEXUS II had very high sensitivity when analysed with a focus on head injured patients who have had a CT performed, similar to the derivation study. With half of the unimaged patients positive for NEXUS II risk criteria the use of this CDR has the potential to increase the number of CTs.

402. Babl, F. E., et al. (2018). "Penetrating head injuries in children presenting to the emergency department in Australia and New Zealand: A PREDICT prospective study." Journal of paediatrics and child health 54(8): 861-865.

AIM: Penetrating head injuries (pHIs) are associated with high morbidity and mortality. Data on pHIs in children outside North America are limited. We describe the mechanism of injuries, neuroimaging findings, neurosurgery and mortality for pHIs in Australia and New Zealand., METHODS: This was a planned secondary analysis of a prospective observational study of children <18 years who presented with a head injury of any severity at any of 10 predominantly paediatric Australian/New Zealand emergency departments (EDs) between 2011 and 2014. We reviewed all cases where clinicians had clinically suspected pHI as well as all cases of clinically important traumatic brain injuries (death, neurosurgery, intubation >24 h, admission >2 days and abnormal computed tomography)., RESULTS: Of 20 137 evaluable patients with a head injury, 21 (0.1%) were identified to have sustained a pHI. All injuries were of non-intentional nature, and there were no gunshot wounds. The mechanisms of injuries varied from falls, animal attack, motor vehicle crashes and impact with objects. Mean Glasgow Coma Scale on ED arrival was 10; 10 (48%) had a history of loss of consciousness, and 7 (33%) children were intubated pre-hospital or in the ED. Fourteen (67%) children underwent neurosurgery, two (10%) craniofacial surgery, and five (24%) were treated conservatively; four (19%) patients died., CONCLUSIONS: Paediatric pHIs are very rare in EDs in Australia and New Zealand but are associated with high morbidity and mortality. The absence of firearm-related injuries compared to North America is striking and may reflect Australian and New Zealand firearm regulations.

403. Baccarani, A., et al. (2006). "Fascio-subcutaneous extension of a free radial forearm flap for frontonasal duct obliteration." The Journal of craniofacial surgery 17(6): 1163-1166.

Frontonasal duct injury is a critical factor in the treatment of frontal sinus fractures. We present the case of a 43-year-old man who sustained multiple comminuted fractures of the anterior table of the frontal sinus and of the orbital roof as the result of a gunshot. After adequate debridement, the combined bone and soft tissue defect was reconstructed with a titanium mesh and a free radial forearm flap. The frontonasal duct injury was treated by surgical obliteration with a custom designed fascio-subcutaneous extension of the free radial forearm flap. The postoperative course was uneventful with good functional and aesthetic results. No early or late complications have occurred.

404. Bacciu, A., et al. (2009). "Intracranial facial nerve grafting after removal of vestibular schwannoma." American journal of otolaryngology 30(2): 83-88.

OBJECTIVE: The objectives of this study were to evaluate outcomes from facial nerve (FN) cable grafting in patients who experienced FN transection during vestibular schwannoma removal and to compare the FN outcomes of patients who underwent FN grafting by using fibrin glue with those of patients who underwent FN grafting by using microsuture., MATERIAL AND METHODS: We retrospectively evaluated a series of 33 patients in whom FN grafting was achieved either by using microsuture (8 cases) or fibrin glue (25 cases). Immediate repair of the FN was performed in all cases at the time of initial resection. The patients FN function was assessed preoperatively, in the immediate postoperative period, and at 3, 6, 9, and 12 months or more postoperatively using the House-Brackmann grading system. All patients had at least 1-year follow-up., RESULTS: At 12 months, a House-Brackmann grade III was achieved in 75% of those who underwent cable nerve graft interposition by using microsuture and in 76% of those who underwent cable nerve graft interposition by using fibrin glue. Analysis of final FN function outcomes demonstrated no statistically significant difference in FN outcomes between the 2 groups (P = .891, Mann-Whitney U test; P = .1, Fisher exact test).,

CONCLUSIONS: The functional results after FN cable grafting by using fibrin glue exclusively were equivalent to those obtained with microsuture. However, the technique of FN repair by means of fibrin glue is technically simple, less time-consuming, and imparts less trauma on the nerve than does the traditional suture method.

405. Bacque, M. C., et al. (2018). "Neurocritical Patient Characteristics Related to Brain Death." Transplantation proceedings 50(2): 397-399.

BACKGROUND: The lack of viable organs for transplantation led to the creation in Argentina of the Glasgow 7 Program based on the detection and follow-up of acute neurologic patients admitted with Glasgow scores <=7 in selected hospitals. The objective of this study was to determine the likelihood of hospitalized acute neurologic patients progressing to brain death (BD) based on several variables, including age, sex, and admission diagnosis., METHODS: This study was a retrospective cohort analysis of data obtained from the SINTRA (Procurement and Transplantation National Information System) database between 2006 and 2015. Independent variables included the following: age, sex, and diagnosis at admission; ischemic stroke; spontaneous intracerebral hematoma (SIH); subarachnoid hemorrhage (SH); anoxia, meningitis; penetrating head injury (PHI); closed head injury; and tumors. A multivariate analysis was performed adjusting the diagnosis at admission according to age and sex., RESULTS: A total of 31,877 patients were included: 19,308 (61%) patients died and 9736 (30%) evolved to BD. Overall, 36% of women and 28% of men evolved to BD (relative risk, 0.87 [95% confidence interval (CI), 0.86-0.89]; P < .001). In the multivariate analysis adjusted for age and sex, we observed the following: SIH OR, 1.79 (95% CI, 1.69-1.9; P < .001); ischemic stroke OR, 0.82 (95% CI, 0.73-0.92; P < .001); SH OR, 2.33 (95% CI, 2.16-2.52; P < .001); anoxia OR, 0.71 (95% CI, 0.64-0.79; P < .001); closed head injury OR, 0.41 (95% CI, 0.38-0.43; P < .001); PHI OR, 2.64 (95% CI, 2.38-2.94; P < .001); and tumors OR, 1.07 (95% CI, 0.93-1.24; P = .31)., CONCLUSIONS: Thirty percent of the patients who entered the Glasgow 7 Program evolved with BD. The characteristics most likely to result in BD were age, female sex, PHI, SH, and SIH.

406. Bacyinski, A., et al. (2017). "The paravascular pathway for brain waste clearance: Current understanding, significance and controversy." Frontiers in Neuroanatomy 11.

The paravascular pathway, also known as the “glymphatic” pathway, is a recently described system for waste clearance in the brain. According to this model, cerebrospinal fluid (CSF) enters the paravascular spaces surrounding penetrating arteries of the brain, mixes with interstitial fluid (ISF) and solutes in the parenchyma, and exits along paravascular spaces of draining veins. Studies have shown that metabolic waste products and solutes, including proteins involved in the pathogenesis of neurodegenerative diseases such as amyloid-beta, may be cleared by this pathway. Consequently, a growing body of research has begun to explore the association between glymphatic dysfunction and various disease states. However, significant controversy exists in the literature regarding both the direction of waste clearance as well as the anatomical space in which the waste-fluid mixture is contained. Some studies have found no evidence of interstitial solute clearance along the paravascular space of veins. Rather, they demonstrate a perivascular pathway in which waste is cleared from the brain along an anatomically distinct perivascular space in a direction opposite to that of paravascular flow. Although possible explanations have been offered, none have been able to fully reconcile the discrepancies in the literature, and many questions remain. Given the therapeutic potential that a comprehensive understanding of brain waste clearance pathways might offer, further research and clarification is highly warranted.

407. Badhiwala, J. H., et al. (2014). "Neuropsychiatric changes following Penetrating head injury in children." Surgical neurology international 5(Supplement).

Case Description: We report the case of a 12-year-old boy who suffered a penetrating head injury to the frontal lobes secondary to a self-inflicted gunshot wound, and experienced subsequent resolution of pre-existing bipolar disorder and new onset of attention deficit hyperactivity disorder. Conclusion: Children with penetrating head injury require close multidisciplinary follow-up in order to monitor, and accordingly implement management strategies, for associated sequelae, including behavioral and neuropsychiatric changes. Background: Penetrating head injuries demand the prompt attention of a neurosurgeon. While most neurosurgical centers are experienced in the acute management of these injuries, less is known about the long-term neuropsychiatric sequelae of penetrating head trauma. In adults, direct injury to the frontal lobe classically has been associated with mental status changes. However, there is less published data in children. Copyright:

410. Baek, S.-H., et al. (2008). "Trifocal distraction-compression osteosynthesis in conjunction with passive self-ligating brackets for the reconstruction of a large bony defect and multiple missing teeth." American journal of orthodontics and dentofacial orthopedics : official publication of the American Association of Orthodontists, its constituent societies, and the American Board of Orthodontics 133(4): 601-611.

Reconstruction of a maxillary dentoalveolar defect and closure of a wide oronasal fistula in a patient with a traumatic injury are challenging for both orthodontists and surgeons. A conventional bone graft is used to fill the alveolar bone defect, to restore continuity between bony segments, and to provide bony support for tooth eruption adjacent to the defect or for orthodontic tooth movement into the bony defect. However, if the defect is too large to allow for a conventional bone graft, transport distraction osteogenesis can be used for reconstruction of the alveolar bone and implant placement. However, there is usually a discrepancy in the movement rates between the bony segment and the teeth. Passive self-ligating brackets can minimize friction between the bracket and the archwire; therefore, the rate of tooth movement can be balanced with that of the bony segment. By using orthodontic miniscrew and elastomeric traction, the regenerated bony segments can be bent to form a curved arch in the alveolar bone. In the treatment reported here, trifocal distraction-compression osteosynthesis with orthodontic miniscrews and passive self-ligating brackets helped establish bone continuity in a bony defect area, created anterior curvature of the alveolar bone, and provided good-quality regenerated bone for implant placement.

411. Baer, L. A., et al. (2013). "Coagulopathy in a swine model of penetrating ballistic-like brain injury and trauma patients with penetrating brain injury." Journal of neurotrauma 30(15): A35-A36.

Introduction Hemorrhage resulting from blunt brain injury is caused by the direct injury and secondary multifactorial coagulopthy. Viscoelastometry using thromboelastography (TEG) is a rapid method determining clotting function and coagulopathy. Coagulopathy was determined using a pig

model of penetrating ballistic-like brain injury (PBBI) and in trauma patients with penetrating brain injury. Methods Studies were approved by Institutional Animal Care and Use Committee and Institutional Review Board for the treatment of human subjects. Anesthetized mature male miniature swine were randomly selected: control (C; n = 5), 0.1% (probe only; n = 4) and 2.5% (n = 4) of estimated brain volumes. Following a craniotomy, a fluid-filled intracranial probe was inserted and varying cavitational injuries were created. TEG was measured every hour for 6 hrs. Clinically, patients admitted into the Texas Trauma Institute with a penetrating head injury (PEN; n = 18) and an AIS score of ≥ 3 from March 2012 until January 2013 were compared to a control group of trauma patients discharged within 24 hrs (CON; n = 132) of admission. Viscoelastometry, using Kaolin TEG, was used to determine coagulopathy: split time (SP), reaction time (R), K-time (K), Alpha-Angle (a) and maximum amplitude (MA). Values are mean ± SEM and differences were determined by ANOVA ($p < 0.05$). Results PBBI in swine elicited no changes in TEG between groups or over time. Sixty minutes after injury, SP (min; C: 4.1 ± 0.5; 0%: 4.1 ± 0.5: 2.5%: 3.9 ± 0.5), R (min; C: 5.1 ± 0.5; 0%: 4.9 ± 0.5: 2.5%: 4.7 ± 0.5), K (min; C: 1.1 ± 0.1; 0%: 1.3 ± 0.1: 2.5%: 1.1 ± 0.1), a (C: 75 ± 2; 0%: 74 ± 2: 2.5%: 75 ± 2) and MA (mm; C: 80.4 ± 0.9; 0%: 80.9 ± 0.9: 2.5%: 78.7 ± 1.1) were not different between treatments. To assess possible anesthetic and instrumentation effects on coagulopathy, we compared all TEG values to a group of sedated swine and they were similar.As no changes were observed over time in the large animalmodel we specifically wanted to determine if penetrating brain injuries in trauma patients would demonstrate differences. The PEN group had an overall mortality rate of 56%. No differences were observed between CON and PEN in SP (CON:3.4 ± 1.5; PEN:3.7 ± 1.6), R (CON:4.1 ± 1.5; PEN:4.4 ± 1.9), K (CON:1.8 ± 0.1; PEN:1.8 ± 0.2) or MA (62 ± 11 vs 61 ± 6, $p < 0.02$). Alpha-angle, which reflects the speed of fibrin accumulation, was significantly reduced in PEN (CON:65.2 ± 9.6; PEN:59.4 ± 15.6). Conclusions Though there is an extensive body of literature on coagulopathy in traumatic brain injury, data specific to penetrating brain injury is limited. Using a pig model of penetrating brain injury, we found no changes coagulation over time following a moderate penetrating injury. In addition, we found similar results in patients with penetrating brain injuries. In patients there was a reduction in a-angle indicative of a possible fibrinogen deficiency. The reported coagulapothy associated with blunt traumatic brain injury may not occur with penetrating brain injury.

412. Bafaquh, M., et al. (2020). "Classification of internal carotid artery injuries during endoscopic endonasal approaches to the skull base." Surgical neurology international 11.

Background: Internal carotid artery (ICA) injuries are a major complication of endoscopic endonasal approaches (EEAs), which can be difficult to manage. Adding to the management difficulty is the lack of literature describing the surgical anatomical classification of these types of injuries. This article proposing a novel classification of ICA injuries during EEAs. Methods: The classification of ICA injuries during EEAs was generated from the review of the literature and analysis of the main author observation of ICA injuries in general. All published cases of ICA injuries during EEAs in the literature between January 1990 and January 2020 were carefully reviewed. We reviewed all patients' demographic features, preoperative diagnoses, modes of injury, cerebral angiography results, surgical and medical management techniques, and reported functional outcomes. Results: There were 31 papers that reported ICA injuries during EEAs in the past three decades, most studies did not document the type of injury, and few described major laceration type of it. From that review of the literature, we classified ICA injuries into three main categories (Types I-III) and six sub-types. Type I is ICA branch injury, Type II is a penetrating injury to the ICA, and Type III is a laceration of the ICA wall. The functional neurological outcome was found to be worse with Type III and better with Type I. Conclusion: This is a novel classification system for ICA injuries during EEAs; it defines the patterns of injury. It could potentially lead to advancements in the management of ICA injuries in EEAs and facilitate communication to develop guidelines.

413. Bagga, V., et al. (2013). "Lymphoblastic leukaemia presenting as a carotid-cavernous fistula." The neuroradiology journal 26(1): 94-96.

A carotid-cavernous fistula is a life-threatening condition characterised by an abnormal communication between the carotid arterial vessels and the cavernous venous system. Although these fistulae can arise spontaneously, they mainly occur after trauma, especially road traffic accidents, falls and penetrating cranial or orbital injuries. The mainstay of treatment involves endovascular embolization, but in those patients where this is not possible or where embolization fails, direct surgical intervention and ligation of the artery may be necessary. Here we describe an interesting case of a suspected carotid-cavernous fistula which turned out to be cavernous sinus syndrome secondary to lymphoma.

414. Bagheri, S. C., et al. (2005). "Comparison of the severity of bilateral Le Fort injuries in isolated midface trauma." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons 63(8): 1123-1129.

PURPOSE: The Le Fort classification pattern established in 1901 by the French surgeon Rene Le Fort is commonly used in describing midface fractures. This frequently used classification system is based on predictable patterns of midface fractures initially described for blunt trauma. The purpose of this study was to compare the profile and outcome of patients with isolated bilateral Le Fort I, II, and III fractures., PATIENTS AND METHODS: All patients presenting to the emergency department (ED) at Legacy Emanuel Hospital (Level I trauma center) in Portland, OR, between December 1990 and December 2003 with isolated bilateral Le Fort I, II, or III fractures with or without concomitant nonfacial injuries were identified retrospectively using the Hospital Trauma Registry. Patients were classified into study groups I (n = 22), II (n = 22), or III (n = 23) corresponding to the Le Fort classification, respectively., RESULTS: Sixty-seven patients had a diagnosis of isolated bilateral Le Fort I, II, or III fracture. The average Injury Severity Score (ISS) and hospital length of stay were 18.8 +/- 8.9 and 9.5 +/- 11.9 days, respectively. Blood alcohol was detected in 19 patients. Sixty-four injuries (95.5%) were secondary to blunt trauma, and the remaining 3 (4.5%), penetrating injuries. More than half of the patients (n = 35, 52.2%) were admitted to the intensive care unit (ICU), 18 patients (26.8%) were transferred to the hospital trauma ward from the ED, and 14 patients (20.9%) were taken directly to the operating room. Fifteen (22.4%) patients required a tracheostomy secondary to their maxillofacial injuries. A statistically significant difference in the ISS was detected between patients with Le Fort I versus those with II or III injuries ($P < .0001$). Patients with Le Fort II or III fractures had a significantly higher probability of ICU admission or immediate operative intervention. Ten patients (43.5%) with Le Fort III injuries required tracheostomy versus 3 patients (13.6%) with Le Fort I, and 2 patients (9.1%) with Le Fort II injuries. This was statistically significant. None of the patients with Le Fort I injuries had a negative outcome (death); however, 1 patient with Le Fort II injuries (4.5%) and 2 with Le Fort III injuries (8.7%) had a negative outcome. No statistically significant differences or emerging trends were observed among the 3 groups for age, gender, length of stay, number of operations, and number of associated injuries., CONCLUSIONS: Patients with higher Le Fort injuries are characterized by an overall greater severity of injuries as measured by the ISS and the more frequent need for a surgical airway. Patients with Le Fort III injuries have a higher chance of requiring neurosurgical intervention or of experiencing vision-threatening ocular trauma. Immediate operative intervention and/or ICU care is more frequently indicated in these patients.

415. Bagi, Z., et al. (2018). "Selectively impaired vasodilation of human white matter penetrating cerebral arterioles in microvascular brain injury and Alzheimer's disease." FASEB Journal 32(1).

Microvascular brain injury (mVBI) is a common pathologic correlate of vascular contributions to cognitive impairment and dementia (VCID) that leads to white matter (WM) injury. VCID appears to arise from chronic recurrent WM ischemia. We hypothesized that in mVBI WM injury is specifically attributed to vasodilator dysfunction of WM penetrating arterioles. We analyzed 38 cases of mVBI with

low and high Alzheimer's disease (AD) neuropathologic changes in prefrontal cortex WM from rapid autopsies in a population-based cohort where VCID and AD frequently occur. Arteriolar vasodilator function was quantified by videomicroscopy. Acetylcholine-mediated arteriolar dilation in mVBI with low AD pathology was significantly reduced in WM penetrators relative to pial arterioles. Astrogliosis-defined WM injury was associated with impaired vasodilator function of WM penetrating arterioles. In mVBI with high AD pathology vasodilator function of WM penetrating arterioles was further diminished. Presence of moderate/frequent neuritic plaques and cerebral amyloid angiopathy were associated with impaired dilation in WM penetrating, but not in pial arterioles. In conclusion, we successfully assessed vasodilator function of human WM penetrating arterioles in postmortem rapid autopsy samples. We found that selectively impaired vasodilator function of WM penetrating arterioles in mVBI occurs in association with WM injury and AD neuropathologic change.

416. Bahnini, A., et al. (1986). "Gunshot pellet embolus to the middle cerebral artery." Annals of vascular surgery 1(1): 139-142.

A 24-year-old man sustained a gunshot wound to the upper right hemithorax and neck, with injury to the subclavian and carotid arteries. A cerebral artery pellet embolus resulted in contralateral hemiplegia. The injured vessels were repaired, but the middle cerebral artery pellet was left undisturbed. Neurologic improvement occurred. Fifteen cases of foreign body embolus to cerebral vessels are reviewed and the management of this unusual injury is discussed.

418. Bai, W., et al. (2011). "Conservative management of transnasal intracranial injury." American journal of otolaryngology 32(2): 165-167.

The purpose of this study was to explore the conservative management for an unusual case of transnasal intracranial injury. A 3-year-old female child presenting with transnasal injuries after a domestic accident whereby she apparently fell while holding a large pair of scissors, which then penetrated her left nasal cavity, piercing her nasal cavity, ethmoid sinus, and skull base. The scissors were removed from her nasal cavity. The patient had scant cerebrospinal rhinorrhea and no other additional neurologic deficits noted at the time, as well as no long-term developmental deficits. This report highlights the occurrence of this rare condition. The role of radiologic studies such as computed tomographic scans and plain films in diagnosis and management of this case is affirmed. The strategy of minimally invasive treatment of this injury can be a reasonable treatment option.

419. Bailey, D. J., et al. (2019). "Reliability and stability of the metrical stress effect on segmental production accuracy in persons with apraxia of speech." International journal of language & communication disorders 54(6): 902-913.

BACKGROUND: Acquired apraxia of speech (AOS) involves speech-production deficits on both the segmental and suprasegmental levels. Recent research has identified a non-linear interaction between the metrical structure of bisyllabic words and word-production accuracy in German speakers with AOS, with trochaic words (strong-weak stress) being resistant to errors compared with iambic words (weak-strong)., AIMS: To replicate previous findings in English speakers with AOS, to measure the test-retest reliability of the effect, and to examine the potential impact of different methods of word scoring., METHODS & PROCEDURES: Speech samples were collected from 27 speakers with AOS and aphasia. Participants were at least 12 months post-stroke or penetrating brain injury, and represented

a large range of AOS and aphasia severities. Productions were elicited via verbal model. Sampling was conducted on three separate occasions: the initial data-collection session and then repeated samplings at 1- and 4-week intervals. Bisyllabic words with a CVCVC segmental structure were selected. The list was divided into sublists representing differing lexical stress patterns: A list of 42 trochees, and one of 37 iambs. All speech samples were phonetically transcribed and then aligned with canonical transcriptions via an edit distance algorithm that followed transcription alignment principles. Phonetic-level errors (distortions) were penalized less severely than phonemic-level errors. Per cent consonants correct and whole-word accuracy were also examined. Trochee and iamb lists were analysed separately., OUTCOMES & RESULTS: Paired samples t-tests indicated that the modified edit distance was significantly lower for the trochee lists than for the iamb lists. There was a lack of a significant effect of time on the absolute difference between modified edit distance for both lists. Intraclass coefficients suggested the list and procedures used are appropriate as an outcome measure for group research., CONCLUSIONS & IMPLICATIONS: The results suggest that in English, as in German, the trochaic structure is more resistant to segmental errors in persons with AOS and aphasia, providing replication of the findings of Aichert et al. in 2016. Further, this effect is stable over repeated sampling occasions. Implications for clinical management of AOS include possible ways to scaffold item difficulty and potentially improve stimulus generalization. Copyright Published 2019. This article is a U.S. Government work and is in the public domain in the USA.

420. Bailey, Z., et al. (2018). "Resuscitative endovascular balloon occlusion of the aorta alters cerebral physiology and blood composition after brain injury." Journal of neurotrauma 35(16): A214.

Recent technical advancements have created opportunity for resuscitative endovascular balloon occlusion of the aorta (REBOA) as a promising alternative to control non-compressible hemorrhage in a pre-hospital setting. Traumatic events often elicit a multifaceted pathology including both hemorrhage and traumatic brain injury (TBI). While REBOA treatment has proven efficacious in increasing afterload and reducing mortality, the effects on concomitant TBI is not well understood. This study sought to elucidate the REBOA effects on systemic and cerebral physiology in the acute stages following TBI. Rats were randomly divided into four groups (n = 10/ group): penetrating ballistic-like brain injury (PBBI), continuous REBOA, PBBI+cREBOA, PBBI+intermittent REBOA (iREBOA). Continuous measurements of mean arterial pressure (femoral and common carotid), intracranial pressure (ICP) and brain tissue oxygen tension (PbtO2) were recorded. All animals underwent a 10-minute baseline recording followed by PBBI or sham procedures (craniotomy). PBBI was induced via inflation/deflation of a balloon probe within the right frontal cortex. REBOA was initiated 30 minutes afterwards and maintained continuously (cREBOA) or intermittently for 30 minutes (iREBOA: three 10-minute occlusions separated by 1-minute reperfusions). Physiological parameters were monitored for an additional 60 minutes following REBOA. PBBI elicited a decrease in PbtO2 and an increase in ICP. cREBOA caused a transient decrease in ICP which correlated with increased PbtO2 levels. No significant differences were observed between PBBI and sham levels of ICP and PbtO2 following cREBOA. Alternatively, iREBOA increased ICP and decreased PbtO2 for the remainder of the experiment. The blood composition was evaluated during the baseline, during occlusion, and immediately following occlusion. A significant increase in lactate levels were observed in each treatment group receiving REBOA. The lactate levels were strongly correlated with decreased pH, indicating lactic acidosis. Increased blood glucose levels were also observed which may be detrimental to PBBI recovery as hyperglycemia has been correlated to cerebral edema. No significant changes were observed for oxygen, carbon dioxide, electrolyte, hematocrit, or hemoglobin levels of the blood. Overall, these results suggest that cREBOA may aide in acute TBI stabilization whereas iREBOA may exacerbate injury. Further optimization should mitigate REBOA-induced lactic acidosis and hyperglycemia which may further complicate secondary injury cascades.

421. Bailey, Z., et al. (2019). "Hematological changes induced by polytrauma with concomitant concussion involve altered coagulopathy and biomarker levels." Journal of neurotrauma 36(13): A108.

Traumatic brain injury (TBI) is not an isolated injury to the brain but also results in widespread systemic changes to the blood involving coagulation, gas delivery, and ion balance. Importantly, the damage to brain can also result in the release of brain proteins to the blood. However, the hematological changes and biomarker levels are not well understood in patients that have sustained TBI with hypoxia and hemorrhagic insults. To elucidate these changes, rats were divided into six groups: sham, hemorrhage and hypoxia (HH), single-TBI (sTBI), repeated-TBI (rTBI, 3x5min), sTBI+HH, and rTBI+HH. Hypoxia was induced following TBI/sham procedures by decreasing the inspired air to 10% oxygen for 60 minutes. Normoxia was returned and hemorrhagic shock was induced for 60 minutes before resuscitation with lactated Ringer's. Blood samples were collected immediately following these procedures for blood gas and thromoboelastography and at 2 or 24 hrs post-injury for biomarker (GFAP, UCHL1, neurofilament-light chain (NF-L), tau) analysis. Indications of a hypercoagulable state was observed from HH, sTBI+HH, and rTBI+HH groups following resuscitation compared to sham ($p < 0.05$). These groups also demonstrated increased lactate levels and decreased oxygen in the blood ($p< 0.05$). The rTBI group showed similar pathology including an increased K value and decreased blood oxygen compared to sham ($p< 0.05$). The effects of HH were prominent on circulating biomarker levels. At 2 hours post-injury, GFAP, UCHL1, and NF-L were significantly increased in sTBI+HH and rTBI+HH groups. NF-L was also increased in sTBI and rTBI groups. At 24 hours post-injury, NF-L had returned to sham levels but GFAP and UCHL1 remained increased compared to sham ($p< 0.05$). No significant changes were observed for tau. These results suggest that hemorrhage and hypoxia may exacerbate the TBI pathology and alter blood-based biomarker dynamics.

422. Bailey, Z. S., et al. (2019). "The Effects of Balloon Occlusion of the Aorta on Cerebral Blood Flow, Intracranial Pressure, and Brain Tissue Oxygen Tension in a Rodent Model of Penetrating Ballistic-Like Brain Injury." Frontiers in neurology 10: 1309.

Trauma is among the leading causes of death in the United States. Technological advancements have led to the development of resuscitative endovascular balloon occlusion of the aorta (REBOA) which offers a pre-hospital option to non-compressible hemorrhage control. Due to the prevalence of concomitant traumatic brain injury (TBI), an understanding of the effects of REBOA on cerebral physiology is critical. To further this understanding, we employed a rat model of penetrating ballistic-like brain injury (PBBI). PBBI produced an injury pattern within the right frontal cortex and striatum that replicates the pathology from a penetrating ballistic round. Aortic occlusion was initiated 30 min post-PBBI and maintained continuously (cAO) or intermittently (iAO) for 30 min. Continuous measurements of mean arterial pressure (MAP), intracranial pressure (ICP), cerebral blood flow (CBF), and brain tissue oxygen tension (PbtO2) were recorded during, and for 60 min following occlusion. PBBI increased ICP and decreased CBF and PbtO2. The arterial balloon catheter effectively occluded the descending aorta which augmented MAP in the carotid artery. Despite this, CBF levels were not changed by aortic occlusion. iAO caused sustained adverse effects to ICP and PbtO2 while cAO demonstrated no adverse effects on either. Temporary increases in PbtO2 were observed during occlusion, along with restoration of sham levels of ICP for the remainder of the recordings. These results suggest that iAO may lead to prolonged cerebral hypertension following PBBI. Following cAO, ICP, and PbtO2 levels were temporarily improved. This information warrants further investigation using TBI-polytrauma model and provides foundational knowledge surrounding the non-hemorrhage applications of REBOA including neurogenic shock and stroke.

423. Bailey, Z. S., et al. (2021). "Prehospital Whole Blood Resuscitation Reduces Fluid Requirement While Maintaining Critical Physiology in a Model of Penetrating Traumatic Brain Injury and

Hemorrhage: Implications on Resource-Limited Combat Casualty Care." Shock (Augusta, Ga.) 55(4): 545-553.

ABSTRACT: Prehospital resuscitation using whole blood (WB) is the standard of care for hemorrhagic shock (HS) but there is no consensus recommendation for resuscitation in the presence of traumatic brain injury (TBI) due to a lack of sufficient evidence. In order to evaluate the optimal resuscitation strategies for TBI+HS, Sprague-Dawley rats were randomized into four groups based on resuscitation fluid and prehospital mean arterial pressure (MAP) threshold (n = 9-10/group): Lactated Ringer's (LR)-60 mm Hg (LR60), LR-70 mm Hg (LR70), WB-60 mm Hg (WB60), WB-70 mm Hg (WB70). All groups received a frontal penetrating ballistic-like brain injury followed by a 35-min period of HS. During the prehospital phase, rats received an initial bolus of resuscitation fluid (WB or LR) followed by LR as needed to maintain MAP above the designated threshold for 90 min. During the in-hospital phase, rats received definitive resuscitation with shed WB. Physiological parameters were recorded continuously and cerebral edema was measured at 3 and 24 h postinjury. The WB60 group demonstrated a significantly lower prehospital fluid requirement compared WB70, LR60, and LR70 ($P < 0.05$). Compared to the respective LR groups, both the WB60 and WB70 groups also demonstrated improved MAP, cerebral perfusion pressure, brain tissue oxygen tension, and cerebral edema. The edema benefits were observed at 3 h, but not 24 h postinjury, and were localized to the injury site. Together, these results provide evidence that prehospital WB resuscitation and lower MAP resuscitation thresholds can reduce the prehospital fluid requirement while still maintaining critical cerebral physiology in a model of HS and concomitant TBI.

424. Baillard, C., et al. (2002). "Brain death assessment using instant spectral analysis of heart rate variability." Critical care medicine 30(2): 306-310.

OBJECTIVE: Confirmation of brain death requires an urgent diagnosis to allow rapid vital organ removal for transplantation. Evaluation of forebrain functions is commonly performed through electroencephalogram. Nevertheless, there are, for the moment, no methods that allow for an instantaneous evaluation of brainstem functions. During acute brain injury, heart rate variability is an independent neurologic prognosis indicator resulting from a close relationship between brain stem and cardiac autonomic nervous system. This study aims to evaluate a new heart rate variability spectral analysis method, on a beat-to-beat basis, continuously over the time, during brain death., DESIGN: Prospective, nonrandomized, observational study., SETTING: Intensive care unit., SUBJECTS: Ten patients (age range 25-64 yrs, mean age 41 yrs) with acute brain injury leading to brain death., INTERVENTION: No intervention beyond standard of care, MEASUREMENTS AND MAIN RESULTS: Heart rate, arterial blood pressure, heart rate variability in time and frequency domains method, which included calculation of the instant center frequency of spectrum. Brain death was associated with tachycardia (R-R interval 703 +/- 69 vs. 551 +/- 34 msec, $p < .05$), dramatic reduction of the global spectral power (44.919 +/- 31.511 vs. 3.204 +/- 1.469 msec(2), $p < .05$), and an abrupt shift of instant center frequency to a higher frequency range (0.17 +/- 0.01 vs. 0.26 +/- 0.03 Hz, $p < .05$)., CONCLUSIONS: Such a method allows an instant, noninvasive determination of brainstem death based on a time and frequency domain analysis of heart rate variability.

425. Baillif, S. and V. Paoli (2012). "[Open-globe injuries and intraocular foreign bodies involving the posterior segment]." Plaies et corps etrangers du segment posterieur. 35(2): 136-145.

Open globe injuries involving the posterior segment remain a major cause of visual loss in young adults. They occur more frequently in male than in female populations. The majority is due to domestic accidents, since work-related injuries have been decreasing due to proper education and use of safety equipment. However, leisure-related open globe injuries are on the increase. Prompt recognition and treatment of open globe injuries are essential. At presentation, it is necessary to collect etiological data such as cause, nature, time and place of injury. Anti-tetanus immunization must be confirmed. The presenting visual acuity and clinical examination data must be recorded. The lesion type is classified in

accordance with the Birmingham Eye Trauma Terminology. Ocular ultrasound or computed tomography is performed for patients suspected of having an intra- or periocular foreign body. Functional prognosis is negatively influenced by a posterior or large rupture, the presence of an intraocular foreign body, the presence of retinal lacerations or retinal detachment, or the occurrence of posttraumatic infectious endophthalmitis. Recent advances in microsurgical techniques such as pars plana vitrectomy and new visualization techniques may improve the anatomical and functional prognosis for these patients. However, postoperative proliferative vitreoretinopathy remains a major concern: it is responsible for a significant rate of secondary retinal detachment with negative consequences for visual prognosis.

We are reporting two rare cases of multiple penetrating brain injuries by an indigenously made traditional fishing gear used in an Indian village. Although penetrating injury from varied objects (viz., arrow, smear gun, knife, rod, bullets, etc.) have been reported earlier in the literature, but low-velocity penetrating brain injury by multiple objects is the first to our knowledge. In this report, we discuss the surgical management and outcome with relevant review of literature.

Bullet embolism to the heart is a rare but serious complication of penetrating trauma. Distant migration of foreign bodies via the vascular system must be taken into consideration following penetrating gunshot trauma. Delays in diagnosis may result in poor management and subsequent complications that may lead to grave prognosis. Presently described was a conservatively managed case of asymptomatic intracardiac pellet embolization. Highlighted was the importance of serial scanning for intravascular migration of pellet following penetrating gunshot injury, in addition to conservative management in asymptomatic patients.

---

430. Bakay, L. (1984). "The value of CT scan in gunshot injuries of the brain." Acta neurochirurgica 71(3-4): 189-204.

Fourteen cases of gunshot wounds of the brain, evaluated by CT scanning are presented. The results indicate that CT scanning is superior to other diagnostic tests in missile wounds of the brain. In individual patients it revealed gross injury to the skull, the location of the bullet or its fragments and indriven bone fragments, the track of the bullet, the gross injury suffered by the brain, the extent of oedema, the presence of any intracranial haematoma and late cerebral atrophy. Visualization of the missile track is of particular importance; this cannot be achieved by any other diagnostic method. It is essential for the planning of the surgical approach in these lesions.

---

431. Bakay, L., et al. (1977). "Unusual intracranial foreign bodies. Report of five cases." Acta neurochirurgica 39(3-4): 219-231.

Five patients surgically treated for unusual intracranial foreign bodies are presented. They include representative cases of the three most commonly encountered types of these injuries: industrial accidents, suicidal attempts and the result of criminal assault. Immediate radiological examination is mandatory because the deceptively small entrance wound is usually in no way commensurate with the large size of the foreign body the presence of which is frequently not suspected. The surgical removal of these foreign bodies requires careful pre-operative assessment to avoid hemorrhages and undue injury to the surrounding normal brain tissue.

432. Baker, A. L. and C. R. Sharp (2016). "Decompressive craniotomy for traumatic skull fractures in dogs and cats: A retrospective case series." Journal of Veterinary Emergency and Critical Care 26: S33-S34.

Introduction: Little data has been reported about presentation, diagnosis, and outcome for dogs and cats with traumatic skull fractures requiring decompressive craniotomy. Objectives: The objectives of this studywere to summarize the type of trauma, neurological status at presentation, imaging findings, treatment, and outcome for small animal patients requiring decompressive craniotomy for the management of traumatic skull fractures. We hypothesized that dogs and cats requiring decompressive craniotomy would have predominantly penetrating trauma resulting in depressed skull fractures and variable neurologic status. In addition, we hypothesized that these patients would have a good prognosis, both for return to function and survival to discharge. Methods: Single center, retrospective study of dogs and cats at a university teaching hospital with traumatic skull fractures requiring craniotomy. Patients were identified via medical record search. Results: Over a period of 12 years, 9 dogs and 1 cat sustained traumatic skull fractures and underwent craniotomy. Eight animals suffered bite wounds to the head, one was kicked by a horse, and another was hit by a car. Modified Glasgow Coma Scale (mGCS) scores at presentation ranged from 7 to 17. All animals underwent CT imaging prior to surgery. All animals survived to dischargewith neurological status ranging from normal (8), to mild neurologic deficits (1), and significant disability (1). Decreased mGCS score at admission was associated with increased duration of neurological deficits. One dog was reported to have seizures post discharge. Conclusion: Animals suffering severe head trauma present with a wide range of neurological deficits. Most improved rapidly after craniotomy and were discharged with mild to no neurological signs.

433. Baker, A. M., et al. (2005). "Central penetration and stability of N-terminal tripeptide of insulin-like growth factor-I, glycine-proline-glutamate in adult rat." Neuropeptides 39(2): 81-87.

Insulin-like growth factor-I is a neurotrophic factor and can prevent neurons from ischemic brain injury. However, the large molecular weight and metabolic effects can be problematic in its central delivery. Glycine-proline-glutamate (GPE) is the N-terminal tripeptide of insulin-like growth factor-I, which is naturally cleaved in the plasma and brain tissues. GPE reduces neuronal loss from hypoxic-ischemic brain injury following central administration. Central penetration and the stability of GPE in the plasma and central nervous system were examined in rats using radioimmunoassay and HPLC. GPE was rapidly metabolised in the plasma (8 min) after intraperitoneal administration. Despite having a short half-life in plasma, GPE was detected in the cerebrospinal fluid up to 40 min after intraperitoneal administration. With present of peptidase inhibitors, GPE existed in the brain tissue up to 3 h after intracerebroventricular administration, suggesting a role for peptolysis in its stability. The endopeptidase inhibitors 4- (2-aminoethyl) benzenesulfonyl fluoride hydrochloride (AEBSF) reduced GPE metabolism in the brain tissue while acid peptidase inhibitor pepstatin-A decreased GPE metabolism in the plasma. GPE reduced neuronal loss in the CA1-2 sub-region of the hippocampus given (intraperitoneally) after 30 min of hypoxic-ischemic injury in adult rats, further suggested the effectiveness of GPE central uptake. These results indicated that GPE crosses the blood-CSF and the functional CSF-brain barriers. The longer half-life of GPE in the CNS may be due to its unique enzymatic stability.

434. Baker, C. C., et al. (1980). "Epidemiology of trauma deaths." American journal of surgery 140(1): 144-150.

The records of all 437 persons who died from trauma in San Francisco in 1977 were examined. Sixty-five percent of the sample (285 younger than 50 years, and 119 were between ages 21 and 30. Gunshot wounds (140 or 32 percent) and falls (122 or 28 percent) were the most common causes of injury. Fifty-three percent of the sample were dead at the scene of injury before transport could be accomplished, 7.5 percent died in the emergency room, and 39.5 percent died in the hospital. Fifty-five percent of the 359 patients who died within the first 2 days died from brain injury, while 78 percent of the 55 late deaths were due to sepsis and multiple organ failure. In 10 cases (2 percent), death was due to delayed transport or to errors in diagnosis and treatment and was deemed preventable. The key areas in which advances are necessary in order to reduce the number of trauma deaths are prevention of trauma, more rapid and skilled transport of injured victims, better early management of primary brain injuries, and more effective treatment of the late complications of sepsis and multiple organ failure.

436. Baker, S. A. (2020). "The Morphology of Ballistic Trauma." FASEB Journal 34(SUPPL 1).

In forensic anthropology, bone fracture morphology provides potential evidence in the mechanism of injury or death. Specifically, the type of weapon used, the trajectory of impact, and the direction of fire can also be interpreted from internal and external bone morphology. Morphological characteristics, such as buttresses and sutures, are also applicable when analyzing ballistic trauma. This study analyzed fracture morphology of sagittal and coronal plane cranio-maxillofacial gunshot wounds of five specimens from the Applied Anatomical Research Center's (AARC) skeletal collection. Methodologies include enumerating and describing the etiology of ectocranial fractures, any missing bony segments, and the macroscopic fractures for each specimen. Sliding calipers were used to measure the distance (mm) of the entrance and exit wounds in relation to identifiable bony landmarks. The distribution of fractures and fracture locations on the cranio-maxillofacial region were analyzed and assessed to determine similarities and differences among the sagittal and coronal plane gunshot wound specimens. Results indicate that radiating fractures run parallel to buttressed areas of the cranial vault in both sagittal and coronal plane gunshot wounds but run perpendicular to buttressed areas of the face in sagittal plane specimens only. The value of this research could provide additional evidence to reconstruct death histories of relatively incomplete skulls with suspected ballistic trauma. The ultimate goal is to provide the medicolegal community with a larger, more refined data set to better understand ballistic trauma by examining fracture morphologies of sagittal and coronal gunshot wounds in skeletonized human remains.

437. Bakhos, D., et al. (2015). "Head Spear Gun Injury: An Atypical Suicide Attempt." The Journal of craniofacial surgery 26(6): e547-548.

Weapon injuries with spear gun are rare. The aim of this case report is to report the emergency and surgical management when this event occurs. A 35-year-old man attempted suicide with a spear gun. The entry of the shaft was localized through the submental area without an obvious exit point. The projectile passed through the tongue and palatal bone. A tracheotomy was performed. Preoperative cranial computed tomography (CT) showed the harpoon was gone upward through the submental area, the oral cavity, the ethmoid paranasal sinus, the cribriform plate, and the frontal region without vessel damages. Under general anesthesia, the harpoon was pulled out in order to extract the shaft tip and the articulated wishbone. Osteo-meningeal defect of the ethmoid roof was closed using a middle turbinate flap. There were no neurologic deficit and no cerebro-spinal rhinorrhea at his 3-year follow-up visit. The trajectory of the shaft is different between attempted suicide and accident. Cranial CT scan is helpful to

show the trajectory of the shaft. Angiogram can be helpful to see the relations between the tip shaft and the vessels. The knowledge of the shaft tip and the imagery findings are important to decide the best surgical approach.

438. Bakir, A., et al. (2005). "High-velocity gunshot wounds to the head: analysis of 135 patients." Neurologia medico-chirurgica 45(6): 281-287.

Head injuries due to high-velocity missiles and shrapnel as a result of military conflicts have become a very important cause of death or severe neurological deficits. Military-type missiles have high velocities and transfer higher amounts of energy to neural tissue, compared to civil-type missiles. This physical phenomenon also causes greater neural tissue destruction. Shrapnel particles derive from blasts and cause less severe injury because of the irregular particle shape and low energy transmission. This study analyzed 135 patients with head trauma, 80 patients (59%) injured by missiles and 55 patients (41%) by shrapnel. Glasgow Coma Scale (GCS) scores at admission were 3 to 7 in 69 patients, 8 to 10 in 29 patients, and 11 to 15 in 37 patients. The most common anatomical localizations were the right frontoparietal region in 42 patients and the left frontoparietal region in 40 patients. One hundred patients (74%) were operated on immediately and 35 patients (26%) were treated conservatively in the intensive care unit. Ten of the 135 patients died (7.4%), seven from missile injury and three from shrapnel injury. In this study, we found that high mortality was associated with low GCS score at admission, presence of multilobar or skull base injuries, and involvement of ventricles. Early and aggressive surgical intervention decreased the mortality.

439. Bakker, K., et al. (2017). "Olfactory function in paediatric traumatic brain injury: Recovery patterns and functional implications." Brain Impairment 18(3): 392-393.

Background and aims: Recent research indicates that disruption of olfactory function after paediatric traumatic brain injury (pTBI) is common. Importantly, olfactory dysfunction (OD) is known to have significant functional implications in areas of health, safety and quality of life. Despite this longitudinal research investigating olfactory recovery and the functional impact of OD in pTBI is limited. This study aimed to track the recovery of olfactory function following pTBI and investigate predictors of early and late olfactory outcomes. Method: The olfactory function of 37 children with TBI, aged 8-16 years, was assessed at 0-3, 8 and 18 months post-injury using the University of Pennsylvania Smell Identification Test. Data were collected on demographic and injury variables as well as the impact of OD on day-to-day function. Results: Significant improvements in olfactory performance were evident over time in the group presenting with OD acutely. For the subgroup with the most severe OD only 16% showed recovery to normal olfactory function, with the remainder demonstrating ongoing olfactory impairment 18months post-injury. While predictors of early and late olfactory outcomes varied, occipital site of impact was a significant predictor of later olfactory performance. Conclusions: Our results suggest that while there is evidence of recovery of OD over time after pTBI, those children with more severe OD acutely are likely to have persisting OD. Given this limited recovery, understanding the functional implications of OD and implementation of appropriatemanagement strategies is considered an important aspect of overall rehabilitation management of children with TBI.

---

440. Bakker, K., et al. (2017). "The relationship between olfactory dysfunction and executive function in children with traumatic brain injury." Journal of clinical and experimental neuropsychology 39(9): 876-889.

INTRODUCTION: Olfactory dysfunction (OD) has been suggested as a possible marker of executive function (EF) deficits after traumatic brain injury (TBI) in adults. Little is known about the relationship between EF and OD in pediatric TBI (pTBI). This study aimed to investigate EF, explore the relationship between OD and EF, and determine the utility of olfactory performance as a marker of later EF in pTBI. It was hypothesized that (i) children with TBI would perform more poorly on EF

measures relative to normative expectation; (ii) children with OD would perform more poorly on tests of EF than those with normal olfaction after TBI; and (iii) acute olfactory function would predict later EF for children with TBI., METHOD: This was a prospective longitudinal study. Twenty seven children aged 8-16 with TBI completed olfactory assessment using the University of Pennsylvania Smell Identification Test at 0-3, 8 and 18 months post injury. Assessment of EF occurred at 8 and 18 month follow-up., RESULTS: At 8 month follow-up the pTBI cohort did not demonstrate a consistent pattern of impairment in EF, contrary to our first hypothesis. Children with OD showed significantly poorer performance on a single EF measure of Fluency when compared to those with normal olfaction at 8 months post injury, partially supporting our second hypothesis. Acute olfactory function did not significantly predict EF outcomes at either 8 or 18 months post injury., CONCLUSIONS: Overall our findings provide little support for a significant relationship between EF and OD in pTBI. In particular, there was no strong evidence that acute olfactory function is an accurate predictor of later EF in pTBI. Given the dearth of pediatric research, the limitations of our study and the potential significance of acute olfactory performance as an early marker of later EF deficits in children, further investigation is warranted.

Camel bites are uncommon. They are more common during the rutting season where male camels become more aggressive. Herein, we report a unique case of a 25-year-old man who was repeatedly bitten to his face and neck by an aggressive camel that resulted in left eye evisceration, parotid duct, and facial nerve injury. To our knowledge, Globe rupture caused by a camel bite has not been previously reported.

444. Balasingam, V., et al. (1994). "Reactive astrogliosis in the neonatal mouse brain and its modulation by cytokines." The Journal of neuroscience : the official journal of the Society for Neuroscience 14(2): 846-856.

Reactive astrogliosis is a characteristic response of astrocytes to inflammation and trauma of the adult CNS. To assess the hypothesis that cytokines from inflammatory mononuclear cells that accumulate around lesion sites have a role in modulating astrogliosis, this study sought to take advantage of the neonatal system in which astrogliosis is reported to be minimal following injury and in which the immune system is relatively immature compared to adult animals. A nitrocellulose membrane implant into the cortex of postnatal day 3 mice resulted in a tremendous astrogliotic response 4 d later, as measured by glial fibrillary acidic protein (GFAP) immunoreactivity and GFAP content. In contrast, a neonatal stab wound produced limited astroglial response when compared to the adult stab wound. Utilizing the neonatal stab wound model, cytokines were microinjected into the wound site at the time of injury. All cytokines tested (gamma-IFN, IL-1, IL-2, IL-6, TNF-alpha, and M-CSF) resulted in a significantly increased astrogliosis. The specificity of the cytokine response was demonstrated by the

inability of human gamma-IFN, but not mouse gamma-IFN, in enhancing neonatal mouse astrogliosis, in accordance with reports that the interaction of gamma-IFN with its receptor occurs in a species-specific manner. We conclude that neonatal astrocytes can become reactive if an adequate injury stimulus is presented, and that the release of immunoregulatory cytokines by cells around lesion sites may be a mechanism that contributes to the production of gliosis.

445. Balasubramanian, C., et al. (2009). "Transorbital intracranial penetrating injury-an anatomical classification." Surgical neurology 71(2): 238-240.

BACKGROUND: A transorbital intracranial injury with a wooden foreign body can be very difficult to diagnose and manage. The orbit forms an easy path for low-velocity foreign bodies into the intracranial space. The severity of the injury is often masked by unobtrusive superficial wounds. Computed tomography (CT) findings may be misinterpreted as pneumocephalus., CASE DESCRIPTION: We present a young gentleman who had a fall under the influence of alcohol near a bush and, on clinical presentation, had very little signs of a penetrating injury in the skin. There was some numbness in the V1 distribution of the trigeminal nerve. Further investigation and management are described., CONCLUSION: Although magnetic resonance imaging is more sensitive and specific, a CT angiogram with 3-dimensional reconstruction will provide much insight into the mode of intervention required. We present an anatomical classification for such injuries.

---

446. Balbir, A., et al. (2009). "The effect of topiramate on electroencephalography in a model of penetrating ballistic-type brain injury in rats." Journal of neurotrauma 26(8): A30.

We recently characterized pathological electroencephalographic (EEG) activity associated with severe penetrating ballistic-type brain injury (PBBI; 12-13% of the total brain volume). These include the presence of significantly increased EEG-slowing in the form of polymorphic delta activity, and sporadic non-convulsive seizures (NCS) persisting for 72h. Topiramate (TPM), a broad spectrum anti-epileptic drug, has been shown to attenuate NCS in a model of middle cerebral artery occlusion and offer neuroprotection in a variety of brain injury models. In this study we evaluated the effect of TPM on PBBI induced EEG pathology. Rats (n= 17) were instrumented with 7 electrodes for cortical topographical EEG recording prior to injury. Following injury, rats were treated with a TPM loading dose (30mg/kg, i.v, 30 min post-PBBI) and a subsequent daily maintenance dose (15mg/kg, i.v.) for 72h. Control rats received a matching volume of saline treatment. EEG was recorded continuously for the 72h period as well as on the 7 day post-injury. TPM treated rats (10/10) survived the protocol while some control rats (3/7) died within the 72h treatment phase. Neurological impairment was measured using a neuroscore evaluation (0 = no deficit; lO = maximum deficit) 3Omin, 72h and 7d post-PBBI. Both TPM treated (n=10; neuroscore = 7.1 ±0.6) and vehicle (VEH) treated rats (n = 4; 8.8 ±0.5) demonstrated acute neurological deficits 30 min following injury which did not resolve at 7d. EEG delta power (expressed as a percent of the total EEG power) increased significantly compared to the baseline levels ($p < 0.05$) in both treatment groups and remained elevated through 72h post-injury (VEH-Baseline: 40.0 ±2.4% vs. VEH-72h: 69.4±3.5%; TPM-Baseline: 4l.8±2.l% vs. TPM-72h: 56.9±3.5%). However, when compared to VEH treated, delta power was significantly lower in the TPM group at 24h and 72h post-injury (VEH-24h: 83.4 ± 3.7% vs. TPM-24h: 73.7 ± 2.3%; VEH-72h: 69.4 ± 3.5% vs. TPM-72h: 56.9 ± 3.5%). NCS activity was presentinTPM (40%; 4/10) and VEH (71%; 5/7) treated groups. The significance of the effect of TPM on measures of NCS frequency and duration are the subject of ongoing experiments. In summary, TPM significantly attenuated injury-induced polymorphic delta activity, and appears to decrease the NCS activity and mortality associated with a severe PBBI trauma providing support for its role as a potential neuroprotection therapeutic.

447. Baleydier, C. and C. Quoex (1975). "Epileptic activity and anatomical characteristics of different lesions in cat cortex. Ultrastructural study." Acta neuropathologica 33(2): 143-152.

Three different types of lesions have been studied in the cortex of the cat, by means of electroencephalography and electron microscopy. These three types of lesions can be listed in order of increasing magnitude according to their capacity to induce abnormal electrical activity: 1. incision of the cortex gives paroxymal activity, 2. intracortical insertion of a resin pellet generates weak epileptic activity, 3. intracortical insertion of a colbalt resin pellet produces epileptic activity. A parallel can be drawn between electrophysiological and anatomical data: there seems to be a quantitative relationship between the degree of epileptic activity and the extent of perilesional tissue. Furthermore, in this perilesional tissue, oedema is observed, the intensity of which varies according to the type of lesion. Thus, the epileptic activity of a lesion seems to be proportional not only to the volume of the perilesional tissue but also to the development of the oedema.

448. Ball, C. G. (2015). "Penetrating nontorso trauma: the head and the neck." Canadian journal of surgery. Journal canadien de chirurgie 58(4): 284-285.

Acute penetrating injuries to the head and neck cause considerable anxiety for most clinicians owing to concern for airway control and neurologic injury and to limited clinician experience in most centres. This article discusses an organized approach to the evaluation and initial treatment of penetrating injuries to the head and neck based on regional anatomy and clinical examination. The approach is particularly helpful in the context of ongoing hemorrhage and/or airway compromise.

450. Bamjee, Y., et al. (1996). "Maxillofacial injuries in a group of South Africans under 18 years of age." The British journal of oral & maxillofacial surgery 34(4): 298-302.

OBJECTIVE: To find out the incidence of maxillofacial injuries in South African children aged 18 years or less., DESIGN: Retrospective study of casenotes., SETTING: Six teaching hospitals affiliated to the University of Witwatersrand, Johannesburg, serving a population of about 5 million people., SUBJECTS: All 326 children treated for facial injuries in the maxillofacial and oral departments of the six hospitals between 1 January 1989 and 30 June 1992., MAIN OUTCOME MEASURES: Classification of the types of injury, associated injuries, cause of the injury, and methods of diagnosis., RESULTS: Of the total of 4192 patients of all ages treated for facial injuries, 326 (8%) were within the age range of the study. The female:male ratio was 1:2.3. Most of the injuries (227, 70%) occurred in the 13-18 age group, and assaults, fights and gunshot wounds accounted for 155 injuries (48%). Of the 326 children, 173 (53%) had single injuries and 153 (47%) had multiple injuries. Mandibular fractures were the most common (64%) followed by maxillomandibular fractures (25%). Violence was the most common cause of injury, as in the USA and Zimbabwe, but unlike the rest of the world in which it is motor vehicle accidents. Soft tissue injuries were the most common associated injuries, and conventional plain radiography was the usual investigation., CONCLUSION: The incidence of 8% compares favourably with those in other countries, but far too many injuries are the result of violence.

452. Bandeira-de-Mello, R. G., et al. (2018). "Pyogenic Liver Abscess Secondary to Foreign Body (Fish Bone) Treated by Laparoscopy: A Case Report." Annals of hepatology 17(1): 169-173.

Liver abscess due to perforation of the gastrointestinal tract by a foreign body is a rare and possibly fatal event. Diagnosing this pathology is complicated by the lack of specific symptoms and unfamiliarity of ingestion by the patient and low clinical suspicion of this disease. In the case of liver abscess unresponsive to aspiration and administration of antibiotics, this hypothesis must be made, despite its low incidence. This case report describes and illustrates a case of liver abscess secondary to fish bone ingestion with consequent piercing of the lesser gastric curvature, diagnosed by computed tomography and specific anamnesis. Laparoscopy was performed to extract the foreign body, without complications; the patient is currently asymptomatic and does not present any abnormal physical examination findings. We believe this represents the first case report of a successful laparoscopic treatment in South America for the removal of an ingested foreign body associated with pyogenic liver abscess.

453. Bandt, S. K., et al. (2012). "Management of pediatric intracranial gunshot wounds: predictors of favorable clinical outcome and a new proposed treatment paradigm." Journal of neurosurgery. Pediatrics 10(6): 511-517.

OBJECT: There has been an increase in civilian gun violence since the late 1980s, with a disproportionately high increase occurring within the pediatric population. To date, no definite treatment paradigm exists for the management of these patients, nor is there a full understanding of the predictors of favorable clinical outcome in this population., METHODS: The authors completed a retrospective review of all victims of intracranial gunshot injury from birth to age 18 years at a major metropolitan Level 1 trauma center (n = 48) from 2002 to 2011. The predictive values of widely accepted adult clinical and radiographic factors for poor prognosis were investigated., RESULTS: Eight statistically significant factors ($p < 0.05$) for favorable outcome were identified. These factors include single hemispheric involvement, absence of a transventricular trajectory, < 3 lobes involved, >= 1 reactive pupil on arrival, systolic blood pressure > 100 mm Hg on arrival, absence of deep nuclei and/or third ventricular involvement, initial ICP < 30 mm Hg when monitored, and absence of midline shift. Of these 8 factors, 5 were strong predictors of favorable clinical outcome as defined by Glasgow Outcome Scale score of 4 or 5. These predictive factors included absence of a transventricular trajectory, < 3 lobes involved, >= 1 reactive pupil on arrival, absence of deep nuclei and/or third ventricular involvement, and initial ICP < 30 mm Hg. These findings form the basis of the St. Louis Scale for Pediatric Gunshot Wounds to the Head, a novel metric to inform treatment decisions for pediatric patients who sustain these devastating injuries., CONCLUSIONS: The pediatric population tends to demonstrate more favorable outcomes following intracranial gunshot injury when compared with the adult population; therefore some patients may benefit from more aggressive treatment than is considered for adults. The St. Louis Scale for Pediatric Gunshot Wounds to the Head may provide critical data toward evidence-based guidelines for clinical decision making.

454. Bandyopadhyay, S., et al. (2021). "Traumatic brain injury related paediatric mortality and morbidity in low-and middle-income countries: A systematic review and meta-analysis." British Journal of Surgery 108(SUPPL 6): vi1.

Aim: Three million cases of paediatric traumatic brain injury (pTBI) occur annually, the majority of which occur in low-and-middle-income countries (LMICs). However, there is a paucity of data on the outcomes of pTBI available. We aimed to systematically review and synthesise the reported morbidity andmortality from pTBI in the published literature about LMICs. Method: A systematic review and meta-analysis were conducted. MEDLINE, EMBASE, Global Health, and Global Index Medicus were searched for relevant articles from January 2000 to May 2020. Observational or experimental studies on pTBI (individuals between the ages of 0 to 16 years) in LMICs were included. Morbidity data were descriptively analysed, and a random-effects model was used to pool mortality rates. PROSPERO ID: CRD42020171276. Results: We included 145 studies from 38 countries representing 174073 patients with pTBI. Males were twice (95% CI: 1.6 - 2.4) as likely to have a pTBI than females. Where available, mild TBI represented ≥ 60% of all pTBI cases in most reports (n=24/43, 56%). The commonest cited cause of pTBI was road traffic accidents (n=16643/43083, 39%), followed by falls (n=10927/43083, 25%). 4385 patients (n=4385/18092, 24%) had a reduction from normal function on discharge. On average, there were 6.7 deaths per 100 cases of pTBI. Conclusions: Only 38 LMICs have published data on the volume and burden of pTBI in their country. Limited data available suggests that young male children are at a high-risk of pTBIs in LMICs, particularly from road traffic accidents.

459. Banker, T. P., et al. (2017). "Culture-Positive Endophthalmitis After Open Globe Injuries With and Without Retained Intraocular Foreign Bodies." Ophthalmic surgery, lasers & imaging retina 48(8): 632-637.

BACKGROUND AND OBJECTIVE: To report the visual and anatomical outcomes and microbiologic spectrum of culture-positive endophthalmitis in open globe injuries (OGIs) with or without intraocular foreign bodies (IOFBs)., PATIENTS AND METHODS: A retrospective,

interventional case series of OGIs (n = 718) treated between 2004 and 2015. Patients underwent a management protocol for OGI, including systemic broad-spectrum antibiotics, on presentation., RESULTS: Culture-positive cases of endophthalmitis after open globe repair occurred in 2.1% of eyes (n = 15 of 718 eyes); two eyes had evidence of endophthalmitis on presentation. The most common organism was Staphylococcus species (five of 17 eyes). An IOFB was present in 6.8% of eyes (n = 49 of 718 eyes). All of these eyes received prophylactic intravitreal antimicrobials. In eyes with IOFB, the rate of culture-positive endophthalmitis after initial globe repair was 8.1% (n = 4 of 49 eyes) versus 1.6% (n = 11 of 669 eyes) in eyes without IOFB (P < .01)., CONCLUSION: Culture-positive endophthalmitis was identified after OGIs more often in eyes with a concurrent IOFB. [Ophthalmic Surg Lasers Imaging Retina. 2017;48:632-637.]. Copyright 2017, SLACK Incorporated.

460. Banks, G., et al. (1989). "The alien hand syndrome. Clinical and postmortem findings." Archives of neurology 46(4): 456-459.

Two patients had automatonlike movements of their left hands and arms (alien hand syndrome) following damage to the brain. Autopsy findings in one patient demonstrated gunshot wound damage to the medial frontal white matter bilaterally, as well as the corpus callosum, right basal ganglia, internal capsule, and thalamus. The other patient had a ruptured anterior communicating aneurysm, with subsequent resection of the right frontal gyrus rectus. We postulate that this syndrome is due to the combination of a partial callosectomy and mesial frontal lesions.

462. Bannon, M. J., et al. (2015). "Investigating the potential influence of cause of death and cocaine levels on the differential expression of genes associated with cocaine abuse." PloS one 10(2): e0117580.

The development of new therapeutic strategies for the treatment of complex brain disorders such as drug addiction is likely to be advanced by a more complete understanding of the underlying molecular pathophysiology. Although the study of postmortem human brain represents a unique resource in this regard, it can be challenging to disentangle the relative contribution of chronic pathological processes versus perimortem events to the observed changes in gene expression. To begin to unravel this issue, we analyzed by quantitative PCR the midbrain expression of numerous candidate genes previously associated with cocaine abuse. Data obtained from chronic cocaine abusers (and matched control subjects) dying of gunshot wounds were compared with a prior study of subjects with deaths directly attributable to cocaine abuse. Most of the genes studied (i.e., tyrosine hydroxylase, dopamine transporter, forkhead box A2, histone variant H3 family 3B, nuclear factor kappa B inhibitor alpha, growth arrest and DNA damage-inducible beta) were found to be differentially expressed in chronic cocaine abusers irrespective of immediate cause of death or perimortem levels of cocaine, suggesting that these may represent core pathophysiological changes arising with chronic drug abuse. On the other hand, chemokine C-C motif ligand 2 and jun proto-oncogene expression were unaffected in cocaine-abusing subjects dying of gunshot wounds, in contrast to the differential expression previously reported in cocaine-related fatalities. The possible influence of cause of death and other factors on the cocaine-responsiveness of these genes is discussed.

463. Barac, Y. D., et al. (2019). "Heart Transplantation Survival and the Use of Traumatically Brain-Injured Donors: UNOS Registry Propensity-Matched Analysis." Journal of the American Heart Association 8(17): e012894.

Background The transplantation of hearts from traumatically brain-injured (TBI) donors has been associated with inferior long-term survival in single-center analyses. However, in a more recent analysis, death caused by cerebrovascular accident was associated with worse posttransplant survival in recipients. The purpose of this study was to explore the outcomes of heart transplantation in recipients receiving donor hearts from TBI and non-TBI donors in a large national registry. Methods and Results We performed a retrospective cohort analysis of the UNOS (United Network of Organ Sharing) Registry Organ Procurement and Transplantation Network between 2006 and 2018 for adult candidates wait-listed for isolated heart transplantation. Recipients were stratified into 2 groups, TBI and non-TBI donors. Propensity score matching was performed. Kaplan-Meier analysis was used to estimate survival posttransplant. A total of 24 894 candidates met inclusion criteria. TBI was the leading cause of death in the donor population. Recipients of TBI donor hearts (N=13 07) were younger (median age, 55 versus 57 years; P<0.001) and less likely women (21.6% versus 29.8%; P<0.001). At 10 years, the TBI group had better long-term survival compared with the non-TBI group (62.8% versus 59.9%; P<0.001). After propensity group matching, the 10-year survival was similar between groups. Conclusions In the largest analysis of heart transplants and their survival, according to the type of donor injury (TBI versus non-TBI), we found similar survival in heart transplant recipients. Future studies should address specific subpopulations (eg, hemorrhagic stroke) in the non-TBI group to address concerns about reduced posttransplant survival.

464. Barakat, K. and A. Ali (2014). "Thermoplastic vestibuloplasty: A novel technique for treatment of lip and cheek adhesion." Craniomaxillofacial Trauma and Reconstruction 7(4): 258-262.

Lip and cheek adhesion to the opposing alveolus with complete or partial loss of the vestibular dimension represents a challenging problem for reconstruction. It usually occurs due to primary inadequate vestibular soft tissue repair following complicated trauma cases, burns, and lesions of the oral cavity. Surgical removal of scar tissue and creation of new vestibule is complicated by readhesion between the opposing connective tissue surfaces. Skin grafts and acellular dermal matrix represent the most dominant modalities used to treat deficient vestibule dimensions, but they are difficult to fix and lack the required stability during healing. Several devices have been created in an attempt to keep the tissues apart but their complex anchorage methods seriously reduced their reliability and usage. We devised a simple and reliable technique "thermoplastic vestibuloplasty" (TV) that benefit from the inherent reepithelialization capabilities of the oral mucosa to prevent readhesion and to resurface the created vestibule with its exact tissue color and texture. In total, 10 patients suffering from complete or partial lip or cheek adhesion with concomitant loss of vestibule were surgically treated by excising scar tissue and creating a new vestibule, followed by TV technique. Pre and posttreatment results were compared in terms of vestibular length, lip or cheek mobility, and change by time in vestibular length from 2 weeks up to 3months. Moreover, the patient satisfaction and outcomes were measured using visual analogue scale score. All patients tolerated the procedure without complication. The mean vestibule length and mobility signi ficantly increased from 3.8 + 0.6 mm to 11.4 + 1.4 mm ($p < 0.001$) and from 0.3 to 2 ($p < 0.001$), respectively. Regarding the stability of the achieved vestibular length it decreased by 14% when compared from 2 weeks to 3 months postoperatively. TV technique is a new simple and reliable technique that can effectively prevent readhesion of opposing connective tissue surfaces until intrinsic reepithelialization can resurface the newly created vestibular tissues forming a stable vestibular length with excellent color and texture.

465. Baranov, I. V., et al. (2011). "[Surgical treatment of posttraumatic deformity of the orbital floor]." Vestnik khirurgii imeni I. I. Grekova 170(6): 63-65.

The article is devoted to an actual problem of surgical treatment of patients with posttraumatic deformities of the orbital floor. On the material of 21 observations it was shown that for the successful treatment of deformities of the orbit bottom autogenous costal cartilage graft should be used as a plastic material. Removal of enophthalmos in longstanding fractures can be reached only by reducing the

volume of the orbit which can be achieved by retrobulbar placement of the graft. An analysis of the results demonstrated high efficiency of this method in the treatment of such patients.

---

466. Baransel, A., et al. (2004). "Loss of facial identification of the survivor after firearm injury to the head." Military medicine 169(3): 227-229.

Firearm wounds to the head are often fatal and are routinely encountered in the practice of forensic medicine. Herein we presented a patient who was wounded with a military rifle. This condition is unique and interesting for forensic medicine because none of the vital structures or major vessels were injured although the patient had a firearm injury to his head. In contrast to many other cases, the vital signs of our patient were normal and he was conscious on admission. Although the patient was considered lucky because he was still alive, he now had an unrecognizable face.

468. Barbey, A. K., et al. (2014). "Architecture of fluid intelligence and working memory revealed by lesion mapping." Brain structure & function 219(2): 485-494.

Although cognitive neuroscience has made valuable progress in understanding the role of the prefrontal cortex in human intelligence, the functional networks that support adaptive behavior and novel problem solving remain to be well characterized. Here, we studied 158 human brain lesion patients to investigate the cognitive and neural foundations of key competencies for fluid intelligence and working memory. We administered a battery of neuropsychological tests, including the Wechsler Adult Intelligence Scale (WAIS) and the N-Back task. Latent variable modeling was applied to obtain error-free scores of fluid intelligence and working memory, followed by voxel-based lesion-symptom mapping to elucidate their neural substrates. The observed latent variable modeling and lesion results support an integrative framework for understanding the architecture of fluid intelligence and working memory and make specific recommendations for the interpretation and application of the WAIS and N-Back task to the study of fluid intelligence in health and disease.

469. Barbian, L. T. and P. S. Sledzik (2008). "Healing following cranial trauma." Journal of forensic sciences 53(2): 263-268.

This paper reports on the gross appearance of the initial osseous response following cranial gunshot wounds. A total of 127 adult crania and cranial sections were analyzed for four types of bone response: osteoblastic, osteoclastic, line of demarcation, and sequestration. In general, no osteoblastic or osteoclastic response was noted during the first week. This response was followed by an increasing prevalence of expression after this time. By the sixth week postfracture both osteoclastic and osteoblastic activity was scored for 100% of the sample. Further, our observations suggest that the line of demarcation may establish the boundary between the living bone and bone not surviving the fracture. Sequestration appears to be a long-term event and was scored as present well past the eighth week of healing. The osseous expression of infection following fracture was also considered.

470. Barbois, S., et al. (2016). "Management of penetrating abdominal and thoraco-abdominal wounds: A retrospective study of 186 patients." Journal of visceral surgery 153(4 Suppl): 69-78.

This is a single center retrospective review of abdominal or abdomino-thoracic penetrating wounds treated between 2004 and 2013 in the gastrointestinal and emergency unit of the university hospital of Grenoble, France. This study did not include patients who sustained blunt trauma or non-traumatic wounds, as well as patients with penetrating head and neck injury, limb injury, ano-perineal

injury, or isolated thoracic injury above the fifth costal interspace. In addition, we also included cases that were reviewed in emergency department morbidity and mortality conferences during the same period. Mortality was 5.9% (11/186 patients). Mean age was 36 years (range: 13-87). Seventy-eight percent (145 patients) suffered stab wounds. Most patients were hemodynamically stable or stabilized upon arrival at the hospital (163 patients: 87.6%). Six resuscitative thoracotomies were performed, five for gunshot wounds, one for a stab wound. When abdominal exploration was necessary, laparotomy was chosen most often (78/186: 41.9%), while laparoscopy was performed in 46 cases (24.7%), with conversion to laparotomy in nine cases. Abdominal penetration was found in 103 cases (55.4%) and thoracic penetration in 44 patients (23.7%). Twenty-nine patients (15.6%) had both thoracic and abdominal penetration (with 16 diaphragmatic wounds). Suicide attempts were recorded in 43 patients (23.1%), 31 (72.1%) with peritoneal penetration. Two patients (1.1%) required operation for delayed peritonitis, one who had had a laparotomy qualified as "negative", and another who had undergone surgical exploration of his wound under general anesthesia. In conclusion, management of clear-cut or suspected penetrating injury represents a medico-surgical challenge and requires effective management protocols.

471. Barbosa, G. d. S., et al. (2022). "Performance of the Modified Rapid Emergency Medicine Score in Patients With and Without Traumatic Brain Injury." The Journal of neuroscience nursing : journal of the American Association of Neuroscience Nurses 54(3): 130-135.

ABSTRACT: BACKGROUND: The modified Rapid Emergency Medicine Score (mREMS) is a recently published index to estimate the severity of trauma patients; however, little is known about its performance in patients with different types of trauma. This study verified the predictive capacity of mREMS in-hospital mortality in patients of blunt and penetrating trauma with and without traumatic brain injury (TBI) and the performance of this index compared with the Rapid Emergency Medicine Score, Injury Severity Score, New Injury Severity Score, and Trauma and Injury Severity Score. METHODS: This is a retrospective, correlational study that analyzed trauma patients 18 years or older, who attended at a hospital in Rio de Janeiro, Brazil. The receiver operating characteristic (ROC) curve was applied in the analyses. RESULTS: The sample consisted of 987 patients, 359 (36.4%) with TBI (225 blunt and 134 penetrating trauma). Regarding mREMS, the area under the ROC curve for TBI patients for in-hospital mortality was 0.506 (95% confidence interval [CI], 0.404-0.609) for penetrating injuries and 0.486 (95% CI, 0.402-0.571) for blunt injuries; the values in patients without TBI were 0.629 (95% CI, 0.554-0.703) and 0.618 (95% CI, 0.552-0.684), respectively. In relation to the other indices the mREMS presented the lowest area under the curve/ROC for penetrating and blunt TBI, and the Rapid Emergency Medicine Score for extracranial injuries. CONCLUSION : The mREMS showed no prognostic capacity for patients with TBI, and it presented the worst performance in relation to the Injury Severity Score, New Injury Severity Score, and Trauma and Injury Severity Score to discriminate cases of in-hospital mortality when considering trauma patients with and without TBI.

473. Barfield, D. M., et al. (2016). "Retrospective evaluation of recurrent secondary septic peritonitis in dogs (2000-2011): 41 cases." Journal of veterinary emergency and critical care (San Antonio, Tex. : 2001) 26(2): 281-287.

OBJECTIVE: To describe the clinical characteristics of recurrent septic peritonitis in dogs., DESIGN: Multicenter retrospective observational study., ANIMALS: Client-owned dogs with recurrent septic peritonitis., SETTING: Three university emergency and referral hospitals., INTERVENTIONS: None., MEASUREMENTS AND MAIN RESULTS: Medical records from 3 veterinary university

teaching hospitals were reviewed and data were collected using a standardized data collection sheet for all cases of septic peritonitis during the study period (2000-2011). Forty one dogs met the inclusion criteria for recurrent peritonitis. All dogs underwent relaparotomy. The original cause of septic peritonitis in these cases included previous surgery for gastrointestinal foreign body removal (n = 26), gastrointestinal neoplasia (n = 3), gastric or duodenal ulceration (n = 3), biliary tract leakage (n = 2), and single instance for each of the following: penetrating foreign body, hernia strangulation, intussusception, mesenteric volvulus, infection of the laparotomy incision, prostatic abscess, and trauma. Eighteen animals survived to discharge. There was no difference detected between survivors and nonsurvivors with recurrent peritonitis in terms of inciting cause, serum albumin concentration, surgical management, or provision of appropriate initial antimicrobials. The survival rate for dogs having recurrent peritonitis was 43.9% (18/41 dogs)., CONCLUSIONS: This retrospective study did not identify any significant prognostic indicators for dogs with recurrent peritonitis and that the mortality rate for dogs having more than one surgery for septic peritonitis is similar to that reported for a single surgery for septic peritonitis.

474. Barhoum, M., et al. (2015). "Syria civil war: Outcomes of humanitarian neurosurgical care provided to Syrian wounded refugees in Israel." Brain injury 29(11): 1370-1375.

BACKGROUND: As an expected consequence of the civil war in Syria, emergent neurosurgical care for battlefield trauma has been provided for severely head-injured Syrians transferred to Northern Israel., METHODS: Sixty-six patients suffering from brain injury were brought to the border and then referred to the institution after initial resuscitation. Both the time and type of injury were recorded based on paramedic testimony, forensic material or on details provided by patients. A retrospective analysis of all medical charts and imaging material was performed., RESULTS: Most injuries were combat-related, either caused by blast (13.6%), shrapnel (24.2%), assault (28.8%) or gunshot wound (15.2%). Only a minority of patients (18.2%) suffered from injuries that were not directly caused by weapon. A total of 55 surgical procedures were performed in 46 out of 66 patients, including craniotomies in 40 patients, burr hole alone for placement of intraparenchymal intracranial pressure (ICP) sensor in nine instances and ventricle peritoneal shunt in two patients. Decompressive craniectomy was used only for the treatment of gunshot wound and was performed in eight out of 10 patients. The most common complication consisted in cerebrospinal fluid fistulas (16.7%). Post-operative infections occurred in seven patients (10.6%). Short-term outcomes were favourable in 60.7%, with a mortality rate of 4.5%., DISCUSSION: The present findings suggest that aggressive surgery and neuro-intensive care measures may lead to good functional results, even in the presence of seemingly devastating injuries in some selected patients.

476. Barker-Griffith, A. E., et al. (1998). "Potato gun ocular injury." Ophthalmology 105(3): 535-538.

PURPOSE: This study aimed to identify a dangerous new weapon capable of causing damage to the ocular and periocular regions., METHODS: The authors report two patients who had penetrating ocular injury in the past year because of homemade recreational potato guns., RESULTS: In one 14-year-old boy, projectiles from the firing of a potato gun resulted in orbital and cranial injuries that were life threatening with widespread fractures, marked disruption of facial structures, a cerebrospinal fluid fistula requiring bifrontal surgical repair, and loss of one eye. In a separate accident with a different potato gun, a 14-year-old boy who was wearing glasses at the time of injury had a sight-threatening perforating corneal laceration., CONCLUSION: Practitioners must be aware of the existence of these new, homemade unregulated devices. Information about the use and construction of these guns is

widespread on the Internet, but no injuries resulting from these guns currently are documented in the medical literature.

477. Barnard, E. B. G., et al. (2013). "Anterior chamber gas bubbles in open globe injury." Journal of the Royal Naval Medical Service 99(2): 53-54.

We present a case of a 40-year-old soldier who was in close proximity to the detonation of an improvised explosive device (IED). Bubbles of gas were visible within the anterior chamber of his left eye. The authors propose that intraocular gas, present acutely after trauma, is diagnostic of open globe injury and is of particular importance in remote military environments.

479. Barreda-Manso, M. A., et al. (2017). "Neuroprotection and Blood-Brain Barrier Restoration by Salubrinal After a Cortical Stab Injury." Journal of cellular physiology 232(6): 1501-1510.

Following a central nervous system (CNS) injury, restoration of the blood-brain barrier (BBB) integrity is essential for recovering homeostasis. When this process is delayed or impeded, blood substances and cells enter the CNS parenchyma, initiating an additional inflammatory process that extends the initial injury and causes so-called secondary neuronal loss. Astrocytes and profibrotic mesenchymal cells react to the injury and migrate to the lesion site, creating a new glia limitans that restores the BBB. This process is beneficial for the resolution of the inflammation, neuronal survival, and the initiation of the healing process. Salubrinal is a small molecule with neuroprotective properties in different animal models of stroke and trauma to the CNS. Here, we show that salubrinal increased neuronal survival in the neighbourhood of a cerebral cortex stab injury. Moreover, salubrinal reduced cortical blood leakage into the parenchyma of injured animals compared with injured controls. Adjacent to the site of injury, salubrinal induced immunoreactivity for platelet-derived growth factor subunit B (PDGF-B), a specific mitogenic factor for mesenchymal cells. This effect might be responsible for the increased immunoreactivity for fibronectin and the decreased activation of microglia and macrophages in injured mice treated with salubrinal, compared with injured controls. The immunoreactivity for PDGF-B colocalized with neuronal nuclei (NeuN), suggesting that cortical neurons in the proximity of the injury were the main source of PDGF-B. Our results suggest that after an injury, neurons play an important role in both, the healing process and the restoration of the BBB integrity. J. Cell. 480. Barreto, G. E., et al. (2014). "Selective estrogen receptor modulators regulate reactive microglia after penetrating brain injury." Frontiers in Aging Neuroscience 6(JUN).

Following brain injury, microglia assume a reactive-like state and secrete pro-inflammatory molecules that can potentiate damage. A therapeutic strategy that may limit microgliosis is of potential interest. In this context, selective estrogen receptor modulators, such as raloxifene and tamoxifen, are known to reduce microglia activation induced by neuroinflammatory stimuli in young animals. In the present study, we have assessed whether raloxifene and tamoxifen are able to affect microglia activation after brain injury in young and aged animals in time points relevant to clinics, which is hours after brain trauma. Volume fraction of MHC-II+ microglia was estimated according to the point-counting method of Weibel within a distance of 350 μm from the lateral border of the wound, and cellular morphology

was measured by fractal analysis. Two groups of animals were studied: (1) young rats, ovariectomized at 2 months of age and (2) aged rats, ovariectomized at 18 months of age. Fifteen days after ovariectomy animals received a stab wound brain injury and the treatment with estrogenic compounds. Our findings indicate that raloxifene and tamoxifen reduced microglia activation in both young and aged animals. Although the volume fraction of reactive microglia was found lower in aged animals, this was accompanied by important changes in cell morphology, where aged microglia assume a bushier and hyperplasic aspect when compared to young microglia. These data suggest that early regulation of microglia activation provides a mechanism by which selective estrogen receptors modulators (SERMs) may exert a neuroprotective effect in the setting of a brain trauma.© 2014 Barreto, Santos-Galindo and Garcia-Segura.

481. Barreto, S. M., et al. (2000). "Predictors of first nonfatal occupational injury following employment in a Brazilian steelworks." Scandinavian journal of work, environment & health 26(6): 523-528.

OBJECTIVES: This study investigated the influence of sociodemographic and occupational factors on the risk of 1st injury among Brazilian steelworkers., METHODS: Workers 1st employed between 1 January 1977 and 31 December 1985 and still employed on 1 December 1983 were followed from the date of hire until 30 October 1992. Occupational injuries were ascertained from a database. Kaplan-Meier curves for time to 1st injury were calculated for the total cohort and for different subgroups. A multivariate analysis of risk factors for 1st injury was carried out using the Cox proportional hazards regression model., RESULTS: Forty-one percent of the workers had > or = 1 occupational injuries, and 39% of 1st injuries occurred in the 1st year of employment. Lacerations, contusions, penetration by foreign bodies, bums, sprains, and fractures constituted the main diagnostic groups. Injuries to the hands, eyes, feet, arms, and legs dominated. Over 5% of the injured workers were on temporary disability leave (cumulative total 10,660 days). The probability for an occupational injury was 16% for the 1st year, rising to 25% in the 2nd year. The risk of nonfatal injury was highest for laborers [hazard ratio (HR) 1.76, 95% confidence interval (95% CI) 1.35-2.29] and employees in the steel mill (HR 1.40, 95% CI 1.21-1.63), and inversely related to worker age and educational level. The risk of injury decreased significantly with calendar period of employment., CONCLUSIONS: Substantial reductions in nonfatal injuries may reflect changes in work organization, increased automation, and improved safety standards. Knowledge of predictors of work-related injury may contribute to injury prevention strategies, especially among newly employed workers.

483. Barrow, D. L., et al. (1984). "The use of greater omentum vascularized free flaps for neurosurgical disorders requiring reconstruction." Journal of neurosurgery 60(2): 305-311.

The heterotopic transfer of composite tissue, with microvascular anastomosis of an arterial supply and venous drainage to locally existing vessels, has received considerable attention in the plastic surgical literature. The use of latissimus dorsi musculocutaneous free flaps has been reported in the repair of large defects of the scalp, cranium, and dura following resection of invasive neoplasms or trauma. When the defect involves primarily subcutaneous tissue loss resulting in abnormal contour, omental free flaps provide effective coverage and restoration of contour. In addition, the inherent capability of the omentum to combat infection and form an ideal bed for the establishment of skin or bone grafts provides further indications for its use. The authors have used omental free flaps in nine cases to reconstruct gunshot wounds of the head, orbit, and face, heal chronic cavitating frontal sinus infections, form a base over exposed dura for reconstruction of the skull with rib grafts, and cover large defects after resection of invasive tumors or infected scalp. These wounds of neurosurgical interest were reconstructed with acceptable structural and aesthetic results. The indications, surgical techniques,

results, alternative procedures, and potential complications of this procedure are discussed. The authors believe that omental free flaps should be considered an option in the armamentarium of reconstructive approaches for skull, dural, scalp, orbital, and facial wounds.

484. Barrs, D. M. (1991). "Facial nerve trauma: optimal timing for repair." The Laryngoscope 101(8): 835-848.

Due to the uncertainty of optimal timing for facial nerve repair after severe trauma, a study was designed to investigate facial nerve repair in micro-pigs by grafting at intervals after nerve transection ranging from 0 to 90 days. Following adequate time for regeneration, it was possible to electrically stimulate across the nerve graft in all animals. No significant difference existed between operative groups for electrophysiologic testing. Axon counts demonstrated a trend toward a lower regeneration rate in more delayed grafts. This trend and the ease of grafting with less scar and nerve stump resection suggest that the best results may be obtained with grafting as early as possible. Grafting at 21 days, the peak of neuron cell-body metabolic activity, did not produce better results. Since statistically significant differences do not exist between individual groups, grafting several months after trauma can be successful, if medically necessary.

485. Barrs, V. R., et al. (2007). "Intracranial empyema: literature review and two novel cases in cats." The Journal of small animal practice 48(8): 449-454.

OBJECTIVES: To review the literature on intracranial empyema and report two new cases in cats., METHODS: Literature review and case reports., RESULTS: Intracranial empyema has been rarely reported in small animals. In two novel cases in cats, the route of infection was postulated to be local extension from a retrobulbar abscess of odontogenic origin in one case and direct inoculation from a penetrating bite wound to the skull, confirmed at post-mortem examination, in the other. On magnetic resonance imaging of the first case, there was a contrast-enhancing large extra-axial fluid collection overlying the right cerebral hemisphere, consistent with subdural empyema. Infection was caused by an Actinomyces spp. This is the first report of successful treatment of intracranial empyema by craniotomy, drainage and antibiotics., CLINICAL SIGNIFICANCE: Intracranial empyema is a neurosurgical emergency. Favourable outcomes may be achieved with surgical decompression, antimicrobial therapy and intensive care.

486. Bartee, B. K. (1995). "The use of high-density polytetrafluoroethylene membrane to treat osseous defects: clinical reports." Implant dentistry 4(1): 21-26.

Alveolar bone resorption can result from tooth loss, periodontal disease, or trauma. Guided tissue regeneration is used in an attempt to exclude tissues devoid of osteogenic potential from a bone defect or cavity and promote new bone growth to replace missing osseous structure. Many types of barrier membranes have been used, but none have been found to be ideal for every clinical situation. Macroporous membranes, such as expanded polytetrafluoroethylene, require primary closure and a second surgical procedure for their removal. Macroporous membranes can incorporate bacteria and may become infected if exposed in the oral cavity. Membranes manufactured of resorbable polymers require primary closure of the augmentation site and exhibit variable patterns of resorption, introducing a degree of unpredictability into the procedure. The use of high-density polytetrafluoroethylene membrane to promote deposition of bone for ridge augmentation in the oral cavity is described. Two clinical reports are presented.

487. Bartholomew, B. J., et al. (2003). "Unusual transoral penetrating injury of the foramen magnum: case report." Neurosurgery 53(4): 989-991.

OBJECTIVE AND IMPORTANCE: Penetrating injuries of the cranium and spine are frequent to the civilian neurosurgical practice. Although a variety of unusual objects have been reported, to our knowledge, there has never been a craniocerebral or spinal injury caused by a fish. An unusual case of transoral penetration of the foramen magnum by a billed fish is described. The history, radiographic studies, and treatment are presented., CLINICAL PRESENTATION: A fisherman struck by a jumping fish initially presented with severe neck pain and stiffness, bleeding from the mouth, and a laceration in the right posterior pharynx. A computed tomographic scan of the cervical spine revealed a wedge-shaped, hyperdense object extending from the posterior pharynx into the spinal canal between the atlas and the occiput. Because of the time factor involved, the fisherman was brought directly to surgery for transoral removal of the object., INTERVENTION: The patient was placed under general anesthesia, and with a tonsillar retractor, a kipner, and hand-held retractors, the object was visualized and identified as a fish bill. Further dissection above the anterior aspect of the atlas permitted removal of the object by means of a grabber from an arthroscopic set. No expression of cerebrospinal fluid was noted, and a Penrose drain was placed., CONCLUSION: The patient was treated under the assumption that penetrating foreign objects in continuity with the cerebrospinal fluid space and the outside environment should be removed as soon as possible. The patient was provided appropriate antibiotics to treat potential infection of normal pharyngeal flora and organisms unique to the marine environment. The patient recovered and did not experience any residual neurological deficit.

488. Bartholomew, S. and A. Young (2019). "Observing pneumothoraces: The 35-millimeter rule is safe for both blunt and penetrating chest trauma: Eddine SBZ, Boyle K, Dodgion CM, et al. J Trauma Acute Care Surg. 2019;86(4):557–564." Journal of Emergency Medicine 57(3): 420.

With the increased use of chest computed tomography (CT) in trauma patients, providers are detecting occult pneumothoraces more frequently. While standard practice has been to place a chest tube in all patients with a traumatic pneumothorax, more recently providers are observing some hemodynamically stable patients with pneumothoraces. Prior trials have concluded that using a cut-off of pneumothoraces <35mm could predict successful observation. This study aimed to demonstrate that there is an objective measurement that can be used to determine which traumatic pneumothoraces can be safely observed without requiring placement of a chest tube. This was a single center retrospective study of patients admitted to a level 1 trauma center between 2011 and 2016. Inclusion criteria consisted of patients over age 18 that had chest CT at the time of admission following trauma. Exclusion criteria included patients who had no chest CT performed, had an ipsilateral hemothorax or hemopneumothorax, had a chest tube inserted before doing a chest CT, and patients who were mechanically ventilated during their index admission. To obtain the measurement for the cutoff value, study authors measured the distance between the parietal pleura and the mediastinum in a line perpendicular to the chest wall, measuring the largest air pocket. Measurements were categorized into those with a measurement greater than or less than 35mm. Patient management was categorized into those who were observed or those who had placement of a chest tube. Observation was defined as not requiring a chest tube within 4 hours of presentation to the emergency department (ED). The primary outcome was successful observation of the pneumothorax. Failure of observation included interventions such as delayed chest tube placement, video assisted thorascopic surgery (VATS), intrapleural tissue plasminogen activator, or thoracotomy. Secondary outcomes included hospital length of stay and intensive care unit (ICU) length of stay. 1,767 patients with a traumatic pneumothorax were identified in the institution’s trauma registry, of which 935 were immediately excluded due to presence of hemothorax or hemopneumothorax, 116 excluded due to initiation of mechanical ventilation, resulting in 336 eligible patients with CT identified occult pneumothorax. 94.3% of the patients had a blunt mechanism of injury. The median measurement of pneumothoraces was 10.4mm, with 293 (87.2%) of the pneumothoraces measuring 35mm or less. The median length of stay in the hospital was 4 days. 47 patients received a chest tube within the first 4 hours and 257 (89%) were observed. There were 272 patients in the trauma registry with pneumothorax ≤ 35mm; of these, 25 patients (9%) failed observation. There were 17 patients with a pneumothorax of >35mm, of which 41% failed observation. Reasons for failure included progression of pneumothorax,

development of pleural effusion, tension pneumothorax, and hemothorax. In those with a pneumothorax of 35mm or less, there was a positive predictive value of successful observation of 90.8%, with a negative predictive value of 41.2%. Significant predictors for failing observation included: pneumothorax measurement category (≤35 mm vs. >35 mm) ($P < 0.0001$), GCS ($p = 0.012$), and number of rib fractures ($p = 0.048$) in a univariate logistic regression analysis, but in a multivariate logistic regression analysis, the size of pneumothorax ≤ 35mm was the single predictor of success (OR for failure 0.142, 95% CI 0.047-0.428). The authors of the article conclude that although Advanced Trauma Life Support (ATLS) suggests the placement of a chest tube for all traumatic pneumothoraces to prevent the development of a tension pneumothorax, given the lack of guidelines the decision to place a chest tube in these pneumothoraces should be balanced between the risks and benefits to potentially spare patients the avoidable morbidity and even mortality. The authors concluded that this study adds validity to the use of the 35-mm rule in guiding decisions to observe stable patients with pneumothoraces based on their low failure rate of 9% and use of the rule at a different institution and with a different practice group than prior studies. The limitations of the study include determination of a 4 hour cut-off for observation based on institution physician practice patterns, unclear reasons for placing the chest tube in 34.4% of the patients, visual measurement of the largest air pocket on CT, and imbalance between incidence of blunt (94.3%) and penetrating trauma. The latter raises the question as to whether the results are generalizable to penetrating trauma resulting in isolated pneumothorax. Commentary: Avoiding unnecessary chest tube placement in traumatic pneumothorax is a no-brainer. This study showed that pneumothorax size ≤ 35mm was an independent predictor of successful observation without chest tube placement. However, the retrospective nature of this study does limit it's applicability. Significant selection bias exists and it is not clear which of the patients who had physiologic deterioration or required a second intervention were in the observed cohort ≤ 35mm and or not. A prospective observational or randomized trial will be needed before this suggested algorithm should be adopted for all traumatic pneumothorax.

---

489. Barton, J. J. S. (2008). "Structure and function in acquired prosopagnosia: lessons from a series of 10 patients with brain damage." Journal of neuropsychology 2(1): 197-225.

Acquired prosopagnosia varies in both behavioural manifestations and the location and extent of underlying lesions. We studied 10 patients with adult-onset lesions on a battery of face-processing tests. Using signal detection methods, we found that discriminative power for the familiarity of famous faces was most reduced by bilateral occipitotemporal lesions that involved the fusiform gyri, and better preserved with unilateral right-sided lesions. Tests of perception of facial structural configuration showed severe deficits with lesions that included the right fusiform gyrus, whether unilateral or bilateral. This deficit was most consistent for eye configuration, with some patients performing normally for mouth configuration. Patients with anterior temporal lesions had better configuration perception, though at least one patient showed a more subtle failure to integrate configural data from different facial regions. Facial imagery, an index of facial memories, was severely impaired by bilateral lesions that included the right anterior temporal lobe and marginally impaired by fusiform lesions alone; unilateral right fusiform lesions tended to spare imagery for facial features. These findings suggest that (I) prosopagnosia is more severe with bilateral than unilateral lesions, indicating a minor contribution of the left hemisphere to face recognition, (2) perception of facial configuration critically involves the right fusiform gyrus and (3) access to facial memories is most disrupted by bilateral lesions that also include the right anterior temporal lobe. This supports assertions that more apperceptive variants of prosopagnosia are linked to fusiform damage, whereas more associative variants are linked to anterior temporal damage. Next, we found that behavioural indices of covert recognition correlated with measures of overt familiarity, consistent with theories that covert behaviour emerges from the output of damaged neural networks, rather than alternative pathways. Finally, to probe the face specificity of the prosopagnosic defect, we tested recognition of fruits and vegetables: While face specificity was not found in most of our patients, the data of one patient suggested that this may be possible with more focal lesions of the right fusiform gyrus.

491. Bashir, M.-U., et al. (2013). "Craniocerebral injuries in war against terrorism --- a contemporary series from Pakistan." Chinese journal of traumatology = Zhonghua chuang shang za zhi 16(3): 149-157.

OBJECTIVE: Terrorism-related bomb attacks on civilian population have increased dramatically over the last decade. Craniocerebral injuries secondary to improvised explosive devices have not been widely reported in the context of unarmored civilians. This series intends to report the spectrum of these injuries secondary to suicidal and implanted bombs as encountered at the Aga Khan University Hospital, Pakistan (AKUH). Further, a few pertinent management guidelines have also been discussed., METHODS: The hospital database and clinical coding during a 5-year period were examined for head injuries secondary to terrorism-associated blasts. In addition to patient demographics, data analysis for our series included initial Glasgow Coma Scale, presenting neurological complaints, associated non-neurological injuries, management (conservative or operative) to associated complications, and discharge neurological status., RESULTS: A total of 16 patients were included in this series. Among them 9 were victims of suicidal blasts while 7 were exposed to implanted devices. The patients presented with diverse patterns of injury secondary to a variety of shrapnel. A follow-up record was available for 12 of the 16 patients (mean follow-up: 7.8 months), with most patients having no active complaints., CONCLUSION: The results of this series show that civilian victims of suicidal and improvised bombings present with a wide range of neurological symptoms and injury patterns, which often differ from the neurological injuries incurred by military personnel in similar situations, and thereby often require individualized care.

---

492. Basit, R., et al. (2023). "Simulating traumatic brain injury in vitro: Developing high throughput models to test biomaterial based therapies." Neural Regeneration Research 18(2): 289-292.

Traumatic brain injuries are serious clinical incidents associated with some of the poorest outcomes in neurological practice. Coupled with the limited regenerative capacity of the brain, this has significant implications for patients, carers, and healthcare systems, and the requirement for life-long care in some cases. Clinical treatment currently focuses on limiting the initial neural damage with long-Term care/support from multidisciplinary teams. Therapies targeting neuroprotection and neural regeneration are not currently available but are the focus of intensive research. Biomaterial-based interventions are gaining popularity for a range of applications including biomolecule and drug delivery, and to function as cellular scaffolds. Experimental investigations into the development of such novel therapeutics for traumatic brain injury will be critically underpinned by the availability of appropriate high throughput, facile, ethically viable, and pathomimetic biological model systems. This represents a significant challenge for researchers given the pathological complexity of traumatic brain injury. Specifically, there is a concerted post-injury response mounted by multiple neural cell types which includes microglial activation and astroglial scarring with the expression of a range of growth inhibitory molecules and cytokines in the lesion environment. Here, we review common models used for the study of traumatic brain injury (ranging from live animal models to in vitro systems), focusing on penetrating traumatic brain injury models. We discuss their relative advantages and drawbacks for the developmental testing of biomaterial-based therapies.

---

493. Basit, R. H., et al. (2021). "New in vitro model of traumatic brain injury to assess biomaterial based regenerative strategies." British Journal of Surgery 108(SUPPL 2): ii1.

Introduction: Penetrating traumatic brain injury (pTBI) management is largely supportive, with no clinically established regenerative therapies. Neurocompatible biomaterials offer a high potential to

promote regenerative mechanisms but facile, high throughput, pathomimetic in vitro pTBI models for the developmental testing of neuro-materials is lacking. Method: A mouse mixed glial culture system was utilised within which penetrating injuries could be induced. DuraGen Plus™-an FDA approved neurosurgical grade biomaterial could be implanted into lesions to assess cell-biomaterial responses. Reactive gliosis (astrocytic morphological responses/GFAP expression) and microglial infiltration (Iba1 expression) were assessed/quantified. Results: Key pathological features of pTBI were observed in the model, with the ability to (i) introduce reproducible lesions (diameter 949 6 26 μm) and (ii) for DuraGen Plus™ to be implanted into lesions. Perilesional astrocytes displayed hypertrophic palisading morphologies and GFAP upregulation, analogous to gliosis in vivo. Significant microglial numbers infiltrated the DuraGen Plus™ implant at 7 days post-lesion (132.41 ± 15.83 cells/mm2) versus lesion only (82.04 ± 5.11 cells/ Mm2), $p<0.05$). Conclusions: We have developed a novel, neuropathomimetic pTBI model, wherein biomaterial implantation enables investigation of neural cell-biomaterial responses. This model can facilitate early-stage evaluation of novel biomaterials as high throughput, inexpensive and facile screening tool.

494. Basit, R. H., et al. (2021). "In vitro model of traumatic brain injury to screen neuro-regenerative biomaterials." Materials science & engineering. C, Materials for biological applications 128: 112253.

Penetrating traumatic brain injury (pTBI) causes serious neurological deficits with no clinical regenerative therapies currently available. Tissue engineering strategies using biomaterial-based 'structural bridges' offer high potential to promote neural regeneration post-injury. This includes surgical grade materials which can be repurposed as biological scaffolds to overcome challenges associated with long approval processes and scaleup for human application. However, high throughput, pathomimetic models of pTBI are lacking for the developmental testing of such neuro-materials, representing a bottleneck in this rapidly emergent field. We have established a high throughput and facile culture model containing the major neural cell types which govern biomaterial handling in the central nervous system. We show that induction of traumatic injuries was feasible in the model, with post-injury implantation of a surgical grade biomaterial. Cellular imaging in lesions was achievable using standard epifluorescence microscopy methods. Key pathological features of pTBI were evident in vitro namely immune cell infiltration of lesions/biomaterial, with responses characteristic of cell scarring, namely hypertrophic astrocytes with GFAP upregulation. Based on our observations, we consider the high-throughput, inexpensive and facile pTBI model can be used to study biomaterial 'implantation' and evaluate neural cell-biomaterial responses. The model is highly versatile to test a range of laboratory and clinical grade materials for neural regeneration.

495. Basmadjian, G., et al. (1975). "Retinal detachment after strabismus surgery." American journal of ophthalmology 79(2): 305-309.

Four nonmyopic eyes in three patients developed retinal detachment after strabismus surgery. Certain features common in all four eyes included the presence of a chorioretinal scar corresponding in location to the muscle operated on, proliferating fibrous tissue adjacent to the scar, and varying degrees of vitreous hemorrhage. These findings were similar to those in retinal detachments after perforation of the eye by foreign bodies. Penetration of the globe by the needle during muscle surgery was considered the etiologic factor. The use of spatula needles to prevent piercing of the globe is suggested, and in case such accident is suspected, diathermy or cryoapplication over the perforation site is advised.

496. Bast, C., et al. (2018). "Incidence of infection in patients receiving short vs. long duration of antimicrobial prophylaxis in neurosurgery." Open forum infectious diseases 5: S631.

Background. Surgical site infections in neurosurgery occur in up to 10% of procedures. The American Society of Health-System Pharmacists guidelines promote antimicrobial prophylaxis (AP) for up to 24 hours from neurosurgery using cefazolin while the Neurocritical Care Society guidelines

promote single pre-procedural dose of AP for extraventricular drain (EVD) monitoring. Despite these guidelines, practice variation exists with often longer antimicrobial exposure and subsequent complications. Methods. This retrospective study included patients admitted to Baylor University Medical Center from January 1, 2014 to September 20, 2017 and underwent cranial or spinal neurosurgery requiring AP. This study excluded patients with basilar skull fracture, presence of cerebrospinal fluid leak, penetrating trauma, meningitis, and patients receiving antibiotics for documented or suspected infection unrelated to neurosurgery. Patients who received AP for up to 24H (short course) were compared with patients who received AP for greater than 24H (long course) at 90 days. Data were analyzed using the Fisher exact test, Student's t-test and Wilcoxon rank-sum tests as applicable. Results. A total of 183 patients were included with 90 and 93 patients receiving short or long courses of AP, respectively. Baseline characteristics were similar for the groups. Patients in the short course AP group received a mean antibiotic duration of 16.9 ± 4.3H while those in the long course AP group received 72.2 ± 50.9H ($P < 0.001$). The mean number of antimicrobials prescribed was 1.1 vs. 1.8 ($P < 0.001$) in the short vs. long groups, respectively. At 90 days, there were no significant differences in the rate of surgical site infections (1.1% vs. 2.1%, $P = 0.99$), development of multi-drug-resistant infections (2.2% vs. 2.2%, $P = 0.99$), and Clostridium difficile infection (0% vs. 1.1%, $P = 0.99$) in the short vs. long groups, respectively. Conclusion. The rate of surgical site infections was not significantly different in patients that received short vs. long durations of antimicrobial prophylaxis. These results highlight an opportunity to improve antibiotic use and promote principles of antimicrobial stewardship in neurosurgery.

497. Bater, M. C., et al. (2007). "Use of an inferior orbitotomy for safe removal of a wooden foreign body penetrating the orbit." The British journal of oral & maxillofacial surgery 45(8): 664-666.

Penetrating orbital foreign bodies must be removed in a safe and controlled manner. Adequate access is necessary so that there is no further damage to the orbital structures and to allow haemostasis. We describe a case of a wooden foreign body that penetrated the left orbit and its subsequent removal using an inferior orbitotomy. To our knowledge, this technique has not been previously described for removal of a foreign body.

498. Bates, R. C., et al. (2015). "Increasing pro-survival factors within whole brain tissue of Sprague Dawley rats via intracerebral administration of modified valproic acid." Journal of pharmacological sciences 128(4): 193-201.

Neural tissue exposure to valproic acid (VPA) increases several pro-survival phospho-proteins that can be used as biomarkers for indicating a beneficial drug response (pAkt(Ser473), pGSK3beta(Ser9), pErk1/2(Thr202/Tyr204)). Unfortunately, targeting VPA to neural tissue is a problem due to severe asymmetrical distribution, wherein the drug tends to remain in peripheral blood rather than localizing within the brain. Intracerebral delivery of an amide-linked VPA-PEG conjugate could address these issues by enhancing retention and promoting cerebro-global increases in pro-survival phospho-proteins. It is necessary to assay for the retained bioactivity of a PEGylated valproic acid molecule, along with locating an intracranial cannula placement that optimizes the increase of a known downstream biomarker for chronic VPA exposure. Here we show an acute injection of VPA-PEG conjugate within brain tissue increased virtually all of the assayed phospho-proteins, including well-known pro-survival factors. In contrast, an acute injection of VPA expectedly decreased signaling throughout the hour. Needle penetration into whole brain tissue is the intentional cause of trauma in this procedure. The trauma to brain tissue was observed to overcome known phospho-protein increases for unmodified VPA in the injected solution, while VPA-PEG conjugate appeared to induce significant increases in pro-survival phospho-proteins, despite the procedural trauma.

499. Batsaikhan, B., et al. (2019). "Post-Injury Neuroprotective Effects of the Thalidomide Analog 3,6'-Dithiothalidomide on Traumatic Brain Injury." International journal of molecular sciences 20(3).

Traumatic brain injury (TBI) is a major cause of mortality and disability worldwide. Long-term deficits after TBI arise not only from the direct effects of the injury but also from ongoing processes such as neuronal excitotoxicity, inflammation, oxidative stress and apoptosis. Tumor necrosis factor-alpha (TNF-alpha) is known to contribute to these processes. We have previously shown that 3,6'-dithiothalidomide (3,6'-DT), a thalidomide analog that is more potent than thalidomide with similar brain penetration, selectively inhibits the synthesis of TNF-alpha in cultured cells and reverses behavioral impairments induced by mild TBI in mice. In the present study, we further explored the therapeutic potential of 3,6'-DT in an animal model of moderate TBI using Sprague-Dawley rats subjected to controlled cortical impact. A single dose of 3,6'-DT (28 mg/kg, i.p.) at 5 h after TBI significantly reduced contusion volume, neuronal degeneration, neuronal apoptosis and neurological deficits at 24 h post-injury. Expression of pro-inflammatory cytokines in the contusion regions were also suppressed at the transcription and translation level by 3,6'-DT. Notably, neuronal oxidative stress was also suppressed by 3,6'-DT. We conclude that 3,6'-DT may represent a potential therapy to ameliorate TBI-induced functional deficits.

500. Batur, M., et al. (2018). "Posttraumatic Oculorrhea From the Eyelid." Pediatric emergency care 34(8): e150-e151.

We report a 21-month-old boy with a sutured laceration of the left upper eyelid with drainage of cerebrospinal fluid. Careful evaluation, including computerized tomography, revealed a penetrating injury of the left orbital wall and a linear bone fracture. The wound was resutured carefully. There was no cerebrospinal fluid leakage in the postoperative follow-up period.

501. Bauch, C. D., et al. (1999). "Penetrating injury to the brainstem after a nailgun accident: a case study." American journal of audiology 8(1): 57-64.

Nonfatal penetrating injuries to the brainstem offer a unique opportunity to assess subcortical auditory pathway function. A case study of a patient suffering a severe nailgun accident is presented. Hearing sensitivity and acoustic reflexes were normal bilaterally, but word recognition was reduced for one ear. Auditory brainstem response results indicated waves I-IV were present bilaterally, but wave V was absent bilaterally. Results of vestibular findings indicated central pathology also. Results of audiologic, vestibular, radiologic, neurologic, and physical medicine examinations are discussed.

502. Bauer, M. and D. Patzelt (2002). "Intracranial stab injuries: case report and case study." Forensic science international 129(2): 122-127.

Non-missile penetrating brain injuries are rare events in western countries. We report a case with lethal stab injury of the brain and identification of the weapon used in the assault by digital superimposition on CT scans taken at admission of the victim to a hospital. Furthermore, all cases with knife stab wounds of the skull between 1971 and 2000 were analyzed and compared with literature reports. Results of this study show that there is no region preference despite of differences in bone thickness, that stab wounds of the brain are almost invariably associated with multiple stab wounds to the trunk and that the wound tract may correspond to the dimensions of the blade allowing the identification of the weapon by digital image analysis.

503. Baumgart, E. V., et al. (2012). "Stab wound injury of the zebrafish telencephalon: a model for comparative analysis of reactive gliosis." Glia 60(3): 343-357.

Reactive glia, including astroglia and oligodendrocyte progenitors (OPCs) are at the core of the reaction to injury in the mammalian brain with initially beneficial and later partially adverse functions

such as scar formation. Given the different glial composition in the adult zebrafish brain with radial ependymoglia but no parenchymal astrocytes, we examined the glial response to an invasive stab wound injury model in the adult zebrafish telencephalon. Strikingly, already a few days after injury the wound was closed without any scar tissue. Similar to mammals, microglia cells reacted first and accumulated close to the injury site, while neither GFAP+ radial ependymoglia nor adult OPCs were recruited to the injury site. Moreover, OPCs failed to increase their proliferation after this injury, while the number of proliferating GFAP+ glia was increased until 7 days after injury. Importantly, neurogenesis was also increased after injury, generating additional neurons recruited to the parenchyma which survived for several months. Thus, these data suggest that the specific glial environment in the adult zebrafish telencephalon is not only permissive for long-term neuronal survival, but avoids scar formation. Invasive injury in the adult zebrafish telencephalon may therefore provide a useful model to untangle the molecular mechanisms involved in these beneficial glial reactions.

506. Bauza, A. M., et al. (2013). "Work-related open-globe injuries: demographics and clinical characteristics." European journal of ophthalmology 23(2): 242-248.

PURPOSE: To describe the demographics and clinical characteristics of work-related open-globe injuries (OGIs) at a level I trauma center over a 10-year period., METHODS: Retrospective series., RESULTS: A total of 183 eyes with work-related OGIs were identified. The majority of injuries occurred in men (96.7%). The anatomic site of the wound was zone 1 in 107 eyes (72.3%). The most common cause was nail gun use (47.0%). The types of OGI included 32 ruptures (17.5%), 112 penetrating injuries (61.2%), 38 intraocular foreign bodies (IOFB) (20.8%), and 1 mixed rupture/IOFB injury (0.5%). Presenting visual acuity (VA) was worse than 20/200 in 112 eyes (65.9%) and no light perception (NLP) in 10 eyes (5.8%). Final VA worse than 20/200 occurred in 64 eyes (37.2%); 11 eyes underwent enucleation. In comparison to non-work-related OGIs (420 eyes), we found significant differences in types and zones of injury, initial and final mean VA, enucleation rate, incidence of cataracts, hyphema, retinal detachment, hemorrhagic choroidals, and afferent pupillary defect (APD). Using multivariate analysis, significant prognostic factors for a final VA of NLP were zone 3 injury, rupture injury, and initial VA of NLP. Risk factors for enucleation included zone 3 injury, APD, and endophthalmitis., CONCLUSIONS: Work-related injuries were noted to have a much higher incidence of IOFBs and cataracts compared to non-work-related OGIs. Zone 3 injuries, rupture injuries, and a presenting VA of NLP were found to be significant predictors for a final VA of NLP. Zone 3 injury, APD, and endophthalmitis were found to be significant predictors for enucleation.

507. Bavishi, S., et al. (2010). "Chronic post-traumatic headache resolution after ventriculoperitoneal shunt placement: A case report." Brain injury 24(3): 370.

Objectives: Introduction Decompressive craniectomy is an effective treatment for uncontrolled intracranial hypertension due to severe traumatic Brain Injury (Toussaint&Origitano 2008). However, late complications after this procedure can include post-traumatic hydrocephalus (PTH), particularly when there is also a history of traumatic subarachnoid hemorrhage (SAH), and cerebellar herniation through a craniectomy defect. This case report will summarize the recovery of a 36 y/o Army Staff Sergeant who suffered a severe penetrating traumatic Brain Injury (TBI) while on active duty in

Operation Iraqi Freedom. He was hit by shrapnel from an improvised explosive device while working as a turret gunner in a Humvee. Injuries included obliteration of the right occipital lobe, subdural hemorrhage (SDH), SAH, intraventricular hemorrhage (IVH), retained foreign body, and cortical blindness. He underwent emergent right occipital and posterior fossa craniectomy with intracranial hemorrhage and lateral IVH evacuation. He was stabilized and underwent extensive rehabilitation at the inpatient Polytrauma Rehabilitation Center. He functionally recovered well in spite of significant residual visual impairment. He had a cranioplasty 5 months after injury and serial brain imaging showed right occipital encephalomalacia and stable right cerebellar herniation through his residual craniectomy skull defect. He was followed in the outpatient setting by PM&R and Neurosurgery for nearly two years for severe persistent daily headaches (HAs) and gradual cognitive decline. Objectives This case report discusses the importance of recognizing late complications of decompressive craniectomies that can lead to significant declines in function and quality of life. Method: Case Report Results: Ambulatory EEG demonstrated epileptiform activity; Topamax was started without improvement in either headaches or cognition. CT scan did not show significant ventriculomegaly but did show persistent cerebellar herniation at the posterior skull base under the craniectomy repair. Patient was admitted for a diagnostic high volume spinal tap and experienced temporary resolution of HAs for a four-day period. A ventriculo-peritoneal (VP) shunt was placed, following which the patient had complete resolution of his headaches and experienced significant improvement in cognition. Conclusions: The incidence of post-traumatic hydrocephalus (PTH) varies widely. A higher incidence of PTH is associated with increased length of coma, increased age, decompressive craniectomy (DC), and SAH (Mazzini et al., 2003). This patient had DC, traumatic SAH, and head CTs that showed persistent cerebellar herniation through the residual craniectomy defect. It is possible that the cranioplasty may have altered the pattern of CSF flow at this level leading to late development of PTH. When persisting refractory posttraumatic headaches occur in a patient with this history, one should suspect PTH, particularly since this condition can respond to treatment with a VP shunt.

508. Bayat, M., et al. (2010). "Comparison of conchal cartilage graft with nasal septal cartilage graft for reconstruction of orbital floor blowout fractures." The British journal of oral & maxillofacial surgery 48(8): 617-620.

Our aim was to compare autogenous nasal septal cartilage and conchal cartilage as grafts for reconstruction of orbital blowout fractures. Twenty-two patients with blowout fractures were randomly assigned to two groups for treatment with a graft of nasal septal cartilage or conchal cartilage. Patients were evaluated for the presence of enophthalmos, diplopia, dysfunction of the infraorbital nerve, and restriction of the ocular muscles. Patients with enophthalmos of more than 2 mm were included in the study, and were followed up postoperatively at 10 days, 1 month, and 3-6 months. The patients treated with a nasal septal cartilage graft had significantly better correction of enophthalmos than those treated with conchal cartilage (p=0.02) after 10 days (p=0.02), 1 month (p=0.004), and 3-6 months (p=0.001). There was significantly less residual enophthalmos in the nasal septal graft group after 1 month (0.91 compared with 1.72 mm, p=0.02), and after 3-6 months (1.0 compared with 2.54 mm, p=0.008). Correction of enophthalmos was considerably better in patients who were operated on within 4 weeks of injury. We think that nasal septal cartilage is a better graft than conchal cartilage for reconstruction of blowout fractures. The time to intervention (the earlier the better) is a critical point in the correction of enophthalmos.

509. Bayramoglu, S. E., et al. (2018). "Delayed diagnosis of an intraorbital wooden foreign body." Orbit (Amsterdam, Netherlands) 37(6): 468-471.

A 35-year-old male patient was presented with pain on his right upper eyelid. A piece of wood injured his orbital and supraorbital regions while working at a furniture factory 10 days prior to our hospital admission. It was learned that the patient was discharged following the primary would closure

procedure. Subsequent to the craniofacial computed tomography, primary wound closure was performed in the emergency room of previous hospital. In our clinic, a skin suturing on the nasal side of the right eyebrow was inspected and a foreign body (FB) was palpated on the superonasal contiguity of the patients' right globe. A hyperdense FB measuring 30 x 10 x 5 mm in size with smooth margins on superonasal contour of the globe was detected. Superonasal orbitotomy was performed and the FB was completely removed. Finally, visual acuity was 20/20 and a mild residual ptosis was observed.

510. Bayston, R., et al. (2000). "Use of antibiotics in penetrating craniocerebral injuries. "Infection in Neurosurgery" Working Party of British Society for Antimicrobial Chemotherapy." Lancet (London, England) 355(9217): 1813-1817.

The Working Party was instituted to investigate the rationale of prophylactic and therapeutic antibiotic use in penetrating craniocerebral injuries (PCCI), and to make recommendations for current practice. A systematic review of papers on civilian and military PCCI over the past 25 and 50 years, respectively, was done via electronic databases and secondary sources, and data were evaluated. Guidelines on the removal of indriven bone or metal fragments only if further neural damage can be avoided were supported. However, no publications were identified where the data on infection or its treatment and prevention were complete or satisfactorily derived, and no controlled trials have been published. All studies were retrospective or anecdotal. Working Party recommendations are based on the data available and the professional experience and knowledge of the members. Broad-spectrum antibiotic prophylaxis is recommended for both military and civilian PCCI, Including those due to sports or recreational injuries.

511. Bazarian, J. J., et al. (2018). "Serum GFAP and UCH-L1 for prediction of absence of intracranial injuries on head CT (ALERT-TBI): a multicentre observational study." The Lancet. Neurology 17(9): 782-789.

BACKGROUND: More than 50 million people worldwide sustain a traumatic brain injury (TBI) annually. Detection of intracranial injuries relies on head CT, which is overused and resource intensive. Blood-based brain biomarkers hold the potential to predict absence of intracranial injury and thus reduce unnecessary head CT scanning. We sought to validate a test combining ubiquitin C-terminal hydrolase-L1 (UCH-L1) and glial fibrillary acidic protein (GFAP), at predetermined cutoff values, to predict traumatic intracranial injuries on head CT scan acutely after TBI., METHODS: This prospective, multicentre observational trial included adults (>=18 years) presenting to participating emergency departments with suspected, non-penetrating TBI and a Glasgow Coma Scale score of 9-15. Patients were eligible if they had undergone head CT as part of standard emergency care and blood collection within 12 h of injury. UCH-L1 and GFAP were measured in serum and analysed using prespecified cutoff values of 327 pg/mL and 22 pg/mL, respectively. UCH-L1 and GFAP assay results were combined into a single test result that was compared with head CT results. The primary study outcomes were the sensitivity and the negative predictive value (NPV) of the test result for the detection of traumatic intracranial injury on head CT., FINDINGS: Between Dec 6, 2012, and March 20, 2014, 1977 patients were recruited, of whom 1959 had analysable data. 125 (6%) patients had CT-detected intracranial injuries and eight (<1%) had neurosurgically manageable injuries. 1288 (66%) patients had a positive UCH-L1 and GFAP test result and 671 (34%) had a negative test result. For detection of intracranial injury, the test had a sensitivity of 0.976 (95% CI 0.931-0.995) and an NPV of 0.996 (0.987-0.999). In three (<1%) of 1959 patients, the CT scan was positive when the test was negative., INTERPRETATION: These results show the high sensitivity and NPV of the UCH-L1 and GFAP test. This supports its potential clinical role for ruling out the need for a CT scan among patients with TBI presenting at emergency departments in whom a head CT is felt to be clinically indicated. Future studies to determine the value added by this biomarker test to head CT clinical decision rules could be warranted., FUNDING: Banyan Biomarkers and US Army Medical Research and Materiel Command.

512. Bazarian, J. J., et al. (2009). "Long-term neurologic outcomes after traumatic brain injury." The Journal of head trauma rehabilitation 24(6): 439-451.

OBJECTIVE: To determine the relations between traumatic brain injury (TBI) and several neurologic outcomes 6 months or more after TBI., PARTICIPANTS: Not applicable., DESIGN: Systematic review of the published, peer-reviewed literature., PRIMARY MEASURES: Not applicable., RESULTS: We identified 75 studies that examined the relations between TBI and neurologic outcomes. Unprovoked seizures are causally related to penetrating TBI as well as to moderate and severe TBI. There was only limited evidence of an association between seizures and mild TBI. Dementia of the Alzheimer's type (DAT) was associated with moderate and severe TBI, but not with mild TBI unless there was loss of consciousness (LOC); the evidence for the latter was limited. Parkinsonism was associated with moderate and severe TBI, but there was only modest evidence of a link with mild TBI without LOC. Dementia pugilistica was associated with professional boxing. There was insufficient evidence to support an association between TBI and both multiple sclerosis and amyotrophic lateral sclerosis. TBI appeared to produce a host of postconcussive symptoms (eg, memory problems, dizziness, and irritability). Moderate and severe TBI were associated with endocrine problems such as hypopituitarism and growth hormone deficiency and possibly with diabetes insipidus. There was only limited evidence of an association between mild TBI and the development of ocular/visual motor deterioration., CONCLUSION: TBI is strongly associated with several neurologic disorders 6 months or more after injury. Clinicians caring for TBI patients should monitor them closely for the development of these disorders. While some of these disorders can be treated after they arise (eg, seizures), a greater public health benefit would be achieved by preventing them before they develop. Research efforts to develop therapies aimed at secondary prevention are currently underway.

513. Bearcroft, P. W. and C. E. Freer (1995). "CT of a peripatetic intracranial foreign body." Neuroradiology 37(7): 542-544.

We report the CT appearances of a low-velocity missile that lodged within the brain and which subsequently migrated spontaneously back along the entry path. We review the literature of similar instances of migration and draw conclusions about the presurgical radiological management.

---

514. Beattie, G., et al. (2020). "Automatic acoustic gunshot sensor technology's impact on trauma care." The American journal of emergency medicine 38(7): 1340-1345.

INTRODUCTION: As cities nation-wide combat gun violence, with less than 20% of shots fired reported to police, use of acoustic gunshot sensor (AGS) technology is increasingly common. However, there are no studies to date investigating whether these technologies affect outcomes for victims of gunshot wounds (GSW). We hypothesized that the AGS technology would be associated with decreased prehospital transport time., METHODS: All GSW patients from 2014 to 2016 were collected from our institutional registry and cross-referenced with local police department data regarding times and locations of AGS alerts. Each GSW incident was categorized as related or unrelated to an AGS alert. Admission data, trauma outcomes, and prehospital time were then compared., RESULTS: We analyzed 731 patients. Of these, 192 were AGS-related (26%) and 539 were not (74%). AGS-related patients were more likely to be female ($p < 0.01$), have a higher injury severity score (ISS) ($p < 0.01$), and require an operation ($p = 0.03$). Ventilator days ($p < 0.05$) and hospital length of stay ($p < 0.01$) was greater in the AGS cohort. Mortality, however, did not differ between groups ($p = 0.5$). On multivariable analysis, both total prehospital time and on-scene time were lower in the AGS group ($p < 0.01$)., CONCLUSION: Our study suggests reduced transport times, decreased prehospital and emergency medical service on-scene times with AGS technology. Additionally, despite higher ISS and use of more hospital resources, mortality was similar to non-AGS counterparts. The potential of AGS technology to further decrease

prehospital times in the urban setting may provide an opportunity to improve outcomes in trauma patients with penetrating injuries.

515. Beattie, G., et al. (2022). "A comparison of clinical characteristics, radiographic findings, and outcomes of bihemispheric versus unihemispheric gunshot wounds to the head." The American journal of emergency medicine 60: 78-82.

INTRODUCTION: Unihemispheric head gunshot wound (HGSW) are associated with improved survival; however, specific clinical and radiographic characteristics associated with survival have not been clearly defined. To further guide prognosis estimates and care discussions, this study aims to identify unihemispheric HGSWs injury patterns; comparing them to bihemispheric HGSWs characterizing factors associated with improved clinical outcomes and survival., METHODS: Patients presenting to our Level 1 trauma center from January 2013 through May 2019 with HGSW injury were reviewed. Patients were grouped into those with unihemispheric versus bihemispheric HGSWs and survivors versus non-survivors. Clinical variables and head computed tomography (CT) features were compared using comparative statistics., RESULTS: 62 HGSW patients met study criteria (unihemispheric = 33, bihemispheric = 29). Regardless of injury type, avoidance of injury to multiple lobes, temporal, parietal and basal ganglia brain regions and intracranial vascular injury were also associated with survival ($p < 0.05$). Lower admission GCS score and lower motor GCS score was associated with reduced survival in unihemispheric HGSW injury ($p < 0.05$). Unihemispheric HGSW survivors demonstrated improved clinical outcomes, with reduced hospital length of stay (5 days vs. 47 days, $p = 0.014$) and intensive care unit length of stay (3 days vs. 20 days, $p = 0.021$) and more favorable disposition location., CONCLUSION: We found presenting clinical features and CT imaging patterns previously associated with improved survival in HGSW patients is similar in unihemispheric specific injuries. Importantly, a more favorable admission GCS score may portend survivability in unihemsipheric HGSW. Furthermore, unihemispheric HGSW survivors may have improved clinical outcomes, length of stay and disposition location.

---

516. Beaty, N. B., et al. (2012). "Penetrating intracranial gunshot wound transecting the right transverse sinus." BMJ case reports 2012.

A 23-year-old man sustained a gunshot wound to the posterior head. Imaging demonstrated a transection of the right transverse sinus, a retained bullet fragment and significant cerebellar oedema. The patient emergently underwent suboccipital decompression associated with brisk bleeding from the transverse sinus. Reported examples of surgical management of cerebral venous sinuses include: packing, grafting, patching and ligation. Our patient had a codominant transverse sinus and underwent successful unilateral ligation. His postoperative course was uneventful, however, he did require a ventriculoperitoneal shunt. He was subsequently discharged to rehab with a favourable outcome.

---

517. Bebarta, V. S., et al. (2009). "Disease and non-battle traumatic injuries evaluated by emergency physicians in a U.S. tertiary combat hospital." Annals of emergency medicine 54(3): S59.

Study Objectives: Emergency physicians have played a central role in medical care delivery in Operation Iraqi Freedom. Medical war planning has focused on combat-related injuries; however, since 2004 nearly half of the patients treated in a tertiary U.S. combat hospital in Iraq are not combat related. In order to plan for future wars and properly train emergency physicians, the common emergent and urgent non-combat diagnoses and complex procedures performed should be identified. These data have not been previously collected or studied to determine the types of non-combat injuries and illnesses seen at a tertiary combat hospital and the types of procedures performed to manage these patients. Methods: In our institutional review board-approved study, we enrolled all non-combat injured patients over one year who were evaluated in the emergency department (ED) of a US military tertiary hospital in Iraq. The treating emergency physician used a standard data collection form to enroll all patients who arrived

to the ED whose injury or illness was unrelated to combat. Data collected included age, time of visit, ED diagnoses, emergency procedures, disposition, and consultations. The diagnosis and procedure lists were defined before study start. Results: Data were gathered on 1745 patients with a mean age of 30.2 years (range 6 months - 72 years). 1460 (83%) patients were male and 1316 (75.4%) were U.S. military personnel, with Iraqis, foreign military members and third country nationals making up the remaining. The most common diagnoses evaluated in the ED were abdominal disorders (302 cases, 17.3%), orthopedic injuries (209, 12%), headache (108, 6.2%), ophthalmologic injuries (106, 6.1%), lacerations or abrasions (99, 5.7%), soft tissue infections (94, 5.4%), and renal colic (88, 4.7%). Emergent medical diagnoses consisted of 10.2% (179) of cases (aortic dissection, meningitis, altered mental status, overdose, pulmonary embolism, intestinal bleeding, acute myocardial infarction, chest pain, atrial fibrillation). Urgent medical diagnoses consisted of 4.4% (78) of cases (pneumonia, diverticulitis, deep venous thrombosis, seizure, syncope). Emergent surgical diagnoses consisted of 10.7% (186) of cases (appendicitis, cholecystitis, bowel obstruction, peritonsillar abscess, fracture, dislocation, gunshot wound, eye trauma, brain injury). 52% (909 cases) required IV access, 45% (793) received laboratory testing, 31% (537) received radiographs, and 28% (488) received CT scans. Complex procedures include ECG interpretation (9%, 160 cases), lumbar puncture (1.1%, 20), procedural sedation (0.8%, 14), endotracheal intubation (10), and central line (4). 4.5% of cases were admitted to the operating room, 6.5% to the ICU, and 21.6% to the ward. 12.6% of patients were evacuated out of Iraq. Conclusion: Life-threatening diseases and non-battle traumatic injuries are common in a tertiary-combat hospital emergency department. Providers working in similar settings should have diagnostic and procedural skills to evaluate and treat a range of emergently ill patients.

518. Becelli, R., et al. (2011). "Major facial trauma after helicopter landing." The Journal of craniofacial surgery 22(4): 1517-1519.

Injuries in civil aviation can occur as a consequence of work-related accidents happening in airport. The ground crew can sustain slips, trips, falls, and machinery accidents. Most such accidents are observed when aircraft is departing. This clinical report describes a case of an airport ground assistant severely injured by a helicopter after the strike with a main rotor blade that was slowing after that the craft was landed and the engine was stopped, and reports surgical emergency treatment of life-threatening facial lesions.

519. Becker, H. and E. Schneider (1981). "[CT of the base of the skull in bacterial meningitis (author's transl)]." CT der Schadelbasis bei bakterieller Meningitis. 49(12): 446-450.

CT examinations of 42 cases of bacterial meningitis revealed in 38, 1% of the cases relevant inflammatory processes at the base of the skull which were of significant importance for a transmitted infection. Such infections were: Sinusitis frontalis, ethmoidalis, maxillaris and sphenoidalis, mastoiditis or petrositis, suppurating mucocele, impression fracture, and an intracranially penetrated foreign body. Excepting the identification of fine fractures, conventional x-ray films were diagnostically superior. Hence, especially in the acute stages, special projections can be omitted, if CT is effected in the region of the osseous base of the skull. CT performed in inflammatory diseases of the brain must include the base of the skull, since this will yield reliable pointers to an original focus of the inflammation requiring appropriate treatment and elimination.

520. Beckers, H. (1987). "[Primary management of 2 unusual facial injuries]." Zur Primarversorgung von zwei ungewohnlichen Gesichtsverletzungen. 372: 715-719.

In the first patient a spinning saw-blade cut through the soft tissues and bony structures of the face in a paramedian, vertical section; in another patient a dum-dum bullet fired in suicidal intention from submentally destroyed the frontal half of the mandible and maxilla, the nose and the medial part of both orbits. The facial soft tissues, however, suffered only minor injuries. In the first patient the

immediate treatment included inspection of the frontal sinus, preserving all loose bone fragments, and immediate reconstruction of the medial orbital frame employing bonewires, identification of the lacrimal ducts, reapproximation and stabilisation of these ducts with very flexible silicone threads, soft-tissue closure employing a running z-plasty, interdigitating the z-shaped wound edges caused by the saw. In the second patient stability of the remaining mandibular portions was achieved by mandibular reconstruction plates to which all remaining mandibular bone fragments were attached with bone screws or wires. The stabilized mandible allowed suspension of the tongue.

521. Bede, S. (2013). "Mandibular fractures in Iraq: An epidemiological study." Craniomaxillofacial Trauma and Reconstruction 8(1): 59-63.

The purpose of this study was to evaluate the epidemiological characteristics of the mandibular fractures relating to gender, age, the etiology of injury, and the rendered treatment modalities and complications. The data of the patients who sustained mandibular fractures were retrieved and were analyzed retrospectively, and based on these data a descriptive analysis was conducted. A total of 112 patients were included in this study; the most common cause was road traffic accidents (RTAs) followed by assaults and missile injuries. The most frequently involved age group was 11 to 20 years, treatment modalities included conservative, closed reduction and indirect fixation, and open reduction and internal fixation (ORIF) in 11.6, 79.5, and 8.9% of the cases, respectively. Most of the major complications were injury related. This study showed RTAs to be the most frequent cause followed by assaults, it also showed that a high percentage of assault victims were females mainly of low socioeconomic status. Another distinguishing feature in this study was the high incidence of missile injuries in the form of bullets and blasts. Closed reduction still has an important role in the treatment of fractures of mandible especially when the necessary equipments for ORIF are not readily available. A higher complication rate was observed in patients diagnosed with multiple and comminuted fractures as well as those caused by violence in the form of missile and assault injuries.

522. Bede, S. Y. H. and F. T. Ahmed (2011). "Management of retained foreign bodies in missile injuries of the maxillofacial region." The Journal of craniofacial surgery 22(4): 1440-1444.

This study evaluates 22 patients with retained foreign bodies in the maxillofacial region that were all caused by penetrating missile injuries. Surgical intervention for the retrieval of the foreign bodies was carried out in 20 patients through the existing wounds and through separate incisions; all patients were followed up for a minimum of 2 months during which all the complications were registered and managed. Preoperative imaging is a prerequisite for the accurate localization of the foreign body and the subsequent successful removal of it. All patients developed complications that were categorized in this study into those that result from the injury itself and those that occur because of the retrieval procedure, the latter category being mostly easily managed. In general, all foreign bodies in the maxillofacial region should be removed; the surgeon involved should weigh the benefits and the perils of the removal, and the patient should be well informed about the possibility of the failure of removal of the foreign body.

523. Behera, C., et al. (2008). "Decapitation with egg shelling of the skull in a road traffic accident: a case report." Medicine, science, and the law 48(1): 87-88.

A 40-year-old lady was found dead on a road early one morning. She had allegedly been run over by a speeding vehicle. The head of the deceased had been decapitated, with egg shelling of the skull from the scalp and face. The skull was lying a little distance away from the rest of the body. Although decapitation is not an unknown entity in a road traffic accident, subsequent egg shelling of the skull, leaving behind scalp and face tissue, has not been reported in a road traffic accident in the forensic literature.

524. Behnia, H. and M. H. Motamedi (1997). "Reconstruction and rehabilitation of short-range, high-velocity gunshot injury to the lower face: a case report." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery 25(4): 220-227.

War injuries can range from the most minor to the devastating and life-threatening. Multidisciplinary care is required for successful management of survivors. In the acute phase, care may involve emergency surgeons, anaesthetists, neurosurgeons, ophthalmic surgeons, vascular surgeons and ENT specialists in addition to the oral and maxillofacial surgeon. Afterwards, definitive treatment of facial hard and soft tissue gunshot injuries depends ultimately on the abilities and skills of the oral and maxillofacial surgeon and his appreciation of such injuries. The timing and sequence of the surgical procedures used for reconstruction and rehabilitation of maxillofacial gunshot injuries are crucial to a successful outcome and aesthetic result. If incorrect, they may lead indefinitely to infection, graft rejection, wound dehiscence with consequent multiple revisional operations and complications which will prolong hospital stay, and increase treatment costs and morbidity in these patients. In this article, we describe the treatment protocol for reconstruction and rehabilitation of a typical case of devastating gunshot injury to the lower face and propose a staged sequence of surgical treatment based on an 8-year experience gained in treating war casualties during the Iraq-Iran war (1980-1988).

525. Bein, T., et al. (2006). "[Prevention of organ failure in an organ donor. Early identification and maximum protective therapy after multiple trauma]." Verhinderung des Organversagens beim Organspender. Fruhzeitige Identifikation und maximale protektive Therapie nach Polytrauma. 131(44): 2465-2468.

ANAMNESIS: A 18-year-old woman suffered from severe multi-trauma in combination with acute brain injury (Glasgow Coma Scale Score = 4) after road accident. After prolonged rescue measures and emergency stabilisation the patient was transferred by helicopter to the emergency department of our clinic., INVESTIGATIONS: Cranial computer tomography showed a severe general cerebral edema and a marked reduction in cerebral perfusion. Additionally, blunt abdominal injury, severe chest injury and multiple fractures were seen. Due to the severe and diffuse brain injury, a neurosurgical intervention was not possible. The patient was transferred to the intensive care unit., THERAPY AND COURSE: Intensive supportive therapy was started (artificial ventilation, massive transfusion, volume replacement, insertion of a chest tube, renal replacement therapy). Control cerebral computer tomography indicated a complete destruction of the cerebral parenchyma and infarction. Sedation was stopped. After 48-hours of intensive care therapy brain death was stated and the approval for organ donation was given by the next of kin. Heart and kidneys were explanted and transplanted successfully., CONCLUSION: Even under conditions of limited organ functions early identification and maximal supportive therapy may help to supply organ donation. Under certain condition, multiorgan failure may be reversible in possible organ donors.

526. Beining, T., et al. (2020). "Projectile Wound to Head from Modified Electronic Cigarette Explosion." Journal of forensic sciences 65(4): 1365-1367.

One of the dangers of a rapidly growing technology industry is the risk involved in being intimately close to lithium-ion batteries. When exposed to improper conditions, lithium-ion batteries in a variety of devices have been reported to ignite and, in some cases, explode. With the rise of electronic cigarette use and modifications, the lithium-ion batteries in these devices are subject to a higher risk of malfunction. This is a retrograde analysis of a 38-year-old man who experienced fatal penetrating head trauma while using a modified electronic cigarette device. The findings suggest that the trauma from the explosion was caused by the thermal runaway of the lithium-ion battery in the modified e-cigarette.

528. Bekiroglu, F. and N. M. Whear (2007). "An unusual "sebaceous cyst"." The British journal of oral & maxillofacial surgery 45(4): 338.

A 41-year-old man was referred by his general practitioner to the general surgeons with an "infected sebaceous cyst" above the right medial canthus. "Cyst" was excised by the general surgeons. But this was followed by its recurrence after a number of weeks. A lateral skull radiograph showed the presence of a radio-opaque foreign body within the right orbit.

---

529. Belanger, M. E., et al. (2019). "First Canadian facial transplantation: A case report of the anesthetic management." Canadian Journal of Anesthesia 66(2): S189-S191.

Background Globally, facial transplantation has been performed by only a few teams (1). This complex procedure presents many surgical and anesthetic challenges (1,2,3). Here, we report on the anesthetic management of the first Canadian face transplant. Case presentation Extensive preparation and coordination were key to the success of this procedure. The face harvest and transplantation were performed simultaneously in one operating theatre. Each patient had a primary and secondary anesthesiologist at all times. It was understood by all that the viability of the solid organs took precedence over the face. The recipient, who consented to this report's publication, was a 64-year-old man who suffered ballistic trauma to the lower two thirds of the face. His surgery started four hours before the donor's face was harvested in order to minimize the time of graft ischemia (4). Major blood losses and hemodynamic instability were anticipated (3,5). Thus, two arterial lines ' a cardiac output monitor (NICOM cheetah Medical) and femoral central access ' were installed. As the patient had a background of chronic pain, a pain monitor (NOL Medasense) was utilized. The airway was managed with an armored endotracheal tube in the existing tracheostomy. Anesthesia was maintained with sevoflurane, remifentanil, and ketamine infusions. The surgery lasted 36 hours and total blood loss was 2000 ml. Antibiotics and immunosuppressants were meticulously administered to prevent graft rejection and infection (1). The patient was extubated on postoperative day 12 and was discharged from the hospital on day 60. Acute pain management was the cause for the prolonged intubation and hospital stay. The donor was a 48-year-old man who was declared brain dead after a cerebral hemorrhage. The organs selected for transplant were face, heart, kidneys, and liver. He developed anemia, thrombocytopenia, and insipidus diabetes, which were corrected prior to harvesting. In preparation for the facial harvest, a tracheotomy and jaw fixation were performed the day prior to the transplant. Femoral venous and arterial access with cardiac output monitoring (FloTrac, Edwards medical) were utilized as most of the neck was part of the graft. The face was harvested first, followed by the liver, kidneys, and heart. Major blood losses were anticipated during the facial osteotomies and the hepatectomy. Dissection of the facial nerves prevented the patient from being paralyzed, while remifentanil and sevoflurane were used to prevent spinal reflexes. The facial harvest lasted 14 hours and the other organs were successfully harvested afterwards. The total blood loss was 1400 mL. A silicone mask was created with the donor's facial impression and sutured to his face to preserve dignity. Conclusion This case report illustrates the anesthetic challenges that were encountered during the first Canadian facial transplantation and credits its success to the coordinated efforts of the entire team.

531. Belding, J. N., et al. (2021). "Occupational Risk of Low-Level Blast Exposure and TBI-Related Medical Diagnoses: A Population-Based Epidemiological Investigation (2005-2015)." International journal of environmental research and public health 18(24).

Because traumatic brain injury (TBI)-most often caused by exposure to high-level blast (HLB)-is a leading cause of medical evacuations of deployed U.S. service members in recent conflicts, researchers seek to identify risk factors for TBI. Previous research using self-reported data has identified low-level blast (LLB) as one such risk factor and suggests an association with susceptibility to and symptoms associated with TBI. This article presents a population-based study of all branches of military service that examines the association between occupational risk for LLB and both clinically diagnosed TBIs-from concussions to severe and penetrating TBIs-and conditions commonly comorbid with concussion. Using archival medical and career records from >2 million service members between 2005-2015, this work demonstrates that occupational risk of LLB is associated with any TBI, mild TBI, moderate TBI, cognitive problems, communication problems, hearing problems, headaches, any behavioral health condition, anxiety, drug abuse/dependence, alcohol abuse/dependence, delirium/dementia, posttraumatic stress disorder, post-concussive syndrome, tinnitus, fatigue, and migraines. Understanding the full scope of the effects of LLB on service members will help ensure the health and readiness of service members and may influence both military policy and clinical practice guidelines for blast-induced injuries.

532. Belen'kaia, R. M. and V. P. Chernenkov (1988). "[Late epilepsy in patients with cerebrovascular pathology with a history of craniocerebral injury]." Pozdniaia epilepsiia u bol'nykh s tserebrovaskuliarnoi patologiei, perenesshikh cherepno-mozgovuiu travmu. 88(5): 22-25.

The authors examined 200 patients with various types of cerebral circulation disorders and a history of a war-time craniocerebral trauma. Twenty-six percent of patients developed late epilepsy or a recurrence of epileptic attacks in old and advanced age. A craniocerebral trauma is a risk factor for the development of late epilepsy. Groups with a "pseudotumorous" and "pseudostroke" course of vascular-traumatic epilepsy have been differentiated. The authors consider the relationship between the traumatic and vascular factors in the etiopathogenesis of "late" epilepsy.

533. Belhumeur, V., et al. (2022). "Cerebrospinal fluid external leak after penetrating trauma in a neurologic intact infant patient: a case report." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery 38(8): 1647-1649.

Cranial cerebrospinal fluid (CSF) leak is an extremely rare complication of blunt head trauma causing skull fractures, especially fractures involving the skull base. We present the case of a 10-month-old male who received glass fragments on the midline and posterior tier of his anterior fontanelle producing a cranial cerebrospinal fluid leak without any skull fracture or symptoms. Neurologic exam was completely normal and a superficial stitch wound repair was performed. He was observed for 24 h, had no antibiotic, and left with a 1-week outpatient neurosurgical follow-up. The patient had no negative outcome. Cerebrospinal fluid leak should be included in the differential diagnosis of a head trauma in a patient with open fontanelles. No similar case was found in literature.

535. Bell, D. G. and E. T. McCann (2016). "Transfusions in trauma Topical Collection on Pulmonology in Combat Medicine." Current Pulmonology Reports 5(2): 94-100.

Trauma associated with massive bleeding carries a high mortality even in the setting of early care in a trauma center. Such patients develop a significant coagulopathy soon after injury which contributes to these poor outcomes. Practices such as aggressive resuscitation with crystalloid fluids and red blood cell (RBC) transfusions appear to be associated with worse outcomes when compared to a practice of early blood product resuscitation with a ratio of plasma to platelets to RBCs approaching 1:1:1. Early therapy with tranexamic acid (TXA) appears beneficial as well, perhaps helping to prevent fibrinolysis. Viscoelastic testing offers advantages over conventional coagulation testing in the evaluation of further fibrinolysis and offers some guidance for additional targeted therapy. Many societies and organizations have released updated guidelines and recommendations that reflect these changes.

536. Bell, M. D. D. (2005). "Non-heartbeating organ donation: clinical process and fundamental issues." British journal of anaesthesia 94(4): 474-478.

This case report outlines the clinical process whereby a patient with severe traumatic brain injury became a non-heartbeating organ donor after a withdrawal-of-care decision. This process raises a series of ethical questions regarding decision-making on grounds of futility, the role of the next of kin, informed consent, the accommodation of manoeuvres directed towards organ retrieval at maximal viability, and the timing and determination of death. Although many aspects of the process can be accommodated within fundamental ethical principles and a broad interpretation of the concept of the 'best interests', the variance with established law requires authoritative clarification if a need for transplantable organs is to be responded to without compromising the reputation of practitioners involved in this area of care. Therefore, this recruitment strategy warrants wide public and professional debate to achieve longer-term sustainability and ensure the protection of all parties.

539. Bell, R. S., et al. (2010). "The evolution of the treatment of traumatic cerebrovascular injury during wartime." Neurosurgical focus 28(5): E5.

The approach to traumatic craniocervical vascular injury has evolved significantly in recent years. Conflicts prior to Operations Iraqi and Enduring Freedom were characterized by minimal intervention in the setting of severe penetrating head injury, in large part due to limited far-forward resource availability. Consequently, sequelae of penetrating head injury like traumatic aneurysm formation remained poorly characterized with a paucity of pathophysiological descriptions. The current conflicts have seen dramatic improvements with respect to the management of severe penetrating and closed head injuries. As a result of the rapid field resuscitation and early cranial decompression, patients are surviving longer, which has led to diagnosis and treatment of entities that had previously gone undiagnosed. Therefore, in this paper the authors' purpose is to review their experience with severe traumatic brain injury complicated by injury to the craniocervical vasculature. Historical approaches will be reviewed, and the importance of modern endovascular techniques will be emphasized.

---

540. Bell, R. S., et al. (2010). "Early decompressive craniectomy for severe penetrating and closed head injury during wartime." Neurosurgical focus 28(5): E1.

OBJECT: Decompressive craniectomy has defined this era of damage-control wartime neurosurgery. Injuries that in previous conflicts were treated in an expectant manner are now aggressively decompressed at the far-forward Combat Support Hospital and transferred to Walter Reed Army Medical Center (WRAMC) and National Naval Medical Center (NNMC) in Bethesda for definitive care. The purpose of this paper is to examine the baseline characteristics of those injured warriors who received decompressive craniectomies. The importance of this procedure will be emphasized and guidance provided to current and future neurosurgeons deployed in theater., METHODS: The authors retrospectively searched a database for all soldiers injured in Operations Iraqi Freedom and Enduring Freedom between April 2003 and October 2008 at WRAMC and NNMC. Criteria for inclusion in this study included either a closed or penetrating head injury suffered during combat operations in either Iraq or Afghanistan with subsequent neurosurgical evaluation at NNMC or WRAMC. Exclusion criteria included all cases in which primary demographic data could not be verified. Primary outcome data included the type and mechanism of injury, Glasgow Coma Scale (GCS) score and injury severity score (ISS) at admission, and Glasgow Outcome Scale (GOS) score at discharge, 6 months, and 1-2 years., RESULTS: Four hundred eight patients presented with head injury during the study period. In this population, a total of 188 decompressive craniectomies were performed (154 for penetrating head injury, 22 for closed head injury, and 12 for unknown injury mechanism). Patients who underwent decompressive craniectomies in the combat theater had significantly lower initial GCS scores (7.7 +/- 4.2 vs 10.8 +/- 4.0, $p < 0.05$) and higher ISSs (32.5 +/- 9.4 vs 26.8 +/- 11.8, $p < 0.05$) than those who did not. When comparing the GOS scores at hospital discharge, 6 months, and 1-2 years after discharge, those receiving decompressive craniectomies had significantly lower scores (3.0 +/- 0.9 vs 3.7 +/- 0.9, 3.5 +/- 1.2 vs 4.0 +/- 1.0, and 3.7 +/- 1.2 vs 4.4 +/- 0.9, respectively) than those who did not undergo decompressive craniectomies. That said, intragroup analysis indicated consistent improvement for those with craniectomy with time, allowing them, on average, to participate in and improve from rehabilitation ($p < 0.05$). Overall, 83% of those for whom follow-up data are available achieved a 1-year GOS score of greater than 3., CONCLUSIONS: This study of the provision of early decompressive craniectomy in a military population that sustained severe penetrating and closed head injuries represents one of the largest to date in both the civilian and military literature. The findings suggest that patients who undergo decompressive craniectomy had worse injuries than those receiving craniotomy and, while not achieving the same outcomes as those with a lesser injury, did improve with time. The authors recommend hemicraniectomy for damage control to protect patients from the effects of brain swelling during the long overseas transport to their definitive care, and it should be conducted with foresight concerning future complications and reconstructive surgical procedures.

---

541. Bell, R. S., et al. (2009). "Military traumatic brain and spinal column injury: a 5-year study of the impact blast and other military grade weaponry on the central nervous system." The Journal of trauma 66(4 Suppl): S104-111.

BACKGROUND: During the past 5 years of Operation Iraqi Freedom (OIF), a significant majority of the severe closed and penetrating head trauma has presented for definitive care at the National Naval Medical Center (NNMC) in Bethesda, MD, and at the Walter Reed Army Medical Center (WRAMC) in Washington, DC. The purpose of this article is to review our experience with this population of patients., MATERIALS: A retrospective review of all inpatient admissions from OIF was performed during a 5-year period (April 2003 to April 2008). Criteria for inclusion in this study included either a closed or penetrating head trauma suffered during combat operations in Iraq who subsequently received a neurosurgical evaluation at NNMC or WRAMC. Exclusion criteria included all patients for whom primary demographic data could not be verified. Primary outcome data included the type and mechanism of injury, Glasgow coma scale (GCS) and injury severity score at admission, and Glasgow outcome scale (GOS) at discharge, 6 months, and 1 to 2 years., RESULTS: Five hundred thirteen consultations were performed by the neurosurgery service on the aforementioned population. Four hundred eight patients met the inclusion criteria for this study (401:7, male: female; 228 penetrating brain injury, 139 closed head injury, 41 not specified). Explosive blast injury (229 patients; 56%)

constituted the predominant mechanism of injury. The rates of pulmonary embolism (7%), cerebrospinal fluid leak (8.6%), meningitis (9.1%), spinal cord or column injury (9.8%), and cerebrovascular injury (27%) were characterized. Cerebrospinal fluid leak, vasospasm, penetrating head injury, and lower presenting GCS were statistically associated with longer intensive care unit stays and higher presenting injury severity scores ($p < 0.05$). While presenting GCS 3-5 correlated with worsened short-term and long-term GOS scores ($p < 0.001$), almost half of these patients achieved GOS >or=3 at 1- to 2-year follow-up. Total mortality after reaching NNMC/WRAMC was 4.4%., CONCLUSIONS: OIF has resulted in the highest concentration of severe closed and penetrating head trauma to return to NNMC and WRAMC since the Vietnam Conflict. Management scenarios were complex, incorporating principles designed to maximize outcomes in all body systems. Meaningful survival can potentially be achieved in a subset of patients with presenting GCS <or=5.

---

542. Bell, R. S., et al. (2010). "Wartime traumatic aneurysms: acute presentation, diagnosis, and multimodal treatment of 64 craniocervical arterial injuries." Neurosurgery 66(1): 66-79.

OBJECTIVE: Operation Iraqi Freedom has resulted in a significant number of closed and penetrating head injuries, and a consequence of both has been the accompanying neurovascular injuries. Here we review the largest reported population of patients with traumatic neurovascular disease and offer our experience with both endovascular and surgical management., METHODS: A retrospective analysis of all military casualties returning to the Walter Reed Army Medical Center and the National Naval Medical Center, Bethesda, Maryland, from April 2003 until April 2008 was performed. All patients undergoing diagnostic cerebral angiography during their inpatient stay were included in the study., RESULTS: A total of 513 war trauma-related consults were performed from April 2003 to April 2008, resulting in the evaluation of 408 patients with closed and penetrating head injuries. In this population, 279 angiographic studies were performed in 187 patients (25 closed craniocervical injuries, 162 penetrating craniocervical injuries), resulting in the detection of 64 vascular injuries in 48 patients (26.2% of those studied, 34% prevalence). Vascular injuries were characterized by traumatic intracranial aneurysms (TICAs) (n = 31), traumatic extracalvarial aneurysms (TECAs) (n = 19), arterial dissections (n = 11), and arteriovenous fistulae (n = 3). The average TICA size on admission was 4.1 mm, with an observed increase in aneurysm size in 11 cases. In the TICA/TECA group, 24 aneurysms in 23 patients were treated endovascularly with either coiling or stent-assisted coiling, resulting in preservation of the parent artery in 12 of 24 vessels (50%). The injuries in 3 patients in this group progressed despite endovascular treatment and required definitive clip exclusion. Thirteen additional aneurysms in 8 patients were treated surgically, resulting in parent artery preservation in 4 cases (30.8%). Eleven of the 13 remaining TICAs/TECAs resolved spontaneously without treatment. A total of 6 aneurysm ruptures (average size, 8.25 mm) occurred, resulting in 3 deaths. Four of 6 ruptures occurred in TICAs in which the interval size increase was noted angiographically., CONCLUSION: The management of traumatic vascular injury has evolved with technological advancement and the willingness of the neurosurgeon to intervene. Although open surgical intervention remains a viable solution, endovascular options are available and safe and can effectively temporize a patient while acute sequelae of serious head injury resolve.

---

543. Bellamy, R. F., et al. (1986). "Epidemiology of trauma: military experience." Annals of emergency medicine 15(12): 1384-1388.

Battle injuries sustained in conventional warfare are more likely to be lethal than are injuries sustained by civilians. Depending on the tactical situation, mortality may range from 20% to more than 80% of all casualties. The American experience indicates that about 90% of the total mortality occurs on the battlefield. Such casualties, those classified as killed in action, die before reaching medical care. More than 90% of all battle injuries (morbidity) are caused by penetrating missiles. Exsanguination from wounds of the heart/great vessels and penetrating/perforating wounds of the skull cause the majority of battlefield deaths. The frequency distribution of injury severity appears to be bimodal. A large peak

occurs at low injury severity and indicates a population of casualties with relatively benign soft tissue wounds. A smaller peak at high injury severity represents those killed in action.

545. Beloded, V. G. and V. V. Ryvniak (1985). "[Xenoplasty of the dura mater by means of formalinized grafts]." Ksenoplastika tverdoi mozgovoi obolochki formalinizirovannymi transplantatami.(3): 49-54.

The possibility of using as plastic material animal (neat cattle, pig) dura mater stored in 0.5% formaldehyde solution was studied. The structure of the dura mater tissue is maintained for a 3-year storage period, and it therefore can be used during this period. The results of experiments (on 30 dogs) and clinical observations (63 patients) show that dura mater grafts used to repair a defect ensure airtightness of the subdural space and separate the brain from the overlying tissues, thus preventing the development of an adhesive-cicatricial process. On resorption, the graft is replaced by an organ-typical regenerated material performing the function of the lost dura mater.

A 30-year-old man presented with a knife in his head; it had perforated the left temporal area and its point was located in the mouth. After surgical removal of the knife, the patient left the hospital without functional deficits.

547. Belzberg, H., et al. (2007). "Hemodynamic and oxygen transport patterns after head trauma and brain death: implications for management of the organ donor." The Journal of trauma 63(5): 1032-1042.

OBJECTIVES: The aims of the present study were to describe the temporal hemodynamic and oxygen transport patterns of patients with head injuries as well as the patterns of those who became brain dead to better understand the role of underlying central regulatory hemodynamic mechanisms and ultimately to improve rates of organ donation., METHODS: We studied 388 consecutive noninvasively monitored patients with severe head trauma; 79 of these became brain dead. Monitoring was started shortly after admission to the emergency department and was designed to describe the sequence of cardiac, pulmonary, and tissue perfusion functions by cardiac index (CI), mean arterial pressure, heart rate, arterial saturation by pulse oximetry (Sapo2), and transcutaneous oxygen and carbon dioxide (Ptco2/Fio2 and Ptcco2) patterns. The latter were used as markers of tissue perfusion or oxygenation., RESULTS: Patients with head injuries who subsequently became brain dead initially had low CI with poor tissue perfusion beginning shortly after emergency department admission. This was followed by a prolonged period characterized by high CI (4.43 +/- 1.3 L x min(-1) x m2) and enhanced tissue oxygenation (Ptco2/Fio2 238 +/- 186). In the late or end stage of brain death, hemodynamic deterioration and collapse led rapidly to arrest. In attempts to maintain hemodynamic stability for organ donation, the effects of various therapies on the hemodynamic patterns were preliminarily described., CONCLUSIONS: The hyperdynamic state with exaggerated peripheral tissue perfusion or oxygenation in brain-dead patients associated with loss of central vasoconstrictive mechanisms of the stress response resulted in unopposed peripheral metabolic vasodilatation producing high CI and tissue perfusion.

---

548. Ben Abdessalem, N., et al. (2022). "A challenging case of an intraorbital foreign body in a child: A case report." Annals of Medicine and Surgery 76.

Apart from congenital causes, orbital trauma is a leading cause of unilateral vision loss in children. We report the case of a 2-year-old child who was victim of an orbital trauma of the right eye caused by a ballpoint pen. He consulted us the day after the trauma with significant palpebral edema making the examination difficult. An emergency CT scan of the orbit and brain showed the presence of a right intraorbital foreign body. The patient underwent removal of the foreign body by an anterior orbitotomy with general antibiotic therapy and a simple postoperative course. Penetrating trauma to the orbit should raise the suspicion of the presence of a foreign body. A CT scan should be performed to specify its location. The extraction of the foreign body can be a challenge that requires an experienced surgical team.

549. Benali, L., et al. (2013). "An unusual case of attempted suicide by a depressive woman: self-inflicted intracranial stabbing." Forensic science international 226(1-3): e9-11.

Self-inflicted stab injury to the skull, particularly in the neurocranium, is a rare method used to commit suicide. Herein is presented a case of a 26-year old woman with a temporal wound found by her partner in their home. No weapon was found in the approximate environment and the victim said that she fell. A CT scan performed at admission to the emergency room was interpreted as being compatible with injury from falls. A second CT scan in a neurosurgical unit suggested a cranio-cerebral injury from a sharp object; aggression was suspected. The discording elements led to an interview with a psychiatrist and diagnosis of attempted suicide through the action of a knife in the context of severe depression. This is a rare case that implicates a depressive woman and stabbing directly to the neurocranium.

550. Bendiouri, R., et al. (2021). "Internal jugular vein thrombosis by sewing needle ingestion." International journal of surgery case reports 83: 105988.

INTRODUCTION: The internal jugular vein thrombosis is usually due to intravenous drug abuse, prolonged central venous catheterization or deep head-neck infections or trauma. Related malignancies, or inflammatory etiologies are described. Our case is interesting by the ingestion of a sewing needle that passes from the pharynx to the internal jugular vein via migration, leading to life-threatening complications: deep neck space infection and internal jugular vein thrombosis., CASE REPORT: We report a case of a 40 years old patient, for acute cervical cellulitis in a context of odynophagia and fever, a CT scan revealed a jugular vein thrombosis, penetrated by a metal density foreign body. The diagnosis of ingested foreign body complicated by cervical cellulitis and thrombosis of the internal jugular vein was made. The patient underwent neck surgery with intravenous antibiotics. The postoperative course was uneventful, after one year of follow-up, no complications have been observed., DISCUSSION: no consensus has been reached concerning the management of postoperative and post traumatic vein thrombosis. Taking into account the risk of extension of the thrombus and the hemorrhagic risk each case should involve discussions among a multidisciplinary team., CONCLUSION: The internal jugular vein thrombosis is a rare complication of ingested foreign bodies which may lead to life threat. The early diagnosis and adequate treatment of its life-threatening complications may result in excellent prognosis.

551. Benech, A., et al. (1997). "[Fracture of the glenoid fossa without condylar dislocation and with intact mandibular condyle. Report of a case]." Frattura della fossa glenoidea senza dislocazione condilare e con condilo mandibolare integro. Presentazione di un caso clinico. 46(10): 541-546.

The osteomuscular structure of the cranium presents peculiar anatomic characteristics that aim to preserve the noble organs that are housed inside or are adjacent to them. This is also true of the condylar region which protects the cranial cavity from forces transmitted to the glenoid cavity by the condyle in traumatism to the facial region and above all the genial symphysis. These factors act as "force breakers"

to prevent the condyle penetrating the middle cranial fossa. Of these the most important is the presence of a line of minor resistance at the level of the condyle neck which is often the site of a protective fracture. However, the dislocation of the condyle in the middle cranial fossa is an occurrence that is reported in the literature, albeit very rarely; the fracture of the glenoid fossa with an intact mandibular condyle and without evident dislocation of the latter is even more rare. The paper reports the case of a 22-year-old male patient who was injured in the submental area leading to loss of conscience. CT revealed that the left mandibular condyle was intact whereas there was a comminuted fracture of the roof of the glenoid fossa and two fractures at the mandibular level. The patient also presented left otoliquorrhea. The glenoid fracture was not complete and therefore the mandibular condyle did not show evident dislocation nor was it necessary to resort to surgical or non-surgical treatment. After the reduction and restraint of the two mandibular fractures, occlusion was correct and the position of the left condyle was appropriate following X-ray control, even if the glenoid cavity was partially fractured. Otoliquorrhea resolved spontaneously after about three days and did not require any treatment. The case described here, which was recontrolled after some time, presented excellent functional results demonstrating that conservative treatment of the glenoid cavity fracture was the correct therapeutic choice.

552. Bener, A., et al. (1998). "Injury mortality and morbidity among children in the United Arab Emirates." European journal of epidemiology 14(2): 175-178.

UNLABELLED: The objective of this study was to identify the major causes of accident mortality and morbidity among children (0-14 years) in Al-Ain, United Arab Emirates (UAE). A retrospective descriptive study was set in the Al-Ain Hospital and Preventive Medicine Department, Ministry of Health, Al-Ain. Subjects were all patients aged 0-14 years who were seen at Al-Ain Hospital for injury during the 12-month period January to December 1995, and all recorded deaths aged 0-14 years in Preventive Medicine Department from 1980 to 1995., RESULTS: Mortality: 301 children (69.4% males, 30.6% females) died after accidents from 1980 to 1995. UAE citizens and other Arabs represented the majority of deaths. Most mortality (28.6%) occurred in the 1-4 year age group. Head and neck injury was the major type of injury causing death (57.5%). The most common cause of accidental death was road traffic accidents (boys 67.1%, girls 60.4%), followed by drowning and burns (8%). Morbidity: Pediatric trauma cases seen during 1995 totaled 17,498, representing one third of all patients attending the Hospital Emergency Room. About 70% of encountered injuries occurred among boys; 44.6% of cases were UAE citizens. The most common trauma type was contusion (40.2% boys; 40.6% girls), the most common type of trauma in boys and girls (30.4% and 36%, respectively). In the age group <5 years, the most common causes of trauma were fall (41.1%), blunt trauma (38.7%) and burns or scalds (64%), while in 5-9 year olds, the most common cause was road traffic accidents (40%). Finally, in 10-14 year olds, the most frequent causes were traffic accidents (32.8%) sharp objects injuries (38.3%), and fights and sporting (28.9%)., CONCLUSION: More boys than girls presented with injury and the majority were nationals. Road traffic accidents mainly occurred in children over 10 years.

553. Ben-Moshe, H., et al. (2020). "ApoE4 Exacerbates Hippocampal Pathology Following Acute Brain Penetration Injury in Female Mice." Journal of molecular neuroscience : MN 70(1): 32-44.

The e4 allele of apolipoprotein E (apoE4) is the most prevalent genetic risk factor for Alzheimer's disease. ApoE4 is also associated with poor recovery and functional outcome following traumatic brain injury. This study examined the effects of the apoE genotype on brain pathology following acute injury, induced by penetration of a needle through the cortex and hippocampus, at 3 and 14 days following the injury in female apoE3 and apoE4 alpha-synuclein-deficient targeted replacement (TR) mice. The results obtained revealed a marked inflammatory, synaptic and vascular response following the needle penetration injury (NPI). These results were found to be affected by the apoE genotype such that the inflammatory response, as measured utilizing the astrocytic marker GFAP and the microglial marker iba1, was faster and more prolonged in the apoE4 than in the apoE3 mice. The

synaptic changes following the injury included a transient increase in synaptophysin levels in the apoE3 and not in the apoE4 mice, which was associated with a subsequent decrease in glutamatergic synapses, as measured utilizing VGluT1, in apoE4 and not in the apoE3 mice. Unlike these effects, measurements of the vasculature utilizing collagen IV as a marker revealed a significant increase which was similar in both apoE3 and apoE4 mice. Taken together, these results show that following acute brain injury, there is an apoE4-specific inflammatory and neuronal response to the injury. The NPI model provides a useful tool for studying the mechanism underlying the effects of apoE4 following acute brain injury and for the development of a corresponding anti-apoE4-targeted treatment.

---

554. Benndorf, G., et al. (2011). "Acute endovascular management of gun shot injuries to arteries supplying the head & neck and the brain in civilian patients." Journal of neurointerventional surgery 3: A12-A13.

Purpose To report the use of endovascular techniques for management of gun shot injuries to arteries in the head and neck requiring emergency intervention. Material and Methods Between January 2009 and March 2011, 46 patients, admitted to a Level 1 Trauma Center with suspected gun shot injuries of the extracranial or intracranial circulation (Age range: 17-54, gender distribution: 35 males/11 females), were referred for four vessel angiograms. Four vessel angiograms were performed within 24 h after admission to confirm potential injuries to the external carotid, internal carotid and vertebral arteries (ECA, ICA or VA) and if necessary with the intent to treat by endovascular techniques. Results In 13/46 patients, major vessel injuries, requiring immediate surgical or endovascular intervention were documented. In one patient, an internal carotid dissection causing thrombembolic stroke was successfully treated by stent placement. Two patients presenting with ruptured cervical VAs without angiographically visible active extravasation were treated by endovascular coil occlusions (1) and a combination of coils and NBCA (1). In six patients with life threatening blood loss, significant active extravasations were documented arising from the internal maxillary (4), occipital (1) or superficial temporal (1) arteries. In all cases, immediate transarterial occlusions were performed using NBCA (5) or Onyx (1). Complete occlusion of the rupture site was achieved in all patients. In two patients, arteriovenous fistulas between the common carotid artery and internal jugular vein, and the subclavian artery and vein respectively, were found. Both lesions were surgically corrected. All but two patients recovered partially or completely from their injuries. In 2 cases, intracranial vessel occlusions and extravasations were documented; no treatment was initiated due to elevated intracranial pressure causing restricted cerebral perfusion. Conclusions Minor damages to the vessel wall are often manageable with conservative management and low dose anticoagulation or antiplatelet therapy and short-term angiographic follow-up. Major vessel injuries leading to severe extracranial dissection or angiographic occlusion, may require stent placement or complete endovascular vessel blockage. In cases with significant active extravasations and critical blood loss, immediate transarterial embolization becomes life saving measure. The use of adhesive liquids such as acrylic glue appears more efficient compared to coils or Onyx to achieve the most rapid vessel occlusion in these cases.(figure presented).

---

555. Benndorf, G., et al. (2013). "Endovascular management of traumatic injuries to supraaortic arteries." RoFo Fortschritte auf dem Gebiet der Rontgenstrahlen und der Bildgebenden Verfahren 185.

Ziele: Demonstration of important aspects in the current endovascular management of acute injuries involving arteries of the face and head&neck area. Methode: EVT was performed in 14 patients (10 male/4 female, 17 - 62 yo) suffering from acute injuries to supraaortic arteries who presented with uncontrollable blood loss or neurologic deficit between February 2009 and October 2012. One patient presented with acute and delayed injuries and underwent EVT 4 weeks after initial admission. 11 Patients suffered from gunshot wounds (GSW), 2 patients from stab wounds and 1 one from blunt trauma during a motorcycle accident. Five patients presented with multiple vascular injuries. Ergebnis: EVT was successfully performed in all patients. Five transections of the vertebral (4) and carotid (1) arteries were embolized with coils and/or liquid embolic agent (NBCA, Onyx). Ten penetrated external

carotid artery branches and one inferior thyroid artery were occluded with liquid embolic agents or PVA particles. One severe dissection of the internal carotid artery with a subsequent thromboembolic event was treated with stenting. In 2 patients the circle of Willis was used to approach the bleeding site. 12 patients survived with minor or no residual deficits; two patients had a fatal outcome due to critical blood loss prior to admission. Schlussfolgerung: Management of penetrating injuries to the face, head and neck may involve all aspects of current methods in EVT. Understanding the full spectrum of neuroendovascular techniques and being capable of rapid, appropriate decision making in the setting of acute injuries to supraaortic arteries can be a life saving measure and greatly benefit the patient's outcome.

---

556. Bennett, M. H., et al. "Hyperbaric oxygen therapy for the adjunctive treatment of traumatic brain injury." (12).

Background, Traumatic brain injury is a common health problem with significant effect on quality of life. Each year in the USA approximately 0.56% of the population suffer a head injury, with a case fatality rate of about 40% for severe injuries. These account for a high proportion of deaths in young adults. In the USA, 2% of the population live with long-term disabilities following head injuries. The major causes are motor vehicle crashes, falls, and violence (including attempted suicide). Hyperbaric oxygen therapy (HBOT) is the therapeutic administration of 100% oxygen at environmental pressures greater than 1 atmosphere absolute (ATA). This involves placing the patient in an airtight vessel, increasing the pressure within that vessel, and administering 100% oxygen for respiration. In this way, it is possible to deliver a greatly increased partial pressure of oxygen to the tissues. HBOT can improve oxygen supply to the injured brain, reduce the swelling associated with low oxygen levels and reduce the volume of brain that will ultimately perish. It is, therefore, possible that adding HBOT to the standard intensive care regimen may reduce patient death and disability. However, a concern for patients and families is that using HBOT may result in preventing a patient from dying only to leave them in a vegetative state, entirely dependent on medical care. There are also some potential adverse effects of the therapy, including damage to the ears, sinuses and lungs from the effects of the pressure and oxygen poisoning, so the benefits and risks of the therapy need to be carefully evaluated., Objectives, To assess the effects of adjunctive HBOT for traumatic brain injury., Search methods, We searched CENTRAL, MEDLINE, EMBASE, CINAHL and DORCTHIM electronic databases. We also searched the reference lists of eligible articles, handsearched relevant journals and contacted researchers. All searches were updated to March 2012., Selection criteria, Randomised studies comparing the effect of therapeutic regimens which included HBOT with those that did not, for people with traumatic brain injury., Data collection and analysis, Three authors independently evaluated trial quality and extracted data., Main results, Seven studies are included in this review, involving 571 people (285 receiving HBOT and 286 in the control group). The results of two studies indicate use of HBOT results in a statistically significant decrease in the proportion of people with an unfavourable outcome one month after treatment using the Glasgow Outcome Scale (GOS) (relative risk (RR) for unfavourable outcome with HBOT 0.74, 95% CI 0.61 to 0.88, P = 0.001). This five-point scale rates the outcome from one (dead) to five (good recovery); an 'unfavourable' outcome was considered as a score of one, two or three. Pooled data from final follow-up showed a significant reduction in the risk of dying when HBOT was used (RR 0.69, 95% CI 0.54 to 0.88, P = 0.003) and suggests we would have to treat seven patients to avoid one extra death (number needed to treat (NNT) 7, 95% CI 4 to 22). Two trials suggested favourably lower intracranial pressure in people receiving HBOT and in whom myringotomies had been performed. The results from one study suggested a mean difference (MD) with myringotomy of -8.2 mmHg (95% CI -14.7 to -1.7 mmHg, P = 0.01). The Glasgow Coma Scale (GCS) has a total of 15 points, and two small trials reported a significant improvement in GCS for patients treated with HBOT (MD 2.68 points, 95%CI 1.84 to 3.52, P < 0.0001), although these two trials showed considerable heterogeneity (I(superscript 2) = 83%). Two studies reported an incidence of 13% for significant pulmonary impairment in the HBOT group versus 0% in the non-HBOT group (P = 0.007)., Authors' conclusions, In people with traumatic brain injury, while the addition of HBOT may reduce the risk of death and improve the final GCS, there is little

evidence that the survivors have a good outcome. The improvement of 2.68 points in GCS is difficult to interpret. This scale runs from three (deeply co atose and unresponsive) to 15 (fully conscious), and the clinical importance of an improvement of approximately three points will vary dramatically with the starting value (for example an improvement from 12 to 15 would represent an important clinical benefit, but an improvement from three to six would leave the patient with severe and highly dependent impairment). The routine application of HBOT to these patients cannot be justified from this review. Given the modest number of patients, methodological shortcomings of included trials and poor reporting, the results should be interpreted cautiously. An appropriately powered trial of high methodological rigour is required to define which patients, if any, can be expected to benefit most from HBOT.

557. Bensalem-Owen, M., et al. (2009). "SPECT imaging in four patients with stimulus-induced rhythmic, periodic, or ictal discharges (SIRPIDs)." Epilepsia 50: 17.

Rationale: The electrographic and clinical significance of stimulusinduced rhythmic, periodic or ictal discharges (SIRPIDs) remains unclear and the debate of its ictal origin remains open. We report the findings of single photon emission computed tomography (SPECT) in 4 patients with SIRPIDs. Methods: Four consecutive patients with SIRPIDs were identified prospectively during continuous video-EEG (cVideo-EEG) monitoring. SPECT with 25-31.3 mci 99 mTC-ED injection was performed at the bedside immediately after sensory stimulation was applied and SIRPIDs were noted. Results: Patient 1-A76 year old man with terminal myelodysplastic disorder, was admitted for a self inflicted gun shot wound to the head. He had a complicated hospital course. He was evaluated with 3 days of cVideo-EEG) monitoring after he was found to be in non-convulsive status epilepticus (NCSE). After receiving fosphenytoin, SIRPIDs were identified. SPECT injection was obtained on the second day of monitoring. The study showed diffuse mild increase of tracer uptake in the left occipital cortex. His anti-epileptic drug (AED) regimen was optimized. Patient 2-A 52 year old woman with history of traumatic brain injury, epilepsy and chronic renal failure on hemodialysis was evaluated for mental status changes with 5 days of cVideo-EEG monitoring. She was initially taking phenytoin and eventually levetiracetam was added. Due to logistical reasons, the injection of the radionuclear tracer was done on the fifth day of monitoring. The study showed a localized site of increased uptake in the left parietal cortex. It was unclear however if this finding represented motor activation or an ictal focus. Because of this ambiguous finding and improvement in her mental no change in her AEDs was made. Patient 3-A 79 year old lady with multiple medical problems and an acute right frontal stroke was found to be in NCSE. Fosphenytoin was initiated and was followed by levetiracetam. She underwent monitoring with 3 day cVideo-EEG which showed SIRPIDs. SPECT injection was obtained on the third day of monitoring and did not show any abnormal uptake of the tracer. No changes were made to her AEDS. Patient 4-A 77 year old women with multiple medical problems, including kidney transplant was found to be in NCSE. Intravenous valproic acid was administered. She underwent 4 day cVideo-EEG monitoring. After SIRPIDs were identified a SPECT injection was obtained. The study did not show any abnormal uptake of the tracer. No changes were made to her AED regimen. Conclusions: Our results indicate that SPECT imaging is feasible despite technical aspects such as logistical issues encountered in the critically ill. SPECT imaging with injection of the radionuclear tracer at the time of SIRPIDs is a useful tool in guiding treatment with AEDs.

558. Bentivoglio, M., et al. (1986). "Structural mechanisms of postlesional remodelling in the central nervous system." Italian journal of neurological sciences Suppl 5: 29-36.

Numerous recent experimental studies have evidenced that considerable remodelling takes place in the central nervous system following an injury. The postlesional reorganization is particularly active in the central circuits when the injury occurs during development. The basic structural postlesional mechanisms, such as axonal sprouting and synaptic rearrangement, are here briefly outlined.

Experimental evidence of postlesional structural reorganization of central neurons is provided, with special reference to the remodelling that follows cerebellar lesions.

559. Bento, R. F. and R. V. de Brito (2004). "Gunshot wounds to the facial nerve." Otology & neurotology : official publication of the American Otological Society, American Neurotology Society [and] European Academy of Otology and Neurotology 25(6): 1009-1013.

OBJECTIVE: This paper presents our experience with gunshot wounds to the temporal bone and discusses facial nerve lesions, surgical indication, surgical timing, and other findings., STUDY DESIGN: We performed a retrospective review of patients treated for facial nerve lesion after gunshot injury to the temporal bone., SETTING: The study was performed in the Otolaryngology Department of the University of Sao Paulo Medical School, Sao Paulo, Brazil., PATIENTS: Ninety-eight patients treated between 1988 and 1999 were analyzed., INTERVENTION: Facial nerve lesions, bullet locations, and surgical techniques were analyzed. Patients were monitored for 2 years., RESULTS: Gunshot trauma to the temporal bone presented considerable tissue loss resulting from the abrasion effect and severity of the impact. The third segment of the facial nerve was most affected, and the bullet was typically found lodged in the mastoid tip. Postoperative infection was common. Such cases required revision surgery, resulting in worse cosmetic outcomes than in cases of closed trauma., CONCLUSIONS: Surgical exploration of the facial nerve should be performed as soon as possible, since long delays increase the chance of traumatic neuroma and more pronounced scarring around the facial nerve. Open mastoidectomy with meatoplasty is the surgical technique recommended for repairing the mastoid and the facial nerve. In the majority of cases, a cable graft is necessary. Since nerve lesion in proximity to the stylomastoid foramen and extratemporal facial nerve is common, these areas must be explored carefully.

---

560. Benzel, E. C., et al. (1991). "Civilian craniocerebral gunshot wounds." Neurosurgery 29(1): 67-62.

Experience with 120 patients who incurred a gunshot wound to the head with dural penetration is presented. All of the patients were managed by a standard resuscitation protocol and assigned a clinical grade based on their level of consciousness both at the time of presentation and at 2 to 4 months after injury. Fifty patients (42%) underwent surgery. Twenty-eight patients (23%) had a good recovery, 19 (16%) were moderately disabled, 6 (5%) were severely disabled, and 67 (56%) died. All patients who were alert and awake with a normal or near normal neurological examination at the time of admission survived with a good outcome. All but 4 patients who were comatose at the time of admission died. Nine patients, however, who were not comatose at the time of admission died from potentially preventable causes. In 3 of these patients, a more aggressive diagnostic approach (including cerebral angiography) may have altered their ultimate outcome. An expeditious approach to the trauma victim with a comprehensive management scheme after injury may have altered the course in the remainder of these patients.

561. Berenguer, C. M., et al. (2010). "Brain death confirmation: comparison of computed tomographic angiography with nuclear medicine perfusion scan." The Journal of trauma 68(3): 553-559.

INTRODUCTION: : Brain death is a difficult diagnosis to make, relying primarily on clinical examination. Ancillary tests are used when confounders exist. Nuclear medicine perfusion test (NMPT) is currently the preferred test for confirming brain death. Computed tomographic angiography (CTA) may be an alternative test to confirm brain death. It is readily available 24 hours a day at most level I trauma centers and is easy to perform., METHODS: : Patients with a clinical examination consistent with brain death were selected from the intensive care unit at a 550-bed teaching hospital. The patients underwent NMPT followed immediately by CTA. Both studies were read by radiologists blinded to the results of the alternative study. Absence of brain perfusion confirmed brain death. Multiple independent variables were collected on each patient including demographics, core body temperature, apnea

challenge, mechanism of injury, timelines, renal function pre- and posttesting, organ donation, and time to procurement., RESULTS: : There were 25 patients enrolled in the study with multiple injury patterns. No false negative exams were identified on CTA when compared with NMPT. Three patients without flow on NMPT showed minimal flow on CTA. Each of these had open skull defects. Sensitivity of CTA was 0.86 and specificity was 1. There was no induced morbidity with regards to renal failure and organ donation., CONCLUSION: : CTA is a quick and efficient test for brain death confirmation. CTA demonstrated no false negative studies. The resolution of CTA seems to have an increased sensitivity for cerebral blood flow. Further studies with larger sample sizes need to be performed.

562. Berg, J. and J. G. Johansen (1997). "[Penetrating head and neck gunshot injuries. A 10-year neurological material]." Penetrerende skuddskader i hode og hals. Et neurokirurgisk tiarsmateriale. 117(2): 236-240.

37 patients with penetrating injuries of the head or upper neck caused by gunshot wounds were admitted to the neurosurgical department during the ten-year period 1986 to 1995. There was a marked preponderance of males. 29 of the cases were attempted or successful suicides, four were homicides, and four were presumed to be accidents. The most common weapons used were pistol and rifle. Nine patients were under the influence of alcohol or drugs. There were eight survivors, seven of whom were operated on. Four of the patients suffered reduced vision, two of whom became blind. Two had hemiparesis, one had moderate mental dysfunction, and one recovered completely. None of the patients who were unconscious upon admission to hospital and had bilateral brain injury survived.

563. Berg, P., et al. (1986). "[Iatrogenic eye perforation in para- and retrobulbar injections]." Iatrogene Bulbusperforation bei para- und retrobulbaren Injektionen. 189(2): 170-172.

The authors report on 5 cases of inadvertent iatrogenic perforation of the globe in the course of retrobulbar and parabulbar injections. Perforation occurred twice by injection of the drug into the eyeball itself (subretinally or intravitreally), while in 3 cases a double perforation occurred, as a result of which the drug penetrated behind the eye. The prognosis is better in the latter case. Even though perforation of the globe during parabulbar and retrobulbar injections is extremely rare, it must always be considered if there is a sudden deterioration in vision and/or severe pain immediately after the injection; depending on the situation, retinal and/or vitreous surgery must then be performed at once.

565. Berg, R. W. V., et al. (2019). "Brain tissue saving effects by single-dose intralesional administration of Neuroprotectin D1 on experimental focal penetrating brain injury in rats." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia 64: 227-233.

Traumatic brain injury (TBI) is followed by a secondary inflammation in the brain. Neuroprotectin D1 (NPD1) is synthesized from docosahexaenoic acid (DHA) and has anti-inflammatory and antiapoptotic effects in experimental models of neurodegenerative disease and brain ischemia-reperfusion. It is not known whether intralesional administration of NPD1 ameliorates inflammation and cell death after severe TBI. We therefore investigated the effects of NPD1 following a severe form of focal penetrating TBI. A total of 30 male Sprague-Dawley rats weighing between 350 and 450g were exposed to focal penetrating TBI or sham surgery. The rats were randomized to NPD1 treatment (50ng intralesionally, immediately following TBI) or no treatment. The rats were sacrificed at 24 or 72h. All subgroups consisted of 5 rats. Brains were removed, fresh frozen, cut in 14-microm coronal sections and subjected to Fluoro-Jade, TUNEL, MnSOD, 3-NT, COX-2, Ox-42 and NF-kappaB immuno-staining and lesion size analyses. NPD1 decreased the lesion area at 72h compared to no treatment with a mean

change 42% (NPD1 14.1mm2; no treatment 24.5mm2) (p<0.01). No difference was detected in markers for neuronal degeneration, apoptosis, anti-inflammatory or antioxidative enzymes, or immune cells. In conclusion, single-dose intralesional administration of NPD1 had brain tissue sparing effects after focal penetrating TBI, which may be beneficial in preventing brain tissue damage, making NPD1 a potential candidate for further clinical applications. Exact mechanisms of action could not be determined and it is possible that continuous or multiple administration regimens may increase efficacy in sequential preclinical studies.

---

566. Berger, F., et al. (2018). "Retained bullets in the head on computed tomography - Get the most out of iterative metal artifact reduction." European journal of radiology 103: 124-130.

BACKGROUND: Metal artifacts from retained bullets impair the image quality on computed tomography (CT) and may compromise the detection of critical lesions or the bullet path. To reduce metallic artifacts from medical implants on CT, special algorithms have been developed, e.g., iterative metal artifact reduction (iMAR). The aim of this prospective study was to evaluate the application of iMAR in cases of retained bullets., MATERIALS AND METHODS: In this study, nine different types of projectiles (n=9) were selected to evaluate the effect of iMAR. The study consisted of two settings. In the first setting, each projectile was fixed on a thin thread and placed in the middle of a water-filled container to demonstrate the effect of iMAR in a homogenous medium. In the second setting, each projectile was placed in the severed head of a pig cadaver as a substitute for human tissue to evaluate iMAR in cases of retained bullets. The raw data from CT scans of both settings were reconstructed with and without iMAR (standard filtered back-projection). The reconstructions with iMAR were calculated using eight different presets provided by the software, namely, neuro-coils, dental fillings, spine implants, shoulder implants, pacemaker, thoracic-coils, hip implants and extremity implants. For each setting, nine reconstructions (n=9; iMAR: n=8; without iMAR: n=1) for each projectile were subjectively evaluated for the image quality and extent of streak artifacts by ten independent and blinded raters (residents: n=5; radiologists: n=5). The reconstructions of the second setting were evaluated in a soft tissue window and bone window. A 5-point Likert scale was used for the evaluation of image quality based on the extent of streaks as follows: 1=severe; 2=considerable; 3=moderate; 4=minimal; and 5=not apparent. Kendall's W was used for assessing agreement among the ten raters. The Wilcoxon test was used to reveal whether there was a difference in the subjective evaluations between residents and radiologists. Nonparametric Friedman and post hoc tests were used to analyze the Likert scores. The mean difference was considered significant at the 0.05 level., RESULTS: The agreement among the raters was reasonably high for all projectiles in both settings. In the phantom setting, the iMAR presets neuro-coils and dental fillings yielded the best results. In the pig's head setting regarding the soft tissue window, the presets neuro-coils and extremity implants were preferred. Regarding the bone window, the presets extremity implants and hip implants had the best results. Statistical significance (p<0.01) between reconstructions without iMAR and neuro-coils or extremity implants was calculated. The iMAR preset spine implants had poor values comparable to reconstructions without iMAR., CONCLUSION: The applied iMAR presets revealed different effects on the image quality. Selecting an inappropriate preset (e.g., spine implants) may result in unsatisfactory artifact reduction. The results of this study indicate that the neuro-coils preset is the most appropriate preset for soft tissue, and the preset extremity implants is favorable for bones in cases of retained bullets.

---

567. Bergman, C. and M. Galicia-Castillo (2015). "Failed gun-inflicted suicide attempt in the older adult." Journal of the American Geriatrics Society 63: S236-S237.

Background: Suicide in the older adult remains a top mental health concern. Studies are limited but data suggests high suicide completion rates with white men over the age of 75. The method of suicide can vary greatly from firearms to hanging to intentional overdose. We present a suicide attempt with a gun resulting in a complicated hospitalization with tragic consequences. Case Study: An 80 year

old white male with a history of diabetes, hypertension, and persistent pain presented to the trauma service following a self-inflicted gunshot wound. Following a quick assessment, the patient was found to have an entry wound at his left temple and an exit wound at the right temple with a ruptured left globe. He was combative and complaining of a headache with neck pain and severely reduced vision. Remarkably, his neurological exam was normal except for disturbances related to his ocular injuries. His head CT was equally impressive for the lack of brain injury. Due to the severity of damage to his intraocular muscles, ophthalmology completed a left eye globe enucleation but was unable to complete facial reconstruction due to consent issues. His hospital course was complicated by agitation, confusion, and hallucinations requiring admission to the geriatric psychiatry unit. The patient acknowledged he "shot himself" because "it was all becoming too much." The patient described deteriorating physical health with ambulatory limitations, persistent pain, and financial problems leading to the suicide attempt. After a three week stay in the inpatient geriatric psychiatry unit, it was determined the patient was safe to discharge without suicidal ideations but with a new physical disability. Discussion: This case illustrates the potential for suicide of a violent nature even in the older adult. Older white males are in the highest risk category for more violent methods of suicide. The patient's hospital course was complicated by his own struggles with depression, worsening physical limitations and new psychiatric symptoms. Mental, physical, and social stressors are factors that need to considered potential "triggers" for gun-inflicted attempts to commit suicide. It is important to enquire about the presence of a gun in the home of our older patients who demonstrate high risk.

569. Berlit, P., et al. (1987). "[Gunshot injuries of the skull. Computerized tomography findings and clinical course]." Schussverletzungen des Schadels. Computertomographischer Befund und klinischer Verlauf. 58(5): 300-304.

The clinical and computed tomographic findings in 22 civilian cases of craniocerebral gunshot injury are reported. Fifteen out of the 19 male cases were suicidal attempts; the 3 women were shot by their husbands. In 2 cases the injuries resulted from use of a slaughterer's gun. The level of consciousness is a valuable predictor of outcome from the clinical point of view. CT findings such as bihemispheric injury and detection of intraventricular blood or air were associated with a poor outcome. Surgical intervention appears to be justified only in patients with extensive subdural or epidural hematoma. The mortality rate in this study was 45%.

570. Bernardo Fernandez, H., et al. (2006). "[Posttraumatic pseudoaneurysm of the posterior cerebral artery]." Seudoaneurisma postraumatico de la arteria cerebral posterior. 48(6): 398-400.

We present the case of a traumatic posterior cerebral artery pseudoaneurysm of a 29-year-old man due to a penetrating stab wound to the brain. The patient was brought to the emergency room in coma. The neurological examination revealed a Glasgow Coma Scale Score of 8 and left hemiplegy. The initial CT scan showed right temporal lobe haemorrhage with penetration in the lateral ventricle and subarachnoid haemorrhage. The cerebral angiography performed after three weeks, revealed a high PCA pseudoaneurysm. After surgery, a pseudoaneurysm was demonstrated in the histological study.

571. Bernet, W. (2011). "Ridiculous statements by mental health experts." Child and adolescent psychiatric clinics of North America 20(3): 557-564.

When mental health experts express their opinions in testimony, reports, and articles in professional literature, it is expected that their statements will accurately reflect the current state of knowledge. Experts may disagree about the data that they collected. In some cases, however,

disagreement occurs because an expert has employed a methodology that is far outside usual procedures or simply disregarded objective facts. When that occurs, the expert's opinions may be considered ridiculous. The author presents examples of ridiculous statements by mental health experts and provides suggestions for how a forensic practitioner might address ridiculous statements by mental health experts.

572. Berrington, T., et al. (2015). "Removal of a penetrating orbital and anterior fossa foreign body using an eyebrow incision." British journal of neurosurgery 29(2): 306-307.

In this case, we present an underutilised eyebrow approach for removing penetrating foreign bodies of the orbit extending into the anterior fossa floor. Excellent visualisation of the sub-frontal region is achieved and a large trauma craniotomy is avoided, but care must be taken to preserve the supra-orbital and fronto-temporal nerves.

573. Berryman, H. E. (2019). "A systematic approach to the interpretation of gunshot wound trauma to the cranium." Forensic science international 301: 306-317.

This chapter employs the fracture assessment triad, a systematic analytical approach, as a vehicle to explore the components used to interpret gunshot trauma to the cranium. First, a list of pertinent observations associated with gunshot trauma to the cranium is presented with a brief description of each. These features include entrance and exit wound defect morphology, keyhole defect, gutter defect, radiating fractures, concentric fractures, bone plugs, and associated foreign material, debris and residue. Second, the intrinsic factors that govern the way bone responds to trauma can be surmised through a direct examination or knowledge of the skeletal case. Intrinsic factors rest primarily in bone being a viscoelastic material with anisotropic properties, but include other elements that affect fracture production, such as buttressing, bone architecture, sutures, and influences of age, sex and health. These influences may be discoverable and factored into the analysis. With direct observation of the defect/fracture pattern and an understanding of the intrinsic influences involved, the extrinsic factors can be deduced. Bullet velocity, mass, design and cavitation represent the major extrinsic factors involved in wound production. The interplay of each of these factors imparts varying amounts of kinetic energy to soft and hard tissues. The greater amount of kinetic energy conveyed, the larger the temporary cavity and the greater the potential for destruction. When interpreting gunshot trauma, precision is enhanced by the analyst's familiarity with firearms and ammunition, facilitating determination of firearm type (rifle/handgun or shotgun), bullet direction, range, sequence of fire, and potentially, speculations as to bullet velocity, mass and design. Neither caliber nor gauge can be determined from the entrance defect size, but elimination of certain calibers or gauges may be possible.

---

574. Berryman, H. E., et al. (1995). "Diameter of cranial gunshot wounds as a function of bullet caliber." Journal of forensic sciences 40(5): 751-754.

Determination of bullet caliber becomes increasingly important in homicides where the bullet is missing. In cases with entrance wounds to bone that are circular and well defined it may be tempting to measure the defect and offer suggestions about bullet caliber. For this reason, the relationship between wound diameter and bullet caliber was examined using cranial bones from autopsy cases. The minimum diameter of 35 cranial wounds produced by .22, .25, and .38-caliber bullet was measured. The relationship of minimum wound diameter to bullet caliber was examined using a one way analysis of variance. Fisher's least significant difference test revealed no significant difference between .22-caliber and .25-caliber wounds, while the .38-caliber wounds were significantly different ($P < .001$) from .22-caliber and .25-caliber wounds. Variation in wound size resulting from such factors as bullet shape, surface treatment, strength characteristics, loss of gyroscopic stability, intermediate targets, tangential impacts, and existing fractures are discussed. Also, the large variety of calibers available are noted as

complicating the prediction of caliber from wound size. In view of these factors caution is recommended in any attempt to determine precise bullet caliber from the minimum dimensions of the cranial gunshot entrance wound.

575. Bert, F., et al. (1995). "Brain abscess due to Bacillus macerans following a penetrating periorbital injury." Journal of clinical microbiology 33(7): 1950-1953.

We report a case of a brain abscess due to Bacillus macerans and Clostridium sp. following a penetrating periorbital injury by a wooden branch. Intracranial penetration by and retention of a foreign body were not suspected initially, and neurological symptoms developed only 2.5 months later. Previously reported cases of brain abscesses due to Bacillus species are reviewed.

---

576. Bertani, R., et al. (2019). "Neuronavigation as a minimally invasive tool in the treatment of intracranial gunshot injuries." International Journal of Burns and Trauma 9(1): 19-22.

Gunshot injury is the most common cause of penetrating brain injury. The in-hospital mortality for civilians with penetrating craniocerebral injury is 52-95%. There are many surgical techniques suitable for the treatment of survivors. We report a surgical technique consisting of neuronavigation guidance for wound treatment with smaller incisions and craniotomies, followed by bullet removal if feasible. We report case of a 15 year old male patient who sustained an accidental firearm injury to the occipital region, submitted to surgical treatment that consisted in a minimally invasive approach guided by neuronavigation. Immediate neurological examination showed inferior homonymous quadrantanopsia alone as a clinical finding. Patient was discharged after one week, and no complications arised in follow-up. We conclude that using neuronavigation as a tool was effective in the reported case and that minimally invasive neurosurgical techniques may be a safe and efficient option for the treatment of traumatic brain injuries caused by firearm projectiles.

578. Bertisch, H., et al. (2017). "Characteristics of Firearm Brain Injury Survivors in the Traumatic Brain Injury Model Systems (TBIMS) National Database: A Comparison of Assault and Self-Inflicted Injury Survivors." Archives of physical medicine and rehabilitation 98(11): 2288-2294.

OBJECTIVE: To characterize and compare subgroups of survivors with assault-related versus self-inflicted traumatic brain injuries (TBIs) via firearms at the time of inpatient rehabilitation and at 1-, 2-, and 5-year follow-up., DESIGN: Secondary analysis of data from the Traumatic Brain Injury Model Systems National Database (TBIMS NDB), a multicenter, longitudinal cohort study., SETTING: Retrospective analyses of a subset of individuals enrolled in the TBIMS NDB., PARTICIPANTS: Individuals 16 years and older (N=399; 310 via assault, 89 via self-inflicted injury) with a primary diagnosis of TBI caused by firearm injury enrolled in the TBIMS NDB., INTERVENTIONS: Not applicable., MAIN OUTCOME MEASURES: Disability Rating Scale, Glasgow Outcome Scale-Extended, sociodemographic variables (sex, age, race, marital status), injury-related/acute care information (posttraumatic amnesia, loss of consciousness, time from injury to acute hospital discharge), and mental health variables (substance use history, psychiatric hospitalizations, suicide history, incarcerations)., RESULTS: Individuals who survived TBI secondary to a firearm injury differed by injury mechanism (assault vs self-inflicted) on critical demographic, injury-related/acute care, and mental health variables at inpatient rehabilitation and across long-term recovery. Groups differed in

terms of geographic area, age, ethnicity, education, marital status, admission Glasgow Coma Scale score, and alcohol abuse, suicide attempts, and psychiatric hospitalizations at various time points., CONCLUSIONS: These findings have implications for prevention (eg, mental health programming and access to firearms in targeted areas) and for rehabilitation planning (eg, by incorporating training with coping strategies and implementation of addictions-related services) for firearm-related TBI, based on subtype of injury.

A patient with a bullet wound developed an initially unrecognized vascular lesion revealed after five weeks by a cataclysmic hemorrhagic complication during drainage attempts. Literature on cervicofacial ballistic injuries is reviewed and the practical attitude to adopt with these lesions discussed.

---

581. Besenski, N. (2002). "Traumatic injuries: imaging of head injuries." European radiology 12(6): 1237-1252.

Due to the forces of acceleration, linear translation, as well as rotational and angular acceleration, the brain undergoes deformation and distortion depending on the site of impact of traumatizing force direction, severity of the traumatizing force, and tissue resistance of the brain. Linear translation of accereration in a closed-head injury can run along the shorter diameter of the skull in latero-lateral direction causing mostly extra-axial lesions (subdural hematoma,epidural hematoma, subarachnoidal hemorrhage) or quite pronounced coup and countercoup contusions. Contusions are considerably less frequently present in medial or paramedial centroaxial blows (fronto-occipital or occipito-frontal). The centroaxial blows produce a different pattern of lesions mostly in the deep structures, causing in some cases a special category of the brain injury, the diffuse axonal injury (DAI). The brain stem can also be damaged, but it is damaged more often in patients who have suffered centroaxial traumatic force direction. Computed tomography and MRI are the most common techniques in patients who have suffered brain injury. Computed tomography is currently the first imaging technique to be used after head injury, in those settings where CT is available. Using CT, scalp, bone, extra-axial hematomas, and parenchymal injury can be demonstrated. Computed tomography is rapid and easily performed also in monitored patients. It is the most relevant imaging procedure for surgical lesions. Computed tomography is a suitable method to follow the dynamics of lesion development giving an insight into the corresponding pathological development of the brain injury. Magnetic resonance imaging is more sensitive for all posttraumatic lesions except skull fractures and subarachnoidal hemorrhage, but scanning time is longer, and the problem with the monitoring of patients outside the MRI field is present. If CT does not demonstrate pathology as can adequately be explained to account for clinical state, MRI is warranted. Follow-up is best done with MRI as it is more sensitive to parenchymal changes. In routine MR protocol gradient-recalled-echo sequences should be included at any other time after a traumatic event since they are very sensitive in detection of hemosiderin as well as former hematoma without hemosiderin. The MR signal intensity varies depending on sequences and time scanning after trauma.

582. Besenski, N., et al. (1995). "CT analysis of missile head injury." Neuroradiology 37(3): 207-211.

Between August 1991 and December 1992, CT was performed on 154 patients who had suffered missile head injury during the war in the Republic of Croatia. In 54% CT was performed 1-24 h after injury, and in 27% follow-up CT was also obtained. The wounds were penetrating, tangential or perforating (45%, 34% and 21%, respectively). Haemorrhage was the most frequent lesion in the brain (84%). Follow-up CT evolution of haemorrhage, oedema, cerebritis, abscess, secondary vascular lesions, necrosis, encephalomalacia and hydrocephalus. The most dynamic changes occurred 7-14 days after injury. In 14% of cases, deep cerebral lesions were found in the corpus callosum, septum pellucidum periventricular region and pons, although bone and shell fragments were in a different part of the brain parenchyma. Such lesions were found in penetrating injuries only. CT proved very useful for assessing the extent and type of lesions. Although different mechanisms of brain damage in missile head injury are known, here they are, to the best of our knowledge, shown for the first time by CT.

---

583. Beshay, N., et al. (2017). "The epidemiology of Open Globe Injuries presenting to a tertiary referral eye hospital in Australia." Injury 48(7): 1348-1354.

BACKGROUND: Open globe injuries (OGIs) account for 44% of the cost of ocular trauma within Australia. It is estimated that 90% of ocular trauma is preventable. However, there have been few epidemiological studies within Australia that have identified groups at risk of OGIs specifically. The aim of our study was to review the epidemiology of OGIs presenting to a tertiary referral eye hospital in Australia., METHODS: The Birmingham Eye Trauma Terminology (BETT) system was used to classify injuries as globe ruptures, penetrating eye injuries (PEIs), intraocular foreign bodies (IOFBs) or perforating injuries. Demographic data, past ocular history, mechanism of trauma, ocular injuries, and best-corrected visual acuity (BCVA) before and after treatment were recorded., RESULTS: The 205 OGIs included 80 globe ruptures, 71 PEIs, 48 IOFBs and six perforating injuries. Falls predominated in older age groups compared to the other mechanisms of injury ($p<0.0001$). A fall was responsible for 33 globe ruptures and 82% of these had a history of previous intraocular surgery. Globe rupture and perforating injuries had poorer visual outcomes ($p<0.05$), consistent with previous studies. Alcohol was implicated in 20 cases of OGI, with 11 of these due to assault. PEIs and IOFBs commonly occurred while working with metal. BCVA was significantly worse following removal of an intraocular foreign body. We found presenting BCVA to be a good predictor of BCVA at the time of discharge., CONCLUSIONS: The causes of OGI varied in association with age, with older people mostly incurring their OGI through falls and younger adults through assault and working with metal. Globe ruptures occurring after a fall often had a history of intraocular surgery. The initial BCVA is useful for non-ophthalmologists who are unfamiliar with the ocular trauma score to help predict the BCVA following treatment.

584. Besra, S. K., et al. (2018). "An Interesting Case of Penetrating Brain Injury by a Self-Hammered Nail." Indian Journal of Neurotrauma 15(2-3): 62-66.

Penetrating brain injuries by nails are rare. These usually have been reported as work-related accidents such as from falls or nail gun misfires and in cases of assault. The authors present a case of a 38-year-old psychiatric patient who attempted suicide by self-impalement of nail in the vertex near the midline of the head. Surprisingly, he was asymptomatic after a brief loss of consciousness, and with a Glasgow Coma Scale of 15. There was no history of vomiting or seizures. Intraoperative and postoperative periods were uneventful. Many unusual intracranial foreign bodies have been reported in medical literature, but one of a self-inflicted intracranial injury by hammering a nail is rare. In this article, the authors describe their case report and discuss the challenges encountered in the management of a patient with intracranial injuries by nail, along with a brief review of literature.

585. Bessho, M., et al. (2012). "A case in which a bone fragment caused by a bullet made a second channel in addition to the bullet channel." Legal medicine (Tokyo, Japan) 14(4): 188-190.

A 64-year-old male was found dead in his house with his face covered with blood and a 38-caliber revolver between his legs. He had been suffering from type 2 diabetes mellitus and aftereffects of cerebral infarction. Autopsy revealed a normal round contact wound in the left lateral cervical region. A bullet from the firearm had entered through the left lateral cervical region and traveled to the outer right sternocleidomastoid muscle. This also triggered another wound from the fifth cervical vertebra to the muscle tissue near the right cartilage thyroid. At the end of this channel, there were three bone fragments. Here, we report this interesting case with two channels caused by a bullet and by a resulting bone fragment. We also discuss the characteristics of an ear lobe injury found on the victim and show how this injury and blood and skin on the revolver were used as clues to determine the posture at the time of the shot.

---

586. Betz, P., et al. (1995). ""Tentative" injuries in a homicide." The American journal of forensic medicine and pathology 16(3): 246-248.

A homicide caused by blunt trauma to the neck and head is reported. On the left side of the victim's neck were multiple superficial cuts that ran parallel to deeper ones that appeared to be the typical pattern of tentative or hesitation injuries. Further information on the perpetration of the crime could not be obtained from the offender, but it must be assumed that the cuts were made after the victim had already been knocked unconscious by blows or kicks. The considerable blood alcohol concentration of the perpetrator and the rather reduced sharpness of the serrated kitchen knife used probably contributed to the development of these injuries.

---

587. Betz, P., et al. (1994). "[Penetrating injuries of the orbital roof caused by the point of an umbrella]." Perforationsverletzungen des Orbitadachs durch Regenschirmspitze. 91(1): 46-48.

Two lethal cases of penetration injury of the orbita are reported. The injuries were caused directly by the point of an umbrella (accident or homicide), leading to canalicular destruction of the frontal lobe of the cerebrum. The mechanism of injury with cerebral involvement was not determinable except by autopsy, and the importance of a thorough clinical examination is therefore emphasized.

588. Bevivino, J. R., et al. (1994). "Reconstruction of traumatic orbital floor defects using irradiated cartilage homografts." Annals of plastic surgery 33(1): 32-37.

The important role of orbital shape and volume reconstruction has been studied by many investigators. There is, however, no consensus on the material that should be used in the reconstruction of the orbit. Both biologic and alloplastic materials have been used, each with its advantages and disadvantages. Here we report our experience with irradiated costal cartilage homograft in the reconstruction of the orbital floor. Irradiated cartilage grafts were used in 31 patients with significant traumatic defects in the orbital floor. Long-term follow-up in 21 patients up to 48 months revealed no incidence of graft infections, extrusions, or clinically detectable graft distortion or resorption. Irradiated cartilage homograft appears to be an excellent material for reconstruction of the orbital floor.

---

590. Bhat, R., et al. (2012). "Non-metallic and metallic craniocerebral missile injuries in civilian Kashmir - Varied outcome." Brain injury 26(4-5): 404.

Objective: To seek comparative results of nonmetallic and metallic craniocerebal missile injuries after aggresive treatment. Methods: Prospective and retrospective study of 694 craniocerebral missile injuries over a period of 21 years from September 1988 to March 2o1o in Sher - i- Kashmir Institute of

Medical Sciences, Kashmir India. Results: The study revealed an overall mortality of 32.70% (227 out of 694). A total of 664 adults and 30 children (mostly teenagers) were studied. The 79.1% (549 out of 694) patients were metallic missile (metal bullets, grenade, bomb and improvised ex-plosive device (IED) blasts, shrapnels, bolts, splinters and pellets used by shotgun etc) inju-ries whereas 20.8% (145 out of 694) patients were non-metallic missile injuries. The non-metallic missile injury group mostly (72.4% i.e.; 105 out of 145) had low GCS (Glasgow Coma Scale) score and overall worse prognosis with zero good-recovery, 47.5% disabilities and 52.4% mortality as compared to the metallic missile injury group. The nonmetallic group comprised of 60% (18 out of 30) children which resulted in only one death. The metallic missile injury deaths amounted to 21.75% (151 out of 694 patients) and non-metallic missile injuries accounted for 10.95% (76 out of 694 patients) of total deaths. Most complications i.e. 287 complications in only 145 patients, mostly infective were found in non-metallic missile injuries with worst outcome. The common non-metallic missiles used were stone balls (stone-bullets) and spherical glass balls (lo-cally Buanta) fired by Gulail (modified catapult) or slingshot, red rubber bullets, plastic tear gas shells and cartridges, wooden (pulped mulberry stem) and card-board wads used in shotguns (pellet-guns). Results: Predictors of poor outcome were low admission GCS score, non-metallic penetrating injury due to tear-gas cartridges, rubber bullets and stonebullets, perforating metallic missile injuries and delayed and maltransportation. The stone pelting, throwing stone projectiles (stone-bullets and glassbullets) by Gulail and manually has become a common way to inflict head and eye injuries in Kashmir. The non-metallic missiles are not lesslethal and have high disabling, killing and infective.

591. Bhatia, K. D., et al. (2020). "Cavernous sinus embolisation prior to removal of penetrating foreign body in a 6-year-old child." BMJ case reports 13(12).

Transorbital penetrating foreign bodies are extremely rare in children and may penetrate the cavernous sinus or the underlying internal carotid artery. Parent vessel sacrifice and temporary balloon occlusion are feasible options for managing arterial injury during removal of the foreign body. Even in the absence of arterial injury, the ophthalmologist may encounter significant bleeding from the cavernous sinus deep in their operative field that is difficult to control. We present a case of a 6-year-old child with a stick penetrating the left superior orbit to enter the cavernous sinus but sparing the internal carotid artery. We describe the first reported experience of prophylactic coil embolisation of the cavernous sinus to minimise intraoperative bleeding during transorbital removal of a foreign body with an excellent clinical outcome.

---

593. Bhatjiwale, M. G., et al. (2001). "Transnasal intracranial entry of a flying wire fragment." British journal of neurosurgery 15(3): 256-258.

A 7-year-old boy was playfully revolving a partly insulated electric wire which accidentally struck a bamboo pole in its path. He soon found that his left nostril was hit and blood trickled from the site. Unsuspected on investigation, a small fragment of the wire was found within the brain. The sequence of events is reported.

---

594. Bhatoe, H. S. (2001). "Retained intracranial splinters : a follow up study in survivors of low intensity military conflicts." Neurology India 49(1): 29-32.

With improvements in the ballistic physics, patient evacuation, imaging, neurosurgical management and intensive care facilities, there has been overall improvement in the survival of patients

with missile injuries of the brain. Patients with retained intracranial fragments have been followed up and the sequelae of such fragments were analysed. We present our observations in 43 such patients who had survived low velocity missile injuries of the brain during military conflicts and had retained intracranial fragments. Over a follow up period of 2 to 7 years, suppurative sequelae (brain abscess, recurrent meningitis) were seen in 6 patients, two of these progressing to formation of brain abscess. Three patients developed hydrocephalus and one seizures. Patients with orbitocranial or faciocranial wound of entry had a higher incidence of suppurative complications (3 out of 4), while those with skull vault entry had a lower incidence of such sequelae (7 out of 30). Nine patients were lost to follow up. Other determinants of suppurative complications were postoperative CSF leak and intraventricular lodgement of the fragment.

---

595. Bhatoe, H. S. (2004). "Missile injuries of the anterior skull base." Skull Base 14(1): 1-8.

Missile injuries of the anterior skull base usually occur during war or warlike situations. These injuries may be isolated or associated with multiple traumatic injuries. We report 23 such cases managed during military conflicts and peacekeeping operations. All were adult males. Four of these patients sustained bullet injuries; the rest were injured from shrapnel. Eighteen patients had injury to the visual apparatus with permanent blindness. Proptosis was seen in 16, cerebrospinal fluid (CSF) leak from the wound in seven, and CSF orbitorrhea in three patients. Sixteen had irreparable injury to the eye necessitating evisceration/enucleation, and two had retrobulbar optic nerve injury. Three patients were comatose [Glasgow Coma Scale (GCS) 3/15], and 14 had altered sensorium. Six patients were fully conscious. All were investigated by computed tomography (CT), which revealed injury to the eyeball and skull base, orbital fracture, frontal hematoma, contusion, and pneumocephalus. Seventeen patients underwent emergency surgery, and six patients were initially managed conservatively. Neurosurgical management consisted of making bifrontal flaps, craniotomy/craniectomy, debridement, and repair of the base with fascia lata. Reconstruction of the orbital rim was required in three cases. All were managed postoperatively with cerebral decongestants and antibiotics in antimeningitic dosages. There was one death in the postoperative period; outcome was good in 16 and moderate in four patients. Twelve patients had retained intracranial splinters; three of these developed recurrent suppurative meningitis. Of the six patients initially managed conservatively, three were subsequently operated for CSF rhinorrhea. Gross communition, dural loss, and injury to the frontal scalp often preclude the use of pericranial repair of the skull base. Fascia lata is extremely useful for reconstruction and repair. Anterior cranial fossa injury probably carries a better prognosis; however, there is increased risk of suppurative complications due to breach of air-filled sinuses by the missile and contamination of the intradural compartment, as compared with supratentorial vault injuries not involving the orbit or paranasal sinuses. Three patients who underwent no operative procedure and remain asymptomatic are under follow-up.

596. Bhatoe, H. S. (2018). "Operative management of gunshot wounds of the brain." Journal of neurotrauma 35(16): A56-A57.

While managing a patient (often a soldier) with gunshot injury to the brain, the paramedics and surgeons/neurosurgeons are often racing the biological clock, in effort to salvage a rapidly perishable entity. Thus, it has to be clear to all paramedics in field and the surgeons who may be called to treat these patients in austere environments, the scope and limits of surgical intervention in a given situation. In a mass casualty situation, rapid triage is the precursor to optimizing management and evacuation. In a peripheral setup, all that can be done is hemostasis from cranial wounds, administration of cerebral decongestants (hyperosmolar agents and osmotic diuretics), and rapid evacuation. Computed tomography of the cranium provides the information about the extent and severity of injury, prognostication and helps chalk out the surgical plan. Under anesthesia, dressings are opened, and after preliminary debridement and raising the scalp flap, damage is assessed. Unless bone is grossly communited and contaminated, craniotomy flap can be planned. Normal dura is defined and radial

incisions given with insertion of stay sutures. Grossly communited bone, pulped brain and foreign bodies are removed with copious irrigation. A brain conserving attitude is advocated and radical debridement is avoided. Hemostasis should be perfect, which can be achieved by tamponade and bipolar coagulation. No attempt should be made to dissect the brain tissue to remove bullets and shrapnel if they are not visible after debridement. Dura is reconstituted with autologous pericranium, temporalis fascia or fascia lata to achieve water-tight closure. Large bone flaps can be washed with iodinated antiseptic solutions and replaced. Scalp is closed water-tight. Delayed consequences of such injuries (delayed cerebrospinal fluid leaks, and problems related to retained intracranial fragments) can be planned after due assessment with imaging. CSF leaks require repair of the dural and skull base defect, and retained intracranial fragments can be removed if they are accessible and their removal will not enhance neurological deficits. Suppurative sequelae (recurrent pyogenic meningitis, brain abscess) need appropriate antibiotic therapy and removal of the offending shrapnel. Other sequelae like hydrocephalus and migration of the bullet/shrapnel will need appropriate planning and their removal.

597. Bhiansha, A. L. D. and T. Selvaraj (2019). "Postmortem study of pattern of ligature mark and injuries to the neck structures in case of suicidal hanging." Indian Journal of Forensic Medicine and Toxicology 13(3): 130-134.

The death due to suicide are highly incidental in the morden way of life. The present study was conducted in Department of Forensic Medicine, Madurai Medical College, Madurai during January 2014 to December 2014 to find out the various patterns of ligature and the neck injuries during the autopsy examinations in deaths due to hanging. Total 210 cases of autopsy were studied irrespective of age, gender, religion, casteetc., who has died due to hanging. All the data is related to ligature pattern, internal injuries in neck, marital status etc are recorded with detailed autopsy examination subsequently analysed statistically. We conclude that majority of victims were male of 21-30 years age involved in hanging, due to love, financial factor, work related issues and other motivational factors.

598. Bhimani, A. A., et al. (2006). "Complex motor function in humans: validating and extending the postulates of Alexandr R. Luria." Cognitive and behavioral neurology : official journal of the Society for Behavioral and Cognitive Neurology 19(1): 11-20.

OBJECTIVE: We used functional brain imaging to reevaluate Luria's postulates and to elaborate the neural circuitry underlying performance of complex motor tasks., BACKGROUND: The anatomic organization and physiologic functioning of the normal human motor system have great significance for understanding motor dysfunction and remediation in neurology. Working with victims of penetrating head injuries, noted Russian neuropsychologist Aleksandr R. Luria designed several tests of fine motor control to understand their difficulties with complex voluntary movements. This led to his postulates that such function involves the premotor cortices and their interaction with the parietal lobe., METHOD: Six healthy young adults performed the hand imitation, fist-scissors-gun, and piano key tasks during blood oxygen level-dependent functional magnetic resonance imaging at 3 T., RESULTS: All 3 tasks revealed activation of both premotor and parietal cortices. Furthermore, while hand Imitation relied more on the ventral premotor area and right parietal lobe, fist-scissors-gun and piano key relied more on the supplementary motor cortex., CONCLUSIONS: We postulate that differences in task-dependent activations across these tasks relate to degrees of sequential movement, pacing, and imitation. These results uphold Luria's original hypotheses, and extend that work by providing a further characterization of the motor areas involved in complex motor behaviors.

---

600. Bhoopat, T. (1995). "A case of internal beveling with an exit gunshot wound to the skull." Forensic science international 71(2): 97-101.

Exit gunshot wounds of the skull generally have external beveling while entrance wounds show internal beveling. With rare exceptions, entrance gunshot wounds show external beveling, usually of two types: the asymmetric 'keyhole' type and the symmetric 'non-keyhole' type. In exit gunshot wounds of the skull, only the keyhole type has been reported. This report shows that symmetric internal beveling from an exit gunshot wound to the skull may confuse medical personnel.

---

601. Bhootra, B. K. (1985). "An unusual penetrating head wound by a yard broom and its medicolegal aspects." Journal of forensic sciences 30(2): 567-571.

A fatal case of a homicidal penetrating head injury by a blunt object (yard broom) is described. A piece of wood penetrated the skull and remained in the intracranial cavity resulting in infection. The need of careful examination of the head injury is emphasized.

---

602. Bhootra, B. L. (2007). "Retained intra cranial blade - medicolegal perspectives." Journal of forensic and legal medicine 14(1): 31-34.

A fatal case of a homicidal penetrating head injury by retained blade of knife is reported. The blade of knife penetrated the skull bone after breaking from a knife handle and remained lodged in the intracranial cavity for 5 days resulting in death from intracranial bleeding and brain oedema. The need of proper and complete examination of the head injury and its medico-legal importance is emphasized.

603. Bhootra, B. L. and B. D. Bhana (2004). "An unusual missile-type head injury caused by a stone: case report and medicolegal perspectives." The American journal of forensic medicine and pathology 25(4): 355-357.

Missile head injury is predominantly caused by firearms; however, small blunt objects such as a stone can be propelled into the air and cause a low-velocity-type missile injury, as described in this case report. Since the cerebral damage in low-velocity missile injuries is usually focal, there might not be disturbance of consciousness until secondary brain damage occurs; therefore, adequate medical supervision is necessary to prevent and treat potentially fatal complications in a timely manner. This is a rare case of a penetrating missile wound of the head, most likely caused by the use of a stone propelled by a slingshot that penetrated the skull and lacerated the brain with the stone embedded within the substance of the brain. The deceased died at home 2 days later from focal suppurative meningitis with cerebral abscess formation and a subdural hemorrhage.

604. Bibb, J., et al. (2014). "Neuroprotection from traumatic brain injury by targeting intracellular neuronal signal transduction mechanisms." Brain injury 28(5-6): 521.

TBI is a major health problem associated with poor prognosis, acute and latent effects and long-term disability. Severity varies across a broad spectrum. Mild TBI is under-diagnosed, with many episodes going unreported. Severe TBI with or without cranial penetration is better documented and includes neuronal injury in response to blast exposure, particularly in the military combat setting. Immediate brain damage involves massive neuronal depolarization and influx of ions. In response to activation of voltage-gated Ca2+ channels, extremely high levels of the excitatory neurotransmitter glutamate are released, triggering excitotoxicity. Cerebral oedema and metabolic disturbances quickly follow. Swelling of neurons, oxidative stress and free radical production all contribute acutely to neuronal death. Following initial trauma, a delayed and spreading process of injury occurs. White matter fibre degenerates as axonal damage results from axolemmmal or cytoskeletal destabilization and collapse. Injured brains also exhibit increased sensitivity to secondary ischaemic insult, changes in cerebral blood flow and persistent excitotoxicity. Neuroinflammation may also contribute to lesion

spread. To better understand the mechanisms mediating TBI, this study assessed the histopathological, neurophysiological, biochemical and behavioural effects of both cortical controlled impact (CCI) and blast-induced traumatic brain injury in rodent models. It was found that the deleterious effects of injury closely correlate with excitotoxic activation of calpain, aberrant activation of the neuronal protein kinase, Cdk5, and hyperphosphorylation of the microtubule associated protein tau. Conditional knockout of Cdk5 in adult mice dramatically reduced in vivo imaged TBI lesions and deleterious neurophysiological, histopathological and behavioural effects. These results implicate aberrant Cdk5 activity as a critical contributor to excitotoxic TBI and suggest that acute therapies targeting its acute activation or the mechanisms by which it causes neuronal injury and death may serve as effective therapies to mitigate TBI and improve recovery.

605. Bichler, E. and F. Daxecker (1986). "[Surgical treatment of traumatic amaurosis]." Ein Beitrag zur operativen Behandlung der traumatischen Amaurose. 189(4): 334-335.

Exploration of the optic canal was performed in 5 patients with traumatic amaurosis. Fractures of the optical canal were found in 4 cases. One case in which the canal was intact was interpreted as evulsion of the optic nerve. Vision improved in one of the cases with a fractured optical canal. Exploration of the optic nerve is recommended in cases of traumatic amaurosis, always provided that the indication is correct.

606. Bieniek, K. F., et al. (2019). "Pathological epidemiology of chronic traumatic encephalopathy in Southeastern Minnesota, U.S.A." Brain Pathology 29: 134.

Introduction: Traumatic brain injury (TBI) is a strong environmental risk factor for the development of dementia. TBI-dementia risk has been reported to be dose-dependent based on TBI severity and number of TBI. Pathologically, single-incident TBI can lead to hypoxic-ischemic injury, inflammation, and axonal injury whereas repetitive TBI can result in a progressive neurodegenerative disorder known as chronic traumatic encephalopathy (CTE). CTE is defined by focal deposits of hyperphosphorylated tau in neurons and astroglia at the depths of cerebral sulci and surrounding penetrating blood vessels. The frequency of CTE pathology in the general population, especially former amateur contact sports athletes, is unknown. Methods: The goal of this study is to identify the known pathognomonic CTE lesions in cortical autopsied tissue from Mayo Clinic Tissue Registry cases (N = 2,651) and clinically characterize individuals with and without CTE pathology to establish the relevance of contact sports participation as risk factors of CTE. Using historical obituary and yearbook records, 308 former athletes and 454 non-athletes were identified. Phospho-tau immunohistochemistry was performed on three unique neocortical sections (frontal, temporal, and parietal) from these athlete and non-athlete cases. Results: Of the 283 cases screened to date, 15 (5.3%) have pathology consistent with CTE. All 15 cases were male and 9/15 had a documented history of contact sports participation (12.2% of known male athletes with CTE). Conclusion: While additional case screening and clinical characterization remains ongoing, this preliminary data suggests CTE pathology is a common neuropathological finding, especially in individuals with prior documented participation in a contact sport.

607. Biesterveld, B. E., et al. (2020). "Valproic acid treatment rescues injured tissues after traumatic brain injury." The journal of trauma and acute care surgery 89(6): 1156-1165.

BACKGROUND: No agents that are specifically neuroprotective are currently approved to emergently treat patients with traumatic brain injury (TBI). The histone deacetylase inhibitor, high-dose valproic acid (VPA) has been shown to have cytoprotective potential in models of combined TBI and hemorrhagic shock, but it has not been tested in an isolated TBI model. We hypothesized that VPA, administered after isolated TBI, will penetrate the injured brain, attenuate the lesion size, and activate prosurvival pathways., METHODS: Yorkshire swine were subjected to severe TBI by cortical impact.

One hour later, animals were randomized to VPA treatment (150 mg/kg delivered intravenously for 1 hour; n = 4) or control (saline vehicle; n = 4) groups. Seven hours after injury, animals were sacrificed, and brain lesion size was measured. Mass spectrometry imaging was used to visualize and quantitate brain tissue distribution of VPA. Sequential serum samples were assayed for key biomarkers and subjected to proteomic and pathway analysis., RESULTS: Brain lesion size was 50% smaller (p = 0.01) in the VPA-treated animals (3,837 +/- 948 mm) compared with the controls (1,900 +/- 614 mm). Endothelial regions had eightfold higher VPA concentrations than perivascular regions by mass spectrometry imaging, and it readily penetrated the injured brain tissues. Serum glial fibrillary acid protein was significantly lower in the VPA-treated compared with the control animals (p < 0.05). More than 500 proteins were differentially expressed in the brain, and pathway analysis revealed that VPA affected critical modulators of TBI response including calcium signaling pathways, mitochondria metabolism, and biosynthetic machinery., CONCLUSION: Valproic acid penetrates injured brain tissues and exerts neuroprotective and prosurvival effects that resulted in a significant reduction in brain lesion size after isolated TBI. Levels of serum biomarkers reflect these changes, which could be useful for monitoring the response of TBI patients during clinical studies.

608. Biffl, W. L., et al. (2005). "The evolution of trauma care at a level I trauma center." Journal of the American College of Surgeons 200(6): 922-929.

BACKGROUND: My colleagues and I compared trauma patient demographics and outcomes between two time periods in the last 10 years in our Level I trauma center to evaluate the impact of the marked evolution in trauma care and determine additional opportunities for improvement., METHODS: Our trauma registry was queried for adult trauma patients admitted from 1991 to 1993 (EARLY) and 1999 to 2001 (LATE). The EARLY period predated creation and maturation of a dedicated trauma service and Level I trauma center verification. Continuous data were compared using Student's t-test, and categorical data using chi-square., RESULTS: Increased transfers of severely injured patients from regional hospitals, combined with fewer admissions for "observation," resulted in fewer, but sicker, patients admitted in the LATE period. Patients were considerably older in the LATE period and mortality was higher. Despite higher acuity of patients, hospital and ICU lengths of stay were shorter in the LATE period. Nonoperative management of solid organ injuries was more common in the LATE period, but the overall operative volume was similar. Nonsurvivors in the LATE period had higher Injury Severity Scores and were older compared with the EARLY period. Mortality attributable to blunt CNS injury was higher, and that attributed to late sepsis and multiple organ failure was lower in the LATE period., CONCLUSIONS: Over the past decade, more older, severely injured patients have been admitted to our Level I trauma center. Overall mortality among these higher acuity patients has increased, with a marked shift in attributable mortality to CNS injury and away from late sepsis and multiple organ failure. This highlights the need for continued efforts to identify optimal management strategies for severe brain injury. Additional areas for improvement include enhancement of our regional trauma network and injury prevention initiatives.

609. Biggs, A. T., et al. (2021). "Effect sizes for symptomatic and cognitive improvements in traumatic brain injury following hyperbaric oxygen therapy." Journal of applied physiology (Bethesda, Md. : 1985) 130(5): 1594-1603.

Hyperbaric oxygen therapy has been proposed as a method to treat traumatic brain injuries. The combination of pressure and increased oxygen concentration produces a higher content of dissolved oxygen in the bloodstream, which could generate a therapeutic benefit for brain injuries. This dissolved oxygen penetrates deeper into damaged brain tissue than otherwise possible and promotes healing. The result includes improved cognitive functioning and an alleviation of symptoms. However, randomized controlled trials have failed to produce consistent conclusions across multiple studies. There are numerous explanations that might account for the mixed evidence, although one possibility is that prior evidence focuses primarily on statistical significance. The current analyses explored existing evidence

by calculating an effect size from each active treatment group and each control group among previous studies. An effect size measure offers several advantages when comparing across studies, as it can be used to directly contrast evidence from different scales, and it provides a proximal measure of clinical significance. When exploring the therapeutic benefit through effect sizes, there was a robust and consistent benefit to individuals who underwent hyperbaric oxygen therapy. Placebo effects from the control condition could account for approximately one-third of the observed benefits, but there appeared to be a clinically significant benefit to using hyperbaric oxygen therapy as a treatment intervention for traumatic brain injuries. This evidence highlights the need for design improvements when exploring interventions for traumatic brain injury and the importance of focusing on clinical significance in addition to statistical significance.

610. Biggs, A. T., et al. (2022). "Head Wounds Received During Force-on-Force Training With Non-lethal Ammunition." Military medicine 187(5-6): e787-e791.

Close quarters combat training is designed to replicate the mental and physiological stressors of firing upon an adversary while in close proximity. One method to replicate combat stressors is to use non-lethal training ammunition specifically designed for force-on-force exercises. These rounds can be fired from slightly modified service-issued weapons and provide a pain sensation upon striking the opponent. The current investigation presents a case study of several injuries when these rounds impacted the head directly, which is a primary area of concern for safety issues. Most impacts produced initial swelling that reduced substantially within the first few hours. Approximately 24 hours later, the swelling disappeared entirely with a visible contusion near the impact center. Bruising would typically clear within a few days. However, another example produced sufficient bleeding to require intervention before continuing with the training exercises and sanguineous crust or scabbing rather than the typical contusion. Pain was minimal for all wounds after only several days, which aligns with previous research on pain from non-lethal training ammunition wounds. Based on the head wounds observed here, loss of eyesight is a realistic possibility. Eye protection should be a requisite across all force-on-force training exercises without exception. This case study documents some potential hazards of force-on-force training, but more importantly, it further highlights the need for medically informed training standards about engagement distances and personal protective equipment. 612. Bilal, S., et al. (2021). "Cross-sectional survey of treatments and outcomes among injured adult patients in Kigali, Rwanda." African Journal of Emergency Medicine 11(2): 299-302.

Introduction: Traumatic injuries and their resulting mortality and disability impose a disproportionate burden on sub-Saharan countries like Rwanda. An important facet of addressing injury burdens is to comprehend injury patterns and aetiologies of trauma. This study is a cross-sectional analysis of injuries, treatments and outcomes at the University Teaching Hospital-Kigali (CHUK). Methods: A random sample of Emergency Centre (EC) injury patients presenting during August 2015 through July 2016 was accrued. Patients were excluded if they had non-traumatic illness. Data included demographics, clinical presentation, injury type(s), mechanism of injury, and EC disposition. Descriptive statics were utilised to explore characteristics of the population. Results: A random sample of 786 trauma patients met inclusion criteria and were analysed. The median age was 28 (IQR 6–50) years and 69.4% were male. Of all trauma patients 49.4% presented secondary to road traffic injuries (RTIs), 23.9% due to falls, 10.9% due to penetrating trauma. Craniofacial trauma was the most frequent traumatic injury location at 36.3%. Lower limb trauma and upper limb trauma constituted 35.8% and

27.1% of all injuries. Admission was required in 68.2% of cases, 23.3% were admitted to the orthopaedic service with the second highest admission to the surgical service (19.2%). Of those admitted to the hospital, the median LOS was 6 days (IQR 3–14), in the subset of patients requiring operative intervention, the median LOS was also 6 days (IQR 3–16). Death occurred in 5.5% of admitted patients in the hospital. Conclusion: The traumatic injury burden is borne more proportionally by young males in Kigali, Rwanda. Blunt trauma accounts for a majority of trauma patient presentations; of these RTIs constitute nearly half the injury mechanisms. These findings suggest that this population has substantial injury burdens and prevention and care interventions focused in this demographic group could provide positive impacts in the study setting.

613. Biler, E. D., et al. (2017). "Unusual route of a bullet: From scapula to eye." Indian journal of ophthalmology 65(1): 52-54.

Herein, an awkward case of globe perforation with a bullet-entering from the right posterior scapular region and leaving the body from the right orbit through the eye - is reported. Route of the bullet could be devastating - as it passed through the neck and the maxillofacial region-however by chance no vital damage occurred. Its path was assessed by plain radiography and computed tomography scans. Sometimes prediction of the trajectory is very difficult without additional radiological investigations. Especially, in the case of any high velocity projectile wounding, physician must be aware of the fact that the bullet's course will not be a linear but most probably a complicated one. Prognosis of the injury depends on the path of the bullet or shrapnel fragment, close clinical observation, an open-minded approach, and the multidisciplinary care. Moreover, even the crime investigation might be needed.

---

614. Bilge, Y., et al. (2003). "The identification of a dismembered human body: a multidisciplinary approach." Forensic science international 137(2-3): 141-146.

A criminal case was directed to a multidisciplinary forensic team for identification, concerning a victim whose head, having two gunshot wounds, had been separated by a sharp instrument and was recovered 6 months later. The purpose of this research was to determine the sex and age of the victim for human identification. Primarily, macroscopic examination of the skull, tooth, and DNA analysis was conducted for sex determination. A rough assessment of age was made from the skull based on anthropological findings, however a more definitive result of age estimation was determined utilizing dental morphology. The dental data showed an age range of 32-37 from the mineral examination and the formulation of microscopic measurements. The results obtained from the skull and dental analysis matched with the physical characteristics of the victim's body, the known personal data of this person, and with the superposition of the photos gathered by a formal request. Besides, the result of DNA profiling of the victim showed male gender and direct relationship with the victim's presumed wife and daughter. Generally, research on human identification consists of sex and age determination. The sex characteristics can be precisely proved from DNA tests. However, age can be estimated by skeletal, and dental analysis. In this case the performed sex and age analysis lead the research to the selective matching of the missing person's identity.

615. Bilkay, U., et al. (2008). "Free-tissue transfers for reconstruction of oromandibular area in children." Microsurgery 28(2): 91-98.

INTRODUCTION: Currently, free-tissue transfers are commonly used for various reconstructive purposes in adults. However, there is a lack of large series of free flap reconstruction in children, especially for reconstruction of oromandibular defects. Our study aims to share our experience in free-flap reconstruction of some challenging pediatric cases., MATERIALS AND METHODS: Pediatric free-flap interventions (<18-year-old) that were performed between 2000 and 2006 in our clinic were retrospectively evaluated. Eighteen free-tissue transfers were performed in 17 pediatric cases.

Epidemiologic data, etiology, defects, preferred free flaps, and results have been compared and analyzed., RESULTS: A total of 17 patients (18 free flaps) were analyzed. Mean age was 10.4 years. The etiology was tumor in 11 cases, traffic accident in 5 cases, and gunshot in 1 case. Double-flap transfer was performed to one patient with a devastating shotgun wound and single flap transfers to others. A total of 8 osseous flaps, 7 osteocutaneous flaps, and 3 septocutaneous flaps were transferred. Total superficial flap necrosis was encountered in one flap (5.8%) while partial superficial necrosis was seen on two flaps (11.7%). Sixteen of the 17 cases reconstructed, including the three cases with complications, resulted in good functional and cosmetic outcome. One case was lost in the sixth postoperative month due to septisemia during chemotherapy. All the surviving 16 cases acquired bony fusion, mastication, and speech in addition to good cosmetic results., CONCLUSION: Pediatric free-tissue transfers are increasing due to the development of better equipment, finer surgical technique, and a better understanding of the unique characteristics of pediatric cases. In our opinion, high success rates with good cosmetic and functional results can be obtained if the specific requirements of the pediatric procedures are met. Copyright 2008 Wiley-Liss, Inc. Microsurgery, 2008.

616. Binder, P. S. (1978). "Evaluation of the eye following periorbital trauma." Head & neck surgery 1(2): 139-147.

Periorbital trauma is usually associated with ocular complications. When confronted with a traumatized patient, one should therefore evaluate the eyes to determine the extent of injury. First, a noncontact examination should be conducted to assess the degree of ocular integrity. Once it is established that the eye is not damaged, further diagnostic work-up and evaluation can be performed. Although most ocular complications are treated by ophthalmologists, eyelid lacerations, orbital hemorrhage, blowout fractures, and brain injuries may be treated by other subspecialists. Before orbital and ocular adnexal reconstructive surgery is performed, however, one must establish the patient's ocular status so that ocular damage will not be increased during surgery.

617. Birbilis, T. and V. Bockermann (1998). "A new forceps for the safe and easier insertion of subdural catheter: technical note." Acta neurochirurgica 140(7): 721-722.

A new forceps suitable for the safe and easier insertion of a silicon catheter into the subdural space is described. The use of this new tool has two advantages: Firstly, the insertion of the silicon subdural catheter is parallel to the brain surface and secondly, the movement of the catheter's end in the subdural space is controlled with greater accuracy. Thus, the surgeon has the opportunity to direct the catheter to the right position avoiding penetration or injury of the brain.

618. Bird, C. E. and J. M. Fleischman (2015). "A Rare Case of an Intact Bone Plug Associated with a Gunshot Exit Wound." Journal of forensic sciences 60(4): 1074-1077.

This case study presents an unusual manifestation of gunshot trauma in skeletal tissue from a post-World War II human rights abuse sample uncovered in Vilnius, Lithuania. After briefly reviewing the typical wound appearance of projectile trauma in the cranium, we discuss the presence of an intact bone plug associated with a gunshot exit wound in an individual from the Tuskulenai Case. While this individual demonstrated typical gunshot entry and exit wounds to the cranium consistent with high-velocity trauma, the bone plug indicates that the projectile likely lost much of its kinetic energy while traveling through the cranium resulting in a low-velocity impact at the exit site. This study reviews a similar instance of a bone plug recovered from a bioarcheological sample in Peru and emphasizes the importance of thorough archeological excavations of mass graves. 619. Birk, D. M., et al. (2015). "Improvement in venous outflow following superior sagittal sinus decompression after a gunshot wound to the head: case report." Journal of neurosurgery 123(1): 81-85.

The most commonly described indications for surgical management of closed depressed skull fractures are hematoma evacuation and repair of extensive cosmetic deformity. Venous sinus injury, which occurs in a subset of depressed skull fractures, is not typically listed as an indication for surgical treatment due to the potential for major venous hemorrhage associated with surgery near these structures. However, if patients exhibit signs and symptoms of intracranial hypertension and radiographic findings demonstrate sinus compromise, surgical elevation of the depressed skull fragments is indicated. The authors present the case of a 25-year-old woman with a depressed skull fracture secondary to a gunshot wound with symptomatic compromise in venous outflow of the posterior one-third of the superior sagittal sinus. The patient was treated with surgical decompression via bilateral craniectomy along with intracranial pressure-lowering medical therapy and had almost full resolution of her presenting symptoms with documented improvement in flow through the superior sagittal sinus. While the use of surgical treatment for these types of injuries is highly debated, the authors demonstrate here that safe, effective surgical management of these patients is possible and that surgical decompression should always be considered in the case of symptomatic venous sinus flow obstruction.

621. Biros, M. H. and R. Nordness (1996). "Effects of chemical pretreatment on posttraumatic cortical edema in the rat." The American journal of emergency medicine 14(1): 27-32.

The purpose of this study was to evaluate the effects of mannitol (Man), dexamethasone (DM), dichloroacetic acid (DCA) and 1,3-butanediol (BD) in reduction of posttraumatic cortical edema following brain deformation injury to rats. Ten minutes prior to fluid percussion injury, each animal received one of four pretreatments or placebo: Man, 1 g/kg intravenously, DM 3.0 mg/kg intravenously, DCA 25 mg/kg intraperitoneally BD 0.5 mg/kg intraperitoneally (n = 12 per treatment group), or equivolume saline (n = 8 per corresponding trauma group). Six hours after trauma, cortical tissue was harvested. Using a benzene-kerosene gradient column calibrated with potassium sulfate standards, the specific gravity (SpG) of cortical tissue from each group was measured and compared (ANOVA, $P < .05$). The measured cortical SpG from traumatized animals receiving Man (mean 1.037 +/- SEM .001), DCA (1.038 +/- .001), and BD (1.039 +/- .001) were equal to SpG from untraumitized cortex (1.041 +/- .001), and were significantly greater than SpG from traumatized cortex for animals receiving DM (1.035 +/- .001) or placebo (1.033 +/- .002). Pretreatment with DCA, Man, and BD appears to protect against development of posttraumatic cortical edema when measured 6 hours after blunt head trauma in the rat. Each of these chemical treatments appears effective in preventing or reducing posttraumatic cortical edema.

623. Bitar, G. and P. Touska (2020). "Imaging in trauma of the facial skeleton and soft tissues of the neck." British journal of hospital medicine (London, England : 2005) 81(6): 1-15.

Trauma to the face and neck is a frequent reason for emergency department attendance. Imaging is invaluable in the characterisation of such injuries, enabling delineation of fracture patterns as well as identification of vascular and other soft tissue injuries. It may also be used to prevent long-term mortality and morbidity and provide a roadmap for surgical intervention so that form and function may be restored. This article gives a pictorial review of the imaging of craniofacial trauma, stratified according to the thirds of the face, followed by a review of blunt and penetrating trauma of the neck. It discusses appropriate imaging modalities for each trauma category, describes major patterns of craniofacial trauma on cross-sectional imaging and identifies clinically relevant imaging features that should trigger subspecialist review or be of relevance to pre-surgical planning. It starts with the upper third comprising frontal sinus fractures before describing the component fractures of the middle third (including nasal, zygomaticomaxillary and orbital fractures) and then focusing on the lower third (specifically mandibular and dentoalveolar fractures). The article concludes with a review of soft tissue injuries of the neck, particularly penetrating, blunt and laryngeal trauma.

624. Bitseff, E. L. and R. B. Adkins, Jr. (1984). "Splenic trauma: a trial at selective management." Southern medical journal 77(10): 1286-1290.

The experience with splenic trauma at the Metropolitan Nashville General Hospital and at Vanderbilt University Hospital between 1972 and 1983 is the subject of this report. Of 154 emergency cases involving splenic injury, 134 were due to blunt trauma, with 20 cases resulting from penetrating injury. In 124 patients, exploratory laparotomy was done immediately after resuscitation and evaluation. Splenectomy was done in 113 (92%) cases, and in ten cases the spleen was repaired. Thirty patients (19.4%) were initially managed by observation of vital signs, serial hematocrit determinations, and serial physical examination. Of these 30 patients, 21 (70%) required exploratory laparotomy for continued bleeding after observation of 12 hours to six days. Eighteen of this group had splenectomy, and three had splenorrhaphy. Nine (5.8% of the total and 30% of the observed group) were successfully managed nonoperatively. Complications were encountered in 53 of the total 154 cases. There were 19 deaths (12.3%), 11 of them from head injuries. Splenectomy should be done promptly in cases of concomitant splenic and cerebral injury and in patients with injury of multiple organ systems. Nonoperative management of suspected splenic injury should be reserved for patients in stable condition and with few if any associated injuries.

625. Bjørk, M. H. (2021). "Post-traumatic epilepsy-current treatment." European Journal of Neurology 28(SUPPL 1): 8.

Post-traumatic epilepsy is defined as seizures occurring more than seven days after traumatic brain injury. Seizures occurring within seven days of injury are classified as early post-traumatic seizures. Approximately 4% of all epilepsy cases are post-traumatic, and it's the most important cause of symptomatic epilepsy in young people. After traumatic brain injury, the 10-year incidence is 2-4% and increases with injury severity. In severe brain injury, more than 10% of patients develop epilepsy. Other risk factors are early post-traumatic seizures, impressed skull fractures, penetrating brain injuries, intracranial hemorrhage, temporal/frontal cortical damage, chronic alcohol consumption, psychiatric disease, a family history of epilepsy, and repeated head injuries, as well as abusive head trauma in children. Post-traumatic epilepsy may develop several years after the injury, but more than 50% of patients experience their first seizure within the following year. The cascade of events leading to post-traumatic epilepsy include excitotoxicity, neuroinflammation, oxidative stress, and neurodegeneration. Many patients develop hippocampal sclerosis. Anti-seizure medication prevents early posttraumatic seizures and is recommended in high-risk patients to avoid further brain injury and status epilepticus. Metaanalyses have shown that levetiracetam and phenytoin/ fosphenytoin are equally effective, but levetiracetam is easier to administer and better tolerated. Anti-seizure prophylaxis does not reduce the

risk of post-traumatic epilepsy and should be tapered down after hospital discharge. Several agents have had promising antiepileptogenic effects in animal studies but have not been tested in humans. Post-traumatic epilepsy is treated with anti-seizure medication recommended for focal epilepsy. Surgery can be considered for select patients.

626. Bjornsson, C. S., et al. (2006). "Effects of insertion conditions on tissue strain and vascular damage during neuroprosthetic device insertion." Journal of neural engineering 3(3): 196-207.

Long-term integration of neuroprosthetic devices is challenged by reactive responses that compromise the brain-device interface. The contribution of physical insertion parameters to immediate damage is not well described. We have developed an ex vivo preparation to capture real-time images of tissue deformation during device insertion using thick tissue slices from rat brains prepared with fluorescently labeled vasculature. Qualitative and quantitative assessments of damage were made for insertions using devices with different tip shapes inserted at different speeds. Direct damage to the vasculature included severing, rupturing and dragging, and was often observed several hundred micrometers from the insertion site. Slower insertions generally resulted in more vascular damage. Cortical surface features greatly affected insertion success; insertions attempted through pial blood vessels resulted in severe tissue compression. Automated image analysis techniques were developed to quantify tissue deformation and calculate mean effective strain. Quantitative measures demonstrated that, within the range of experimental conditions studied, faster insertion of sharp devices resulted in lower mean effective strain. Variability within each insertion condition indicates that multiple biological factors may influence insertion success. Multiple biological factors may contribute to tissue distortion, thus a wide variability was observed among insertions made under the same conditions.

627. Bjugstad, K. B., et al. (2013). "Changes in neurocan and hyaluronic acid as a function of TBI, down syndrome, and aging: Potential for changing our approach to neural transplantation." Cell Transplantation 22(5): 895-896.

Transplantation of neural cells into the brain to repair neurodegenerative disorders itself creates traumatic brain injury (TBI). TBI, along with Down syndrome (DS), is one of the biggest risk factors for developing Alzheimer's disease (AD). By attempting to repair one neurological disorder by transplantation, it is possible that we are putting the brain at risk for developing AD. The aggregation of tau and amyloid into the classic plaques and tangles of AD occurs only in the presence of sulfated proteoglycans, the primary components of the extracellular matrix (ECM). By understanding the changes that occur to the ECM as a function of TBI or DS, we might be able to develop better transplantation approaches that minimize the risk for AD. Hyaluronic acid (HA), a nonsulfated proteoglycan, is the foundation of the brain's ECM. Neurocan (NCN) is expressed in juvenile brain tissue and during times of neurogenesis. Using DS modeling and control mice, we measured changes in the brain HA and NCN 4 and 12 months after a neonatal penetrationtype TBI. In the hippocampus and the septum, NCN changed primarily as a function of injury and time postinjury. In the septum, NCN greatly increased in mice 12 months postinjury compared to mice 4 months postinjury. CA1 and dentate gyrus (DG) had an age-associated increase in NCN from 4 to 12 months, which was amplified by TBI. CA3 was the only area with a karyotype effect in NCN expression. While age (12 months) and injury increased neurocan, the increase was greater in DS-modeling mice especially in the pyramidal cell layer. In the septum, HA expression decreased as a function of age with no effects of injury or DS modeling. In contrast, age significantly increased HA expression in CA1, especially in the oriens and lacunosum moleculare, and in the DG. These age effects were primarily expressed in the DS-modeling mice. CA3 again revealed both aging, injury, and DS effects. Injury increased HA expression more so in control mice than in DS-modeling mice. This effect was mostly found in mice 12 months postinjury. Thus, enhanced NCN expression is mostly associated with TBI and time postinjury, whereas HA expression is more consistently altered by DS modeling. By understanding the differences in ECM component in two models at risk for developing AD, we might be able to approach neural transplantation in a way that

limits subsequent brain damage. For example, by adding certain growth factors to the transplants, which regulate ECM activities or by developing biomaterials based on ECM components, which do not promote tau/amyloid aggregation.

631. Black, F. W. and R. L. Strub (1976). "Constructional apraxia in patients with discrete missile wounds of the brain." Cortex; a journal devoted to the study of the nervous system and behavior 12(3): 212-220.

Sixty patients with missile wounds confined to one of the four quadrants of the brain were investigated. All patients had neurosurgical verification of the limits of their lesions. The incidence and severity of constructional apraxia was studied using the WAIS Block Design and Object Assembly subtests, and the Bender Gestalt Test. A uniformly significant caudality effect was obtained with more posteriorly localized lesions resulting in more severe constructional apraxia. A significant laterality effect was obtained on two of three criterion measures with uniformly inferior performance by patients with right hemisphere lesions. The magnitude of the laterality effect, however, was less than that of the caudality effect for all criterion variables. The degree of severity of constructional apraxia in patients with right posterior lesions was uniformly greater than that of patients with other quadrant loci. The incidence of constructional apraxia in the four quadrants varied as expected with the left anterior lesion sample showing very little evidence of constructional apraxia, while the right posterior sample showed a high incidence of such deficits. The absolute incidence of significant constructional apraxia in all samples was suprisingly low. This finding might be partially accounted for by the age and general good health of the subjects studied, the relative absence of general cognitive impairment in the majority of subjects, and the discrete nature of the lesions.

632. Black, K. L., et al. (2002). "Blunt versus penetrating violent traumatic brain injury: frequency and factors associated with secondary conditions and complications." The Journal of head trauma rehabilitation 17(6): 489-496.

OBJECTIVE: To compare types and frequency of medical complications and comorbidities associated with violence-related penetrating traumatic brain injury (TBI) as compared to violence-related blunt TBI., METHOD: Data were collected prospectively at four medical centers participating in the TBI Model Systems (TBIMS) of Care project. A total of 317 individuals met the inclusion criteria for the TBIMS (i.e., showed evidence of a TBI, were age 16 or older, presented to the TBIMS emergency department within 24 hours of injury, and received acute and rehabilitation services within the model system)., MAIN OUTCOME MEASURES: Frequency of medical complications and comorbid diseases., RESULTS: Patients with penetrating injuries suffered significantly higher rates of respiratory failure (P =.004), pneumonitis/pneumonia, (P =.002), skull fracture (P =.001), cerebrospinal fluid leak (P =.0005), and hypotonia (P =.001) than did patients with blunt injuries. Prediction of complications and comorbidities via multiple regression revealed that a penetrating violent injury and the severity of injury were independent predictors of a higher rate of medical complications, whereas

age and gender did not account for unique variance in the equation., CONCLUSIONS: Penetrating injuries are associated with higher rates of certain medical complications, especially to the pulmonary and central nervous systems. Acute care physicians and physiatrists must be prepared to treat these complications more often in patients with penetrating injuries.

633. Black, S. P. (1978). "Reconstruction of the supraorbital ridge using aluminum." Surgical neurology 9(2): 121-128.

Aluminum was used to reconstruct the supraorbital ridge and adjacent frontal bone in six patients. Its malleability makes it particularly useful for this purpose. Each cranioplasty was done several months after injury. The longest follow-up is 19 years and the shortest three years. There were no complications. The results are satisfactory.

635. Blackshear, K., et al. (2018). "Exogenous progesterone is neuroprotective following injury to the male zebra finch brain." Journal of neuroscience research 96(4): 545-555.

The use of progesterone following brain injury has a controversial history. On one hand, some lab-based models have showed progesterone as being neuroprotective, but on the other, clinical trials have showed quite the opposite. One of many complaints that arose from this discrepancy was the lack of a diverse pool of animal models and paradigms employed during the preclinical phase. However, over the past decade, the zebra finch has emerged as an optimal organism for the study of steroid-mediated neuroprotection. Following an injury, steroid hormones and receptors are upregulated, serving to decrease neuroinflammation and overall damage to the brain. As compared to other vertebrate models, zebra finches can upregulate expression of both estrogens and androgens at a faster and more robust response, suggesting that vertebrates differ in their neuroprotective mechanisms and timing following injury. Therefore, to expand the types organisms studied in pre-clinical trials, we chose to use zebra finches. While the majority of work in the zebra finch brain has focused on estrogens and androgens, we sought to clarify the role of progesterone following injury. Adult male zebra finches were given daily injections of progesterone following a penetrating injury and then were assessed for the size of injury and expression of various genes associated with neuroinflammation and cell survival. Treatment with progesterone decreased the injury size in zebra finches over controls and increased expression of various genes associated with cell survival and neuroinflammation. These data suggest that progesterone does mediate neuroprotection, most likely through the alteration of neuroinflammatory and cell survival pathways.

636. Blackwood, B. P., et al. (2016). "Observation for isolated traumatic skull fractures in the pediatric population: unnecessary and costly." Journal of pediatric surgery 51(4): 654-658.

BACKGROUND: Blunt head trauma accounts for a majority of pediatric trauma admissions. There is a growing subset of these patients with isolated skull fractures, but little evidence guiding their management. We hypothesized that inpatient neurological observation for pediatric patients with isolated skull fractures and normal neurological examinations is unnecessary and costly., METHODS: We performed a single center 10year retrospective review of all head traumas with isolated traumatic skull fractures and normal neurological examination. Exclusion criteria included: penetrating head trauma, depressed fractures, intracranial hemorrhage, skull base fracture, pneumocephalus, and poly-trauma. In each patient, we analyzed: age, fracture location, loss of consciousness, injury mechanism, Emergency Department (ED) disposition, need for repeat imaging, hospital costs, intracranial hemorrhage, and surgical intervention., RESULTS: Seventy-one patients presented to our ED with acute

isolated skull fractures, 56% were male and 44% were female. Their ages ranged from 1week to 12.4years old. The minority (22.5%) of patients were discharged from the ED following evaluation, whereas 77.5% were admitted for neurological observation. None of the patients required neurosurgical intervention. Age was not associated with repeat imaging or inpatient observation (p=0.7474, p=0.9670). No patients underwent repeat head imaging during their index admission. Repeat imaging was obtained in three previously admitted patients who returned to the ED. Cost analysis revealed a significant difference in total hospital costs between the groups, with an average increase in charges of $4,291.50 for admitted patients (p<0.0001)., CONCLUSION: Pediatric isolated skull fractures are low risk conditions with a low likelihood of complications. Further studies are necessary to change clinical practice, but our research indicates that these patients can be discharged safely from the ED without inpatient observation. This change in practice, additionally, would allow for huge health care dollar savings.

---

639. Blank-Reid, C. and P. C. Reid (2000). "Penetrating trauma to the head." Critical care nursing clinics of North America 12(4): 477-487.

Penetrating trauma to the brain is not as common as blunt trauma; however, the incidence is becoming a frequent occurrence in our society. Rapid transport to trauma centers where definitive care can be rendered is essential. Outcome depends on the site of the missile tract, the presenting neurologic status, and the extent of neurologic tissue destruction. Neurologic deterioration occurs rapidly, and outcome results seem to depend on the patient's neurologic status at the time of surgery. CT scanning is the diagnostic procedure of choice and should be performed if the patient's condition is stable (see Fig. 3). Aggressive removal of missile and bone fragments needs to be balanced by the knowledge that it is preferable to leave behind a few hard-to-reach fragments than to increase the patient's neurologic deficit. CT scanning in the postoperative period is very helpful in identifying abscess formation as well as new or recurrent hematomas, edema, and areas of tissue injury not evident at the time of initial scanning. Antibiotic therapy should be initiated preoperatively. Control of elevated ICP plays a significant role in decreasing mortality and morbidity. Judicious debridement of injured brain combined with medical management of increased ICP will maximize the quality of recovery and increase survivability. Although great strides have been made in reducing mortality and morbidity for trauma patients, the sad issue is that the majority of traumas are preventable. Until society is willing to understand that it needs to make firearm safety a priority, there will always be patients to care for who have sustained a penetrating injury.

---

640. Blennow, K., et al. (2016). "Traumatic brain injuries." Nature reviews. Disease primers 2: 16084.

Traumatic brain injuries (TBIs) are clinically grouped by severity: mild, moderate and severe. Mild TBI (the least severe form) is synonymous with concussion and is typically caused by blunt non-penetrating head trauma. The trauma causes stretching and tearing of axons, which leads to diffuse

axonal injury - the best-studied pathogenetic mechanism of this disorder. However, mild TBI is defined on clinical grounds and no well-validated imaging or fluid biomarkers to determine the presence of neuronal damage in patients with mild TBI is available. Most patients with mild TBI will recover quickly, but others report persistent symptoms, called post-concussive syndrome, the underlying pathophysiology of which is largely unknown. Repeated concussive and subconcussive head injuries have been linked to the neurodegenerative condition chronic traumatic encephalopathy (CTE), which has been reported post-mortem in contact sports athletes and soldiers exposed to blasts. Insights from severe injuries and CTE plausibly shed light on the underlying cellular and molecular processes involved in mild TBI. MRI techniques and blood tests for axonal proteins to identify and grade axonal injury, in addition to PET for tau pathology, show promise as tools to explore CTE pathophysiology in longitudinal clinical studies, and might be developed into diagnostic tools for CTE. Given that CTE is attributed to repeated head trauma, prevention might be possible through rule changes by sports organizations and legislators.

641. Blissitt, P. A. (2006). "Care of the critically ill patient with penetrating head injury." Critical care nursing clinics of North America 18(3): 321-332.

Patients who have penetrating head injury all too often present with some of the most devastating and challenging intracranial injuries. The mechanisms of injury and associated neuropathology affect every body system and require a multidisciplinary approach. Evidence-based guidelines have been developed to offer some direction to clinicians involved in their care. Much remains scientifically unsubstantiated, however. Optimal management of critically ill patients who have penetrating head injury requires clinical expertise and care of the highest quality.

642. Bloch-Boguslawska, E., et al. (2008). "[Using X-ray results in head gunshot wounds]." Wykorzystanie badan radiologicznych w ranach postrzalowych glowy. 58(4): 221-223.

The authors draw attention to the importance of X-ray examinations in craniocerebral gunshot injuries. A life-saving neurosurgical operation of a victim resulted in changes occurring not only in the soft tissue, but also in the bony structures of the cranium, which practically rendered impossible any assessment of and differentiation between the location of entrance and exit wounds during autopsy. The assessment of preoperative head X-ray demonstrated the presence of characteristic crater-like bone defects, what allowed for determining the location of the entrance and exit wounds. The medico-legal examination of bone defects indicated that the entrance wound was situated on the left side, contrary to information provided by hospital medical records.

643. Blois, M., et al. (2019). "Prototyping for the treatment of a comminuted mandibular fracture by gunshot." International journal of oral and maxillofacial surgery 48: 195.

Background: It is difficult to accurately reconstruct a large defect in the mandible when not enough mandibular reference blueprints remain. Objectives: This case report describes a large comminuted mandibular defect after a gunshot. Methods: Before surgery, spiral computed tomography scanning of the whole skull of the patient was performed. Using three-dimensional reconstruction and mirror imaging coupled with laser stereolithographic technique, a complete mandibular biomodel with idealized shape was fabricated. A titanium reconstruction plate was made using the biomodel as a guide. Findings: The large mandibular defect was then reconstructed with the precontoured titanium plate. Conclusion: The complex defect in the mandible was thus repaired with satisfactory functioning and esthetic result. We suggest that with the help of mirror imaging coupled with laser stereolithographic technique, a precontoured titanium plate can be made for the reconstruction of large mandibular defects. Reference: [1]Fowell, C., et al. Rapid prototyping and patient-specific pre-contoured reconstruction plate for comminuted fractures of the mandible. British Journal of Oral and Maxillofacial Surgery 53(10):1035–1037.

644. Blount, P. J., et al. (2002). "Clinical use of cholinomimetic agents: a review." The Journal of head trauma rehabilitation 17(4): 314-321.

BACKGROUND: There are many agents in clinical use that manipulate central nervous system levels of epinephrine, dopamine, and serotonin. However, development of pharmacological options to manipulate central acetylcholine systems has lagged behind because of poor penetration of the blood-brain barrier and significant peripheral nervous system side effects. Newer agents have demonstrated some efficacy in the management of behavioral and cognitive side effects in Alzheimer's disease, and preliminary data in traumatic brain injury suggest acetylcholine esterase inhibitors may play a significant role in the treatment of this patient population as well., CONCLUSIONS: In this article, the basic neuroanatomy and pharmacology of the central acetylcholine system are reviewed, along with agents currently available for clinical use.

645. Blumenthal, R. (2007). "Suicidal gunshot wounds to the head: a retrospective review of 406 cases." The American journal of forensic medicine and pathology 28(4): 288-291.

A retrospective review of 406 suicidal gunshot wounds to the head, investigated at the Medico-Legal Laboratory of Pretoria, between 1997 and 2000 was performed. Fifty-seven percent of fatal suicidal firearm injury to the head occurred in the 21- to 40-year age range in both male and female victims. Eighty-two percent of all these victims of suicidal firearm fatalities to the head were male. Of the 406 cases, 63% were white, 31% were black, and 6% were of mixed ethnic and/or Asian decent. There was a slight increase in incidence around spring and autumn. Handguns were used in the majority of cases with shoulder weapons being used in 18 of the 406 cases. Ninety-two percent of the suicidal gunshot wounds to the head occurred indoors. A positive blood alcohol concentration was seen in 40% of cases. Of those examined, 81% were contact gunshot wounds. The trajectory was upward in 51% of cases and horizontal in 24% of cases. The right temple was the most common entrance gunshot wound site. Findings are in keeping with previously published literature.

650. Bodanapally, U. K., et al. (2014). "Predicting arterial injuries after penetrating brain trauma based on scoring signs from emergency CT studies." The neuroradiology journal 27(2): 138-145.

The objective of this study was to determine the accuracy of individual radiologists in detection of vascular injury in patients after penetrating brain injury (PBI) based on head CT findings at admission. We retrospectively evaluated 54 PBI patients who underwent admission head CT and digital subtraction angiography (DSA), used here as a reference standard. Two readers reviewed the CT images to determine the presence or absence of the 29 CT variables of injury profile and quantified selected variables. Four experienced trauma radiologists and one neuroradiologist assigned their own specific scores for each CT variable, a high score indicative of a high probability of artery injury. A sixth set consisted of the average score obtained from the five sets, generated by five experts. Receiver operating characteristic (ROC) curves were constructed for each set to assess the diagnostic performance of an individual radiologist in predicting an underlying vascular injury. The area under ROC curve (AUC) was higher for CT scores obtained from the sixth set (average of five sets of scores) of variable rank score 0.75 (95% CI 0.62-0.88) and for the rest of the data sets, the value ranged from 0.70 (95% CI 0.56-0.84) to 0.74 (95% CI 0.6-0.88). In conclusion, radiologists may be able to recommend DSA with a fair accuracy rate in selected patients, deemed 'high-risk' for developing intracranial vascular injuries after PBI based on admission CT studies. A better approach needs to be developed to reduce the false positive rate to avoid unnecessary emergency DSA.

651. Bodanapally, U. K., et al. (2015). "Arterial injuries after penetrating brain injury in civilians: risk factors on admission head computed tomography." Journal of neurosurgery 122(1): 219-226.

OBJECT: The object of this study was to determine the specific CT findings of the injury profile in penetrating brain injury (PBI) that are risk factors related to intracranial arterial injuries., METHODS: The authors retrospectively evaluated admission head CTs and accompanying digital subtraction angiography (DSA) studies from patients with penetrating trauma to the head in the period between January 2005 and December 2012. Two authors reviewed the CT images to determine the presence or absence of 30 injury profile variables and quantified selected variables. The CT characteristics in patients with and without arterial injuries were compared using univariate analysis, multivariate analysis, and receiver operating characteristic (ROC) curve analysis to determine the respective risk factors, independent predictors, and optimal threshold values for the continuous variables., RESULTS: Fifty-five patients were eligible for study inclusion. The risk factors for an intracranial arterial injury on univariate analysis were an entry wound over the frontobasal-temporal regions, a bihemispheric wound trajectory, a wound trajectory in proximity to the circle of Willis (COW), a subarachnoid hemorrhage (SAH), a higher SAH score, an intraventricular hemorrhage (IVH), and a higher IVH score. A trajectory in proximity to the COW was the best predictor of injury (OR 6.8 and $p = 0.005$ for all penetrating brain injuries [PBIs]; OR 13.3 and $p = 0.001$ for gunshot wounds [GSWs]). Significant quantitative variables were higher SAH and IVH scores. An SAH score of 3 (area under the ROC curve [AUC] for all PBIs 0.72; AUC for GSWs 0.71) and an IVH score of 3 (AUC for all PBIs 0.65; AUC for GSWs 0.65) could be used as threshold values to suggest an arterial injury., CONCLUSIONS: The risk factors identified may help radiologists suggest the possibility of arterial injury and prioritize neurointerventional consultation and potential DSA studies.

652. Bodanapally, U. K., et al. (2014). "Vascular complications of penetrating brain injury: comparison of helical CT angiography and conventional angiography." Journal of neurosurgery 121(5): 1275-1283.

OBJECT: The authors conducted a study to compare the sensitivity and specificity of helical CT angiography (CTA) and digital subtraction angiography (DSA) in detecting intracranial arterial injuries after penetrating traumatic brain injury (PTBI)., METHODS: In a retrospective evaluation of 48 sets of angiograms from 45 consecutive patients with PTBI, 3 readers unaware of the DSA findings reviewed the CTA images to determine the presence or absence of arterial injuries. A fourth reader reviewed all the disagreements and decided among the 3 interpretations. Sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) of CTA were calculated on a per-injury basis and in a subpopulation of patients with traumatic intracranial aneurysms (TICAs)., RESULTS: Sensitivity of CTA for detecting arterial injuries was 72.7% (95% CI 49.8%-89.3%); specificity, 93.5% (95% CI 78.6%-99.2%); PPV, 88.9% (95% CI 65.3%-98.6%); and NPV, 82.9% (95% CI 66.4%-93.4%). All 7 TICAs were correctly identified by CTA. Sensitivity, specificity, PPV, and NPV of CTA in detecting TICAs were 100%. To compare agreement with DSA, the standard of reference, confidence scores categorized as low, intermediate, and high probability yielded an overall effectiveness of 77.8% (95% CI 71.8%-82.9%)., CONCLUSIONS: Computed tomography angiography had limited overall sensitivity in detecting arterial injuries in patients with PTBI. However, it was accurate in identifying TICAs, a subgroup of injuries usually managed by either surgical or endovascular approaches, and non-TICA injuries involving the first-order branches of intracranial arteries.

654. Bodhit, A., et al. (2014). "How much does a traumatic brain injury cost?" Neurology 82(10).

OBJECTIVE: To determine the predictors of hospital costs associated with traumatic brain injury. BACKGROUND:DESIGN/METHODS: These data are derived from the Florida Brain and Spinal Cord injury prospective registry from our institution, a level I trauma center. In order to be eligible for the BSCIP, the patient must be a legal resident of the state of Florida, have suffered a moderate to severe brain injury, medically stable, and there should be a reasonable expectation that with the provision of appropriate services and supports, the person can return to a community-based setting, rather than reside in a skilled nursing facility. Data are limited to TBIs from January 1st, 2012 to June 30th, 2013. Costs information was obtained from total hospital charges, vs. actual collections. Statistical analyses were performed in JMP 10 for the Macintosh. RESULTS: A total of 170 TBIs were identified during the study period. The median age of the cohort was 42 years(IQR=24-60).78% were male.The mechanism was 31% MVC, 18% fall, 23% recreational vehicles, 11% assault, 14% pedestrian struck, 2% gun shot wound, and 1% self inflicted. The median length of hospitalization was 16 days(IQR=8-25,Range=1-60).The median hospitalization cost per TBI patient including emergency services, was $162,523. Individual factors associated with increased hospitalization cost of TBI included:reduced probability of survival($p<0.0001$),increased hospital length of days($p<0.0001$),mechanism of injuries(pedestrian struck by vehiclep=0.0001,recreational vehicle injuryp=0.005,motor vehicle accidentp=0.006,assaultp=0.05;all compared to fall),and non-transferred patients(p=0.0003). On multivariate analysis, the factors that remained predictive for increased cost were a lower probability of survival (p=0.0006), a longer hospital length of stay ($p<0.0001$), and patients whose mechanism of injury was not a fall (p=0.039),when controlling for GCS score (p=0.0014). CONCLUSIONS:The cost of hospitalization for TBI is significantly increased by longer hospital stay, lower survival chance, and higher GCS score, while cost is significantly lower for patients who sustain a TBI due fall,vs. motor vehicle collision.

655. Bodwal, J., et al. (2013). "Intracranial penetrating injury by screw driver: a case report and review of literature." Journal of forensic and legal medicine 20(8): 972-975.

Penetrating injury to the head, with the exception of missile injuries is rare owing to thick calvarium. Orbital and temporal areas are comparatively vulnerable to penetrating injuries, due to their relative thinness. A case is presented in which a man killed his wife by forcefully thrusting a screw driver into her cranial cavity. The deceased presented to the hospital with the screw driver embedded in her head. She was declared as 'brought dead on arrival' at the emergency of the hospital. Pre-autopsy plain radiography and Computed Tomography (CT) of the head were done to assess the extent of brain damage. The peculiarity of this case lies in the fact that screw driver as a stabbing weapon in the head is very rarely used. In such cases, there is a need to perform radiography and CT with the weapon in-situ for better interpretation on injuries. In this paper role of radiography and CT in intra cranial penetration is discussed with review of literature.

657. Bogaerts, M., et al. (2014). "Treatment of traumatic stapediovestibular luxation: case report with the introduction of a new technique and review of literature." Otology & neurotology : official publication of the American Otological Society, American Neurotology Society [and] European Academy of Otology and Neurotology 35(4): 582-588.

OBJECTIVE: Stapediovestibular luxations are rare lesions that are most commonly caused by direct, penetrating trauma to the external ear canal. In this type of ossicular dislocation, disruption of the annular ligament or footplate fracture may lead to a perilymphatic fistula (PLF) presenting with cochleovestibular symptoms including (progressive) sensorineural hearing loss, tinnitus, and vestibular symptoms. The objective of this article is to define the optimal treatment of stapediovestibular luxations and review the literature on this topic., PATIENT: We present a case of internal stapediovestibular dislocation and pneumolabyrinth after penetrating trauma with predominantly conductive hearing loss and incapacitating vertigo., INTERVENTION: Middle ear inspection with removal of the luxated incus, repositioning of the stapes with a "stapedial strut" and closure of the tympanic membrane., MAIN OUTCOME MEASURES: Hearing outcome and vestibular symptoms of this patient are presented, and all comparable cases in the literature are reviewed., RESULTS: Complete resolution of the vestibular symptoms and stabilization of the bone conduction thresholds., CONCLUSION: In patients with pneumolabyrinth after middle ear trauma with mild symptoms, we recommend initial conservative treatment with close monitoring of hearing. In patients with severe, persisting, or progressive vestibulocochlear symptoms, exploratory tympanotomy should be performed to check for and treat PLF. Oval window fistula repair is reported to have variable hearing outcomes but offers complete resolution of vestibular symptoms in most cases. The stapedial strut is one of the possible surgical techniques in case of an internally luxated stapes.

658. Bogdanovic, M., et al. (2019). "Gunshot Suicide: Cherry-Red Discoloration of the Temporal Muscle Beneath the Exit Wound." The American journal of forensic medicine and pathology 40(2): 147-149.

The article describes a case of gunshot suicide to the head in a 51-year-old man. The entrance wound was located in the left temple and exit wound in the right temple. The entrance wound had the characteristics of a hard-contact gunshot wound. The most interesting finding in this case was cherry-red discoloration of the right temporal muscle surrounding the exit wound. This finding could make the determination of the entrance versus exit gunshot wound challenging, especially if the wounds are of atypical appearance. In addition, the finding described in the presented case could be the proof that carbon monoxide may follow the missile through the body and may be prominent in the soft tissue at the exit.

659. Bogdanovic, M., et al. (2019). "The use of gasoline in a complex suicide." Forensic science, medicine, and pathology 15(1): 106-109.

This case represents a planned complex suicide in which the victim shot himself in the head after dousing his living quarters with gasoline. The spark induced ignition of gasoline vapors and led to an explosion. Liquid gasoline is not flammable, but the vapor/mixture of gases above the surface of the liquid is. In this case the victim might have counted on the resulting fire and/or explosion, but we are not able to tell that with certainty. We have assumed that the plan was for the gunshot to the head to lead to instantaneous death, and for the flame and/or explosion to lead to the destruction of the body. The explosion launched the body out of the apartment, meaning it did not get charred. It is also our assumption that the victim did not expect that the explosion would eject his body from the flames and lead to less severe burns than he had calculated, making this complex suicide "less successful" than he had planned.

---

660. Bogdanovic, M., et al. (2019). "Late Occurrence of Raccoon Eyes: The Role of the Ligature." The American journal of forensic medicine and pathology 40(2): 165-167.

This case represents a planned complex suicide in which the victim combined gunshot to the head and hanging. The most interesting finding in the presented case was pale face, but without any visible injury to it at the time the body was found (more than 24 hours after death), whereas at autopsy (20 hours later), black eyes were prominent. The removal of the ligature led to the decompression of the neck and its blood vessels with consequential blood redistribution, which, alongside the liquid state of blood, resulted in the aforementioned finding. Considering the described postponed appearance of periorbital ecchymosis, this kind of finding suggests that great caution is necessary when interpreting hematomas in terms of their vitality.

---

661. Boggs, H. K., et al. (2021). "Analysis of Traumatic Carotid Artery Injuries: Clinical Predictors of Management and Outcomes." Journal of vascular surgery 74(3): e197-e198.

Objective: Optimal management of traumatic carotid artery injury (CAI) to preserve neurologic function remains undefined. We sought to evaluate the factors that influence management, stroke, and brain death outcomes of traumatic CAI. Methods: A search of a prospectively maintained institutional trauma registry of patients older than 18 years with a diagnosis of CAI was performed at a Level 1 Trauma Center from 2013 to 2019. Injuries limited to the external carotid artery were excluded. Patient demographics, type of injury, the timing of presentation, Biffl Classification of Cerebrovascular Injury Grade, Injury Severity Score (ISS), and Abbreviated Injury Scale (AIS) were documented. Ultimate treatments (medical management, procedural interventions) and brain-related outcomes (stroke and brain death) were recorded. Results: Carotid artery injuries were identified in 30 patients. There were 25 (83.3%) blunt and 5 (16.7%) penetrating carotid injuries. The internal carotid was affected in 27 patients (90%) and the common carotid artery in 3 patients (10%). Whereas a higher Biffl grade was predictive of vascular intervention over medical management (3.6 vs 2.4; P =.03, respectively), the ISS and AIS scores were not. A higher ISS score was a predictor of stroke (33.33 vs 22.86; P =.012), whereas Biffle grade or AIS scores were not. All stroke patients (50%) declared their neurological change on average within 11.7 hours (standard deviation, ±12.7) of presentation. In addition, a higher ISS score was predictive of brain death (38.6 vs 23.6; P =.004), but Biffl grade and AIS scores were not. There was a trend of eventual brain death seen in blunt trauma over penetrating trauma (36% vs 0%; P =.11). Conclusions: Analysis of carotid artery injuries revealed certain predictors of management and clinical outcomes. A higher Biffl grade can help predict vascular intervention, whereas a higher ISS score can help predict stroke and brain death.

662. Bogle, J. M., et al. (2015). "Labyrinthine concussion following gunshot injury: A case report." International journal of audiology 55(7): 425-428.

OBJECTIVE: Labyrinthine concussion due to a postauricular gunshot wound has not been well reported., DESIGN: Retrospective chart review., STUDY SAMPLE: We describe an otherwise healthy 22-year-old male who received a gunshot wound to the left mastoid and subsequently reported hearing loss and rotational vertigo., RESULTS: Audiometric testing demonstrated significant inverted scoop shaped sensorineural hearing loss. Vestibular diagnostic testing indicated a significant uncompensated left peripheral vestibulopathy. Imaging demonstrated no structural changes to the middle ear or labyrinth, suggesting that the auditory and vestibular losses noted on diagnostic examination were likely due to labyrinthine concussion., CONCLUSIONS: Labyrinthine concussion may lead to reduced vestibular reflex pathway following gunshot wounds to the temporal bone. Clinical presentation is likely to vary significantly among cases.

663. Bohatyrewicz, R., et al. (2007). "Unusual movements, "spontaneous" breathing, and unclear cerebral vessels sonography in a brain-dead patient: a case report." Transplantation proceedings 39(9): 2707-2708.

A patient with a brain injury fulfilled all clinical criteria for brainstem death diagnosis. Two standard sets of tests were performed; according to Polish regulations, the patient could be declared brain dead. However, shortly after the completion of the tests and before the final brain death declaration, 6 triggered "assisted" breaths/min were noticed. After careful analysis of the ventilator settings, it was concluded that low trigger sensitivity and airway pressure oscillations during heart contractions were the reasons. Additionally, a few minutes later, spontaneous jerking movements of lower limbs and clonic movements of neck muscles secondary to painful stimuli were noticed. The situation became confusing; therefore, cerebral Doppler sonography was performed, showing circulatory arrest in both of the internal carotid, middle cerebral, and left vertebral arteries. The basilar artery was not visualized. Forward flow with increased pulsatility was recorded in extracranial and intracranial segments of the right vertebral artery. Cerebral circulatory arrest was still uncertain; therefore, the diagnostic procedures were completed with conventional cerebral angiography, which showed a lack of cerebral blood flow. Finally, the patient was declared brain dead; kidneys and bones were harvested. Cardiogenic oscillations associated with incorrect low ventilator trigger settings may falsely suggest persistence of breathing efforts in a brain-dead patient. In the case of any unusual events during brain death diagnosis, cerebral perfusion tests should be performed with cerebral angiography as the "gold standard."

665. Bohnert, M. and S. Pollak (2004). "[Complex suicides--a review of the literature]." Kombinierte Suizide--eine Literaturubersicht. 213(5-6): 138-153.

The term "complex suicide" stands for suicides committed by using more than one method. A distinction can be made between planned and unplanned complex suicides (primary/secondary combinations). In planned complex suicides 2 or more methods are applied simultaneously in order to make sure that death will occur even if one method fails. In unplanned complex suicides the mode of performance is changed after the first method chosen failed or was working too slow or proved to be too painful. In planned complex suicides typically two of the generally common methods of suicide (e.g. ingestion of medicines, hanging, use of firearms, drowning, fall from a height) are combined. But also unusual combinations have been described such as the simultaneous firing of two guns, self-immolation in combination with other suicide methods or shooting oneself while driving a car. In unplanned

complex suicides self-inflicted injuries by sharp force, especially cuts of the wrists, are often found as the primary act of suicide. In some cases the suicide switches from cuts to stabs (mostly to the heart region). Other methods often used after the first phase of suicide are hanging and jump from a height. In the literature the use of up to 5 suicidal methods applied one after the other have been described.

---

666. Boker, D. K., et al. (1991). "[Craniocerebral trauma and glioma]." Schadel-Hirn-Trauma und Gliom. 59(12): 488-492.

There are only a few well documented cases in the literature which allow for the assumption of traumatic origin of some intracranial tumors. Four cases are presented in whom the authors have accepted the traumatic origin of gliomas because of it's evidence, but--from their scientific understanding of tumor development--without being convinced of such a correlation. It is stressed that scientific points of view and argumentation in social insurance affairs may differ and that they should be carefully distinguished.

667. Bolatkale, M. and A. C. Acara (2019). "The intracranial number of foreign bodies as a predictor of mortality after penetrating brain injury." The American journal of emergency medicine 37(3): 433-438.

INTRODUCTION: Penetrating brain injury (PBI) is the most lethal form of traumatic brain injury, which is a leading cause of mortality. PBI has a mortality rate of 23%-93% and 87%-100% with poor neurological status. Despite the use of various prognostic factors there is still a need for a specific prognostic factor for early prediction of mortality in PBI to reduce mortality and provide good outcomes with cost-effective surgical treatments. The aim of this study was to investigate the predictive value of the number of intracranial foreign bodies (FBs) on mortality in PBI in the Emergency Department., METHODS: The study included 95 patients admitted with PBI caused by barrel bomb explosion. The intracranial number of FB was examined by brain computed tomography. Logistic regression was used to assess the association of the intracranial number of FB on mortality. Correlation analyses were performed to investigate the association of Glasgow Coma Scale (GCS) with intracranial number of FB., RESULTS: The optimal cut-off value of the intracranial number of FB calculated for mortality was 2, which was effective for predicting mortality ($p<.001$). In patients with >2 intracranial FB, the mortality rate was statistically significantly 51-fold higher than those with <=2 ($p<.001$). A statistically significant negative correlation was determined between GCS and number FB ($r=-0.697$; $p<.001$)., CONCLUSION: When the intracranial number of FB was >2, mortality significantly increased in patients with PBI. The intracranial number of FBs may be considered as a novel prognostic factor for the prediction of mortality in PBI.

668. Boller, F. and G. P. Jacobson (1980). "Unilateral gunshot wound of the pons: clinical, electrophysiologic, and neuroradiologic correlates." Archives of neurology 37(5): 278-281.

Following a gunshot wound to the face, a 17-year-old male patient experienced a right trigeminal and abducens paralysis, dysarthria, right-sided ataxia, left-sided weakness of the lower part of the face and limbs, and left-sided sensory loss from his neck down. Brainstem auditory evoked potentials showed a decreased P5/P1 amplitude ratio for left ear presentation, and inconsistent replication of P2 and P3 on the right and, to a lesser extent, on left ear click presentations. A computerized tomography scan showed right pontine atrophy. These findings point to a unilateral lesion of the right pons.

669. Bolliger, S. A., et al. (2019). "Penetration Depths of Conducted Electrical Weapon Probes Into Human Skull Phantoms." The American journal of forensic medicine and pathology 40(2): 102-107.

Occasional case reports have described isolated cases of conducted electrical weapon (CEW) probes piercing the human skull. In an experimental setting, we examined whether these cases were just unfortunate incidents, how deeply such probes can pierce the skull, and whether firing distance and

CEW probe type play a role in the skull-piercing capability. We fired 5 different CEW cartridges (XP 10.6 m, XP 7.6 m, smart 10.6 m, smart 7.6 m, and smart probe 7.6 m) from 4 different distances (0.5, 1, 2, and 4 m) at head phantoms made of either 5- or 7-mm-thick polyurethane spheres covered with a thin layer of gelatine and buckskin. The piercing depths were recorded by computed tomographic scanning.All tested cartridges managed to pierce the head phantoms. Piercing depths of up to 6.6 mm in the 5-mm heads and depths of almost 5 mm in the 7-mm heads were recorded. Deepest piercing depths were attained with firing distances of 2 m or less.Our results showed that all tested CEW probes are capable of piercing the skull and that shorter firing distances tend to lead to deeper piercing depths.

670. Bolliger, S. A., et al. (2017). "Movement of steel-jacketed projectiles in biological tissue in the magnetic field of a 3-T magnetic resonance unit." International journal of legal medicine 131(5): 1363-1368.

PURPOSE: The fact that ferromagnetic bullets can move in air or gelatine when subjected to magnetic resonance (MR) units is well known. A previous study showed that the movement of 7.5-mm GP 11 Suisse bullets also depends on their orientation toward the gantry. In order to compare the movement in gelatine to that in real tissue, we decided to measure the movement of these bullets, as well as 9-mm Luger bullets, in the brain and liver., METHODS: The GP 11 and 9-mm Luger bullets were inserted into the fresh calf brain or pig liver either vertically or horizontally in the x- or z-axis to the gantry. Before and after exposure to a 3-T MR unit, their position was documented by CT., RESULTS: GP 11 bullets rotated more readily and in general proved to be more mobile than the 9-mm Luger. All GP 11 bullets and a large amount of the 9-mm Luger bullets exited the brain. Sliding toward the gantry was easier for 9-mm Luger bullets in the brain than in the liver., CONCLUSIONS: The orientation of a ferromagnetic object influences its mobility in a strong magnetic field. Tipping is easier than sliding for longish ferromagnetic projectiles, probably due to the lesser tissue resistance. The bullets moved more readily in biological tissue, especially brain tissue, compared to gelatine, thus implying that gelatine is not a suitable substitute for soft tissues when examining the movement of ferromagnetic objects in MR units.

---

671. Boltz, M. M., et al. (2015). "Injuries and outcomes associated with traumatic falls in the elderly population on oral anticoagulant therapy." Injury 46(9): 1765-1771.

INTRODUCTION: Fall risk for older adults is a multi-factorial public health problem as 90% of geriatric injuries are caused by traumatic falls. The CDC estimated 33% of adults >65 years incurred a fall in 2011, with 30% resulting in moderate injury. While much has been written about overall risk to trauma patients on oral anticoagulant (OAC) therapy, less has been reported on outcomes in the elderly trauma population. We used data from the National Trauma Data Bank (NTDB) to identify the types of injury and complications incurred, length of stay, and mortality associated with OACs in elderly patients sustaining a fall., METHODS: Using standard NTDB practices, data were collected on elderly patients (>=65 years) on OACs with diagnosis of fall as the primary mechanism of injury from 2007 to 2010. Univariate analysis was used to determine patient variables influencing risk of fall on OACs. Odds ratios were calculated for types of injury sustained and post-trauma complications. Logistic regression was used to determine mortality associated with type of injury incurred., RESULTS: Of 118,467 elderly patients sampled, OAC use was observed in 444. Predisposing risk factors for fall on OACs were >1 comorbidity ($p<0.0001$). Patients on OACs were 188% and 370% more likely to develop 2 and >3 complications ($p<0.0001$); the most significant being ARDS and ARF ($p<0.0001$). The mortality rate on OACs was 16%. Injuries to the GI tract, liver, spleen, and kidney ($p<0.0002$) were more likely to occur. However, if patients suffered a mortality, the most significant injuries were skull fractures and intracranial haemorrhage ($p<0.0001$)., CONCLUSIONS: Risks of anticoagulation in elderly trauma patients are complex. While OAC use is a predictor of 30-day mortality after fall, the injuries sustained are markedly different between the elderly who die and those who do not. As a result there is a greater

need for healthcare providers to identify preventable and non-preventable risks factors indicative of falls in the anti-coagulated elderly patient.

---

672. Bonan, C., et al. (1998). "[Microsurgery and ballistic traumatology of the face]." Microchirurgie et traumatologie balistique faciale. 43(2): 149-161.

The use of free flaps to fill and repair facial defects due to suicidal gunshot wounds has considerably extended and refined the possibilities available to reconstructive surgeon. The objective is no longer to close the defect at any cost, or "fill a hole", but to replace missing tissue by an identical tissue, able to restore an identical cosmetic appearance, support equivalent constraints, and restore analogous function. Retrospective analysis of 56 cases of large facial defects due to gunshot wounds revealed a total of 66 free flaps for 32 cases. The vascular quality of the flaps allowed better integration in a sometimes hostile recipient site and markedly reduced the treatment time. Although the objective results obtained in the treatment of these severe defects remain poor, the first-line use of these multiple flaps, exclusively reserved for deep repair, as the basis for reconstruction, has modified our behaviour. A real medium-term treatment strategy, based on a decision flow-chart, can be proposed which, despite several inevitable failures, leaves less room for improvisation and piecemeal surgery. Free flaps are only the hidden part of the reconstruction, as surface cover uses local flaps and other conventional reconstructive surgery techniques. However, this humble, hidden role is nevertheless fundamental, in the strict sense of the term, and guides the general approach to this surgery.

676. Bonsignore, A., et al. (2013). "Suicide due to four speargun shots: a case report." The American journal of forensic medicine and pathology 34(3): 201-204.

In the literature, only a few cases of deaths related to the use of atypical firearms are present and even more rare are cases of suicide due to multiple lesions. In the present case, the authors report a rare occurrence of suicide due to 4 speargun shots, 3 to the chest and 1 to the head.A complete forensic approach led to attribute the death to acute cardiac failure due to hemopericardium after the injury of the left coronary artery.Scene investigation and autoptic findings allowed authors to hypothesize that injury to the head was a last attempt of suicide, elapsed during the progression of cardiac tamponade.With this report, the authors would like to share knowledge with the forensic community about speargun-related lesions distinguishing them from the very similar ones produced by cold steels.It also shows how it is possible to survive for some time after being shot by such a weapon.

677. Bontke, C. F., et al. (1993). "Medical complications and associated injuries of persons treated in the traumatic brain injury model systems programs." Journal of Head Trauma Rehabilitation 8(2): 34-46.

This study documents the medical complications and associated injuries that occurred in persons admitted for rehabilitation in the five Traumatic Brain Injury (TBI) Model System projects, The

incidence of specific intracranial hemorrhages, medical complications, and associated injuries are discussed. Two thirds of these individuals had one or more intracranial hemorrhages, the most common being subdural (32%) and subarachnoid (27%) hemorrhages. Persons with one or two intracranial hemorrhages were found to have significantly longer lengths of stay (LOS) in acute care compared to those with no hemorrhages. One or more intracranial hemorrhages were found in persons injured by a fall (84%), while riding a bicycle (81%), while walking (76%), and by assault (73%). Of the nonhemorrhagic cerebral complications/problems investigated, seizures, cerebrospinal fluid (CSF) leak, and hydrocephalus were found to be related to extended LOS in acute care. Seizures were reported in 17% of patients, with 10% of all patients exhibiting a seizure within the first 24 hours postinjury. The extracerebral complications associated with longer LOS in acute care were respiratory failure, pneumonia, urinary tract infection, soft-tissue infection (STI), coagulopathy, renal failure, and septic shock. Persons injured in all-terrain vehicles, pedestrian/auto encounters, gunshot wounds to the head, and automobile crashes were more likely to have extracerebral complications than those injured by other causes. Fractures and cranial nerve injuries were the most common associated injuries. A larger proportion of persons injured in motor vehicle crashes, pedestrian/auto encounters, and bicycle accidents had associated injuries than those injured by other mechanisms.

680. Bootz, F. (1993). "[Immediate management of rupture and soft tissue injuries in the area of the head-neck]." Sofortversorgung von Abriss- und Weichteilverletzungen im Kopf-Hals-Bereich. 41(11): 542-552.

Most injuries to the head and neck region are accompanied by trauma to the soft tissue. The management of the wound depends on whether it is a superficial or a penetrating trauma. Penetrating traumas may injure bloodvessels, nerve structures and the upper aerodigestive tract. The initial evaluation of a patient with a neck wound should proceed with the basic rules of trauma management (Airway, Bleeding, Circulation). It is suggested, that all wounds deep to the platysma should be explored. Penetrating injuries through the airway should be considered in cases of hoarsness, dyspnea or direct visualization of the airway. In case of dyspnoe the patient should be intubated. In an unstable airway a tracheotomy must be considered. Injuries to the airway demand special care and immediate reconstruction since otherwise it can lead to permanent damage. Hemorrhage and hematoma are the most common symptoms of penetrating neck injuries. Poor initial control of bleeding is the most common cause of death. Uncontrolled clamping of vessels in the neck should be avoided since it can lead to damage of uninvolved structures especially nerves. The neck is divided into 3 zones. Zone I is the area below the sternal notch, Zone II lies between the sternal notch and the angle of the mandible. Zone III is the area above the angle of the mandible. Zone I and III injuries are evaluated with angiography. Zone II injuries are evaluated by surgery. Therapy of Zone I and III is difficult and needs

mandibulotomy or resection of the clavicle to gain exposure to the vessels.(ABSTRACT TRUNCATED AT 250 WORDS)

682. Borchardt, B. C., et al. (2018). "Prognostic Impact of Intracranial Pressure Monitoring in Patients with Severe Traumatic Brain Injury." Brazilian Neurosurgery 37(4): 291-296.

Objectives The aim of the present study was to analyze the prognostic impact of intracranial pressure (ICP) monitoring in patients with severe traumatic brain injury (TBI). Methods An observational, retrospective and quantitative study was performed. The sample consisted of 246 patients diagnosed with severe TBI, from January 2009 to August 2017. Results Out of the total sample, 43.56% of the patients were submitted to ICP monitoring. The mean time of use of the catheter was 1.7 days. In both groups, males were the most affected, and the majority of the patients were < 50 years old. Automobile accident was the main etiology of TBI. In the initial clinical evaluation, mydriatic pupils were related to death and normal pupil reaction at hospital discharge. The monitored group performed a larger number of computed tomography (CT) scans, with a mean of 2.6 examinations, with cerebral edema being the most common finding. Regarding the prognosis, those who used a catheter for ICP monitoring had a 47% reduction in the chance of death when compared with those who did not use the catheter. The stay duration both in the hospital and in the intensive care units was higher in patients who underwent ICP monitoring; periods > 30 days were related to meningitis, especially in those who used the catheter. Conclusion Patients who used a catheter for ICP monitoring had a significant improvement in survival.

683. Bordes, J., et al. (2017). "Coagulopathy and transfusion requirements in war related penetrating traumatic brain injury. A single centre study in a French role 3 medical treatment facility in Afghanistan." Injury 48(5): 1047-1053.

INTRODUCTION: Traumatic brain injury associated coagulopathy is frequent, either in isolated traumatic brain injury in civilian practice and in combat traumatic brain injury. In war zone, it is a matter of concern because head and neck are the second most frequent site of wartime casualty burden. Data focusing on transfusion requirements in patients with war related TBI coagulopathy are limited., MATERIALS AND METHODS: A descriptive analysis was conducted of 77 penetrating traumatic brain injuries referred to a French role 3 medical treatment facility in Kabul, Afghanistan, deployed on the Kabul International Airport (KaIA), over a 30 months period., RESULTS: On 77 patients, 23 died during the prehospital phase and were not included in the study. Severe traumatic brain injury represented 50% of patients. Explosions were the most common injury mechanism. Extracranial injuries were present in 72% of patients. Traumatic brain injury coagulopathy was diagnosed in 67% of patients at role 3 admission. Red blood cell units (RBCu) were transfused in 39 (72%) patients, French lyophilized plasma (FLYP) in 41 (76%), and fresh whole blood (FWB) in 17 (31%)., CONCLUSION: The results of this study support previous observations of coagulopathy as a frequent complication of traumatic brain injury. The majority of patients with war related penetrating traumatic brain injury presented with extracranial lesions. Most of them required a high level of transfusion capacity.

684. Borg, A., et al. (2012). "An arrow escape-the anatomy of a near miss." Journal of Neurological Surgery, Part B: Skull Base 73.

Background: We report the case of a 20-year-old gentleman who presented with a self-inflicted transorbital extracranial arrow gun injury. On presentation, the projectile was in situ, the entry point

being superomedial to the left orbit and lateral to the superior part of the bony nasal dorsum. Objective: To delineate the anatomical structures involved in this low-velocity gun injury, and to provide technical notes on the surgical retrieval. Method: Sagittal CT sections demonstrated the depth of penetrance of the arrow and the relationship of the foreign body just below the anterior cranial fossa floor. Axial and coronal views delineated the pathway the arrow travelled, missing the globe and ethmoid sinus. Under general anesthesia, the lodged missile was removed through extension of the entry point incision to facilitate removal of the fully submerged shoulder of the arrow and identification of the anterior ethmoid artery. Results: The projectile was removed successfully. No short- or long-term sequelae occurred. Discussion: The arteries most at risk were the anterior and posterior ethmoidal, branches of the ophthalmic artery, as well as branches of the lacrimal artery. Radiological assessment determined the exact location of the missile, which in turn facilitated surgical retrieval. Conclusion: The anatomical structures involved in the trajectory of such an injury need to be correctly determined radiologically before embarking on surgical removal. Potential complications resulting from vascular injury can be disastrous; therefore, minimal tissue damage should be the main aim of the operation.

Penetrating transorbital injury with skull base involvement is a rare occurrence from a crayon. We report a case of a 2-year-old male who sustained a penetrating crayon injury through the right orbit and lamina papyracea into the posterior ethmoid sinus complicated by cerebrospinal fluid leak. There have been no other reported cases of this type of injury by a crayon.

689. Bös, M. and J. Bauer (2007). "Epileptic seizures due to penetrating gun-shot injury of the head." Aktuelle Neurologie 34(10): 559-563.

Trauma due to penetrating gun-shot injury of the head in the civilian population is a rare cause for post-traumatic epilepsy. The following report concerns three patients who developed epileptic seizures due to a civilian penetrating gun-shot injury. The shots were fired in the context of a domestic quarrel, an attempted homicide and a domestic misfortune. Two patients suffered late post-trauma tic seizures (more than eight days after trauma), one patient developed early post-traumatic seizures (within seven days). In two of the three patients metal fragments were retained intracerebrally. All three patients became seizure-free with prolonged antiepileptic drug treatment. In contrast to military series, traumatic brain injury caused by penetrating gun-shot injury seems to have a much better prognosis in the civilian population.

690. Boschert, E. N., et al. (2021). "Twenty-two Years of Pediatric Musculoskeletal Firearm Injuries: Adverse Outcomes for the Very Young." Journal of pediatric orthopedics 41(2): e153-e160.

BACKGROUND: Firearm injuries are a significant cause of morbidity and mortality for children in the United States. The purpose of this study is to investigate the 22-year experience of pediatric firearm-related musculoskeletal injuries at a major pediatric level 1 hospital and to analyze the risk of adverse outcomes in children under 10 years of age., METHODS: An institutional review board-approved, retrospective cohort analysis was conducted on pediatric firearm-related musculoskeletal injuries at our institution from 1995 to 2017. A total of 189 children aged 0 to 18 years were identified using International Classification of Diseases, 9th Revision/10th Revision codes, focusing on musculoskeletal injuries by firearms. Exclusion criteria were primary treatment at an outside hospital, isolated nonmusculoskeletal injuries (eg, traumatic brain injury), and death before orthopaedic intervention. Two cohorts were included: age below 10 years and age 10 years and above. Primary outcome measure was a serious adverse outcome (death, growth disturbance, amputation, or impairment). Standard statistical analysis was used for demographic data, along with linear mixed models and multivariable logistic regression for adverse outcome., RESULTS: Of the 189 children, 46 (24.3%) were below 10 years of age and 143 (75.7%) were 10 years and above. Fifty-two (27.5%) of the total group had an adverse outcome, with 19 (41.3%) aged below 10 years and 33 (23.1%) aged 10 years and above (P=0.016). Adverse outcomes were 3 deaths, 17 growth disturbances, 7 amputations, and 44 impairments. For those below 10 years of age, rural location (P=0.024), need for surgical treatment (P=0.041), femur injury (P=0.032), peripheral nerve injury (P=0.006), and number of surgeries (P=0.022) were associated with an adverse outcome., CONCLUSIONS: Over one fourth of survivors of musculoskeletal firearm injuries had an adverse outcome. Children 10 years and above represent the majority of firearm injuries in our population; however, when injured, those below 10 years are more likely to have an adverse outcome., LEVEL OF EVIDENCE: Level III.

691. Botelho, R. V., et al. (1999). "Carotid artery-sygmoid sinus fistula: a rare complication of gunshot wound on the base of the cranium." Neurosurgical review 22(2-3): 121-123.

Vascular lesions without clinical manifestation may occur in cranial-facial wounds produced by bullets that course the base of the cranium. This work describes a rare kind of vascular complication in cranial-facial gunshot wound. The authors present the case of a patient, the victim of a cranium-maxillary gunshot wound. Carotid angiography revealed a carotid-sygmoid sinus fistula that filled the sygmoid and transverse sinuses, concomitant to the arterial angiographic phase. A direct communication between the external carotid artery and the sygmoid sinus was disclosed. We are not aware of any other description of this vascular complication in cranial gunshot wound. It is important to recognize this kind of complication in cases of cranial-facial gunshot wound, because new factors harmful to the brain perfusion systems are introduced, in addition to the alterations to venous return and intracranial pressure, caused by the primary trauma. The new non-invasive vascular diagnostic methods are proving useful in filling the gap left by arteriography, which is no longer used in these cases.

692. Bottequin, E., et al. (2012). "Severe traumatic brain injury in a high income country: A population-based prospective cohort study." Brain injury 26(4-5): 523-524.

Introduction: In high income countries only few epidemiological studies on severe traumatic brain injury (TBI) are available, and these few studies have different designs. Severe traumatic brain injury is a high burden for society. Aims of the study: to describe characteristics and the outcome of patients with severe TBI in a national cohort of a high income country. Methods: The study included adults sustaining severe traumatic brain injury (TBI) from blunt or penetrating trauma with an Abbreviated Injury Scale score of the head region (HAIS) of more than 3, admitted to all eleven French

and German speaking trauma centres in Switzerland. The follow-up lasted 1 year. Start of inclusion was May 2007; last followup was in April 2011. Outcome measures were Glasgow Coma Scale (GCS) at 14 days, mortality, and Extended Glasgow Outcome Score (GOSE) at 3, 6 and 12 months. Descriptive statistics were performed. Results: 1012 potential patients were screened for inclusion; 922 patients were included (74.1% men). The incidence rate was 8.9 per 100'000 population. Median age was 55.0 years [inter quartile range 33.0, 71.2] with two peaks (20-29.9, 60-69.9 years). Median GCS at scene was 9 [4, 14] and 5 [3, 14] in the emergency department. Both pupils were reactive in 74.6% at scene and 71.9% in the emergency department. Among all TBI, 95.7% were blunt trauma. Injury Severity Score was 25 [16, 33], and 30.1% of patients had multiple trauma. Falls were the mechanism in 51.9%, road traffic accidents in 32.3% (most were car divers, pedestrians and cyclists). Median arrival time (h:min) to the hospital for direct admission was 00:46 [00:35, 01:01], for indirect admission 3:12 [2:15, 4:20]; 44.1% were intubated on scene. Hematoma evacuation was performed in 23.7%, intraventricular drainage in 8.0% and intracranial monitoring in 19.1%. Median ICU stay was 3 days [1,9], hospital stay was 11 days [6, 21]; SAPS 2 Score 44 [29, 57]. Death rate was 31.4%; median time to death was 2 days [1,6]; most deaths occurred during ICU stay. Median GCS of survivors at 14 days was 15 [13, 15]. Median GOSE of survivors at 3 months was 5 [3, 7], at 6 months 6 [4, 8] and at 12 months 7 [5, 8]. Conclusions: This population-based prospective cohort study included older patients and more falls compared to earlier studies in other European countries. High rates of cyclists and pedestrians with severe TBI were observed in the population with road traffic accidents. Most survivors were conscious at 14 days. GOSE increased slightly over a period of 1 year.

694. Bouguetof, H., et al. (2014). "Noninvasive estimation of cerebral perfusion pressure (NICPP) with transcranial doppler ultrasonography (TCD) in pediatric traumatic brain injury (PTBI)." Pediatric Critical Care Medicine 15(4): 70.

Background and aims: The PTBI is an important cause of morbidity and mortality in children with severe neuropsychological sequelae. The therapeutic goal should be to ensure cerebral blood flow (CBF) sufficient to prevent cerebral ischemia. Accurate measurement of DSC is not possible continuous bedside, different brain monitoring techniques proposed to guide the management of TCG therefore monitor the PPC. Aims: To estimate the values of CPP (niCPP) by the study of flow velocities (systolic: sV. Diastolic:dV mean: mV) at the middle cerebral artery (MCA) non- invasively using the TCD. Methods: As part of the national program of health research, 38 children were studied. ICP, MAP and flow velocities in the MCA were followed. CPP was calculated by the standard formula: CPP = MAP-ICP and niCPP by formula Aaslid: MAP x dV / mV + 14. The correlation between non - invasive and invasive values were analyzed. Results: The non-invasive and invasive CPP / niCPP mean values were 54.26 } 11.93 mmHg and 53.9 } 10.69 mmHg respectively. The correlation between non- invasive and invasive measures CPP was highly significant ($p < 0.001$) with a correlation coefficient of Pearson $r = 0.841$. Conclusions: The niCPP measured by TCD is a parameter that can be quickly obtained from the inlet and can be an alternative in the detection of the risk of cerebral ischemia. It allows you to answer a key question to determine in the first minutes following the admission of children considered at risk oligohemie brain and need close monitoring and the need for continuous monitoring of CPP by monitoring invasive ICP.

695. Bouguetof, H., et al. (2012). "Management of severe paediatric trauma brain injury (PTBI) guided by intracranial pressure (ICP) monitoring in a picu in algeria." Archives of disease in childhood 97: A225.

Background and Aims PTBI is the leading cause of death and long-term morbidity. Current recommendations for the management of severe PTBI (Glasgow Coma [GCS] score ≤8) indicate that ICP monitoring is appropriate in infants and children (Option). The most reliable methods of ICP monitoring are ventricular catheters and intra parenchymal systems. The aim of this study is to evaluate the management of PTBI based on continues monitoring of intraparenchymal ICP in a PICU in Algeria. Methods Between January 2005 and December 2009 we collected 308 PTBI, 57 patients had intraparenchymal ICP monitoring. The consensus is to treat ICP exceeding the 20 mmHg threshold, and to optimize cerebral perfusion pressure (CPP). Results The mean age was 8 years, hypoxia and hypotension were frequent at admission, median GCS after resuscitation = 6, ICP monitoring was set up by the intensivist in the PICU after un average time of 13 hours after trauma. Intracranial hypertension was detected and treated (mannitol, hyerventilation and thiopental) in more than 90% of cases. the average time of ICP monitoring was 5 days. No complications (infection, hemorrhage) with this technique was detected. Conclusion The etiology and the pathophysiology of raised ICP in PTBI is a complex challenge for the intensivist. CPP and ICP were the first brain-specific targets for goal-directed therapies enacted in PTBI. In this study, ICP monitoring allows to detect intracranial hypertension and guide treatment better than when this technique is absent even if it is not a standard of the recommendations.

696. Bouillon, B., et al. (1996). "High dose corticosteroids in patients with multiple trauma." Shock (Augusta, Ga.) 5 Suppl: 45.

Design: Prospective, double-blind randomized trial Aim: The objective of this study was to analyze plasma levels of Phospholipase-A2 and Interleukin-1 and other related mediators in multiple traumatized patients after high-dose corticosteroid application. Material and Methods: Enclosed were patients with a Trauma-Score ranging between 7 and 12. Exclusion criterion was severe, penetrating head injury. Within 40 minutes after the traumatizing event an initial dose of 500 mg/10ml DEXamethason (DEX) i.v or an equal volume of NaC1 solution i.v. was administered. Three hours later further 200 mg DEX were applied followed by 8 applications of the same dose at 6 hour intervals. Blood samples were generally obtained in the emergency room prior to DEX application at day 3,4,5,10,14,21 and 30. Observation period was 30 days. ELISA-kits were used for measuring plasma levels of Phospholipase-A2 and Interleukin-1 ; Cortisol and DEX levels were measured by HPLC. Results: A total of 12 patients were enrolled in the study. 5 of the patients received DEX. Control and verum group were well matched concerning age (45 years), Injury Severity Score (28 points), Trauma Score (10.4 points) and Glasgow Coma Scale (10 points). Dexamethason plasma levels decreased constantly until day 2. Any changes in Phospholipase-A2 and Interleukin-1 plasma levels were observed in this time interval. Plasma levels of these mediators were generally deceased as compared to the control group: Cortisol:60-110 ng/ml (control) and 16-40 ng/ml (DEX); Interleukin-1: 10-12 ng/ml (control) and 8 ng/ml (DEX); Phospholipase A2: 8 - 78 ng/ml (control) and 19 ng/ml (DEX). It was interesting to note that although cortisol plasma levels were suppressed, the typical circadian rhythm of release was still detectable. The results support the concept that systemic release of certain mediators can be suppressed by corticosteroids. Discussion: The results suggest that high dose application of DEX amethasone results in a suppression of certain immunological mediators as well as cortisol. The feedback mechanism seems unaffected due to the unaltered circadian rhythm of cortison release. The study confirmed a rapid elimination of high dose application of DEXamethasone.

A 19-year-old male was referred because of a grease-gun injury of the left orbit, resulting in a 25 mm proptosis and marked decrease in vision. The clinical diagnosis of penetration of the retrobulbar fat space by the grease and the subsequent accurate drainage of the grease was made possible on the basis

of high resolution computed tomography (CT) and magnetic resonance imaging (MRI). As a result, lateral orbitotomy could be avoided. Eight months after the injury the visual acuity was fully recovered and the proptosis reduced to 2 mm. The visual field was relatively undisturbed. The specific value of CT and MRI for the management of this unusual trauma is briefly discussed.

698. Boulanger, B., et al. (2001). "Minimally invasive retrieval of a foreign body after penetrating lung injury." Surgical endoscopy 15(9): 1043.

Minimally invasive techniques are increasingly used in the management of trauma victims. We report the case of a young man in a motor vehicle crash who sustained a penetrating wound to the anterior left chest caused by the automobile stick shift. Subsequent imaging demonstrated a large foreign body in the left lung. The foreign body was removed successfully by videothoracoscopy, and the patient made a full recovery. This case demonstrates the inroads that minimally invasive surgery is making in care of the injured and highlights an excellent technique for dealing with pulmonary foreign bodies.

701. Boutte, A., et al. (2016). "Differential abundance of total and phosphorylated tau in brain tissue and biofluids during subacute penetrating brain injury." Journal of neurotrauma 33: A83-A84.

Severe traumatic brain injury (TBI) is a risk factor for tauopathies. The degree to which TBI contributes to tau pathology, and the role of tau or its phosphorylation state as a TBI biomarker remains debated. This preliminary study sought to determine the effect upon total and phosphorylated tau in a rat model of penetrating ballistic-like brain injury (PBBI). Ipsilateral frontal cortex (FC), cerebral spinal fluid (CSF), and serum were collected 1, 2, and 4 weeks (wks) after craniotomy or PBBI. Total and phosphorylated (threonine 231) tau (pTau) were measured using electrochemilluminescent ELISAs. All values are displayed as the fold change (x) vs. craniotomy per time-point. The p-tau to tau ratio (p-tau: tau) is also described. In the FC, tau increased in a stepwise manner after PBBI. Here, tau rose to 1.67x at 2wks, then to1.89x at 4wks. P-tau increased by 1.85x 2wks after PBBI, yet decreased to 0.22x of craniotomy after 4-wks. Total tau was 12x higher in CSF collected 1wk post-PBBI, yet fell to near craniotomy levels at 2-4wks. CSF p-tau mirrored this trend, and was increased by 3.17x 1wk after injury. Serum tau was suppressed by 0.17x after 1wk, normalized to craniotomylevels at 2wks, but was again suppressed to 0.048x 4 wks post-PBBI. Within the same cohorts, the serum p-tau peaked 1 wk after PBBI to 4.21x. In the FC, the p-tau:tau ratio decreased to 0.77x at 1wk, increased by 1.12x after 2 wks, then fell to 0.047x at 4wks. The ratio in CSF rose from 0.093x at 1wk, to 0.22x at 2 wks, then to 0.33x at 4 wks post-PBBI. Tau, pTau, and the ptau: tau ratio, may be indicators of tauopathies in brain tissues driven by TBI. Further, these analytes remain detectable throughout subacute injury in both serum (2wks) and CSF (4wks). Tau, p-tau and the ratio may be useful as diagnostic and theranostic indicators relevant to the longterm effects of TBI.

---

702. Boutte, A., et al. (2016). "Brain cathepsin B protein levels and cysteine protease activity are affected by subacute craniotomy and penetrating brain trauma." Journal of neurotrauma 33: A79.

Comprehensive analysis of key mediators involved in subacute traumatic brain injury (TBI) is tantamount to understanding, and mitigating, mechanisms of injury progression. Cathepsin B is a cysteine protease implicated in neurodegeneration and TBI. The purpose of this preliminary study was to determine the extent of cathepsin B up-regulation, and enzymatic activity within proximal and distal brain regions affected by subacute craniotomy or penetrating ballistic-like brain injury (PBBI). Rat ipsilateral frontal cortex (FC) and hippocampal (HC) brain tissues were collected 7 days after craniotomy or PBBI. Mature (25-26kDa) cathepsin B protein levels were determined by western blotting. Enzymatic activity was determined by substrate cleavage to generate a fluorescent product. Craniotomy or PBBI values are expressed as a fold change (x) compared to naïve controls. To determine if activity was specific to cathepsin B, assays were repeated with the addition of CA-074. Changes in activity are expressed as percent (%) of values without inhibitors. PBBI led cathepsin B protein levels to increase by 6-7x in the FC and by 1.3-1.6x in the HC compared to naïve and craniotomy cohorts. FC enzyme activity increased by 1.4x and 2.3x after craniotomy or PBBI, respectfully. In FC extracts, CA-074 nearly ablated enzymatic activity caused by craniotomy, and suppressed the PBBI-induced activity by 60%. Within the HC, craniotomy decreased enzymatic activity to 0.8x of naive levels, while PBBI had no effect. CA-074 suppressed activity in naïve, craniotomy, and PBBI by 40-50%. PBBI led to expected upregulation of cathepsin B protein levels the FC and HC. Craniotomy-induced FC enzyme activity is largely due to cathepsin B. In contrast, PBBI likely leads to activation of several proteases. Protease protein levels and activity may be crucial to the elucidating differential mechanisms within lesioned and non-lesioned brain tissues affected by subacute TBI of varying severities.

---

703. Boutte, A., et al. (2017). "Rat brain cathepsin b protein levels and cysteine protease activity after traumatic brain injury." Journal of neurotrauma 34(13): A24.

Cathepsin B is a lysosomal cysteine protease that may be an important therapeutic target and biomarker for traumatic brain injury (TBI). The current study was designed to evaluate the regional and temporal profiles of mature cathepsin B (mCatB) protein levels and cysteine protease activity in the penetrating ballistic-like brain injury (PBBI) model. Rat ipsilateral frontal cortex (FC), hippocampus (HC), and cerebellum (CB) were collected 1-7 d after PBBI or craniotomy alone, compared to unoperated sham controls (baseline for fold change comparison). MCatB increased after 7 d after craniotomy (2.3-fold) and PBBI (11.9-fold) in the FC. HC levels of mCatB were elevated at 3 d (1.6-fold) and 7d (2.5-fold) after PBBI. CB mCatB was suppressed 3 d after craniotomy (0.37-fold) and 1-3 d after PBBI (range: 0.43- 0.55-fold) vs. sham. However, at 7d post-injury CB mCatB levels in PBBI animals exceeded that of sham (1.2-fold). Craniotomy did not have a significant effect on cysteine protease activity in the FC. PBBI resulted in increased FC cysteine protease activity at 3 d (3.4-fold) and 7 d (2.13-fold) post-injury. In the HC, activity increased 7d after craniotomy (1.8-fold). Non-linear dysregulation of mCatB protein levels infer that proteolytic processes within proximal and distal brain regions vary with injury severity and time over the course of TBI progression. Differential increases in cysteine protease activity suggest that TBI elicits a complex proteolytic response, inclusive of cathepsin B, thereby incentivizing the need for spatio-temporally defined therapeutic strategies.

704. Boutte, A. M., et al. (2016). "Serum Glial Fibrillary Acidic Protein Predicts Tissue Glial Fibrillary Acidic Protein Break-Down Products and Therapeutic Efficacy after Penetrating Ballistic-Like Brain Injury." Journal of neurotrauma 33(1): 147-156.

Acute traumatic brain injury (TBI) is associated with neurological dysfunction, changes in brain proteins, and increased serum biomarkers. However, the relationship between these brain proteins and serum biomarkers, and the ability of these serum biomarkers to indicate a neuroprotective/therapeutic response, remains elusive. Penetrating ballistic-like brain injury (PBBI) was used to systematically analyze several key TBI biomarkers, glial fibrillary acidic protein (GFAP) and its break-down products

(BDPs)-ubiquitin C-terminal hydrolase-L1 (UCH-L1), alpha-II spectrin, and alpha-II spectrin BDPs (SBDPs)-in brain tissues and serum during an extended acute-subacute time-frame. In addition, neurological improvement and serum GFAP theranostic value was evaluated after neuroprotective treatment. In brain tissues, total GFAP increased more than three-fold 2 to 7 d after PBBI. However, this change was primarily due to GFAP-BDPs which increased to 2.7-4.8 arbitrary units (AU). Alpha-II spectrin was nearly ablated 3 d after PBBI, but somewhat recovered after 7 d. In conjunction with alpha-II spectrin loss, SBDP-145/150 increased approximately three-fold 2 to 7 d after PBBI (vs. sham, $p<0.05$). UCH-L1 protein levels were slightly decreased 7 d after PBBI but otherwise were unaffected. Serum GFAP was elevated by 3.2- to 8.8-fold at 2 to 4 h (vs. sham; $p<0.05$) and the 4 h increase was strongly correlated to 3 d GFAP-BDP abundance ($r=0.66$; $p<0.05$). Serum GFAP showed such a strong injury effect that it also was evaluated after therapeutic intervention with cyclosporin A (CsA). Administration of 2.5 mg/kg CsA significantly reduced serum GFAP elevation by 22.4-fold 2 h after PBBI (vs. PBBI+vehicle; $p<0.05$) and improved neurological function 1 d post-injury. Serum biomarkers, particularly GFAP, may be correlative tools of brain protein changes and feasible theranostic markers of TBI progression and recovery.

---

705. Boutte, A. M., et al. (2020). "Penetrating Traumatic Brain Injury Triggers Dysregulation of Cathepsin B Protein Levels Independent of Cysteine Protease Activity in Brain and Cerebral Spinal Fluid." Journal of neurotrauma 37(13): 1574-1586.

Cathepsin B (CatB), a lysosomal cysteine protease, is important to brain function and may have dual utility as a peripheral biomarker of moderate-severe traumatic brain injury (TBI). The present study determined levels of pro- and mature (mat) CatB protein as well as cysteine protease activity within the frontal cortex (FC; proximal injury site), hippocampus (HC; distal injury site), and cerebral spinal fluid (CSF) collected 1-7 days after craniotomy and penetrating ballistic-like brain injury (PBBI) in rats. Values were compared with naive controls. Further, the utility of CatB protein as a translational biomarker was determined in CSF derived from patients with severe TBI. Craniotomy increased matCatB levels in the FC and HC, and led to elevation of HC activity at day 7. PBBI caused an even greater elevation in matCatB within the FC and HC within 3-7 days. After PBBI, cysteine protease activity peaked at 3 days in the FC and was elevated at 1 day and 7 days, but not 3 days, in the HC. In rat CSF, proCatB, matCatB, and cysteine protease activity peaked at 3 days after craniotomy and PBBI. Addition of CA-074, a CatB-specific inhibitor, confirmed that protease activity was due to active matCatB in rat brain tissues and CSF at all time-points. In patients, CatB protein was detectable from 6 h through 10 days after TBI. Notably, CatB levels were significantly higher in CSF collected within 3 days after TBI compared with non-TBI controls. Collectively, this work indicates that CatB and its cysteine protease activity may serve as collective molecular signatures of TBI progression that differentially vary within both proximal and distal brain regions. CatB and its protease activity may have utility as a surrogate, translational biomarker of acute-subacute TBI.

---

706. Boutté, A. M., et al. (2013). "Time dependant biomarker abundance in brain tissue and serum after acute PBBI." Journal of neurotrauma 30(15): A64-A65.

Introduction When developing protein biomarkers for diagnosis, prognosis, and therapeutic recovery after traumatic brain injury (TBI), one of the most important factors is understanding temporal protein expression. Therefore, we systematically analyzed protein abundance of three key biomarkers in tissues and serum in our rodent model of penetrating ballistic-like brain injury (PBBI). Methods For this study we employed the penetrating ballistic-like brain injury (PBBI) model to study the expression of glial fibrillary acidic protein (GFAP), ubiquitin carboxy terminal hydrolase (UCH)-L1 and spectrin break down products (SBDP) in serum and brain tissue. Anesthetized rats received a 10% unilateral, frontal injury and sham (control) rats received a craniotomy without probe insertion. Ipsilateral, coronal brain tissue sections 6mm from bregma, were collected 2h 4h, 24h 48h, 72h, and 7d after injury and serum was collected via cardiac puncture. Proteins were extracted from brain tissues and protein

abundance was determined by the following methods: full-length proteins were analyzed by semi-quantitative western blotting and/or ELISA; protein fragments were analyzed by western blotting. In serum, full-length proteins were analyzed by ELISA. Results Serum GFAP was increased at 2h and 4h after PBBI and returned to control levels between 24h-7d post injury. Serum UCH-L1 was only increased above sham levels 2h post injury and then returned to control levels for 4h-7d. Alpha-II spectrin and SBDPs have not yet been determined in serum. In brain tissues, GFAP expression was similar in PBBI and shamcontrols 2-4h after injury, butwas greatly increased above sham between 24h - 7d after PBBI with peak expression at 48-72h. Similarly, brain GFAP-BDPs were minimal 2-4h after injury, but demonstrated a sharp increase between 24h-7d in PBBI with levels above sham controls and peak abundance at 48-72h. SBDP-145/150were unchanged at 2-24h, but were increased compared to sham between 48h - 7d after PBBI, with peak abundance at 48h post injury. Simultaneously, there was loss of the full length a-II spectrin starting at 24h through 48h. Full length alpha-II spectrin started to increase after 72h through 7d but did not reach sham levels. UCH-L1 in brain tissues was relatively unchanged in PBBI compared to sham across all time points studied. Conclusions Like human studies, the TBI biomarkers GFAP and UCH-L1 in rodent PBBI are increased in serum shortly after injury. However, these biomarkers were cleared by 24h. Alternatively, “brain tissue” biomarkers demonstrated a different profile where GFAP, GFAP-BDP, and SBDPs, increased 48-72h and remained elevated 7d after injury. These studies suggest that brain proteins released into serum may be an immediate response to the severe PBBI injury where blood-brain barrier disruption predominates. Thus, these serum biomarkers may be appropriate for acute diagnosis, but not for long term assessment or therapeutic response monitoring. In contrast, detection of biomarkers involved in persistent gliosis (GFAP, GFAP-BDPs) and neuronal damage (spectrin and SBDPs) would be useful targets of in vivo brain imaging probes for diagnoses and long-term therapeutic response assessment.

707. Boutte, A. M., et al. (2012). "Differential protein changes in penetrating and non-penetrating models of TBI." Journal of neurotrauma 29(10): A51-A52.

Introduction Protein biomarkers are being developed for diagnosis of traumatic brain injury (TBI), but their injury specificity is unknown. Rodent models of penetrating and non-penetrating TBI offer distinct models for translational biomarker research. Therefore, we systematically analyzed protein abundance and degradation of multiple protein biomarkers in two models of TBI. Methods Systems biology and immuno-based methods have been used to determine protein biomarker abundance in the penetrating ballistic-like brain injury (PBBI). For this study we employed two distinct cohorts of TBI subjects: (1) PBBI injured rats and (2) repetitive blast overpressure (BOP) injured rats. For PBBI, ipsilateral and contralateral coronal tissue sections 6mm from bregma were collected 24 h after injury. For BOP studies, the prefrontal cortex, cortex, hippocampus and cerebellum were dissected 24 h after the last of three daily, 75 kPa blasts. Proteins extracted from brain tissues were analyzed by semiquantitative western blotting and/or ELISA to determine specific abundance of intact proteins or their degradation fragments. Target proteins were chosen based on informatics data and reported literature. Results Our analyses identified statistically significant increases in GFAP and UCH-L1, but decreases in PSD-95, in ipsilateral tissues 24 h after PBBI. In contrast, GFAP, UCH-L1, and PSD-95 showed no change in BOP. The relative abundance of a-spectrin and different spectrin breakdown products (SBDPs) were differentially expressed in PBBI compared to BOP. In ipsilateral PBBI tissue, there was a loss of full length a-spectrin, with a moderate increase in SBDP- 145/150. BOP exposures lead to a small, albeit non-significant, decrease in alpha-spectrin within the cerebral cortex, hippocampus, and cerebellum, but a moderate increase in SBDP-145/150 in the prefrontal cortex and cerebellum. There was a greater increase of SBDP-120 in the prefrontal cortex, which was not present in the cerebellum. Overall, significantly increased SBDP-145/150 and decreased a-spectrin were detected after PBBI. In contrast, decreased a-spectrin after BOP exposure was not-significant, and there was a larger increase in BOP-induced SBDP-120 compared to SBDP-145/150. Conclusions TBI biomarkers such as GFAP, spectrin and its BDPs, as well as UCH-L1, were increased in PBBI; loss of PSD-95 was also observed. The expression of SBPD-145/150, a product of calpain activity, was greater in PBBI vs.

BOP; whereas SBDP-120, a product of caspase activity, was increased after BOP exposure. Spectrin may be selectively cleaved by different mechanisms of cellular injury. Spatial differences in SBDP abundance may identify the prefrontal cortex as the primary injury site in blast, a region that has been implicated in TBI from BOP due to the unique pattern of symptoms. In addition, the results demonstrated the upregulation of GFAP, UCHL1 and SBDP in the PBBI model similar to the changes seen in human serum. Not only does the study confirm the use of informatics analysis but it also possibly identified different mechanisms and patterns of severe injury that differentiate penetrating from non-penetrating.

708. Boutte, A. M., et al. (2012). "Proteomic analysis and brain-specific systems biology in a rodent model of penetrating ballistic-like brain injury." Electrophoresis 33(24): 3693-3704.

Proteomics and systems biology have significantly contributed to biomarker discovery in the field of brain injury. This study utilized 2D-DIGE-PMF-MS as a preliminary screen to detect biomarkers in a rat model of penetrating ballistic-like brain injury (PBBI). Brain-specific systems biology analysis of brain tissue identified 386 proteins having a fold change of more than 2, of which 321 proteins were increased and 65 were decreased 24 h after PBBI compared to sham controls. The majority of upregulated proteins were cytoskeletal (10.5%), nucleic acid binding (9.3%), or kinases (8.9%). Most proteins were involved in protein metabolism (22.7%), signal transduction (20.4%), and development (9.6%). Pathway analysis indicated that these proteins were involved in neurite outgrowth and cell differentiation. Semiquantitative Western blotting of 6, 24, 48, and 72 h after PBBI indicated ubiquitin carboxyl-terminal hydrolase isozyme L1 (a proposed traumatic brain injury biomarker in human clinical trials), tyrosine hydroxylase, and syntaxin-6 were found to be consistently elevated in brain tissue and cerebral spinal fluid after PBBI compared to sham controls. Combining proteomics and brain-specific systems biology can define underlying mechanisms of traumatic brain injury and provide valuable information in biomarker discovery that, in turn, may lead to novel therapeutic targets.

709. Boutte, A. M., et al. (2012). "Systems biology meta-analyses of genomic datasets to identify conserved mechanisms and novel biomarkers of traumatic brain injury." Journal of neurotrauma 29(10): A102-A103.

Introduction High-throughput technologies quantify expression of thousands of genes, but the plethora data hinders unambiguous gene identification associated with the condition of interest. We exploited systems biology to systematically analyze multiple high-throughput genomic studies of traumatic brain injury (TBI) to gain insights into conserved mechanisms and to infer biomarker candidates. Methods We employed systems biology approaches to incorporate multiple gene expression datasets with biological knowledge in the form of pathways and protein-protein interaction (PPI) networks. We selected four datasets from TBI experiments using different animals and TBI models, integrating the data with over 130 non-metabolic canonical pathways in the KEGG database and a PPI network consisting of over 11,000 proteins and 80,000 interactions. We separately overlaid each set of data onto the pathways and the PPI network to identify a set of pathways and PPI modules that are statistically significant for each dataset. We then inferred TBI biomarker candidates from those specific pathways and biologically relevant PPI modules that are conserved in two or more datasets and validated them by protein abundance changes in rat brain subjected to a penetrating ballistic-like brain injury (PBBI). Results Our analyses identified statistically significant pathways and PPI modules that are conserved in two or more datasets. Functional analyses showed that only down-regulated pathways and PPI modules were specifically associated with the nervous system; those that were up-regulated were associated with immune responses. The 19 conserved down-regulated pathways included 7 out of 9 KEGG nervous system pathways, which are all associated with synaptic functions; the 6 conserved down-regulated PPIs formed a subnetwork of synaptic proteins. Thus, we predicted that PSD-95, DISC1, and NOS1 would be down-regulated in the ipsilateral brain tissues which were confirmed in

subsequent in vivo experiments using the PBBI model. We observed a statistically significant decrease (69%, 47%, and 50%, respectively, $p < 0.05$) in protein abundance in the ipsilateral brain tissues compared to sham controls. We also observed a 50% increase for PSD-95, a 46% decrease for NOS1, but no change for DISC1 in contralateral tissues. Conclusions We employed systems biology approaches to integrate molecular evidence from distinct TBI studies with biological pathways and networks to systematically identify conserved and TBI-specific molecular processes and biomarkers. We found that only down-regulated pathways and PPI modules are associated with the nervous system, especially synaptic functions. This effect is likely due to neuronal loss coupled with increased inflammation caused by TBI. The in vivo experimental results confirmed the TBI biomarker candidates hypothesized using our systems biology approach. Our results suggest that systems biology can provide a high-yield approach to generate testable hypotheses that can be experimentally validated to identify potential TBI biomarkers.

710. Bouwman, D. L., et al. (1983). "Hyperamylasemia: a result of intracranial bleeding." Surgery 94(2): 318-323.

The unexpected finding of hyperamylasemia in a patient with isolated head injury prompted a study of amylase levels in patients with various degrees of cranial trauma. None of seven patients with isolated maxillofacial trauma had hyperamylasemia. This group was studied to discount injury to salivary glands as a source of elevated amylase levels. Only one of ten patients with simple cranial injury without computerized tomographic (CT) scan evidence of intracranial bleeding had hyperamylasemia. Six of ten patients with CT scans positive for intracranial bleeding had hyperamylasemia. Isoamylase analysis showed that the source of the hyperamylasemia was varied. These results suggest a central neural control of serum amylase levels. The reliability of the serum amylase level as an indication of pancreatic trauma in a patient with concomitant head injury is questioned.

711. Bowden, E., et al. (2017). "Management of complex soft tissue injury." British Journal of Oral and Maxillofacial Surgery 55(10): e130.

Introduction: Complex facial lacerations can affect aesthetic outcomes, compromise function and can be life threatening. The psychological impact can be detrimental to patient quality of life. Findings: In a trauma setting difficulties can arise in the thorough assessment and treatment of injuries. In the accident and emergency department achieving haemorrhage control for example, may be complicated by limited equipment availability, lack of lighting magnification and the experience of the practitioner. Initial management must prioritise primary survey and haemodynamic stability. Furthermore, the extent of the soft tissue injury may impede effective treatment under local anaesthetic. Consideration must be given to the appropriate use of imaging to assess underlying hard tissue injury, brain injury and the depth of penetrating wounds, as well as ruling out any foreign body involvement. Case: We discuss management of complex soft tissue injury including haemorrhage control, facial nerve repair, primary closure and post-operative short and long term considerations. We present a case of a young female involved in a road traffic collision, who sustained a large de-gloving injury to the right forehead and temporal region involving severance of the facial nerve.

712. Bowen, D. I. and D. M. Magauran (1973). "Ocular injuries caused by airgun pellets: an analysis of 105 cases." British medical journal 1(5849): 333-337.

One hundred and five cases of airgun pellet injuries of the eye have been analysed. The average age was 14 and the male to female ratio 7.5:1. Forty-five patients had final visual acuities of 6/18 or less in the injured eye and 19 of these had the eye removed. The two main causes for poor vision were retinal damage and cataract. One patient became completely blind after sympathetic ophthalmitis arising 11 years after the injury. The pellet lodged in the orbit in 14 cases and three of these, together with one who

had an intraethmoidal pellet, were investigated for abnormal lead levels in blood and urine. The results were normal. The circumstances of the injury were obtained in 12 cases and most involved careless handling of a gun. Instruction of children and parents in schools and on television, rather than stricter legislation, is suggested as a means of prevention.

713. Bowman, S. and M. Aitken (2009). "Disparities in injury outcomes for people with epilepsy and seizure disorders." Epilepsia 50: 83.

Context: Controlling for injury and patient characteristics, one would expect comparable in-hospital outcomes for patients with and without epilepsy. The historical stigma associated with epilepsy is well-document, yet potential disparities in injury care for people with epilepsy and seizure disorders remain unknown. Objective: To compare in-hospital outcomes of injured patients with epilepsy and seizure disorders with similarly patients without epilepsy/seizures. We tested the hypothesis that people with epilepsy have worse outcomes (i.e., greater in-hospital mortality) than similarly injured people without epilepsy. Design, Setting, and Participants: Analysis of existing data from the Nationwide Inpatient Sample - the largest, longitudinal, all-payer inpatient care database in the United States. Injured patients of all ages were included. Multivariable logistic regression was used to control for patient and hospital characteristics. Main Outcome Measures: In-hospital mortality, stratified by injury mechanism. Results: Controlling for patient and injury characteristics, people with epilepsy were more likely to die in-hospital than people without epilepsy (OR 1.16, $p<0.001$). People with epilepsy were significantly more likely to have a traumatic brain injury diagnosis than similar individuals without epilepsy (OR 2.94, $p<0.001$). By mechanism of injury, significantly increased risk of death was observed for injuries from cuts/pierces (OR 3.24), falls (OR 1.25), motorcycles (OR 1.67), other transport (OR 1.59), struck by/against (OR 1.63), and suffocation (OR 8.0). People with epilepsy/seizures with firearm injuries were less likely to die in-hospital (OR 0.25). Conclusion: Disparities in hospital outcomes for people with epilepsy deserve further attention. Identifying the underlying causes of these disparities is critical.

714. Bowyer, J. F., et al. (2014). "Systemic administration of fluoro-gold for the histological assessment of vascular structure, integrity and damage." Current neurovascular research 11(1): 31-47.

Fluoro-Gold (F-G) has been used extensively as a fluorescent retrograde neuronal-track tracer in the past. We now report that intraperitoneal administration of 10 to 30 mg/ kg of F-G from 30 min to 7 days prior to sacrifice labels vascular endothelial cells of the brain, choroid plexus and meninges and can be used to assess vascular integrity and damage. F-G vascular labeling co-localized with rat endothelial cell antigen (RECA-1) in the membrane. F-G also intensely labeled the nuclei of the endothelial cells, and co-localized with propidium iodide staining of these nuclei. As well, the administration of F-G during neurotoxic insults produced by amphetamine, kainic acid or "penetrating" wound to the brain can detect where vascular leakage/ hemorrhage has occurred. Histological methods to detect F-G labeled brain vasculature were performed in the same manner as that used for fluorescent visualization of neuronal elements labeled with F-G after perfusion fixation and coronal sectioning (15 to 40 microm) of the brain. This in vivo F-G labeling of endothelial cells and their nuclei yields a clear picture of the integrity of the vasculature and can be used to detect changes in structure. Vascular leaks after "penetrating" wounds through the cortex and striatum, hyperthermic amphetamine exposure or excitotoxic kainate exposure were detected by F-G in the extracellular space and via parenchymal F-G subsequently labeling the terminals and neurons adjacent to the lesioned or damaged vasculature. Further studies are necessary to determine the extent of the leakage necessary to detect vasculature damage. Visualization of the F-G labeling of vasculature structure and leakage is compatible with standard fluorescent immuno-labeling methods used to detect the presence and distribution of a protein in histological sections. This method should be directly applicable to studying brain vascular damage that occurs in the progression of Alzheimer's disease, diabetes and for monitoring the brain vascular changes during development.

715. Boyarchuk, O., et al. (2020). "A report of five child tetanus cases." Journal of Pediatric Infectious Diseases 15(4): 200-205.

We present five cases of generalized tetanus in children 5 to 13 years old, who were admitted to the intensive care unit of Ternopil Regional Children's Hospital (Western Ukraine) during the past 6 years (2012-2017). In our study, four children were unvaccinated and one received the full series of vaccinations. Proper vaccination in cases of infected wound may not prevent the development of the disease but improves the prognosis for recovery. Treatment of tetanus in Ukraine requires standardization of treatment protocols according to the World Health Organization recommendations, including making human tetanus immune globulin available, as specified by evidence-based medicine. Vaccines availability and education of physicians and parents about the benefits of immunization should be priority national health measures to prevent tetanus.

716. Boyd, M., et al. (2015). "Blood brain barrier disruption after mild traumatic brain injury in a closed skull model." Journal of Investigative Medicine 63(1): 122-123.

Purpose of Study: Traumatic brain injuries (TBI) are rising significantly. Mild TBI (mTBI), or concussions account for 75% of TBI occurrences. Clinically applicable studies are essential for development of treatments and long term prognostic care. The primary model to study TBI uses a controlled cortical impact (CCI) via craniotomy direct to the dura mater. However, the current model is limited in its application to clinical studies because most current cases of mTBI do not involve penetrating injuries to the brain tissue. The study is aimed to develop a very mild impact, closed skull model that yields a subclinical outcome, relative to mTBI, for study of blood brain barrier (BBB) disruption and neuroinflammation. Methods Used: Utilizing the CCI system, without use of the craniotomy, C57BL/6 male mice were anesthetized by isoflourane, heads shaved and positioned on the stereotaxic frame. Impacts were delivered directly to the skull, posterior to the bregma and recovery followed. BBB permeability was measured by injection of 14C-labeled sucrose followed by washout and beta counts of the samples. Simultaneously, changes in aquaporin-4 (AQP4) and HIF-1a were analyzed by standard western blot procedures. Summary of Results: Standard parameters of 6 impacts, spaced 2 minutes apart at 1.0 m/s and a depth of 0.2mm were used to obtain mTBI. BBB permeability had significant increase with severe impact and a trending increase in the subclinical subjects, compared to the controlmice. Western blot analysis conveyed the same trend; further evidencing the fact that mTBI does impact the chemistry and functionality of the BBB and associated proteins. The use of the CCI to inflict mTBI is validated and repeatable, by control of both depth and velocity. Conclusions: This study demonstrates that a subclinical outcome is possible with a closed skull model. Changes in BBB permeability and edema associated factors, such as AQP4 support the continued use of the model in future studies. Potential targets include factors involved in neurodegeneration, given the increasing rate of mTBI in the population. Continued focus will be on optimizing parameters, determination of peak edema and evaluation of experimental treatment methods.

717. Boyd, N. A. (1975). "A military surgical team in Belfast." Annals of the Royal College of Surgeons of England 56(1): 15-25.

This paper details the experiences of a military surgical team in Belfast from 1972 to early 1974. The overall picture of the problem is given and the current management of 'war' injuries discussed. Up to February 1974 over 1000 servicemen have been injured in Northern Ireland as a result of the vivil disturbance. Over 200 have died. Because of the close proximity of the hospital to many battle areas, casualties may arrive with massive injuries, requiring major resuscitation. Limb wounds have predominated. There is no short cut to adequate wound debridement, especially in the surgery of high-velocity missile injury. Missile wounds of the large bowel require a colostomy. Formal thoracotomy is increasingly used for the through-and-through gunshot wounds of the chest. Controlled ventilation is

playing an increasingly important role in the management of some missile wounds of the head. Mine and bomb explosions frequently cause multiple injuries, requiring extensive surgery on any one patient.

721. Bozan, O., et al. (2019). "Comparison of PECARN and CATCH clinical decision rules in children with minor blunt head trauma." European journal of trauma and emergency surgery : official publication of the European Trauma Society 45(5): 849-855.

INTRODUCTION AND PURPOSE: Computerized brain tomography (CBT) imaging plays a key role in the management of patients with head trauma, and there is an indication for CBT in moderate and severe injuries. However, it is difficult to determine an indication for CBT in patients with minor head trauma. The primary aim of this study is to compare the efficiency of the most commonly used clinical decision rules: the guidelines of the Pediatric Emergency Care Applied Research Network (PECARN), and those of the Canadian Assessment of Tomography for Childhood Head Injury (CATCH)., METHODS: The study, which was designed as a prospective cohort study, sought to determine the appropriate CBT indications for children younger than 18 years who were referred to the emergency department with minor blunt head trauma. The effectiveness of PECARN and CATCH clinical decision rules, which are recommended by literature to be applied in order to diagnose severely injured patients and minimize inappropriate CBT requests, was investigated. All patients included in this study were younger than 18 years of age, were admitted to the study with an isolated blunt head trauma, had a GCS of > 13, and had parental permission to participate in the study. Patients ages 18 and older, those with penetrating head trauma or trauma to other systems, those with GCS <= 13, those with incomplete data, and those whose parents did not agree to participate in the study, were excluded., RESULTS: A total of 256 patients were included in the study. PECARN and CATCH rules were both shown to be statistically significant in detecting the presence of pathology ($p < 0.001$, $p = 0.002$, respectively). Overall, PECARN was more successful than CATCH in detecting intracranial pathology. The sensitivity of PECARN was 95 (95% CI 72-100%) and specificity was 53 (95% CI 47-60%), while the sensitivity of CATCH was 48 (95% CI 25-71%) and specificity was 83 (95% CI 79-88%). Multivariate regression analyses were performed on the parameters (low GCS, abnormal mental status, age, non-frontal hematoma) and other parameters (vomiting, headache, abnormal behavior according to parents) that were considered to be clinically significant despite having a p value of < 0.3. Age, low

GCS, and non-frontal hematoma presence were found to be significant in predicting the presence of pathology. In particular, low GCS increased the probability of pathology 5.94-fold and non-frontal hematoma presence 4.37-fold., CONCLUSION: While both PECARN and CATCH were found to be effective in determining the necessity of CBT for children with minor blunt head trauma, PECARN proved to be more useful for emergency services because of its higher sensitivity. The authors suggest that conducting a CBT scan based on clinical decision rules may be a suitable approach for early detection of the presence of intracranial acute pathologies in young children with minor blunt head trauma, especially if the GCS score is < 15 and non-frontal hematomas are present.

722. Bozic, K. (2009). "[Prophylactic use of antiepileptic drugs for posttraumatic epilepsy]." Medicinski pregled 62(11-12): 501-503.

The link between severe brain trauma and epilepsy in humans is well recognized Posttraumatic epilepsy is reported after 2-5% of closed head injuries but up to 50% or more following penetrating head injury. The control of "early seizures", i.e., those occurring hours or weeks after injury, is mandatory because those acute attacks may add secondary damage to the injured brain. Seizures occuring months or years after injury are called "late seizures". Recurring "late seizures" make up the clinical syndrome of "post-traumatic epilepsy". Prophylaris is the process of guarding against the development of a specific disease by action or treatment that affects pathogenesis. In animal "prophylaxis" by antiepileptic drugs seems efficacious in many experimental models including iron induced epilepsy which is considered a model of post-traumatic epilepsy. In the hunman being "prophylaxis" has been attempted by phenytoin, phenobarbital, carbamazepine and valproate but without any success. During the treatment period the occurrence of scizures is prevented but, after discontinuation of the drug, seizures occur just as in non treated patients. Although prevention of acute seizures that occur following head injury is a practical goal, such treatment is not likely to have a prophylactic effect against late development of epilepsy.

724. Braca, J., et al. (2012). "Ghost image extraction technique utilizing intraoperative angiography for the controlled removal of an intracranial nail." Journal of neurointerventional surgery 4: A60-A61.

Penetrating intracranial trauma via nail gun injury is becoming more common and differs significantly from the sequelae of penetrating cranial trauma of gunshot wounds. Safe, effective extraction techniques are therefore necessary and can employ intraoperative angiography (IA). An (IA) Ghost Image Extraction technique for safe removal of an intracranial nail is described here and can be applied to future such situations. A 32-year-old right-handed male with a history of multiple, non-operative closed-head injuries presented complaining of a 3 day history of right retro-orbital headache, blurry vision in his right eye, and C8 distribution parasthesias on the left forearm. CTrevealed a 6 cm nail lodged in the right posterior frontal lobe, with the distal tip pointing superior and medially, without evidence of intracranial hemorrhage along the tract. On more pointed questioning, the patient admitted to non-accidental trauma. On arrival to our facility, the patient was afebrile and without meningeal signs. He was neurologically intact with the exception of a subtle left pronator drift and decreased sensation to light-touch distally in the left C8 distribution. The patient went to the angiography suite for pre-operative vascular mapping prior to surgical extraction of the embedded nail. Four vessel cerebral angiography demonstrated the course of the major, distal branches and tributaries of the intracranial vessels and, miraculously, none were injured. Given the proximity of the nail to major intracranial vessels and elegant cortex, the consideration for safe, controlled extraction of the nail involved the use of IA. The five French sheath was left in place. In the operating room after curvilinear incision and appropriate exposure a double concentric craniotomy was performed around the head of the nail. At this point, with the assistance of intra-operative fluoroscopy and angiography, the nail was slowly and

carefully removed under direct visualization so as to remove it in the identical course of its entry to avoid further intracranial injury. The subtracted ghost image of the nail (Abstract E-035 figure 1) that appears with IA allows for control of the distal tip of the nail by extraction via the nail's entry path so as to avoid inadvertent laceration of a vessel or further injury to elegant cortex. Periodic angiographic images were obtained during the deliberate extraction to ensure no intracranial vessel injury had occurred. Post-operative CTrevealed a small hemorrhage in along the tract of the nail. The patient did well postoperatively. (Figure presented).

726. Bramlett, H. M., et al. (2016). "Erythropoietin Treatment in Traumatic Brain Injury: Operation Brain Trauma Therapy." Journal of neurotrauma 33(6): 538-552.

Experimental studies targeting traumatic brain injury (TBI) have reported that erythropoietin (EPO) is an endogenous neuroprotectant in multiple models. In addition to its neuroprotective effects, it has also been shown to enhance reparative processes including angiogenesis and neurogenesis. Based on compelling pre-clinical data, EPO was tested by the Operation Brain Trauma Therapy (OBTT) consortium to evaluate therapeutic potential in multiple TBI models along with biomarker assessments. Based on the pre-clinical TBI literature, two doses of EPO (5000 and 10,000 IU/kg) were tested given at 15 min after moderate fluid percussion brain injury (FPI), controlled cortical impact (CCI), or penetrating ballistic-like brain injury (PBBI) with subsequent behavioral, histopathological, and biomarker outcome assessments. There was a significant benefit on beam walk with the 5000 IU dose in CCI, but no benefit on any other motor task across models in OBTT. Also, no benefit of EPO treatment across the three TBI models was noted using the Morris water maze to assess cognitive deficits. Lesion volume analysis showed no treatment effects after either FPI or CCI; however, with the 5000 IU/kg dose of EPO, a paradoxical increase in lesion volume and percent hemispheric tissue loss was seen after PBBI. Biomarker assessments included measurements of glial fibrillary acidic protein (GFAP) and ubiquitin C-terminal hydrolase-L1 (UCH-L1) in blood at 4 or 24 h after injury. No treatment effects were seen on biomarker levels after FPI, whereas treatment at either dose exacerbated the increase in GFAP at 24 h in PBBI but attenuated 24-4 h delta UCH-L1 levels at high dose in CCI. Our data indicate a surprising lack of efficacy of EPO across three established TBI models in terms of behavioral, histopathological, and biomarker assessments. Although we cannot rule out the possibility that other doses or more prolonged treatment could show different effects, the lack of efficacy of EPO reduced enthusiasm for its further investigation in OBTT.

---

727. Branco, B. C., et al. (2017). "Increasing use of endovascular therapy in pediatric arterial trauma." Journal of vascular surgery 66(4): 1175-1183.e1171.

Background Endovascular therapy has been increasingly used for critically injured adults. However, little is known about the epidemiology and outcomes of endovascularly managed arterial injuries in children. We therefore aimed to evaluate recent trends in the endovascular management of pediatric arterial injuries and its association with early survival. Methods An 8-year analysis of the National Trauma Databank (2007-2014) was performed to extract all pediatric trauma patients (aged ≤16 years) with arterial injuries. Demographics, clinical data, interventions (endovascular vs open), and outcomes (in-hospital mortality and length of stay) were extracted. Patients undergoing endovascular or open procedures were compared for differences in clinical characteristics using bivariate analysis. Multivariable logistic regression analysis quantified the association between endovascular therapy and survival in the context of other variables predictive of survival on univariate analysis, with $\alpha \leq .05$. Results There were 35,771 pediatric patients available for analysis. Overall, there was a significant increase in the use of endovascular procedures (from 7.8% in 2007 to 12.9% in 2014; $P < .001$), particularly among blunt trauma patients (5.8% in 2007 to 15.7% in 2014; $P < .001$). Conversely, a

significant decrease was noted for open procedures (P <.001). There was a stepwise increase in the proportion of patients managed endovascularly as the Injury Severity Score (ISS) increased (highest in the ISS spectrum of 31-50). Angioembolization of internal iliac injury and thoracic aortic endograft placement were the two most common endovascular procedures (n = 88 [33.4%] and n = 60 [22.9%], respectively). There were 331 decedents (9.1% vascular injured children), 242 (73.1%) of whom were dead on arrival. After controlling for differences in demographics and clinical data, when outcomes were compared between patients who underwent endovascular and open procedures, there were no significant differences regarding in-hospital mortality (3.0% vs 3.6%; odds ratio, 0.7; 95% confidence interval, 0.1-6.1; P =.778). A logistic regression model identified Glasgow Coma Scale score ≤8, ISS ≥16, positive result of ethanol or drug screen, and systolic blood pressure <90 mm Hg on admission as independent risk factors for death. Conclusions The use of endovascular therapy in pediatric vascular arterial trauma has significantly increased, especially among severely injured blunt trauma patients. Despite this successful integration into care, there was no in-hospital survival advantage conferred by endovascular therapy compared with traditional open therapy. Approximately 10% of children with arterial injuries died during initial trauma assessment before therapy could be offered. Glasgow Coma Scale score ≤8, ISS ≥16, positive result of ethanol or drug screen, and systolic blood pressure <90 mm Hg on admission were identified as independent risk factors for death. As children are a population of vulnerable patients, long-term, multicenter studies are required to determine the most appropriate use of and indications for endovascular therapy in pediatric arterial trauma.

729. Brandi, G., et al. (2018). "Moderate hyperventilation of short duration does not change cerebral metabolism in patients with severe traumatic brain injury." Critical Care 22.

Introduction: Hyperventilation (HV) reduces elevated intracranial pressure (ICP) by changing autoregulatory functions connected to cerebrovascular CO2 reactivity. Criticism to HV is due to the possibility of developing cerebral ischemia and tissue hypoxia because of hypocapnia-induced vasoconstriction. We aimed to investigate the potential adverse effects of moderate HV of short duration in the acute phase in patients with severe traumatic brain injury (TBI), using concomitant monitoring of cerebral metabolism, continuous brain tissue oxygen tension (PbrO2), and cerebral hemodynamic with transcranial color-coded duplex sonography (TCCD). Methods: A prospective trial was conducted between May 2014 and May 2017 at the University Hospital of Zurich. Adults (>18 years), with non-penetrating TBI, first GCS < 9, ICP-monitoring, PbrO2 and/or microdialysis (MD)-probes were included within 36 hours after injury. Data collection and TCCD measurements took place at baseline (A), at the begin of moderate HV (PaCO2 4-4.7 kPa) (C), after 50 minutes of moderate HV (PaCO2 4-4.7 kPa) (D), and after return to baseline (E) (Fig. 1). Repeated measures ANOVA was used to compare variables at the different time points followed by post hoc analysis with Bonferroni adjustment as appropriate. P-value < .05 was considered significant. Results: Eleven patients were included (64% males, mean age 36 ± 14 years). First GCS was 7 (3-8: median and interquartile range). Data concerning PaCO2, ICP, PbrO2, mean flow velocity (MFV) in the middle cerebral artery, and MD values are presented in Table 1. During HV, ICP and MFV decreased significantly. PbrO2 presented a trend of reduction. Glucose, lactate and pyruvate did not change significantly (Table 2). Conclusions: Short episodes of moderate HV have a potent effect on the cerebral blood flow, as assessed by TCCD, reduce ICP and PbrO2, and do not induce significant changes in cerebral metabolism. (Table presented) (Figure presented).

730. Brandt, F., et al. (1983). "[Neurosurgical management of gunshot injuries to the head]." Die neurochirurgische Behandlung von Kopfschussverletzungen. 26(6): 164-171.

The article describes the pathophysiological mechanisms of injuries caused by shots in the head. In particular, the effect exercised on the cerebral tissue by the impact of rapid projectiles is explained. The review is based on 23 patients treated by the authors. These cases are discussed and critically assessed, using the results communicated in other papers as basis. The requisite surgical measures are considered; the need for effecting complete cleansing of the path of the bullet is viewed with some reserve.

732. Brandvold, B., et al. (1990). "Penetrating craniocerebral injuries in the Israeli involvement in the Lebanese conflict, 1982-1985. Analysis of a less aggressive surgical approach." Journal of neurosurgery 72(1): 15-21.

From June, 1982, through June, 1985, 113 patients were evacuated to Rambam Maimonides Medical Center with penetrating craniocerebral injuries sustained in ongoing military hostilities in Lebanon. Two factors distinguished this group of patients from those presenting in earlier conflicts: 1) this was the first large series in which computerized tomography (CT) was routinely used to initially evaluate combat head injuries; and 2) in an effort to preserve maximum cerebral tissue, intracranial debridement was significantly less vigorous than that advocated during the Korean or Vietnam conflicts. No efforts were made to locate or remove in-driven bone or metal fragments visualized on CT unless they readily presented themselves on gentle irrigation. In fact, it was elected to treat a number of patients without intracranial hematomas nonoperatively. The acute outcome was quite similar to that reported in Vietnam series in respect to both complications and mortality. Of the 83 survivors, 46 were Israeli citizens and thus were available for follow-up review. These 46 patients were reevaluated in late 1988, a mean follow-up period of 5.9 years. None had died in the interim; 10 had developed chronic seizure disorders, and there was one case of delayed meningitis in a patient with no retained fragments. Repeat CT scans were performed on 43 patients; 22 (51%) were found to have retained intracranial bone fragments. No relationship existed between the presence of retained fragments and the development of either a seizure disorder or an infection of the central nervous system. These findings suggest that not only is it unnecessary to reoperate for retained bone fragments, but it may also be possible to temper the initial debridement in an effort to preserve additional cerebral tissue.

733. Bratzke, H., et al. (1985). "[An unusual ability following a contact gunshot wound of the head]." Ungewohnliche Handlungsfahigkeit nach Kopfsteckschuss. 175(1-2): 31-39.

---

734. Brauer, M., et al. (2019). "[How many potential organ donors are there really? : Retrospective analysis of why determination of irreversible loss of brain function was not performed in deceased patients with relevant brain damage]." Wie viele potenzielle Organspender gibt es wirklich? : Retrospektive Analyse zu nichterfolgter Diagnostik des irreversiblen Hirnfunktionsausfalls bei verstorbenen Patienten mit relevanter Hirnschadigung. 68(1): 22-29.

BACKGROUND: No systematic study has previously been undertaken in Germany to ascertain why irreversible brain death determination (BDD) has not been carried out., OBJECTIVE: A comprehensive analysis of reasons for unperformed BDD in deceased patients with acute, severe brain damage could improve the identification of potential organ donors., METHOD: Using the Transplantcheck program of the German Organ Transplantation Foundation (DSO) an analysis of the data from 2016 was undertaken in participating hospitals in Saxony, Saxony-Anhalt and Thuringia (Region East of the DSO), regarding why a BDD was not initiated in deceased patients with primary or secondary brain damage., RESULTS: In 128 of the 144 Region East hospitals, 7889 deceased patients

with primary or secondary brain damage were detected. In 7389 patients a BDD was out of the question for a variety of reasons. In 232 patients organ donation was not considered due to an advance directive. In 195 cases treatment was limited based on the patient's infaust neurological prognosis without the possibility of organ donation being discussed with relatives. In 73 cases initiation of BDD was indicated but not performed., CONCLUSION: The number of potential organ donors in Region East of the DSO could be significantly increased by identifying patients where BDD is indicated. By consistent evaluation of patients' wills in terms of organ donation before treatment is withdrawn in patients with poor neurological prognosis, additional potential organ donors could be identified. Furthermore, involving neurointensive care physicians in the care of all patients with brain damage could improve the prognostic assessment.

736. Braun, T., et al. (2015). "[Near-infrared spectroscopy for the detection of traumatic intracranial hemorrhage: Feasibility study in a German army field hospital in Afghanistan]." Nahinfrarotspektroskopie zur Detektion intrakranieller traumatischer Hirnblutungen: Praktikabilitatsstudie in einem Bundeswehrrettungszentrum in Afghanistan. 118(8): 693-700.

Traumatic brain injury (TBI) is one of the most common causes of death in ordinary accidents, natural disasters, or warfare. The gold standard for diagnosis of TBI is the CT scan; a delay of diagnostics or medical care is the strongest independent predictor of mortality of TBI patients--particularly in the case of a surgically treatable intracranial hematoma. The proper classification of these patients is of major importance in situations where a CT is not accessible. A portable screening device that uses near-infrared spectroscopy (NIRS) technology allows a preliminary estimate of an intracranial hematoma. This study assessing practicability shows that the use of the device in a military medical rescue center (Kunduz, Afghanistan) is easy to learn and can be repeatedly used even under emergency room conditions. The technique can be applied in penetrating and blunt TBIs in the absence of an immediately available CT scan in rural areas, preclinically, under mass casualty conditions (e.g., in disaster situations) as well as in humanitarian crises or war zones. Nevertheless, further studies to assess the validity of this device are necessary.

737. Braun, U. (2009). "Traumatic pericarditis in cattle: clinical, radiographic and ultrasonographic findings." Veterinary journal (London, England : 1997) 182(2): 176-186.

Pericarditis is an inflammation of the pericardium with accumulation of serous or fibrinous inflammatory products. In cattle, it is almost always attributable to a reticular foreign body that has penetrated the reticular wall, diaphragm and pericardial sac. The lead signs of pericarditis are tachycardia, muffled heart sounds, asynchronous abnormal heart sounds, distension of the jugular veins and submandibular, brisket and ventral abdominal oedema. The glutaraldehyde test is an important diagnostic tool because it is positive in >90% of affected cattle. Other common laboratory findings are leukocytosis and hyperfibrinogenaemia (indicating inflammation), and elevation of liver enzyme activity (reflecting hepatic congestion). Radiographs of the thorax and reticulum often show a foreign body cranial to the reticulum. In the majority of cases, massive fibrinopurulent adhesions obscure the cardiophrenic angle, cardiac silhouette and ventral diaphragm. Ultrasonography is the method of choice for diagnosis and characterisation of pericardial effusion. Echogenic deposits and strands of fibrin are seen on the epicardium, and the ventricles are compressed by the effusion. Severe pleural effusion is usually evident. In cattle with distension of the jugular veins and tachycardia, the differential diagnosis includes right-sided cardiac insufficiency attributable to other causes. Distension of the jugular veins without signs of right-sided cardiac insufficiency may occur with obstruction or compression of the cranial vena cava. The prognosis is poor, and pericardiocentesis or pericardiotomy are inadequate

methods of treatment. Thus, prompt and humane euthanasia is indicated for cattle with traumatic reticuloperitonitis. Because a definitive diagnosis of traumatic reticuloperitonitis is not always possible based on clinical signs alone, radiography and ultrasonography of the thorax and reticulum are indicated in doubtful cases.

738. Brauner, E., et al. (2022). "Dental Management of Maxillofacial Ballistic Trauma." Journal of Personalized Medicine 12(6).

Maxillofacial ballistic trauma represents a devastating functional and aesthetic trauma. The extensive damage to soft and hard tissue is unpredictable, and because of the diversity and the complexity of these traumas, a systematic algorithm is essential. This study attempts to define the best management of maxillofacial ballistic injuries and to describe a standardized, surgical and prosthetic rehabilitation protocol from the first emergency stage up until the complete aesthetic and functional rehabilitation. In low-velocity ballistic injuries (bullet speed <600 m/s), the wound is usu-ally less severe and not-fatal, and the management should be based on early and definitive surgery associated with reconstruction, followed by oral rehabilitation. High-velocity ballistic injuries (bul-let speed >600 m/s) are associated with an extensive hard and soft tissue disruption, and the management should be based on a three-stage reconstructive algorithm: debridement and fixation, re-construction, and final revision. Rehabilitating a patient with ballistic trauma is a multi-step chal-lenging treatment procedure that requires a long time and a multidisciplinary team to ensure suc-cessful results. The prosthodontic treatment outcome is one of the most important parameters by which a patient measures the restoration of aesthetic, functional, and psychological deficits. This study is a retrospective review: twenty-two patients diagnosed with outcomes of ballistic traumas were identified from the department database, and eleven patients met the inclusion criteria and were enrolled.

739. Brawman-Mintzer, O., et al. (2016). "Rivastigmine transdermal patch treatment for moderate to severe cognitive impairment in veterans with traumatic brain injury: a double-blind, placebocontrolled multicenter study (RiVET Trial)." Neuropsychopharmacology 41: S211.

Background: Traumatic brain injury (TBI) represents one of the most significant health risks related to military duty. Even in peacetime, military personnel have higher rates of TBI than civilians with the risk of TBI increasing significantly during war-time. Since 2000, 348,000 service members were diagnosed with TBI. The most common injuries inflicted in the conflicts in Afghanistan and Iraq are caused by improvised explosive devices (IEDs), rocket propelled grenades, and land mines, with approximately 60% of blasts to which military personnel are exposed resulting in brain injuries. Not surprisingly, TBI is often called the “signature wound” of the Iraq and Afghanistan wars. With the improvement in acute care provided to these patients, treatment of long-term sequelae of TBI is paramount. Despite significant variation in the severity of TBI, data consistently indicate deficits in cognitive functions such as memory, attention, speed of information processing, and executive functions among these individuals. Approximately 10-15% of people with mild TBI have persistent cognitive and behavioral complaints, and 65% of those with moderate to severe TBI experience long-term cognitive difficulties. It is well recognized that cognitive impairment is one of the most debilitating consequences for individuals who attempt to fully function in society. Research findings both in animal models and humans suggest that cholinergic function is chronically deficient among subjects with TBI, and that cholinergic deficits may be a significant contributor to post-traumatic cognitive impairments-particularly memory impairments. As such, cholinergic deficits may be a useful target for the pharmacotherapy of TBI-related cognitive impairments. However, despite recommendations by VA-sponsored consensus groups advocating the use of cholinesterase inhibitors in the treatment of posttraumatic memory deficits in Veterans with TBI, no standard for pharmacological treatment of memory impairments among Veterans with TBI has been established. Herein we will present the first multicenter clinical trial, conducted in five VA Medical Centers, evaluating the efficacy and safety of rivastigmine transdermal patch, an intermediate-acting cholinesterase inhibitor, in Veterans suffering from moderate to severe

posttraumatic memory impairment following TBI. Methods: This is the first phase II, randomized, multi-site, double-blind, placebo-controlled 12-week trial evaluating the effect on cognition and the safety of rivastigmine 9.5 mg/24 hours (10cm2) transdermal patch in Veterans with closed, non-penetrating TBI who present with moderate to severe memory impairment (NCT01670526). The study consisted of a one-week single-blind, placebo run-in phase, and a 12-week double-blind acute treatment phase (Phase I). During this phase, there was an initial 4-week titration period (5cm2 patch for 4 weeks increased to 10 cm2 patch thereafter) followed by an 8-week continuation phase. Following the 12-week acute treatment phase, participants continued in the double-blind phase (Phase II) for an additional 14 weeks or until study treatment period ended. Participants were Veterans with a history of closed head trauma(s) (non-penetrating) at least 12 months prior to study enrollment, based on ICD 9 CM diagnosis code 854.0, and who met or exceeded modified ACRM criteria for mild TBI as determined by TBI diagnostic assessment. Participants were required to have a deficit in verbal memory, as assessed by the Total Recall index (Trials 1-3) of the Hopkins Verbal Learning Test, Revised (HVLT-R). Persistent cognitive deficit was defined as a Total Recall index (Trials 1-3) that is at least 20% lower than an intelligence-adjusted “expected score,” based on the WAIS-IV Information and Vocabulary subtests. Participants who exhibited invalid data on cognitive testing utilizing TOMM and MSVT were excluded. The primary outcome variable was defined as the proportion of responders who had at least 5-word improvement on HVLT-R Trials 1-3. Secondary outcomes inclu ed PASAT, COWAT, Digit Span and Letter-Number Sequencing subtests of WAIS-IV, Trail Making, BVMT-R, Q-LES-Q, SDS, NFI, PCL-M, BDI-II, University of California San Diego Performance-Based Skills Assessment (UPSA-B), CGI, CSSRS and treatment-emergent adverse events. Results: Ninety-six participants were randomized. The last study participant visit occurred on May 25, 2016. Database lock occurred on July 6, 2016. Demographic characteristics of study sample include: mean age 40.7 years; 95.7% males; 68.1% Caucasian. Baseline mean HVLT-R Total Recall index was 20.0, corresponding to severe impairment (2nd percentile compared to HVLT-R normative sample) for the participants' mean age. Study codes have not been broken; pre-planned statistical analyses will be completed by September 26, 2016 and presented at the meeting. Conclusions: This trial provides the largest dataset to date of Veterans with TBI and posttraumatic memory deficits enrolled in a pharmacological clinical trial. Its results will lead to a better understanding of the role that rivastigmine transdermal patch could play in the care of these patients.

---

740. Brawman-Mintzer, O., et al. (2021). "Rivastigmine Transdermal Patch Treatment for Moderate to Severe Cognitive Impairment in Veterans with Traumatic Brain Injury (RiVET Study): A Randomized Clinical Trial." Journal of neurotrauma 38(14): 1943-1952.

Cognitive impairment is common in veterans with histories of traumatic brain injury (TBI). Cholinergic deficits have been hypothesized as contributors to this impairment. We report the effects of cholinesterase inhibitor rivastigmine transdermal patch treatment in veterans with TBI and post-traumatic memory impairment. Our objective was to evaluate the efficacy and safety of a 9.5 mg/24 h (10 cm2) rivastigmine patch in veterans of military conflicts with persistent moderate to severe memory impairment at least 12 weeks after TBI. This randomized, outpatient, double-blind, placebo-controlled 12-week trial with an exploratory double-blind phase of an additional 14 weeks was conducted at 5 VA Medical Centers, among veterans with closed, non-penetrating TBI who met or exceeded modified American Congress of Rehabilitation Medicine criteria for mild TBI with verbal memory deficits, as assessed by the Hopkins Verbal Learning Test, Revised (HVLT-R). Patients were randomized 1:1 to rivastigmine or matching placebo patches after a 1-week single-blind, placebo run-in phase. At randomization, patients received 4.6 mg/24 h rivastigmine patches or matching placebo increased to a 9.5 mg/24 h patch after 4 weeks. The primary efficacy outcome measure was the proportion of participants who had at least a five-word improvement on the HVLT-R Total Recall Index (Trials 1-3). A total of 3671 participants were pre-screened, of whom 257 (7.0%) were screened; 96 (37%) randomized, and 94 included in study analyses. Responder rates were 40.8% (20 of 49) and 51.1% (23 of 45) in the rivastigmine and placebo groups, respectively (p = 0.41). A mixed-effect model including

treatment, time, and treatment-by-time interaction indicated no significant difference in treatment effect over time between the groups (p = 0.24). Overall, there were no significant differences in changes for all secondary outcomes between the rivastigmine and placebo groups. The most commonly observed adverse events were application site reactions. This trial provides the largest sample to date of veterans with TBI and post-traumatic memory deficits enrolled in a pharmacological trial. Trial Registration: clinicaltrials.gov Identifier: NCT01670526.

741. Brazeau, J. and R. K. Wong (1997). "Analysis of gunshot residues on human tissues and clothing by X-ray microfluorescence." Journal of forensic sciences 42(3): 424-428.

The analysis of gunshot residues on human tissues and clothing in suicide, homicide, suspicious death, or attempted murder events, permits the forensic scientist to confirm the possibility of an entry wound caused by a gunshot bullet from a pistol, revolver, rifle, etc. The residues to be detected are lead (Pb), antimony (Sb), barium (Ba) usually from the primer, copper (Cu) and zinc (Zn) usually from the metal jacket bullet and iron (Fe) possibly from the barrel of the gun used. The presence or absence of these elements and their relative concentrations can help in the interpretation of the event.

742. Breeze, J. and D. B. Powers (2020). "Current opinion in the assessment and management of ballistic trauma to the craniomaxillofacial region." Current opinion in otolaryngology & head and neck surgery 28(4): 251-257.

PURPOSE OF REVIEW: Ballistic trauma represents a small proportion of injuries to the craniomaxillofacial (CMF) region, even in societies where the availability of firearms is more prevalent. The aim of this article is to review current opinion in the assessment and management of ballistic injuries sequentially from primary survey to definitive reconstruction., RECENT FINDINGS: For mandibular fractures because of ballistic trauma, load-bearing fixation remains the mainstay in the treatment. The use of load sharing fixation is rarely advised, even if the fracture pattern radiologically appears to fulfil the traditional indications for its use. Clinicians must be aware of specific situations in early internal fixation is contraindicated, particularly in those unstable patients requiring short damage control surgical procedures, avulsive soft and hard tissue defects and those injuries at increased risk of infection., SUMMARY: Staged surgery for complex injuries is increasingly becoming accepted, by which injuries are temporarily stabilized by means of maxillary--mandibular fixation (MMF) or an external fixation. Patients are subsequently repeat CT-scanned, and definitive internal fixation performed a few days later. Increased access to virtual surgical planning (VSP) and three-dimensional plates has revolutionized fracture reconstruction.

---

743. Breeze, J., et al. (2022). "Physiological and radiological parameters predicting outcome from penetrating traumatic brain injury treated in the deployed military setting." BMJ military health.

INTRODUCTION: Penetrating traumatic brain injury (TBI) is the most common cause of death in current military conflicts, and results in significant morbidity in survivors. Identifying those physiological and radiological parameters associated with worse clinical outcomes following penetrating TBI in the austere setting may assist military clinicians to provide optimal care., METHOD: All emergency neurosurgical procedures performed at a Role 3 Medical Treatment Facility in Afghanistan for penetrating TBI between 01 January 2016 and 18 December 2020 were analysed. The odds of certain clinical outcomes (death and functional dependence post-discharge) occurring following surgery were matched to existing agreed preoperative variables described in current US and UK military guidelines. Additional physiological and radiological variables including those comprising the Rotterdam criteria of TBI used in civilian settings were additionally analysed to determine their potential utility in a military austere setting., RESULTS: 55 casualties with penetrating TBI underwent surgery, all either by decompressive craniectomy (n=42) or craniotomy+/-elevation of skull fragments (n=13). The odds of dying in hospital attributable to TBI were greater with casualties with increased glucose on arrival

(OR=70.014, CI=3.0399 to 1612.528, OR=70.014, p=0.008) or a mean arterial pressure <90 mm Hg (OR=4.721, CI=0.969 to 22.979, p=0.049). Preoperative hyperglycaemia was also associated with increased odds of being functionally dependent on others on discharge (OR=11.165, CI=1.905 to 65.427, p=0.007). Bihemispheric injury had greater odds of being functionally dependent on others at discharge (OR=5.275, CI=1.094 to 25.433, p=0.038)., CONCLUSIONS: We would recommend that consideration of these three additional preoperative clinical parameters (hyperglycaemia, hypotension and bihemispheric injury on CT) when managing penetrating TBI be considered in future updates of guidelines for deployed neurosurgical care.

744. Brenke, C., et al. (2013). "Surgical management of basilar artery laceration caused by transorbital penetrating injury: case report." Journal of neurological surgery. Part A, Central European neurosurgery 74 Suppl 1: e239-241.

Transorbital penetrating injuries are rare and present with a heterogeneity of intracranial injury patterns that require individualized therapeutic procedures. In this report, we describe the case of a distal basilar artery laceration in a 16-month-old boy caused by accidental transorbital penetration with a pencil. Surgical removal of the pencil was performed, but hemostasis could only be achieved by clipping the impaired vessel. Adequate diagnostics and an individualized surgical strategy are necessary to deal with these life-threatening injuries.

745. Brennan, J. (2013). "Head and neck trauma in Iraq and Afghanistan: different war, different surgery, lessons learned." The Laryngoscope 123(10): 2411-2417.

OBJECTIVES/HYPOTHESIS: The objectives are to compare and contrast the head and neck trauma experience in Iraq and Afghanistan and to identify trauma lessons learned that are applicable to civilian practice., STUDY DESIGN: A retrospective review of one head and neck surgeon's operative experience in Iraq and Afghanistan was performed using operative logs and medical records., METHODS: The surgeon's daily operative log book with patient demographic data and operative reports was reviewed. Also, patient medical records were examined to identify the preoperative and postoperative course of care., RESULTS: The head and neck trauma experiences in Iraq and Afghanistan were very different, with a higher percentage of emergent cases performed in Iraq. In Iraq, only 10% of patients were pretreated at a facility with surgical capabilities. In Afghanistan, 93% of patients were pretreated at such facilities. Emergent neck exploration for penetrating neck trauma and emergent airway surgery were more common in Iraq, which most likely accounted for the increased perioperative mortality also seen in Iraq (5.3% in Iraq vs. 1.3% in Afghanistan). Valuable lessons regarding soft tissue trauma repair, midface fracture repair, and mandible fracture repair were learned., CONCLUSION: The head and neck trauma experiences in Iraq and Afghanistan were very different, and the future training for mass casualty trauma events should reflect these differences. Furthermore, valuable head and neck trauma lessons learned in both war zones are applicable to the civilian practice of trauma., LEVEL OF EVIDENCE: Level 4.

---

746. Brenner, L. A., et al. (2009). "Self-inflicted traumatic brain injury: Characteristics and outcomes." Brain injury 23(13-14): 991-998.

OBJECTIVE: To characterize the population of those receiving inpatient rehabilitation who sustained a traumatic brain injury (TBI) secondary to a suicide attempt and identify differences between such individuals and a demographically-matched control group (n = 230) of those whose TBIs were of an unintentional aetiology., METHOD: Analysed cases were identified from the TBI Model Systems National Database. Based on ICD-9-CM external cause-of-injury codes, 79 participants incurred a TBI secondary to a suicide attempt. An approximate 1 : 3 matched case-control (age, gender, race, injury

year) design was chosen to make statistical comparisons., RESULTS: Those who sustained a TBI secondary to a suicide attempt had greater pre-existing psychiatric and psychosocial problems (substance use problems ($p = 0.01$) prior suicide attempt ($p < 0.0001$), psychiatric hospitalization ($p = 0.014$) and non-productive activity ($p = 0.014$)), required more resources during acute and rehabilitative hospitalizations (i.e. charges per day; $p = 0.024$, $p = 0.047$) and had greater disability at the time of discharge, even after controlling for injury severity ($p = 0.022$)., CONCLUSION: Individuals who sustained TBIs secondary to a suicide attempt had increased pre-injury psychiatric and psychosocial problems and poorer outcomes at discharge than those who incurred unintentional injuries. For these individuals, acute and rehabilitation charges per day were higher and could not be accounted for by injury severity.

747. Brent, A. J., et al. (2017). "A new cause of lacrimal gland calcification: Retained metallic foreign bodies." Orbit (Amsterdam, Netherlands) 36(2): 118-121.

A 49-year-old male presented with a 4 month history of dysaesthesia in the left periorbital region. A CT scan showed a lacrimal gland mass with areas of dense calcification. Biopsies of the left lacrimal gland revealed a silver material with associated chronic granulomatous inflammation and secondary calcification. The histological specimen was sent for X-ray microanalysis. This confirmed the silver material to be aluminium. The metal fragments were subsequently discovered to be from a car aerial, which caused an orbital impaling injury 20 years prior to presentation. This is the first reported case of lacrimal gland calcification secondary to chronic metal foreign body exposure. The case is presented alongside literature reviews of lacrimal gland calcification and associated radiological findings.

---

749. Breslau, J., et al. (1995). "Phased-array surface coil MR of the orbits and optic nerves." AJNR. American journal of neuroradiology 16(6): 1247-1251.

PURPOSE: To devise a practical technique for high-resolution evaluation of the anterior optic apparatus using a phased-array surface coil system, and to evaluate this system in patients with suspected optic pathway abnormalities., METHODS: A four-element phased-array coil pair was placed on each side of the head, and signal-to-noise measurements were obtained using a head phantom. Comparison between the phased-array coil, the quadrature coil, and a single-turn 12.7-cm (5-in) surface coil was done. T1 spin-echo and T2 fast spin-echo sequences were obtained in the oblique axial and oblique sagittal planes, to approximate the long axis of the optic nerves and the nonoblique coronal plane., RESULTS: The phantom signal-to-noise measurements at simulated locations of the optic nerve head, optic canal, and optic chiasm revealed an improvement of at least 30% using the phased-array system. Of 24 imaged cases, 9 had trauma, 5 had suspected neoplasms, and 2 had optic neuritis. In 3 patients, an unexpected diagnosis of optic pathway contusion or infarction was made. The remaining 8 patients had various suspected visual pathway lesions., CONCLUSION: Phased-array surface coils allow rapid, thin-section imaging of the entire anterior optic pathway, with improved signal-to-noise ratio. This may improve evaluation of optic pathway lesions over conventional techniques.

750. Briceño, F., et al. (2013). "Evaluation of temporomandibular joint total replacement with alloplastic prosthesis: Observational study of 27 patients." Craniomaxillofacial Trauma and Reconstruction 6(3): 171-178.

Background: Temporomandibular joint (TMJ) total replacement with alloplastic prostheses has been performed since 1960s. Research in these last two decades has achieved important improvement in

the development of biomaterials, design, adaptation, and fixation of the prosthesis components. Objective: To evaluate total TMJ replacement with alloplastic prostheses. Methods: We studied 27 patients, between 19 and 73 years old, who had total TMJ uni- or bilateral replacement surgery with custom-made alloplastic prostheses manufactured by TMJ Concepts, Inc. (Ventura, CA) between 1996 and 2011. The general data and preoperative measurements were taken from medical records. Subjective data related to pain, diet consistency, and current quality of life were collected with a questionnaire answered by the patients; measures of maximum interincisal opening and lateral mandibular movements were obtained from direct examination. Results: We found significant difference ($p < 0.05$) comparing pre- to postoperative results about improvement in mouth opening, pain relief, and satisfaction with the surgery and diet consistency. Conclusion: The results of this study show that total alloplastic TMJ prostheses are an efficient, safe, and stable long-term solution for patients who need TMJ total replacement.

751. Brickell, T., et al. (2017). "The relationship between perceived burden and health-related quality of life in caregivers of military service members with traumatic brain injury." Brain injury 31(6-7): 888-889.

Background: Family members often assume the role of 'caregiver' and bear primary responsibility for assisting a service member (SM) with long-term physical, emotional and social care following a traumatic brain injury (TBI). The purpose of this study was to examine the influence of self-reported caregiver burden on overall health-related quality of life in caregivers of military SMs who have sustained a TBI. Methods: Participants were 85 caregivers (female = 96.1%) of US military SMs who sustained a penetrating, severe, moderate or mild TBI. Caregivers were recruited from multiple DoD Medical Treatment Facilities nationwide and by using community outreach initiatives and social media. The mean age of the sample was 39.8 years (SD = 8.2) and the mean number of years caregiving was 5.5 years (SD = 3.0). The majority of the sample was Caucasian (95.3%) and caring for a spouse/partner (88.2%). Participants completed 12 sub-scales from the Patient-Reported Outcomes Measurement Information System (PROMIS), four sub-scales from the TBI-Caregiver Quality of Life (TBI-CareQOL) scale, and the Caregiver Appraisal Scale (CAS). Using the CAS, the sample was divided into three Caregiver Burden groups: High Burden (n = 40); Neutral Burden: (n = 35); Low Burden: (n = 10). Results: There were significant differences across the three Caregiver burden groups on all 16 measures ($p = .001$ to $p < .001$). Pairwise comparisons revealed significant differences ($p < .05$) and large to very large effect sizes for the vast majority of measures/comparisons. For all measures, higher caregiver burden was consistently and significantly associated with worse overall functioning (i.e. High > Neutral > Low). The largest effect sizes were found when comparing High vs. Low burden groups (d = 1.24-2.90), followed by Neutral vs. Low (d=.79-2.16), and High vs. Neutral (d=.44-1.26) groups. Using a series of regression analyses to determine whether CAS-Perceived Burden total scores could predict each of the 16 measures separately, caregiver burden was a significant predictor of all measures (all ps<.001). Those measures accounting for the highest variance were TBI-CareQOL Feelings of Loss (58.3%), followed by TBI-CareQOL Caregiver Strain (51.9%), TBI-CareQOL Feeling Trapped (45.1%), PROMIS Anxiety (42.7%), TBI-CareQOL Specific Anxiety (42.9%), PROMIS Ability to Participate in Social Roles and Activities (39.6%), and PROMIS Global Health- Mental Health (38.8%). When combined, these variables account for 70.8% of the variance towards the prediction of CAS-Perceived Burden total scores. Conclusions: These results suggest that high caregiver burden is associated with a substantial decline in overall physical, mental and social functioning (i.e. anger, general anxiety, caregiver worry, depression, fatigue, poor sleep, stress/strain, social isolation, social dissatisfaction, feelings of being trapped, feelings of grief and loss, and a lack of emotional and informational support). Given that almost half of this sample reported high caregiver burden (i.e. 47.1%), there is an urgent need to increase attention and resources to help this underserved population.

---

752. Brickell, T., et al. (2017). "Post-9/11 family caregivers: examining the characteristics and perceived burden of family members who care for U.S. military service members following traumatic brain injury." Journal of Head Trauma Rehabilitation 32(6): E71-E72.

Introduction/Rational Little is known about the effect of caring for a service member (SM) following traumatic brain injury (TBI) on the post- 9/11 family caregiver. The purpose of this study was to characterize the post-9/11 family caregiver providing care to a SM following TBI and to examine caregiver burden. Method/Approach Participants were 226 caregivers (female = 73.3%) of U.S. military SMs who sustained a mild-severe, or penetrating TBI. The majority were caring for a spouse/partner (89.4%) and had one or more dependent children under the age of 18 years (72.6%; M = 2.3 children, SD = 1.3, range = 1-7). The mean age was 38.6 years (SD = 9.9; range = 20-70) and the mean number of years caregiving was 4.9 years (SD = 2.7; range = 1.1-16.9 years). Caregivers were recruited through community outreach and atWalter Reed National Military Medical Center (Maryland) and Naval Medical Center San Diego (California). Participants completed the Caregiver Appraisal Scale (CAS) and a questionnaire designed for this study. Results/Effects Caregivers typically provided help with physical, medical, self-awareness, cognitive, psychological, social interaction, communication, daily activities, and financial problems (77- 99%), 7 days/week (87%), 11-24 hours/day (52%). Many caregivers rated their emotional (55%) and medical health (39%) as fair/poor; and had experienced some financial loss from caregiving (62%). Caregivers who reported that their responsibilities were a high burden on their lives (66%) were more likely to provide help with physical, social, communication, and financial problems; spend more time in an active caregiver role (i.e., 7 days/week, 11+ hours/day); and rated their physical and mental health as fair/poor (p's < .046). Conclusions/Limitations Caregiving for a SM following TBI can place a significant emotional, personal, financial, and/or health-related burden on the caregiver. While the importance of providing care for an injured SM is routinely acknowledged, it is also critical that similar care is provided to family members who adopt the caregiver role.

---

753. Brickell, T., et al. (2017). "The influence of traumatic brain injury severity on health-related quality of life in caregivers of a service member or veteran with traumatic brain injury." Brain injury 31(6-7): 863-864.

Background: Little is known about the effect of TBI severity on the family member providing care to a service member or veteran (SMV) following a TBI. Objective: The purpose of this study was to examine the impact of TBI severity on the family caregiver's health-related quality of life (HRQOL) for those providing care to a SMV following a TBI. Methods: Participants were 31 caregivers (90.3% female; 71% spouse; age: M = 39.8 years, SD = 10.6) of SMVs who had sustained an equivocal (n = 9), mild (n = 11), moderate (n = 3), severe (n = 3) or penetrating (n = 5) TBI during a combat or non-combat incident. Caregivers were recruited through community outreach initiatives and multiple DoD Medical Treatment Facilities nationwide. Caregiver's participated in one of six focus groups (approx. 90 mins) designed to elicit information regarding HRQOL and access to services. Caregivers were classified into three groups based on the SMV's TBI severity: (a) equivocal, (b) mild and (c) modsevere/ penetrating TBI. Thematic analysis using a constant comparative approach was conducted with qualitative analysis software to identify common themes across the three severity groups. Results: The most commonly endorsed themes for all caregivers were poor physical health (80.7%), having no time for themselves (71.0%) and increased stress/anxiety (64.5%). When stratified by TBI severity group, a greater proportion of the mod-severe/penetrating TBI group reported having no time for themselves (100%) and increased stress/anxiety (100%), compared to the equivocal TBI (55.6% for both themes) and mild TBI groups (54.6% and 36.4%, respectively). Similarly, a greater proportion of the mod-severe/penetrating TBI group reported being depressed (45.5%), exhausted (45.5%), having poor sleep (81.8%) and negative impacts on family life (63.6%), compared to the equivocal TBI (22.2%, 11.1%, 11.1% and 22.2%, respectively) and mild TBI groups (27.3%, 18.2%, 18.2% and 9.1%, respectively). Approximately one-quarter (25.8%) of all caregivers reported a lack of access to services (e.g., health care/support groups). However, a lack of access to services was predominantly reported by the equivocal TBI group (66.7%) when compared to the mild TBI (18.2%) and mod-severe/penetrating groups (0%).

Conclusions: These results suggest that reduced HRQOL (e.g., depression, stress, exhaustion, poor sleep and negative effects on family life) is commonly reported among family caregivers providing care to SMVs following a TBI. Although worse overall HRQOL was associated with caring for a SMV who had sustained a TBI in the higher end of the severity spectrum, some caregivers of SMVs with less severe injuries are also at risk of poor HRQOL. While the importance of providing care for an injured SMV is routinely acknowledged, it is also critical that similar care is provided to family members who adopt the caregiver role. These preliminary results demonstrate a need to increase healthcare provision for family members who care for injured SMVs.

---

754. Brickell, T., et al. (2017). "The influence of caregiver burden on health status and perceived role efficacy in caregivers of US military service members with traumatic brain injury." Brain injury 31(6-7): 886.

Background: Following a traumatic brain injury (TBI), some family members assume the role of 'caregiver' for their loved one who is injured. Caregivers often experience significant burden from the demands placed on them in this role. The purpose of this study was to examine the influence of caregiver burden on overall health status and perceived efficacy of functioning in caregivers of US military service members (SMs). Methods: Participants were 283 caregivers (female = 96.1%) of SMs who sustained a mild-severe or penetrating TBI. The majority of the sample was Caucasian (92.6%) and was caring for a spouse/partner (86.2%). The mean age was 38.7 years (SD = 10.3) and the mean number of years of caregiving was 4.1 years (SD = 2.9). Caregivers were recruited through community outreach initiatives and from multiple DoD Medical Treatment Facilities nationwide. Participants completed the Caregiver Appraisal Scale (CAS) and the SF-36v2 Health Survey (SF36) that included 11 measures of interest. The sample was divided into three Caregiver Burden groups using the CAS-Perceived Burden scale: High (n = 138); Neutral (n = 106); Low (n = 139). Results: The percentage of participants who reported that their caregiving duties were a high burden was 48.8%. Caregiver burden was not associated with age (p =.779), number of years of caregiving (p =.924), or time post injury (p =.317). Using ANOVA, there was a significant main effect across the three Caregiver Burden groups on all 11 CAS and SF36 subscales (p =.010 to p <.001). Pairwise comparisons revealed a significant linear relation between caregiver burden and outcome on 7 of the 11 measures (all ps <.05; i.e. High > Neutral > Low). As caregiver burden increased, there were increasingly worse scores on the SF36 Role Physical (d=.44-1.02), SF36 General Health (d=.51-1.03), SF36 Vitality (d=.66-1.44), SF36 Social Function (d=.54-1.31), SF36 Role Emotional (d=.53-1.15), SF36 Mental Health (d=.64-1.40), and CAS Caregiver Mastery (d=.33-.91) scales. In addition, participants in the High Burden group had significantly worse scores (all p <.05) on the SF36 Physical Functioning (d = 40 and .51), SF36 Bodily Pain (d=.64 and .82) and CAS Caregiver Satisfaction (d=.61 and .82) scales compared to the Neutral Burden and Low Burden groups (i.e. High > Neutral & Low). Using Stepwise Regression Analysis, the SF36 Social Functioning, SF36 Vitality, CAS Caregiver Satisfaction, and CAS Caregiver Mastery scales were significant predictors (p <.001) of CAS Caregiver Burden total scores, accounting for 43.3% of the variance. Conclusions: In this sample, there was a strong linear relation between increased perceived burden and (a) poor overall health status, and (b) negative self-appraisal of their efficacy as a caregiver. These findings suggest that many caregivers may benefit from training programmes designed to increase their caregiving skills in addition to increased support allowing them time to improve their physical, mental and social functioning.

---

755. Brickell, T. A., et al. (2018). "Burden among caregivers of service members and veterans following traumatic brain injury." Brain injury 32(12): 1541-1548.

OBJECTIVES: To determine the (a) health status and caregiving appraisal and (b) influence of perceived burden on health and appraisal in a sample of caregivers helping service member/veterans (SMVs) following a traumatic brain injury (TBI)., METHODS: Participants were caregivers (N = 283, female = 96.1%, 86.2% = spouse/partner) of SMVs who sustained a mild-severe or penetrating TBI.

Participants completed the Caregiver Appraisal Scale (CAS) and the SF-36v2 Health Survey (SF-36v2). Participants were divided into three burden groups: high, neutral, and low., RESULTS: Almost half the sample (48.8%) reported negative feelings on the CAS Perceived Burden scale. A substantial proportion had lower scores than a normative sample on four SF-36v2 physical health scales (35.1-64.5%) and four mental health scales (70.7-79.8%). A significant main effect was found across caregiver burden groups on three CAS scales ($p = 0.010$ to $p < 0.001$), two SF-36v2 component scores (all ps < 0.001), and eight SF-36v2 scales ($p = 0.001$ to $p < 0.001$). Caregivers with high perceived burden reported significantly worse scores, except CAS Caregiving Ideology. All CAS and SF-36v2 scales were significant predictors of CAS Perceived Burden scores (all ps< 0.001), with the SF-36v2 Social Functioning scale accounting for the most variance (32.6%)., CONCLUSIONS: Health care and social services are needed for caregivers who help SMVs to foster resilience, wellness, and growth.

757. Brierley, J. K., et al. (1991). "Diagnostic and management dilemmas in a patient with tracheal trauma." British journal of anaesthesia 66(6): 724-727.

A patient with a foreign body penetrating the neck and chest was found to have physical signs which were consistent with serious tracheal injury and included a large movement of air through the lower part of the neck. The subsequent management of the patient and the difficult problem of securing an airway are described. At operation, the tracheal damage was found to be less severe than anticipated and the observed air flow was a result of penetration of the foreign body into the pleural cavity. The management of the patient is discussed and the potential for misinterpretation of the physical signs in this type of trauma is emphasized.

759. Briggs, M. and M. Shanmugam (2013). "Approximation of a foreign object using x-rays, reference photographs and 3D reconstruction techniques." Journal of visual communication in medicine 36(3-4): 95-100.

This case study describes how a 3D animation was created to approximate the depth and angle of a foreign object (metal bar) that had become embedded into a patient's head. A pre-operative CT scan was not available as the patient could not fit though the CT scanner, therefore a post surgical CT scan, x-ray and photographic images were used. A surface render was made of the skull and imported into Blender (a 3D animation application). The metal bar was not available, however images of a similar object that was retrieved from the scene by the ambulance crew were used to recreate a 3D model. The x-ray images were then imported into Blender and used as background images in order to align the skull reconstruction and metal bar at the correct depth/angle. A 3D animation was then created to fully illustrate the angle and depth of the iron bar in the skull.

760. Brigode, W., et al. (2019). "Alcohol in Traumatic Brain Injury: Toxic or Therapeutic?" The Journal of surgical research 244: 196-204.

BACKGROUND: Alcohol (EtOH) poses a challenge in traumatic brain injuries (TBIs) given its metabolic and neurologic impact. Studies have had opposing results regarding mortality and complication rates in the intoxicated TBI patient. We hypothesized that trauma mechanism, brain injury

severity, and blood alcohol concentration (BAC) would influence the impact of EtOH on mortality in TBI., METHODS: We performed a single-institution retrospective review of consecutive adult trauma patients tested for EtOH and a diagnosis of TBI. The primary outcome was mortality, and secondary outcomes included infectious complications. The primary analysis included univariate and multivariate regression comparing mortality between intoxicated and sober patients, at different values of BAC, different brain injury severities, and among mechanisms of trauma., RESULTS: Admission EtOH was assessed in 583 patients with TBI, with 256 testing positive for EtOH and 327 testing negative. Overall, EtOH was associated with lower mortality on univariate analysis (4.7% versus 8.9%, P = 0.05) but not on multivariate analysis (P = 0.21). There was no effect of EtOH on mortality when patients were stratified by brain injury severity or among penetrating trauma victims. However, EtOH was associated with lower overall infectious complications on univariate and multivariate regression. Finally, EtOH was predictive of mortality with an area under the receiver operator characteristic curve of 0.83., CONCLUSIONS: We found that EtOH is not associated with mortality in the patient with TBI, suggesting no causative effect. However, EtOH showed some predictability of mortality based on a receiver operator characteristic analysis. Interestingly, EtOH was associated with lower infectious complications, suggesting an immunomodulatory effect of EtOH in TBI.

761. Brinck, T., et al. (2015). "Trauma registry comparison: six-year results in trauma care in Southern Finland and Germany." European journal of trauma and emergency surgery : official publication of the European Trauma Society 41(5): 509-516.

PURPOSE: To compare the treatment and survival of trauma patients in Germany and Southern Finland., METHODS: Data from Helsinki University Hospital trauma registry (TR-THEL) and TraumaRegister DGU(R) (TR-DGU) were compared in a period from 2006 until 2011. From TR-DGU level-one trauma centers treating annually >50 injury severity score (ISS) >15 patients were included. The inclusion criterion was ISS >15. Patients under 16 years with penetrating trauma without head injury and transferred in with isolated head injury were excluded. The compared parameters were age, sex, pre-injury ASA, injury scoring, injury pattern, mechanism of injury, injury distribution, pre-hospital timings, transportation method, pre-hospital intubation, treatment at hospital, discharge destination, and 30-day hospital mortality. Expected mortality was defined with the Revised Injury Severity Classification score (RISC)., RESULTS: Eighty-five German level-one trauma centers were included. A total of 15,306 and 1,274 patients were included in the outcome analysis from TR-DGU and TR-THEL, respectively. The difference between the observed and expected mortality of all patients was -4.1% (standardized mortality ratio [SMR] 0.82) at German hospitals and -4.0% (SMR 0.79) in Helsinki. Differences in the pre- and in-hospital treatment between the two countries were noted (transportation method, intubation rate, intensive care unit treatment, ventilation time, length of stay)., CONCLUSION: The overall outcome results of the Helsinki University Hospital trauma unit were similar to those of the German level-one trauma centers. Registry comparison is a feasible method of quality control in a trauma centre.

---

762. Brinck, T., et al. (2016). "Unconscious trauma patients: outcome differences between southern Finland and Germany-lesson learned from trauma-registry comparisons." European journal of trauma and emergency surgery : official publication of the European Trauma Society 42(4): 445-451.

PURPOSE: International trauma registry comparisons are scarce and lack standardised methodology. Recently, we performed a 6-year comparison between southern Finland and Germany. Because an outcome difference emerged in the subgroup of unconscious trauma patients, we aimed to identify factors associated with such difference and to further explore the role of trauma registries for evaluating trauma-care quality., METHODS: Unconscious patients [Glasgow Coma Scale (GCS) 3-8] with severe blunt trauma [Injury Severity Score (ISS) >=16] from Helsinki University Hospital's trauma registry (TR-THEL) and the German Trauma Registry (TR-DGU) were compared from 2006 to 2011.

The primary outcome measure was 30-day in-hospital mortality. Expected mortality was calculated by Revised Injury Severity Classification (RISC) score. Patients were separated into clinically relevant subgroups, for which the standardised mortality ratios (SMR) were calculated and compared between the two trauma registries in order to identify patient groups explaining outcome differences., RESULTS: Of the 5243 patients from the TR-DGU and 398 from the TR-THEL included, nine subgroups were identified and analyzed separately. Poorer outcome appeared in the Finnish patients with penetrating head injury, and in Finnish patients under 60 years with isolated head injury [TR-DGU SMR = 1.06 (95 % CI = 0.94-1.18) vs. TR-THEL SMR = 2.35 (95 % CI = 1.20-3.50), p = 0.001 and TR-DGU SMR = 1.01 (95 % CI = 0.87-1.16) vs. TR-THEL SMR = 1.40 (95 % CI = 0.99-1.81), p = 0.030]. A closer analysis of these subgroups in the TR-THEL revealed early treatment limitations due to their very poor prognosis, which was not accounted for by the RISC., CONCLUSION: Trauma registry comparison has several pitfalls needing acknowledgement: the explanation for outcome differences between trauma systems can be a coincidence, a weakness in the scoring system, true variation in the standard of care, or hospitals' reluctance to include patients with hopeless prognosis in registry. We believe, however, that such comparisons are a feasible method for quality control.

763. Brink, O., et al. (1998). "Pattern of injuries due to interpersonal violence." Injury 29(9): 705-709.

The specific aim of this study was to find characteristics of violence-related injuries, its anatomic distribution and the mechanisms. During a one-year period 1481 consecutive assault victims were interviewed and examined at the Accident and Emergency departments or the Department of Forensic Medicine in Aarhus, Denmark. Information about 2432 violence-related injuries was analysed. The results showed significant differences in injury location, type of injury and injury mechanisms between male and female victims. 69% of all injuries were craniofacial. The injury mechanism was mostly blunt trauma by fist or feet. Cases with penetrating trauma, were predominantly caused by broken drinking glasses. Weapons such as knives and guns only caused 3.7% of all injuries. The results are similar to other studies.

---

765. Brockhoff, H. C., et al. (2012). "Incidence of major blood vessel injuries presenting in mandibular fractures." Journal of oral and maxillofacial surgery 70(9): e104-e105.

Extra-cranial vascular injuries of the head and neck are relatively under-diagnosed in the acute trauma patient and can carry devastating sequale should there be a delay in treatment. Little is known about the overall incidence of injuries to these vessels with regards to a specific fracture or injury pattern of the face. The aim of this study was to review the trauma experience at a single institution level 1 trauma center over a 14-year period. We wished to identify the correlation between mandibular fractures and injuries to major vessels of the head and neck. This information will provide insight into early recognition of these types of injuries to major vessels in patients presenting with a mandibular fracture, and result in timely identification of this potential concomitant injury. Materials and Methods: IRB approval was obtained per institutional protocol, and a retrospective review of our trauma registry was performed from 1993-2007. The data on all mandibular fractures was collected. The metrics of interest included type of mandibular fracture, age, gender, length of stay, mechanism of injury, and associated vascular injuries. All gathered information was then placed into a Microsoft excel spreadsheet and analyzed. Results: Over a 14 year period of time, a total of 2288 patients presented to Parkland Memorial Hospital with mandible fractures and 47 (2%) patients had an injury to a major vessel of the neck. 39 patients were male and 8 female, with ages ranging from 3-72. Nearly half, 23 (48.9%), were the result of a high-velocity penetrating injury, namely gunshot wounds. While 17 (36. 2%) were secondary high velocity blunt motor vehicle or motor cycle collisions. The remaining 7 (14.9%) were a

result of a fall or the mechanism was unknown. High velocity mechanisms accounted for 41 (87.2%), low velocity was 4 (8.5%), and 2 (4.3%) had undocumented mechanisms. The internal carotid artery was injured 18 times (0.8%) and the external carotid was injured a total of 7 times (0.3%) in the 2288 patient series. Injuries to nonspecific blood vessels of the head and neck accounted for 15 (0.66%) patients and injury to multiple blood vessels of the neck occurred 6 (0.26%) times. The remaining 10 injuries were divided between: common carotid artery, external jugular vein, internal jugular vein, subclavian/ innominate artery and vein, and dissection of carotid. Conclusion: When evaluating patients presenting with facial trauma, an awareness of potential concomitant injuries should always be considered. The results of this study demonstrate that those patients who sustain a mandibular fracture in the setting of a high velocity mechanism, should be approached with the possibility of vascular injury of the great vessels and vessels of the neck in mind.

766. Brockman, K., et al. (2021). "AIR INJECTION, RARE YET DEADLY: A CASE OF VENOUS AIR EMBOLISM." Chest 160(4): A1470.

TOPIC: Imaging TYPE: Medical Student/Resident Case Reports INTRODUCTION: Patients with intravenous drug use are at risk for the development of air aneurysm through intravenous introduction of air. In this report, we present a patient with intravenous drug use-induced venous air embolism without cerebral embolism who had a non-operative spontaneous resolution and was ultimately safely discharged home. CASE PRESENTATION: A 35-year-male with ongoing intravenous illicit drug use and alcohol use disorder, presented to the emergency department after being unresponsive on the floor for a prolonged period of time. Patient was found to be in acute renal failure complicated by hyperkalemia and rhabdomyolysis and his urine toxicology was positive for cocaine. On physical examination, he was noted to be disoriented, diaphoretic, and with signs of anterior chest ecchymosis. During his evaluation, a contrast-enhanced CT imaging of the chest demonstrated air in the right ventricle/right pericardium as well as the innominate vein and right internal mammary vein. Head CT imaging revealed no evidence of cerebral air embolism. Patient was managed for metabolic derangements and acute renal failure. His hospitalization was complicated by compartment syndrome of the right upper extremity, requiring surgical decompression. Patient remained hemodynamically stable and ultimately had a non-operative spontaneous resolution of his venous air embolism. Patient was able to be safely discharged home. DISCUSSION: Venous air embolism (VAE) is a condition in which air or gas is introduced to the venous system. Although it is most commonly associated with iatrogenic complications via interventional procedures, it can be caused from a variety of circumstances including penetrating trauma, diving, and intravenous drug use. VAE cases are typically asymptomatic with most cases going unreported and generally found incidentally. Where symptoms are present, they are usually nonspecific and prompt further investigation. Complications can be fatal as air can further embolize through pulmonary and cerebral venous system. In cases where venous air embolism is suspected, prompt Trendelenburg with left lateral decubitus positioning help allow the stabilization of air emboli within the apex of the ventricle and reduces the risk of pulmonary outflow tract obstruction. In cases where intravenous drug use is the suspected etiology, counseling and close monitoring are important to prevent progression or recurrence of VAE. CONCLUSIONS: Patients with history of IV drug use or recent intravenous medical interventions have higher risks for the development of venous air embolism, a rare but potentially fatal condition. Clinicians must have high index of suspicion in those patient populations to ensure prompt investigation and intervention. REFERENCE #1: 1. Groell, Reinhard, et al. 767. Brody, A., et al. (2010). "Fatal gunshot wounds to the head: a critical appraisal of organ donation rates." American journal of surgery 200(6): 728-733.

BACKGROUND: Patients sustaining fatal gunshot wounds to the head are often young, without associated comorbidities, and are potentially ideal transplantation candidates., METHODS: A 5-year review of a level I trauma center's prospective database was performed for all patients sustaining fatal gunshot wounds to the head. Demographic, physiologic, anatomic, and laboratory variables were collected., RESULTS: Sixty-eight patients were identified, of whom 10 (14.7%) were organ donors. Of 25 admitted to the intensive care unit who eventually did not become donors, 15 (60%) were due to lack of consent., CONCLUSIONS: Despite frequent intensive care unit admissions, organ donation is infrequent following fatal gunshot wounds to the head, primarily because of lack of consent. Improved communication with next of kin could improve organ recovery and reduce futile care in this group.

769. Brommeland, T., et al. (2018). "Best practice guidelines for blunt cerebrovascular injury (BCVI)." Scandinavian journal of trauma, resuscitation and emergency medicine 26(1): 90.

Blunt cerebrovascular injury (BCVI) is a non-penetrating injury to the carotid and/or vertebral artery that may cause stroke in trauma patients. Historically BCVI has been considered rare but more recent publications indicate an overall incidence of 1-2% in the in-hospital trauma population and as high as 9% in patients with severe head injury. The indications for screening, treatment and follow-up of these patients have been controversial for years with few clear recommendations. In an attempt to provide a clinically oriented guideline for the handling of BCVI patients a working committee was created. The current guideline is the end result of this committees work. It is based on a systematic literature search and critical review of all available publications in addition to a standardized consensus process. We recommend using the expanded Denver screening criteria and CT angiography (CTA) for the detection of BCVI. Early antithrombotic treatment should be commenced as soon as considered safe and continued for at least 3 months. A CTA at 7 days to confirm or discard the diagnosis as well as a final imaging control at 3 months should be performed.

---

771. Brooks, A., et al. (2002). "Field resuscitation." Current Anaesthesia and Critical Care 13(5): 256-260.

Field resuscitation is constrained by resources and circumstance. These factors influence subsequent anaesthesia and surgery. Current BATLS guidelines are a balance between available evidence, consensus guidelines and pragmatism. These will continue to develop as new evidence becomes available and as field practitioners report their operational experience.

772. Brooks, C. A., et al. (2021). "Traumatic intracranial nail-gun injury of the right internal carotid artery causing pseudoaneurysm and caroticocavernous fistula." BMJ case reports 14(8).

Penetrating trauma due to nail gun is an uncommon yet important clinical entity. There are numerous case reports describing these injuries, yet few describe those resulting in cerebrovascular

injury. Laceration of cerebral blood vessels may result in significant intracranial haemorrhage and cerebral ischaemia, with catastrophic consequences. In the present study, we report a female patient who was shot in the face with a nail gun in a domestic assault. The nail entered her right cavernous sinus and lacerated her right internal carotid artery causing a pseudoaneurysm and a caroticocavernous fistula. This report details the approach to, and pitfalls of, managing a cerebrovascular injury due to penetrating intracranial nail. Catheter cerebral angiography is essential in the diagnosis and treatment of these injuries. Best treatment and outcomes require clinicians with expertise in endovascular and surgical repair strategies.

773. Broos, P. L., et al. (2000). "Life saving surgery in polytrauma patients." Przeglad lekarski 57 Suppl 5: 118-119.

Life saving surgery is the surgery which has to be performed during the acute or reanimation period (1 to 3 h) and during the primary or stabilisation period (first day surgery). During the reanimation period lifethreatening conditions are identified and management is begun simultaneously. Many trauma surgeons talk about the first "golden hours" as the time interval starting immediately after the injury when rapid intervention will save lives and a lack of intervention will result in life loss. Most common, these critical conditions are exsanguinating hemorrhage, acute pump failure, obstruction of airways, mechanical failure of ventilation or severe brain damage with tentorial herniation. During this period, the following acts are necessary: surgical access to live support systems (airway, veins), life saving decompression of body cavities, resuscitative thoracotomy, control of exsanguinating external hemorrhage and control of exsanguinating hemorrhage into the body cavities. The primary or stabilisation period starts when vital functions stabilise. This period consists of further diagnostic procedures and treatment of injuries that are not directly life-threatening, but which may become life endangering or severely disabling if not treated promptly. The priorities of the surgical treatment are: brain injuries, eye- and facial injuries, progressive compression of the spinal cord, visceral injuries, musculoskeletal injuries. By improving prehospital care, rapid transport and last but not least immediate life saving surgical treatment preventable deaths can be reduced from 20-30% to 2-9% (5).

774. Brown, C. and K. O'Toole (2009). "The interaction between development and traumatic brain injury: Using a developmental neuropsychology model is crucial." Archives of Clinical Neuropsychology 24(5): 465.

Objective: The greatest incidence of pediatric traumatic brain injury occurs before age 3. Research shows that longitudinal, neuropsychologic effects of such injuries vary due to interacting detrimental, protective, and developmental factors. The current study examined medical, cognitive, social, and behavioral effects of one child's early brain injury at several points over 12 years, with results framed by a developmental model of cognitive phenotype and medical condition interactions (Dennis, 2000). Methods: Neuropsychologic testing was conducted annually with a child who sustained a right inferior parietal gun-shot wound and craniotomy at 24 months, and subsequently developed seizures and ADHD. Cognitive, behavioral, academic, medical and social results are presented for early childhood, late childhood, and adolescence. CT findings are presented and explained in relationship to neuropsychologic findings. Results: Early childhood results indicated average intelligence, expressive and receptive language, and visuospatial abilities. Weaknesses included bilateral coordination, memory, adaptive functioning, and academic readiness. Late childhood skills showed decreased adaptive functioning and graphomotor difficulties, and improved memory/learning and attention. Approaching adolescence, writing progressed, but the child developed attention and reading comprehension difficulties. Socially and emotionally, he benefited from protective factors. Recent CT show parenchymal defects with multiple metallic fragments in right parietal and basal ganglia regions. Conclusions: Results show the importance of understanding the developmental framework in analyzing devastating effects of early injury. Appropriate school accommodations and proactive parents allowed

the child to gradually improve weak areas. Detrimental medical effects and increasing developmental demands challenge protective variables, leading to attentional difficulties in adolescence. Challenges to the theory of early brain plasticity will be discussed.

775. Brown, F. D., et al. (1979). "Detailed monitoring of the effects of mannitol following experimental head injury." Journal of neurosurgery 50(4): 423-432.

The experimental model of a cerebral missile injury developed by Crockard was used in three groups of Rhesus monkeys treated with mannitol. One group received mannitol 15 minutes after being injured with a BB pellet at 90 m/sec impact. Another group was wounded identically, but mannitol treatment was delayed until 1 hour after injury. The last group was wounded with the missile traveling at 180 m/sec, and mannitol was started 15 minutes after trauma. The data were contrasted with the results from the original model. After receiving mannitol, all groups showed marked improvement in mean blood pressure, cerebral perfusion pressure, cerebral blood flow, and cerebral metabolic rate of oxygen consumption out of proportion to the degree of reduction in intracranial pressure (ICP). The authors conclude that the therapeutic value of mannitol may, in some injuries, be directly related to its effects on blood flow and metabolism, as well as to its better known effects upon ICP.

776. Brown, J. B. and M. L. Gestring (2013). "Does helicopter transport impact outcome following trauma?" Trauma (United Kingdom) 15(4): 279-288.

Helicopter transport (HT) has evolved from military roots into a critical component of trauma systems throughout the world. Concerns over cost and safety continue to challenge the role of HT in the civilian setting. Despite this, recent evidence has demonstrated a survival advantage for trauma patients undergoing HT. For patients transported from the scene of injury, improved survival has been shown in several multicenter studies as well as evaluation of large national databases. Issues of overtriage, however, remain problematic for scene HT and represent a prime area for future research in helicopter emergency medical systems (EMS). Patients undergoing inter-facility transfer have also been shown to have improved outcomes over ground transport in terms of shorter transfer times and increased survival particularly in more severely injured patients. The benefits seen are likely a result of a combination of rapid transport, advanced medical capabilities, and accessibility to remote terrain. Several subgroups of patients undergoing HT have been the subject of study as well. Patients with severe head injury have consistently been shown to have superior outcomes over ground ambulance, attributable to improvements in airway management early in the course of their injury. Conversely, HT for urban and penetrating injury has not seen similar benefits, likely due to proximity of trauma centers and recent advancements in urban EMS systems. The benefits of including physicians in helicopter crews are less clear and vary by region and system. Helicopter transport for trauma does appear to improve outcomes for trauma patients, and optimizing utilization of this valuable resource will be key as the role of helicopter EMS continues to develop within trauma systems.

777. Brown, S. J., et al. (2014). "A puzzling case of cryptococcal meningitis." South African medical journal = Suid-Afrikaanse tydskrif vir geneeskunde 104(11): 720.

---

778. Browne, A., et al. (2000). "The ethics of elective (non-therapeutic) ventilation." Bioethics 14(1): 42-57.

Elective ventilation (EV) is ventilation applied, not in the interest of patients, but in order to secure transplantable organs. It carries with it a small risk that patients who would otherwise have died will survive in a persistent vegetative state. Is EV ever justifiable? We argue: (1) The only thing which can justify exposing patients to risk not taken for their benefit is their consent, and we cannot rely on

implied consent or third party consent in the case of EV. Thus absent explicit consent of patients, EV is not justifiable. (2) It is not clear that explicit consent should be sought, or where it is offered honoured, given the potential EV has for deterring organ donors and causing stress to staff and families.

779. Browning, J., et al. (2019). "Early post-traumatic seizures do not correlate with mossy fiber outgrowth in sub-acute phase of TBI in rats." Journal of neurotrauma 36(13): A55.

It is unknown whether early post-traumatic seizures are associated with the development of chronic post-traumatic epilepsy. Mossy fiber sprouting in the hippocampus has been implicated in epileptogenesis and may play a crucial role in the development of post-traumatic epilepsy. In this study we examined whether mossy fiber sprouting was associated with early post-traumatic seizures 2 weeks after a penetrating traumatic brain injury (pTBI) as a potential mechanism of post-traumatic epileptogenesis. Rats received skull EEG electrode implantation bilaterally over the frontal and parietal cortices. PTBI was performed through the right frontal cortex 3 days after EEG surgery. Spontaneous seizures were detected by continuous video-EEG recording for 72 hours following injury. Mossy fiber outgrowth was examined in the pyramidal and granular cell layers of the hippocampus bilaterally and scored on a 3 point scale. Seizure frequency was correlated with mossy fiber outgrowth at 2 weeks following brain injury. The majority of PTBI rats (74%) experienced non-convulsive seizures detected by EEG during the 72-hour post-injury monitoring period with an average frequency of 18.05 ± 5.3 seizures per animal (range: 0-69 seizures). Scores for mossy fiber outgrowth were low amongst all animals with an average score of 1.08 ± 0.15 in the pyramidal cell layer and 0.85 ± 0.10 in the granular cell layer. However, no significant correlations were detected between acute seizure frequency and mossy fiber outgrowth at 2 weeks post-injury. Low mossy fiber sprouting scores at 2 weeks post injury may indicate a slow process of post-traumatic epileptogenesis. Additional longitudinal studies are needed to correlate the time-course of mossy fiber sprouting and the development of delayed post-traumatic epilepsy during a longer latent period.

---

780. Browning, J. R., et al. (2018). "Topiramate lowers seizure activities in a rat model post-traumatic seizures." Journal of neurotrauma 35(16): A202.

Background: Traumatic brain injury (TBI) carries a risk of developing acute post-traumatic seizures (PTS) that can lead to secondary injury and escalate the mortality rate by increasing metabolic demands, intracranial pressure, and the release of excitatory neurotransmitters. The most frequently used anti-epileptic drugs (AEDs) for early PTS are phenytoin and levetiracetam. While both drugs decrease PTS in some patients, a significant number of patients are nonresponsive to these treatments. In this study, we tested topiramate as a potential novel AED therapy for PTS. Topiramate has diverse mechanisms of action and has been used to treat seizures and epilepsies not associated with TBI. Topiramate was tested as monotherapy in order to determine its dose-response profile. Methods: Adult male Sprague-Dawley rats were anesthetized and EEG electrodes were implanted bilaterally into the skull above the frontal and parietal cortical regions. Penetrating ballistic-like brain injury (10% brain volume) was performed unilaterally in the right hemisphere. Rats were assigned to one of 5 treatment groups (vehicle, 5 10 20, or 30 mg/kg topiramate). Injections were given IV twice per day for a total of 3 days beginning 30 minutes post-injury. Spontaneously occurring PTS were detected by continuous video-EEG recording for 3 days following injury. Results: Topiramate significantly reduced PTS incidence (number of animals which experienced seizures within a dose group) and frequency of seizures experienced by individual animals compared to vehicle treated controls. A 50% reduction in seizure incidence was achieved at doses of 10mg/kg or higher. The average frequency of seizures was reduced by 50% at 5mg/kg and further suppressed at doses of 10mg/kg or higher. Conclusions: The current study provides support for the anti-seizure activities of topiramate monotherapy to suppress seizures following penetrating TBI, suggesting that topiramate may be an alternative treatment for early PTS. Although the data suggests that topiramate may be effective as a monotherapy, insolubility at higher doses may limit its use. The dose-response profile provides a dose range which is useful for the

consideration of its combined treatment with phenytoin or levetiracetam to improve the overall anti-seizure therapy in treating PTS.

781. Browning, M., et al. (2016). "Levetiracetam Treatment in Traumatic Brain Injury: Operation Brain Trauma Therapy." Journal of neurotrauma 33(6): 581-594.

Levetiracetam (LEV) is an antiepileptic agent targeting novel pathways. Coupled with a favorable safety profile and increasing empirical clinical use, it was the fifth drug tested by Operation Brain Trauma Therapy (OBTT). We assessed the efficacy of a single 15 min post-injury intravenous (IV) dose (54 or 170 mg/kg) on behavioral, histopathological, and biomarker outcomes after parasagittal fluid percussion brain injury (FPI), controlled cortical impact (CCI), and penetrating ballistic-like brain injury (PBBI) in rats. In FPI, there was no benefit on motor function, but on Morris water maze (MWM), both doses improved latencies and path lengths versus vehicle ($p < 0.05$). On probe trial, the vehicle group was impaired versus sham, but both LEV treated groups did not differ versus sham, and the 54 mg/kg group was improved versus vehicle ($p < 0.05$). No histological benefit was seen. In CCI, there was a benefit on beam balance at 170 mg/kg ($p < 0.05$ vs. vehicle). On MWM, the 54 mg/kg dose was improved and not different from sham. Probe trial did not differ between groups for either dose. There was a reduction in hemispheric tissue loss ($p < 0.05$ vs. vehicle) with 170 mg/kg. In PBBI, there was no motor, cognitive, or histological benefit from either dose. Regarding biomarkers, in CCI, 24 h glial fibrillary acidic protein (GFAP) blood levels were lower in the 170 mg/kg group versus vehicle ($p < 0.05$). In PBBI, GFAP blood levels were increased in vehicle and 170 mg/kg groups versus sham ($p < 0.05$) but not in the 54 mg/kg group. No treatment effects were seen for ubiquitin C-terminal hydrolase-L1 across models. Early single IV LEV produced multiple benefits in CCI and FPI and reduced GFAP levels in PBBI. LEV achieved 10 points at each dose, is the most promising drug tested thus far by OBTT, and the only drug to improve cognitive outcome in any model. LEV has been advanced to testing in the micropig model in OBTT.

782. Brozek, M., et al. (2005). "[Pneumoencephalon and pneumatocoele intrabulbaris--the consequence of penetrating wounds of the orbital cavity and severe ocular injury--case reports]." Odma srodczaszkowa (pneumoencephalon) oraz odma wewnatrzgalkowa (pneumatocoele intrabulbaris) w nastepstwie urazu oczodolu-- opis przypadkow. 107(4-6): 348-350.

Pneumoencephalon i.e. the presence of the intracranial air is commonly detected in the consequence of the head injury or penetrating wound of orbital cavity. The most characteristic sign of pneumoencephalon is the bruit hydroaerique, which is a splashing sound heard only by the patient on postural change. The diagnosis of this rare complication was possible on clinical symptoms and computed tomography (CT) brain scan. The article outlines another case of the intraocular presence of the air (pneumatocoele intrabulbaris) after severe ocular injury with almost total absence of vitreous body, choroid and retina and hypotony.

783. Brozek-Mucha, Z. and K. Zdeb (2018). "Controversial Suicide Case Using a Submachine Gun with a Sound Suppressor-The Need of Team Work of Forensic Chemistry and Firearm Examiners." Journal of forensic sciences 63(3): 921-929.

Evidence materials in a presumed suicide case were studied by a firearm examiner and a forensic chemist. The victim's body with double gunshot wounding in his forehead, a machine gun in the sustained fire mode with a silencer, and four cartridge cases were found. Examinations of the evidence, the case file studies, and experiments dedicated to the case were carried out. Relationships between the placement of cartridge cases and the gun were established using a fast camera. The distributions of gunshot residues on the evidence materials and within the comparative gunshot patterns were studied by means of optical and electron microscopy, X-ray microanalysis, and infrared spectroscopy. The shooting distance was assessed to be 30 cm or more, whereas the greatest distance that could have been achieved

by the victim himself was about 11-13 cm. The obtained results supported the version of homicide rather than suicide. Copyright © 2017 American Academy of Forensic Sciences.

784. Bruce, D. (1995). "Craniofacial trauma in children." The Journal of cranio-maxillofacial trauma 1(1): 9-19.

Craniofacial trauma is relatively uncommon in children, but the potential involvement of the structures at the base of the skull and the intracranial space makes it important for physicians to understand the potential dangers presented by such injuries. This report delineates the different types of injury that can damage the upper facial skeleton and the brain of a child. The author reviews initial management and diagnosis of such injuries and examines the approach to definitive reconstructive surgery using three case studies as examples for discussion.

785. Bruckmann, H., et al. (1986). "Orbital venous congestion in childhood. Diagnostic and therapeutical implications." Klinische Padiatrie 198(6): 489-492.

A case study of 2 patients with venous congestion of the orbit due to different etiologies is presented. Both the children demonstrated orbital pain, proptosis, chemosis and conjunctival injection. In one case early diagnosis left to complete recovery by conservative treatment in a patient with a pyogenic cavernous sinus thrombosis. In the other case a traumatic carotid sinus cavernous fistula could be treated successfully using transvasculary navigated detachable balloons.

---

786. Brune, J. E., et al. (2018). "Delayed lethal pulmonary air embolism after a gunshot head injury." BMJ case reports 2018.

We present a case of a young male patient with a fatal pulmonary air embolism following a penetrating gunshot head injury. He suffered from severe head trauma including a laceration of the superior sagittal sinus. Operative neurosurgical intervention did not establish a watertight closure of the wounds. Eight days after the trauma, the patient suddenly collapsed and died after an attempt to mobilise him to the vertical. Forensic autopsy indicated pulmonary air embolism as the cause of death. Retrospectively, we postulate an entry of air to the venous system via the incompletely occluded wounds and the lacerated superior sagittal sinus while mobilisation to the vertical created a negative pressure in the dural sinus.

787. Bruno, J. R., et al. (1999). "Treatment of traumatic mandibular nonunion." The Journal of cranio-maxillofacial trauma 5(2): 27-32.

BACKGROUND AND OBJECTIVES: Nonunion is a complication in mandibular fractures. The causative factors include delay in treatment, infection, inadequate immobilization, and improper internal fixation; concomitant infection may be present. Pain, mobility of the fracture segments, and radiographic evidence of radiolucency did in diagnosis., METHODS AND MATERIALS: Three clinical cases are used to present the methods of treatment to manage nonunion following a gunshot wound, assault with a blunt object, and a fall. Treatment included antimicrobial therapy, fracture site debridement, segment immobilization, and bone grafting. Maxillomandibular fixation, debridement, and placement of a reconstruction plate were used in the first case; reconstruction plate, autogenous bone graft in a polyglactin resorbable mesh, and screw buttons in the second; and custom reconstruction plate and iliac crest bone graft in the third., RESULTS AND/OR CONCLUSIONS: All cases healed uneventfully. Due to rapid revascularization, use of autogenous cancellous bone grafts is preferred to cortical bone. Custom-molded polyglactin mesh provides control of the loose cancellous bone graft.

---

788. Bruns, B. R., et al. (2014). "Blunt cerebrovascular injury screening guidelines: what are we willing to miss?" The journal of trauma and acute care surgery 76(3): 691-695.

BACKGROUND: Blunt cerebrovascular injury (BCVI) is reported to occur in approximately 2% of blunt trauma patients, with a stroke rate of up to 20%. Guidelines for BCVI screening are based on clinical and radiographic findings. We hypothesized that liberal screening of the neck vasculature, as part of initial computed tomographic (CT) imaging in blunt trauma patients with significant mechanisms of injury, identifies BCVI that may go undetected., METHODS: As per protocol, patients at risk for significant injuries undergo a noncontrast head CT scan followed by a multislice CT scan (40-slice or 64-slice) incorporating an intravenous contrast-enhanced pass from the circle of Willis through the pelvis (whole-body CT [WBCT] scan). The trauma registry was retrospectively reviewed, and all patients with BCVI from 2009 to 2012 were analyzed. Patients undergoing WBCT scan were then identified, and records were reviewed for BCVI indicators (skull base fracture, cervical spine injury, displaced facial fracture, mandible fracture, Glasgow Coma Scale score <= 8, flexion mechanism, hard signs of neck vascular injury, or focal neurologic deficit)., RESULTS: Of 16,026 patients evaluated during the study period, 256 (1.6%) were diagnosed with BCVI. The population consisted of 185 patients with suspected BCVI after WBCT scan. One hundred twenty-nine patients (70%) had at least one indicator for BCVI screening, while 56 (30%) had no radiographic or clinical risk factors; 48 of the 56 patients underwent confirmatory CT angiography of the neck within 71 hours of initial WBCT scan, with 35 patients having 45 injuries., CONCLUSION: More liberalized screening for BCVI during initial CT imaging in trauma patients clinically judged to have sufficient mechanism is warranted. Using current BCVI screening guidelines leads to missed BCVI and risk of stroke., LEVEL OF EVIDENCE: Diagnostic study, level III.

789. Bryant, J. E., et al. (2011). "A retrospective cohort study on the use of dexmedetomidine in patients with traumatic brain injury." Pharmacotherapy 31(10): 422e.

PURPOSE: Dexmedetomidine is known for its unique sedative properties in critically ill patients however, its effects in patients with traumatic brain injury (TBI) are not well studied. This study was designed to characterize the safety and efficacy of dexmedetomidine use in TBI patients. METHODS: Retrospective review of medical records for patients who received dexmedetomidine at our institution between December 1, 2008 and December 31, 2010 was conducted. Patients included in the study were adults with non-penetrating TBI and no past medical history related to any neurologic illness or impairment. Richmond Agitation Sedation Scale (RASS) score, Glasgow Coma Scale (GCS) score, heart rate, mean arterial pressure (MAP), intracranial pressure (ICP), and dexmedetomidine dose were recorded. RESULTS: For the 27 patients included in the study, mean age was 41 years, and 24 patients were male. The average dexmedetomidine dose administered was 0.65 μg/kg/hour. Median admission GCS score was 6 with 51.9% of patients classified as minor brain injury, 14.8% as moderate, and 33.3% as severe. RASS scores were generally within target range with 276 of the 402 (68.7%) scores assessed between -2 to +1. Fifteen patients experienced 110 total episodes of bradycardia (< 60 beats per minute), and 21 patients experienced 300 total episodes of tachycardia (> 110 beats per minute). Twelve patients had a total of 17 MAP readings < 60 mmHg. ICP was monitored in two patients, both of which were controlled (ICP<20 mmHg). CONCLUSION: Overall, the use of dexmedetomidine in this study population proved to be safe and efficacious. Episodes of bradycardia occurred less often than previously observed. Based on the limited ICP data, dexmedetomidine did not appear to adversely affect ICP in this study population.

790. Bryden, D. W., et al. (2019). "Blast-Related Traumatic Brain Injury: Current Concepts and Research Considerations." Journal of Experimental Neuroscience 13.

Traumatic brain injury (TBI) is a well-known consequence of participation in activities such as military combat or collision sports. But the wide variability in eliciting circumstances and injury severities makes the study of TBI as a uniform disease state impossible. Military Service members are

under additional, unique threats such as exposure to explosive blast and its unique effects on the body. This review is aimed toward TBI researchers, as it covers important concepts and considerations for studying blast-induced head trauma. These include the comparability of blast-induced head trauma to other mechanisms of TBI, whether blast overpressure induces measureable biomarkers, and whether a biodosimeter can link blast exposure to health outcomes, using acute radiation exposure as a corollary. This examination is contextualized by the understanding of concussive events and their psychological effects throughout the past century's wars, as well as the variables that predict sustaining a TBI and those that precipitate or exacerbate psychological conditions. Disclaimer: The views expressed in this article are solely the views of the authors and not those of the Department of Defense Blast Injury Research Coordinating Office, US Army Medical Research and Development Command, US Army Futures Command, US Army, or the Department of Defense.

791. Buchalter, G. M., et al. (2002). "Penetrating trauma to the head and neck from a nail gun: a unique mechanism of injury." Ear, nose, & throat journal 81(11): 779-783.

Published reports of nail gun injuries to the head and neck are rare. We describe the cases of three patients who sustained nail gun injuries to the head and who were managed at our institution. All patients were treated successfully and all recovered with minimal morbidity. Any physician who is called on to manage a nail gun injury to the head or neck should understand that most likely the patient will have sustained a surprisingly limited amount of tissue injury, owing to the relatively low velocity of the projectile compared with that delivered by firearms. Computed tomography and selective angiography can play a vital role in assessing the integrity of relevant vascular structures. Moreover, catheter angiography with embolization can be a most useful nonsurgical adjunct to control the extent of vascular injury.

792. Buchwald, C., et al. (1991). "Cerebrospinal fluid leak from nontumor ear after acoustic neuroma surgery: diagnostic and therapeutic problems." The American journal of otology 12(5): 384-387.

An unusual case of CSF leak from the nontumor ear after removal of a 3-cm acoustic neuroma is presented. Prior to tumor removal a ventricular-peritoneal shunt was established because of increased intracranial pressure. After the shunt was clamped the patient twice developed rhinoliquorrhea and underwent in both instances unsuccessful closure of the leak on the tumor side. Finally the leak was established in the nontumor ear, most likely due to sequelae after a hunting accident 20 years before, where a projectile created a defect in the tegmen tympani. The CSF leak was probably provoked by the pressure changes following tumor removal and shunt treatment.

793. Buck, U., et al. (2008). "Haptics in forensics: the possibilities and advantages in using the haptic device for reconstruction approaches in forensic science." Forensic science international 180(2-3): 86-92.

Non-invasive documentation methods such as surface scanning and radiological imaging are gaining in importance in the forensic field. These three-dimensional technologies provide digital 3D data, which are processed and handled in the computer. However, the sense of touch gets lost using the virtual approach. The haptic device enables the use of the sense of touch to handle and feel digital 3D data. The multifunctional application of a haptic device for forensic approaches is evaluated and illustrated in three different cases: the representation of bone fractures of the lower extremities, by traffic accidents, in a non-invasive manner; the comparison of bone injuries with the presumed injury-inflicting instrument; and in a gunshot case, the identification of the gun by the muzzle imprint, and the reconstruction of the holding position of the gun. The 3D models of the bones are generated from the Computed Tomography (CT) images. The 3D models of the exterior injuries, the injury-inflicting tools and the bone injuries, where a higher resolution is necessary, are created by the optical surface scan. The haptic device is used in combination with the software FreeForm Modelling Plus for touching the

surface of the 3D models to feel the minute injuries and the surface of tools, to reposition displaced bone parts and to compare an injury-causing instrument with an injury. The repositioning of 3D models in a reconstruction is easier, faster and more precisely executed by means of using the sense of touch and with the user-friendly movement in the 3D space. For representation purposes, the fracture lines of bones are coloured. This work demonstrates that the haptic device is a suitable and efficient application in forensic science. The haptic device offers a new way in the handling of digital data in the virtual 3D space.

794. Buczek, M. and A. Pieninski (1993). "[Deep penetrating brain injury with 20 years of asymptomatic survival: a case report]." Przypadek glebokiego urazu drazacego mozgu Z 20-letnim bezobjawowym przezyciem. 47(6): 553-556.

Authors report the case of penetrating injury of the head with large metallic fragment embedded to the brain with 20 years asymptomatic survival. Patient sustained head injury during work, 20 years ago and for these period of time was not aware of having foreign body intracranially with excellent general condition and no signs of neurological deficit. Metal nail was detected incidentally by plain skull X-ray films (and subsequent CT scan) during routine procedures when patient was admitted to the Laryngologic Dpt. for surgical procedure. In our opinion presented case in uncommon because of asymptomatic course. Most of penetrating head injuries are considered as life threatening due to sudden onset, severe general patient condition and possible deterioration according to the type of injury and extent of cerebral destruction. For those reasons earliest possible definitive neurosurgical treatment is recommended. We emphasize the role of debridement for most of brain penetration injuries.

---

795. Buente, H. and D. Filler (1974). "The acute abdomen caused by trauma." Munchener Medizinische Wochenschrift 116(27): 1301-1308.

The acute abdomen caused by trauma may be summarized: Far more patients die as a result of operating too late than of operating unnecessarily. Laparotomy should therefore be carried out in case of doubt. Wrong diagnoses are rare if the patient is repeatedly examined by the same experienced physician. Serious traumatic sequelae must not be overlooked on laparotomy. The statistics of surgical results will be improved by the advice of an experienced anesthetist when assessing the operability and the postoperative treatment.

796. Bugra, A. and T. Das (2020). "Embolism of Cerebral Tissue to the Lung After Head Trauma: A Case Report." The American journal of forensic medicine and pathology 41(4): e64-e66.

Embolism of cerebral tissue to pulmonary circulation is a rare entity. It can be occur because of penetrating or closed head trauma at any age or during difficult vaginal deliveries at any age. We present a case of cerebral tissue pulmonary embolization after severe head trauma in a male adult. The autopsy revealed multiple skull fractures, subdural hematoma, subarachnoid hemorrhages, and contusions. Microscopically, we observed cerebral tissue inside the branches of the pulmonary arteries. Embolism of cerebral tissue to the pulmonary circulation is a rare condition. It should always be kept in mind in sudden unexpected deaths during delivery and head trauma cases at any age.

797. Buhas, C., et al. (2016). "The difficulty in establishing the generating mechanism of cranial and vertebral lesions in a cadaver partially skeletonised." Romanian Journal of Legal Medicine 24(4): 300-303.

The presented case is a 71 year old male, found deceased in the woods during summer, two weeks after his death, partially skeletonised (at the level of cranium and thorax), exposed to the effect of the environment and insects. From the investigation data, it was initially believed that the mechanism which caused the cranial and cervical vertebrae fractures was a series of repeated impacts with a hard,

blunt object. Based on the investigation data and assessments of the cadaver, the supposed aggressor was sentenced to 25 years in prison. The case was reopened and a new medico-legal assessment was performed. Fully reexamining the fractured bones by performing cranial reconstruction and using radiographic investigations which showed small metallic fragments on these bones, it allowed precise identification of the real mechanism which produced the lesion: a gunshot wound from a hunting rifle.

798. Bui, J., et al. (2021). "Multidisciplinary Management of an Aorto-esophageal Injury Caused by Foreign Body Ingestion." Annals of vascular surgery 72: 668.e661-668.e664.

A 37-year-old incarcerated male ingested a complex "X-shaped" foreign body that resulted in a penetrating aorto-esophageal injury. A primary esophagotomy with retrieval of the foreign body and muscle flap closure was performed simultaneously with thoracic endovascular aortic repair. This multidisciplinary surgical approach controls for both immediate exsanguination and postoperative complications to improve patient outcome.

799. Buitendag, J. J. P., et al. (2017). "The spectrum and outcome of paediatric traumatic brain injury in KwaZulu-Natal Province, South Africa has not changed over the last two decades." South African Medical Journal 107(9): 777-780.

Objectives. This retrospective review of a prospectively entered and maintained hybrid electronic trauma registry was intended to develop a comprehensive overview of traumatic brain injury (TBI) in children and adolescents and to compare it with previous audits from our local environment and from other developing world centres. All TBI patients admitted to hospital were included in this study. We reviewed the age, gender, outcomes, radiological findings and treatment of the patients. Methods. All patients aged ≤18 years old who were admitted by the Pietermaritzburg Metropolitan Trauma Service (PMTS) with TBI between December 2012 and December 2016 were included in this audit. Results. During the 4-year period under review, a total of 563 children and adolescents were treated for TBI by the PMTS. The median age was 6.4 years and 29% (n=165) were females. The mechanism of TBI was blunt trauma in 96% (n=544) of cases, with 4% (n=19) suffering penetrating trauma. The penetrating mechanisms included impalement by a cow horn and miscellaneous injuries due to saws, axes, barbed wire, spades, stones and knives. The blunt mechanisms included falls (n=102), assaults (n=108), collapse of a building (n=28), bicycle-related injury (n=14), falling off a moving vehicle (n=280), motor vehicle accident (MVA; n=59), pedestrian vehicle accident (PVA; n=183) and animal-related injuries (n=8). There were 454 (80%) mild, 67 (12%) moderate and 42 (7%) severe cases of TBI. A total of 48 patients were admitted to the intensive care unit and 23 were admitted to the high care unit. Nine patients died. All the deaths were in the MVA and PVA group. The spectrum of TBI as diagnosed on computed tomography scans was nonspecific cerebral contusion (n=92), depressed skull fracture (n=70), sub-arachnoid haemorrhage (n=60), extradural haemorrhage (n=41), intracerebral haemorrhage (n=19), free air (n=19), subdural haemorrhage (n=13), intraventricular haemorrhage (n=9). A total of 62 (11%) patients required surgery. Conclusion. There is a significant burden of paediatric TBI in Pietermaritzburg. The majority of TBI was related to blunt trauma and assaults were very common. Although the short-term outcomes are good, the long-term consequences are poorly understood. Injury prevention programmes are needed to help reduce this burden of disease and a nationwide trauma registry is long overdue.

---

800. Buitendag, J. J. P., et al. (2020). "A comparison of blunt and penetrating pancreatic trauma." South African journal of surgery. Suid-Afrikaanse tydskrif vir chirurgie 58(4): 218.

BACKGROUND: This project reviews our experience with managing pancreatic trauma from 2012 to 2018., METHODS: All patients over the age of 15 years with a pancreatic injury during the period December 2012-December 2018 were retrieved from the Hybrid Electronic Medical Registry at Grey's Hospital and reviewed., RESULTS: During the study period 161 patients sustained a pancreatic

injury. The mechanism of trauma was penetrating in 86 patients (53%) and blunt in 75 (47%). The blunt mechanisms included MVA in 27, PVA in 15, falls in four and assaults in the remaining 29. There were 52 stab wounds and 34 gunshot wounds of the pancreas. A total of 26 patients (16%) were shocked on presentation with a systolic blood pressure of 90 mm Hg or less. The median injury severity score was 16. There were 90 patients with American Association for the Surgery of Trauma (AAST) grade I injury to the pancreas, 36 AAST grade II, 27 AAST grade III, 7 AAST grade IV and a single AAST grade V. Fifty-four patients (34%) were initially treated non-operatively of which three eventually required surgery. Of the patients who required surgery, 26 (16%) underwent a distal pancreatectomy. The remainder simply underwent pancreatic drainage. The overall mortality rate was 13% (21/161). The operative mortality was 11% (18/161). Thirteen patients (8%) with penetrating injuries and eight patients (5%) with blunt injuries died. Of the 21 patients who died, 14 had multiple injuries. Five patients died due to overwhelming sepsis. One patient died due to hypovolemic shock and another due to a traumatic brain injury., CONCLUSION: Our centre not infrequently deals with pancreatic trauma secondary to both blunt and penetrating trauma. We follow the general principles outlined in the literature. Despite this, pancreatic trauma is still associated with significant morbidity and mortality.

801. Bukach, C. M., et al. (2008). "Preservation of mouth region processing in two cases of prosopagnosia." Journal of neuropsychology 2(1): 227-244.

Although most adults are considered experts in face recognition, brain trauma can produce a selective loss in this ability, a condition referred to as prosopagnosia. This study examined the processing strategies of prosopagnosic patients LR and HH using the Face Dimensions Test. In this test, featural and configural information in the upper and lower halves of the face was parametrically varied and sensitivity to these changes measured. We found that relative to age-matched control participants, LR and HH exhibited an impaired ability to discriminate differences in the eye region, but a preserved ability to detect featural and configural differences in the mouth region. This pattern of impairment and sparing was demonstrated in tests of direct perception and immediate memory. The obtained findings demonstrate that prosopagnosia does not necessarily cause a global impairment to face perception, but a selective impairment to the perception of information in the upper half of the face.

802. Bula-Sternberg, J., et al. (2011). "[CT-findings in penetrating captive bolt injuries to the head and brain: analysis of the trauma-related CT-findings and review of the literature]." CT-Befunde bei penetrierenden Kopfverletzungen durch Bolzenschussgerate--Analyse der verletzungsspezifischen CT-Befunde und eine Ubersicht uber die relevante Literatur. 183(11): 1070-1074.

Penetrating gunshot injuries to the head and brain are rare in Germany and the rest of Western Europe. Due to the small number of cases over here no consistent diagnostic and therapeutic standards exist in this respect. Thus these kinds of injuries present a great challenge to the attending physicians. Most of these violations are a result of a suicidal attempt or an accident. Beside violations by firearms also penetrating injuries to the head and brain due to captive bolt devices, as used in slaughtery business for the "humane" killing of animals, occur from time to time. The impact on the head differs from that caused by firearms because no projectile is leaving the barrel and the used bolt, as a fix part of the device, does not remain in the affected tissue. That implies characteristic results within the radiological imaging that might be pathbreaking for the further treatment, because the origin of such a head injury is often unknown during primary care. Consequently the knowledge of these specific findings is central to the radiologist to make the appropriate diagnosis. Based on some clinical examples the trauma-related CT-findings are introduced and a short overview of the relevant literature is also given.

803. Bullingham, A., et al. (1994). "An impaled neck. Management of difficult airway access." Anaesthesia 49(10): 866-869.

We describe the management of a patient impaled through the lower submandibular area by the top spike of some iron railings which immobilised his jaw and blocked access to the trachea. The Fire Brigade used specialised equipment to cut out a section of the railings so that the patient could be transported to hospital. Awake fibreoptic intubation was used to gain access to the patient's airway before induction of anaesthesia.

804. Bullock, J. D., et al. (1994). "Unusual penetrating intraorbital foreign body." Archives of ophthalmology (Chicago, Ill. : 1960) 112(12): 1618-1619.

---

805. Bullock, J. D., et al. (1999). "Unusual orbital foreign bodies." Ophthalmic plastic and reconstructive surgery 15(1): 44-51.

PURPOSE: To describe the clinical features of patients with unusual orbital foreign bodies., METHODS: The clinical histories, preoperative photographs, imaging studies, and surgical pathologic findings of five patients with unusual orbital foreign bodies are presented. Additionally, published reports pertaining to similar cases were reviewed., RESULTS: The five patients treated by the authors had good outcomes., CONCLUSIONS: An orbital foreign body may be overlooked because a small penetrating wound may be accompanied by minimal or no signs of inflammation early in the clinical course. A careful history and physical examination, imaging studies, and a strong suspicion are helpful for establishing the diagnosis of an orbital foreign body.

---

807. Bullock, M. R., et al. (2006). "Surgical management of depressed cranial fractures." Neurosurgery 58(3 Suppl): S56-iv.

INDICATIONS: Patients with open (compound) cranial fractures depressed greater than the thickness of the cranium should undergo operative intervention to prevent infection. Patients with open (compound) depressed cranial fractures may be treated nonoperatively if there is no clinical or radiographic evidence of dural penetration, significant intracranial hematoma, depression greater than 1 cm, frontal sinus involvement, gross cosmetic deformity, wound infection, pneumocephalus, or gross wound contamination. Nonoperative management of closed (simple) depressed cranial fractures is a treatment option., TIMING: Early operation is recommended to reduce the incidence of infection., METHODS: Elevation and debridement is recommended as the surgical method of choice. Primary bone fragment replacement is a surgical option in the absence of wound infection at the time of surgery. All management strategies for open (compound) depressed fractures should include antibiotics.

808. Bullock, M. R., et al. (1999). "An open-label study of CP-101,606 in subjects with a severe traumatic head injury or spontaneous intracerebral hemorrhage." Annals of the New York Academy of Sciences 890: 51-58.

CP-101,606 is a postsynaptic antagonist of N-methyl-D-aspartate (NMDA) receptors bearing the NR2B subunit. When administered intravenously (i.v.), it decreases the effects of traumatic brain injury (TBI) and focal ischemia in animal models. Therapeutic plasma concentrations (200 ng/ml) in animals, have been well tolerated in healthy human volunteers. The purpose of the present dose escalation study was to assess the safety, tolerability, and pharmacokinetics of CP-101,606 in subjects who had suffered either an acute severe TBI (Glasgow Coma Scale 3-8) or spontaneous intracerebral hemorrhage. Thirty

patients, 20 with a TBI and 10 with a stroke, were enrolled in the trial and began receiving an i.v. infusion of CP-101,606 for 2 hours, 24 hours, or 72 hours within 12 hours of brain injury. For the first two hours, the drug was given a rate of 0.75 mg/kg/hr and then stopped (n = 17) or continued for 22 (n = 2) or 70 hours (n = 11) at 0.37 mg/kg/hr. Plasma and cerebrospinal fluid (CSF) were collected at serial times during and after treatment. There were no consistent changes in blood pressure or pulse nor any clinically significant hematological or electrocardiogram (ECG) abnormalities attributable to CP-101,606. No adverse events or behavioral changes were considered to be related to the drug. Plasma concentrations of CP-101,606 over 200 ng/ml were rapidly achieved in the blood and CSF within two hours and were sustained there as long as the drug was infused. CSF concentrations were slightly higher than that in plasma by the end of infusion suggesting good penetration of CP-101,606 into the CSF. Outcome in the severe TBI patients, as measured by the Glasgow Outcome Score at six months, suggested that a two-hour infusion yielded a range of scores similar to contemporary patients with a severe TBI treated at our hospital while the outcomes of the patients treated with either a 24- or 72-hour infusion were better on average. Thus, these results indicate that CP-101,606 infused for up to 72 hours is well tolerated, penetrates the CSF and brain, and may improve outcome in the brain-injured patient.

810. Bullock, R. M., et al. (2009). "Outcome s following cranial gunshot wounds a clinical study." Journal of neurotrauma 26(8): A83.

Cranial Gunshot Wounds (CGSW) unfortunately remains common in the USA and is increasing in frequency, in urban areas, and due to military conflict. They represent up to 20% of severe TBI deaths, in some areas. Self-inflicted CGSW have increased exponentially, in recent months. We therefore reviewed and audited our experience with CGSW, over one year (Feb, 2008-Feb, 2009) at the Ryder Trauma Center, Jackson Hospital and University of Miami, which serves approximately three million people. Of 480 severe and moderate traumatic brain injuries, patients arriving alive at the trauma center, 98 were due to CGSW (20.42 %). Of these, 46 became brain dead or died in the trauma unit, within four hours (9.58%). 32 patients were admitted to neurosurgery/trauma surgery and all underwent craniotomy/craniotomy and de-bridement of these. The survival rate was 65.6 % (21 patients). Of the survivors, 2 remain vegetative but the remainders were discharged home. With aggressive surgical decompression=debridement, and neuro-intensive care, CGSW's can achieve outcomes comparable to closed severe TBI, and in accord with recent military reports.

811. Bunc, G., et al. (2001). "Pneumocephalus secondary to a neck stab wound without neurologic injury in a 13-year-old girl." Pediatric neurosurgery 34(5): 239-241.

Pneumocephalus is usually caused by injury that damages the brain meninges and thus allows air to enter the intracranial cavity. Our intention was to establish the importance of considering a stab wound in the neck as a possible cause of traumatic pneumocephalus. The paper presents the case of a 13-year-old girl who was accidentally stabbed in the neck with a kitchen knife by her brother. She had no neurological deficit but had developed headaches. An examination showed cerebrospinal fluid leaking from the neck wound and a CT scan revealed the pneumocephalus. Following surgical treatment, the patient's clinical symptoms regressed. To our knowledge, this case is the first report of the manifestation of pneumocephalus as the result of a neck stab wound in a child; overall, there are only three reported cases of pneumocephalus caused by a neck stab wound. Copyright 2001 S. Karger AG, Basel

812. Bunevicius, A., et al. (2016). "Penetrating Anterior Skull Base Fracture Inflicted by a Cow's Horn." Journal of neurosciences in rural practice 7(Suppl 1): S106-S108.

Farm workers are at increased risk for animal-inflicted head injuries that are associated with significant morbidity and occasionally may be fatal. These injuries may cause permanent eye damage with or without concomitant skull base fracture. Here, we present a male farmer who suffered a cow attack that resulted in perforating orbital injury with comminuted frontobasal cranial fracture caused by a cow's horn. The next day, the patient developed nasal and orbital cerebrospinal fluid (CSF) leak. Computed Tomography cisternography revealed CSF leakage to frontal and maxillary sinuses. The patient was treated using prophylactic antibiotic therapy, lumbar drainage, and underwent craniotomy for debridement and dural tear plastic. Post operative course was uneventful and there were no signs of CSF leak 1 year after the surgery. The case illustrates unusual injury inflicted by a cow's horn and underscores the importance of careful investigation for underlying skull base fracture and CSF leakage in patients sustaining perforating orbital injuries. Adequate and timely management of dural tears is associated with favorable outcomes.

813. Bungardt, N., et al. (2005). "[Suicidal shot in the mouth with an unmodified blank cartridge pistol]." Suizidaler Mundschuss mit nicht manipulierter Schreckschusspistole. 216(1-2): 1-6.

In the medicolegal literature reports of suicides with weapons designed for self-defence, especially gas pistols, are rare. We report on a suicide of a 54-year-old woman who fired a fatal shot in her mouth with an unmanipulated blank cartridge pistol, make Rohm RG 8, calibre 8 mm. The autopsy findings (lips and mucosa of the buccal vestibule without injuries, but extensive lesions of the tongue and the middle and rear third of the smooth palate) suggest that the shot was fired - as observed by a witness - with the barrel of the weapon inside the oral cavity. Both macroscopic inspection and histological investigations excluded the possibility that death was caused by an injury of the brain, in particular the brain stem. The immediate cause of death was deep aspiration of chyme with concurrent aspiration of blood.

814. Bunse, J. (1987). "[Unchanged ability following temporal gunshot injury with multiple intracerebral gunshot pellets]." Ungestorte Handlungsfahigkeit nach temporaler Schussverletzung mit zahlreichen intrazerebralen Schrotkugeln. 58(5): 305-307.

The case of a 25-year-old male schizophrenic patient is reported, who with suicidal intent wounded himself in the left temporal region, using a shotgun. Despite having about 30 intacerebral smallshot, he remained continuously conscious. The clinical neurological status did not reveal any abnormalities in the course of treatment. The differing results of CT and NMR examination are reported. Finally, the complications reported in the literature are discussed.

815. Bunzel, B., et al. (2007). "Mechanical circulatory support as a bridge to heart transplantation: what remains? Long-term emotional sequelae in patients and spouses." The Journal of heart and lung transplantation : the official publication of the International Society for Heart Transplantation 26(4): 384-389.

BACKGROUND: Implantation of a ventricular assist device (VAD) reduces short-term mortality and morbidity and provides patients with reasonable quality of life even though it may also be a long-lasting emotional burden. This study was conducted to analyze the long-time emotional consequences of VAD implantation, followed by heart transplantation in patients and spouses., METHODS: This cross-sectional study used the Impact of Event Scale-Revised (IES-R) Version, recording avoidance, intrusion, and hyperarousal, to investigate symptoms of post-traumatic stress disorder (PTSD), and VAD-related fears and concerns. The study cohort comprised 38 patients (36 men,

2 women) and 27 spouses (26 women, 1 man), 6 to 135 months post-operatively., RESULTS: Seven (26%) of the 27 spouses but none of the patients met the criteria for PTSD. Patients who were operated at the early stage of our VAD program (82.0 +/- 31.4 months between implantation and evaluation) were significantly more likely to have a spouse with PTSD syndromes than those whose operation took place later on (42.1 +/- 31.1 months, p = 0.007). Patients with higher avoidance scores and a higher level of hyperarousal were significantly more often affiliated with a PTSD spouse than those with lower avoidance (p = 0.008) and hyperarousal scores (p = 0.001). Spouses displayed significantly higher scores in all IES-R dimensions, and they worried more about device-related problems (malfunctioning, pain, infection, and stroke) than the patients themselves. The noise of the device system was not a crucial issue., CONCLUSION: Our study found that implantation of a VAD, followed by transplantation, does not lead to PTSD in patients but it does in their spouses in the long run. Their emotional well being deserves much closer attention.

816. Burke, D. J. and S. H. Y. Chou (2018). "Anoxic brain injury and non-convulsive status epilepticus secondary to gunshot wound to airway: A case with favorable prognosis." Neurocritical care 29(1): S58.

Introduction We present a patient with anoxic brain injury and non-convulsive status epilepticus. Despite poor prognosis, as evidenced by marked cerebral edema and non-convulsive status epilepticus, the patient had a favorable prognosis. Methods A case report of a patient presenting with non-convulsive status epilepticus following anoxic injury. Results An 18-year-old healthy male presented following a gunshot wound to the oropharynx requiring emergent cricothyrotomy in the field due to compromised airway and desaturation. He had numerous desaturations in transport to SpO2 60% requiring urgent correction on arrival to our institution. Two hours post injury, the patient remained unresponsive and EEG showed non-convulsive status epilepticus with high amplitude 3 Hz generalized discharges. He was given 4mg of IV lorazepam push with resolution of the generalized discharges and emergence of a diffuse delta-theta background with spontaneous variability. At this point, aggressive treatment was pursued due to favorable background. Nonconvulsive status resumed and was refractory despite high dose levetiracetam, phenobarbital and midazolam drip. CT head showed diffuse cerebral edema and patient was started on pentobarbital infusion for both refractory cerebral edema and NCSE. An intracranial bolt was placed by Neurosurgery to monitor ICP. ICP was periodically >25mmHg and 23.4 percent NaCl was given. He was on pentobarbital for total of 14 days for both malignant cerebral edema and NCSE. One month after discontinuing pentobarbital, his exam improved with spontaneous eye opening and spontaneous movements of all extremities. His exam continues to improve and he is pending follow-up in Epilepsy Clinic. Conclusions We report a case of severe anoxic brain injury and non-convulsive status epilepticus with malignant cerebral edema. With aggressive management including 14 days of pentobarbital and intracranial multi-modality monitoring of ICP, he had a favorable prognosis.

817. Burke, D. T., et al. (2003). "A mysterious temporal penetrating head wound without fracture." Brain injury 17(3): 245-253.

Unwitnessed head injuries are often diagnostic and management dilemmas. Low-velocity penetrating head wounds are rare. This paper describes a case of an accidental low-velocity penetrating head wound through the soft tissue of the temporal region. This lesion resulted in a deep intra-cerebral haemorrhage, after the initial assessment revealed no evidence of skull fracture, missile or missile track. The diagnostic evaluation and medical course of this case are presented. This is the first case in the medical literature of a brain injury by an object that penetrated the calvarium at low velocity but which did not produce a fracture of the skull. The evolving diagnostic dilemma is outlined to its conclusion, through 3 years of follow-up observation.

818. Burnett, B. R. (1991). "Detection of bone and bone-plus-bullet particles in backspatter from close-range shots to heads." Journal of forensic sciences 36(6): 1745-1752.

A victim was shot in the head with a 9-mm Smith & Wesson pistol using Winchester Silvertip hollow-point ammunition. Of interest in this case was the distance from the muzzle of the weapon to the victim's head, since the wound characteristics were equivocal for firing distance. Two other handguns (revolvers) were involved in this shooting, in addition to a revolver owned by the victim. The handguns were sampled using tape lifts, and the casings were sampled by washing them in distilled water, followed by vacuum filtration of the washing water through 0.2-microns-pore Nuclepore filters. These materials were examined by scanning electron microscopy/energy-dispersive X-ray analysis. Calcium-phosphorous (bone) particles were detected on the 9-mm Smith & Wesson pistol, on two casings found at the scene, and on one of the revolvers. Two of the calcium-phosphorous particles on the casings had associated bullet fragments. Test shots on live pigs destined for slaughter showed that bone particles are a feature of backspatter from close-range shots to heads. Contamination of nearby surfaces by bone fragments and bone-plus-bullet fragments, as well as other organic debris, appears to be quite heavy.

---

819. Burnett, B. R., et al. (2022). "Errors, omissions and mistaken testimony in a shooting case." Forensic Science International: Reports 6.

The female victim died 17 h after the discharge of a.38 caliber unjacketed bullet into the temporal bone above her right ear. Her boyfriend was accused of homicide and convicted. The victim was able to affect coordinated movements for some seconds after her devastating head wound. Her post shooting movements were documented by bloodstains. Two forensic pathologists where mistaken in calling gunpowder stippling on the victim's scalp as suture punctate wounds. The ruptured right meningeal artery was spurting. Blowback spatter transitioned into the arterial spurting spatter as the victim fell to the floor. The post-shooting movements of the victim created stains that confused two bloodstain experts who believed the victim could not move after her cranial wounding. The victim's hair sample, taken by the emergency room doctor, lacked chain and was subsampled by an unknown party prior to chemical gunshot residue (GSR) testing. The tests were negative which led to the erroneous conclusion the shot was from a distance. The mishandling of the hair sample was not discovered until after trial. A GSR expert testified that the airborne GSR settles in seconds in an enclosed area. However, later publications concluded GSR remains airborne for many minutes. The GSR contamination of the defendant was instrumental in his conviction. The GSR expert never informed the DA or the Court of his error. The evidence indicates the victim's gunshot wound was self inflicted.

820. Burnett, C. A. and T. J. Clifford (2012). "Prosthodontic rehabilitation of patients with orofacial defects." Dental update 39(4): 291-296.

In 2007 in the UK, 5410 people were diagnosed with an oral cancer. It is therefore imperative that all dentists, medical practitioners and dental care practitioners are vigilant when examining the oral cavity so that any suspicious ulcers, swellings or changes in colour of the mucosa are referred at the earliest stage. To give the patient the best prognosis with an orofacial defect following tumour removal or trauma, it is most important to have the appropriate skills in a multidisciplinary team. The management of patients comprises pre-surgical, surgical and post-surgical phases.

---

821. Burns, E. C., et al. (2015). "Pediatric mild traumatic brain injury with intracranial hemorrhage: Identifying low-risk patients who may not benefit from ICU admission." Academic emergency medicine 22(5): S209.

Background: Care of pediatric traumatic brain injury (TBI) is generally dictated by depth of coma and presence of traumatic intracranial hemorrhage (tICH). Patients with a Glasgow Coma Scale (GCS) score ≤13 are frequently admitted to intensive care areas (ICU) for monitoring. Though no guidelines exist, patients with tICH of any severity are often admitted to ICU for early detection of

secondary brain injury. We hypothesize there is a subset of children with mild TBI/ tICH for whom ICU care is unnecessary. Objectives: The aims of this study are to: 1) Quantify and assess TBI/tICH frequency and disposition within our catchment area; 2) identify a subset of patients at low-risk of receiving critical care interventions (CCI). Methods: This was a retrospective cohort study. We reviewed patients 0-17 years seen at two Level I trauma centers in Oregon from Mar 2008 - Aug 2013. We identified all potential subjects via ICD-9 visit codes, then manually reviewed and abstracted these records for completeness. Exclusions were made for penetrating trauma, coagulopathy, direct admit, or field CCI. CCI included mechanical ventilation, invasive monitoring, blood product transfusion, hyperosmolar therapy, and neurosurgery. Outcomes were ED disposition and incidence of CCI, and a multivariable regression analysis was conducted. Results: Of the 650 potential subjects reviewed, 270 had tICH. We excluded 49 patients for direct admit, penetrating trauma, or field CCI, leaving 221 patients for the primary sample. One-hundred ninety four (88%) were initially admitted to ICU; no patients initially admitted to non- ICU received CCI. In total, 37 (17%) had CCI, an outcome associated with low GCS, epidural hematoma (EDH), depressed skull fracture, and severe/ unknown mechanism. Of 80 patients with GCS >13, non-EDH, absence of depressed fracture, and mild-moderate mechanism, 1 had CCI, resulting in a decision rule with a negative predictive value (NPV) of 99%. Conclusion: Our results demonstrate a subset of low-risk patients that may not require ICU care. We propose a decision rule including physiologic, historical and imaging factors to identify low-risk children with tICH who may be observed outside ICU, barring other critical injuries. This decision rule will require prospective validation.

---

822. Burns, J. J., et al. (2020). "Absence of caregiver explanation for injury as a predictor of serious traumatic brain injury in children." Journal of Investigative Medicine 68(2): 629.

Purpose of study The goal of this study is to compare the outcomes of traumatic brain injury (TBI) for children whose caregivers present with no explanation for the injury vs. those with an explanation. Methods used A retrospective study of 253 children, 0-36 months old who presented with TBI to the Emergency Department was conducted. Mechanisms of injury that had a degree of uncertainty such as falls, no explanation, struck by object were included whereas motor vehicle, bicycle related accidents or penetrating injury were excluded. Data was further stratified based whether an explanation of head injury was present vs. no explanation. Chi-square was used to compare outcomes including clinically important traumatic brain injury (CiTBI), clinical markers of serious head injury including Glascow score ≤8, seizures on presentation, or intensitve care unit admission for those with vs. without caregiver explanation of mechanism of injury. Also, comparisons of suspicion of abuse, and outcomes after discharge were conducted. Summary of results 19 of 24 infants (79.2%) with no explanation vs. 65 of 229 (28.4%) with explanation were found to have ciTBI ($p<0.001$). For no explanation there were higher rates vs. explanation of having: GCS ≤8 (16.7% vs. 4.8%; $p=0.041$ Fisher exact test), seizures (29.2% vs. 12.8%; $p=0.038$ Fisher Exact Test) and admission to ICU (66.7% vs. 39.1%; $p=0.009$). Suspicion for abuse was found in 100% for no explanation vs. 45.2% with explanation ($p<0.001$). Also, outcomes at discharge were unfavorable in 33.3% with no explanation vs. 7.9% with explanation ($p=0.001$ Fisher Exact Test). Conclusions Head injury in children is a major cause of morbidity and mortality. When no explanation is given in cases of traumatic brain injury, this study revealed increased incidence of ciTBI, increased markers of clinical acuity, higher suspicion for abuse, and poorer outcomes when compared to cases with caregiver explanation of the mechanism of injury. Lack of history should serve as a strong indicator to evaluate for ciTBI, especially in the children.

---

We describe a rare case of depressed skull fracture after a dog bite. To our knowledge only three such cases have been reported.

---

824. Burns, T. G., et al. (2022). "A longitudinal evaluation of a penetrating traumatic brain injury: Theories of plasticity and vulnerability." Applied neuropsychology. Adult 29(4): 881-886.

Penetrating traumatic brain injury (TBI) is uncommon in infancy. The consequences may be devastating, especially when the injury is extensive and affects eloquent areas of the brain. There is the potential for neuropsychological dysfunction that may impact the individual's development and well-being into adulthood. In the context of early brain injury, the developing brain is both remarkably resilient and vulnerable. The present case study describes a patient who experienced a penetrating TBI at 9 days of age, subsequently developed intractable seizures, and underwent left hemispherectomy. Neuropsychological testing at ages 5, 10, 11, and 19 years are presented alongside fMRI and Wada testing. While the patient initially developed cognitive functions in the low-average range by age 5, scores on neuropsychological assessments began to decrease thereafter. This case is discussed with attention to vulnerability and plasticity theories. It highlights the ability of the brain to reorganize and allow the development of functions that would normally be sub-served by damaged areas and the limits of plasticity. Further, this case illustrates the vulnerability of the early brain to insult, the potential to grow into deficits, and the need to consider a variety of factors when predicting outcomes for cases of pediatric brain injury.

825. Bursick, D. M. and R. G. Selker (1981). "Intracranial pencil injuries." Surgical neurology 16(6): 427-431.

A case of delayed central nervous system manifestations of intracranial penetration by a pencil is presented. Twenty-one additional cases of cerebral injury by pencils are reviewed and discussed. A high index of suspicion, liberal use of the computed tomographic scan, and early operative intervention in cases with cranial perforation are important points in the management of these injuries.

826. Burstein, E. S. and D. R. Lazzaro (2013). "Traumatic ruptured globe eye injuries in a large urban center." Clinical Ophthalmology 7: 485-488.

Background: The purpose of this study was to examine patient characteristics and outcomes in a group of consecutive patients with ruptured globe eye injuries at Kings County Hospital Center, a large, urban, level 1 trauma center. Methods: A retrospective chart review was performed to identify all patients with ruptured globe eye injuries seen between January 2009 and October 2011. Thirty-eight patients who sustained ruptured globe eye injuries from all causes were investigated for etiology and final visual outcomes Results: Eight eyes in which vision could be assessed were evaluated as having no light perception at presentation and three of these eyes required primary enucleation. Of the 38 eyes, orbit fractures were found in 15 eyes and an intraocular foreign body was found in six eyes. Discussion: Our cohort revealed a 37.5% rate of primary enucleation in eyes with no light perception, which we believe to be a reflection of the severity of injury. All three cases were secondary to a gunshot wound. Further, our sample, although small in size, revealed a very high percentage of eyes that were ruptured secondary to violent causes compared with other studies.

828. Bush, T. G., et al. (1999). "Leukocyte infiltration, neuronal degeneration, and neurite outgrowth after ablation of scar-forming, reactive astrocytes in adult transgenic mice." Neuron 23(2): 297-308.

Reactive astrocytes adjacent to a forebrain stab injury were selectively ablated in adult mice expressing HSV-TK from the Gfap promoter by treatment with ganciclovir. Injured tissue that was depleted of GFAP-positive astrocytes exhibited (1) a prolonged 25-fold increase in infiltration of CD45-

positive leukocytes, including ultrastructurally identified monocytes, macrophages, neutrophils, and lymphocytes, (2) failure of blood-brain barrier (BBB) repair, (3) substantial neuronal degeneration that could be attenuated by chronic glutamate receptor blockade, and (4) a pronounced increase in local neurite outgrowth. These findings show that genetic targeting can be used to ablate scar-forming astrocytes and demonstrate roles for astrocytes in regulating leukocyte trafficking, repairing the BBB, protecting neurons, and restricting nerve fiber growth after injury in the adult central nervous system.

829. Busin, M., et al. (2016). "Corneal Epithelial Stem Cells Repopulate the Donor Area within 1 Year from Limbus Removal for Limbal Autograft." Ophthalmology 123(12): 2481-2488.

PURPOSE: To determine whether limbal epithelial stem cells (LESCs) repopulate the site harvested for limbal autograft transplantation (LAT), the expression of LESCs markers was evaluated in bioptic specimens obtained from the donor area 12 months or more after surgery., DESIGN: Interventional case series., PARTICIPANTS: Patients who underwent LAT for unilateral acquired limbal stem cell deficiency after chemical burn., METHODS: Corneal limbal explants were obtained from 2 sites, the harvested area and the untouched control area, in the donor eyes of 6 patients who previously underwent LAT for unilateral acquired limbal stem cell deficiency after chemical burn. Limbal epithelial stem cells were isolated, and cellular, immunohistochemistry, and histologic parameters were assessed to compare differences between LESCs isolated from harvested or control sites., MAIN OUTCOME MEASURES: Presence of LESCs 1 year or more after LAT., RESULTS: Specific markers (p63, Ki67, K12), percentage of LESCs, cell doubling, and number of passages in culture did not differ significantly between harvested and control sites. However, the distinctive structure of the palisades of Vogt was found only in 2 of 6 harvested sites., CONCLUSIONS: Limbal epithelial stem cells repopulate the donor site as early as 1 year after limbus removal for LAT. Autologous transplantation of conjunctiva and limbus are safe procedures and can be performed in cases that cannot be treated by simple grafting of LESCs cultured ex vivo.

830. Bustos, J. L., et al. (2006). "Glasgow coma scale 7 or less surveillance program for brain death identification in Argentina: Epidemiology and outcome." Transplantation proceedings 38(10): 3697-3699.

BACKGROUND: In Argentina, the rate of cadaveric organ donation per million inhabitants has recently increased to 10.5 (it was previously <7)., PURPOSE: To overcome this challenge, the National Institute for Organ Donation and Transplantation (INCUCAI) created a proactive donor detection plan performed by intensive care unit (ICU) physicians (hospital transplantation coordinators) from 90 selected hospitals across the country., METHODS: A prospective, observational study of patients in severe coma status was conducted from September 2003 to December 2005. We enrolled hospitalized patients who displayed a Glasgow Coma Scale (GCS) of 7 or less and who were admitted to ICUs. Data included demographics, etiology of coma, cardiac arrest, brain death, discharge or derivation, and positive/negative donation., RESULTS: Among 9841 enrolled patients, we excluded 498 who were discharged to another hospital or had unknown outcomes, leaving 9343 for analysis including 64% males and 36% females of overall mean age 50 +/- 19 years (adults) and 5 +/- 4 years (children). Herein, we have highlighted the high risk of death during the first 2 days in the ICU of patients with GCS 7 or less. Gunshot to the head-injured patients and those with hemorrhagic strokes were less likely to survive. In this study, cardiac arrest events and organ donors (OD) GCS 7 or less ratios emerged as quality control markers of ICU care, unraveling problems of potential donor maintenance or inadequate policies., CONCLUSIONS: The GCS 7 or less surveillance program seemed to be a valuable tool for identifying organ donors and potentially treatable events, such as the high rate of cardiac arrest observed in this study.

831. Butler, E. K., et al. (2021). "Surgeon choice in management of pediatric abdominal trauma." Journal of pediatric surgery 56(1): 146-152.

BACKGROUND: No guidelines exist for management of hemodynamically stable children with suspected hollow viscus injury. We sought to determine factors contributing to surgeon management of these patients., METHODS: Surgeon members of the Eastern Association for the Surgery of Trauma and American Pediatric Surgical Association completed a survey on 3 blunt abdominal injury scenarios: (1) isolated, (2) with multisystem injury, and (3) with traumatic brain injury (TBI), and a penetrating injury scenario. Multivariable logistic regression was used to determine factors associated with initial management of observation vs. operation for blunt injury and observation vs. local wound exploration versus laparoscopy for penetrating injury., RESULTS: Of 394 surgeons (response rate 22.3%), 50.3% were pediatric surgeons. For scenarios 1-3, 32.2%, 49.3%, and 60.7% of surgeons chose operation over observation, respectively. Compared to isolated blunt injury, surgeons were more likely to choose operation for patients with multisystem injury (aOR 2.20, 95%CI: 1.78-2.72) or TBI (aOR 3.60, 95%CI: 2.79-4.66). Pediatric surgeons were less likely to choose operation (aOR 0.32, 95%CI: 0.22-0.44). For penetrating injury, 39.1%, 29.5%, and 31.5% of surgeons chose observation, local wound exploration, and laparoscopy, respectively., CONCLUSIONS: Large variation exists in management of hemodynamically stable children with suspected hollow viscus injury. Although patient injury characteristics account for some variation, surgeon factors such as type of surgeon also play a role. Evidence-based practice guidelines should be developed to standardize care., TYPE OF STUDY: Cross-Sectional Survey., LEVEL OF EVIDENCE: N/A.

833. Buwembo, J. and J. G. De Villiers (1995). "Migrating retained intracranial missiles." African Journal of Neurological Sciences 14(1): 1-5.

Five cases of retained, migrating intracranial bullets are presented. The bullet migrated transventricularly in four patients and subdurally in one. In five cases the bullets were safely removed: via craniotomy for the four patients with an intraventricular location and through a borehole for the patient with a subcortical location. One patient presented a year after injury with severe headache, due to the bullet having become a third ventricular foreign body. The difficulties experienced in localising the missile using computerised tomography (CT) due to metallic artefact and the usefulness of air encephalography in one of the cases, are demonstrated. Intra-operative localisation using an image intensifier prior to siting the craniotomy, is essential.

835. Buyuk, Y., et al. (2009). "Fatal cranial shot by blank cartridge gun: two suicide cases." Journal of forensic and legal medicine 16(6): 354-356.

Blank firing pistols are generally considered to be harmless and these guns are not accepted as being firearms in most countries. Due to lack of legal regulations these guns are easily purchased by anyone aged over 18 years. Reports of serious injuries and even fatalities due to these guns are increasing in the literature. These guns when modified or even unmodified can cause serious and potentially fatal injuries. Without doing any changes to the barrel, using blank or tear gas cartridges, firing at contact range can cause penetration of gas into the body including bone originated from gun

powder. We report two suicide cases shooting themselves at temporal region with a blank cartridge gun at contact range. There was no foreign body on radiological examination and there was no trajectory of a bullet inside the brain. In both cases the wound was at the right temporal region and there was defect at temporal bone. There was circular soot around this bone defect. The injury of the brain tissue was localized at the level of the defect but there was widespread subarachnoidal bleeding. We discussed the potential danger of these guns and stressed the need of legal regulations concerning these guns.

836. Buyukkaya, R., et al. (2014). "Massive cerebrovascular air embolism during posttraumatic cardiopulmonary resuscitation." The American journal of emergency medicine 32(2): 194.e191-192.

Air embolism is known to be a complicating factor in several clinical settings, including thoracic, cardiovascular, and neurosurgical operations; central line placement; and penetrating thoracic and cranial trauma. There are, however, only few case descriptions for cardiopulmonary resuscitation massive cerebral air embolism, and the frequency of this supposedly rare complication is unknown. Computed tomography is useful for showing cerebral air embolism. In this report, we present a 16-year-old adolescent girl with cerebrovascular air embolism on computed tomographic examination after a posttraumatic cardiopulmonary resuscitation and discuss the reasonable mechanisms of cerebrovascular air embolism.

837. Buz, S., et al. (2008). "Conventional surgical repair and endovascular treatment of acute traumatic aortic rupture." European journal of cardio-thoracic surgery : official journal of the European Association for Cardio-thoracic Surgery 33(2): 143-149.

OBJECTIVE: Endoluminal aortic stent grafting offers a potentially less invasive alternative to open chest surgery, especially in patients with polytrauma. We compare the results of conventional surgical repair and endovascular treatment of traumatic aortic rupture., METHODS: Retrospectively, 74 patients with acute traumatic aortic rupture were analyzed. Most of the patients had a rupture limited to the isthmus, and severe associated injuries. Thirty-five patients (6 female, 29 male, mean age 36 years) underwent surgical repair. Two patients were operated upon without cardiopulmonary bypass. In 39 patients (5 female, 34 male, mean age 36 years) thoracic endografts were implanted. The delay between trauma and treatment was comparable in the two groups., RESULTS: Hospital mortality was 20% (7 of 35 patients) in the surgical group and 7.7% (3 of 39 patients) in the endovascular group. The most common cause of death in the surgical group was brain death in severe traumatic patients. Ten surgical complications occurred in 5 patients: respiratory insufficiency (n=3), pulmonary infection (n=2), recurrent nerve palsy (n=2), repeat thoracotomy (n=2), and compartment syndrome (n=1). No patient in this group had paraplegia. Except for one case, which required conversion to conventional surgery, stent-graft implantation was successful in all cases, without peri-interventional complications or procedure-induced paraplegia. In 9 patients the left subclavian artery was covered with the device. Two patients underwent surgical repair 15 days and 4 months after endografting because of injury of the aortic wall by the stent and development of a spurious aneurysm, respectively., CONCLUSIONS: In the treatment of traumatic thoracic aortic rupture, the early outcome of patients treated with endovascular stent grafts appears to be better than that with conventional surgical repair. The new technique allows safe and successful repair of this life-threatening injury in the early phase of trauma management. How far this potential benefit is sustained in the long term remains unclear at present.

838. Buznyk, O., et al. (2015). "Bioengineered Corneas Grafted as Alternatives to Human Donor Corneas in Three High-Risk Patients." Clinical and translational science 8(5): 558-562.

Corneas with severe pathologies have a high risk of rejection when conventionally grafted with human donor tissues. In this early observational study, we grafted bioengineered corneal implants made from recombinant human collagen and synthetic phosphorylcholine polymer into three patients for whom donor cornea transplantation carried a high risk of transplant failure. These patients suffered from

corneal ulcers and recurrent erosions preoperatively. The implants provided relief from pain and discomfort, restored corneal integrity by promoting endogenous regeneration of corneal tissues, and improved vision in two of three patients. Such implants could in the future be alternatives to donor corneas for high-risk patients, and therefore, merits further testing in a clinical trial.

839. Byard, R. W. (2013). "Suicide attempts involving power drills." Journal of forensic and legal medicine 20(8): 1032-1034.

A 61-year-old man was found dead next to a power drill soiled with blood and bone dust. A 5 mm circular wound of the forehead corresponded to the size of the drill bit. Subarachnoid haemorrhage was present over the anterior pole of the left frontal lobe with a penetrating injury extending 75 mm into the frontal lobe white matter towards, but not involving, the basal ganglia. No major intracranial vessels had been injured and there was no significant intraparenchymal haemorrhage. Death was due to haemorrhage from self-inflicted stab wounds to the abdomen with an associated penetrating intracranial wound from a power drill. Deaths due to power drills are rare and are either accidents or suicides. Wounds caused by power drills may be mistaken for bullet entrance wounds, and the marks around a wound from the drill chuck as muzzle imprints. A lack of internal bevelling helps to distinguish the entrance wound from that due to a projectile. Significant penetration of the brain may occur without lethal injury.

840. Byard, R. W. and P. Blumbergs (2011). "Foreign body penetration of the fontanelle: mechanisms and manner of death." The American journal of forensic medicine and pathology 32(3): 197-199.

Penetrating injuries of the anterior fontanelle are exceedingly uncommon and are most often associated with inflicted injury. This report of an 11-month-old boy, who fell backward onto a lamp-shade strut that penetrated his anterior fontanelle and left frontal lobe, demonstrates that accidental injuries may also rarely occur. Death was due to hypoxic-ischemic encephalopathy complicating raised intracranial pressure after a penetrating injury of the brain. Careful evaluation of the death scene with reconstruction incorporating the autopsy findings was required to establish the veracity of the history and the credibility of the proposed sequence of events. Mechanisms of death after penetrating injuries of the fontanelle include immediate effects from direct damage to cerebral vital structures or blood vessels with hemorrhage or delayed effects from either cerebral edema with hypoxic-ischemic encephalopathy or sepsis.

841. Byrne, J. P., et al. (2017). "Effectiveness of low-molecular-weight heparin versus unfractionated heparin to prevent pulmonary embolism following major trauma: A propensity-matched analysis." The journal of trauma and acute care surgery 82(2): 252-262.

BACKGROUND: Pulmonary embolism (PE) is a leading cause of delayed mortality in patients with severe injury. While low-molecular-weight heparin (LMWH) is often favored over unfractionated heparin (UH) for thromboprophylaxis, evidence is lacking to demonstrate an effect on the occurrence of PE. This study compared the effectiveness of LMWH versus UH to prevent PE in patients following major trauma., METHODS: Data for adults with severe injury who received thromboprophylaxis with LMWH or UH were derived from the American College of Surgeons Trauma Quality Improvement Program (2012-2015). Patients who died or were discharged within 5 days were excluded. Rates of PE were compared between propensity-matched LMWH and UH groups. Subgroup analyses included patients with blunt multisystem injury, penetrating truncal injury, shock, severe traumatic brain injury, and isolated orthopedic injury. A center-level analysis was performed to determine if practices with respect to choice of prophylaxis type influence hospital PE rates., RESULTS: We identified 153,474 patients at 217 trauma centers who received thromboprophylaxis with LMWH or UH. Low-molecular-

weight heparin was given in 74% of patients. Pulmonary embolism occurred in 1.8%. Propensity score matching yielded a well-balanced cohort of 75,920 patients. After matching, LMWH was associated with a significantly lower rate of PE compared with UH (1.4% vs. 2.4%; odds ratio, 0.56; 95% confidence interval, 0.50-0.63). This finding was consistent across injury subgroups. Trauma centers in the highest quartile of LMWH utilization (median LMWH use, 95%) reported significantly fewer PE compared with centers in the lowest quartile (median LMWH use, 39%; 1.2% vs. 2.0%; odds ratio, 0.59; 95% confidence interval, 0.48-0.74)., CONCLUSIONS: Thromboprophylaxis with LMWH (vs. UH) was associated with significantly lower risk of PE. Trauma centers favoring LMWH-based prophylaxis strategies reported lower rates of PE. Low-molecular-weight heparin should be the anticoagulant agent of choice for prevention of PE in patients with major trauma., LEVEL OF EVIDENCE: Therapeutic study, level III.

845. Byvaltsev, V. A., et al. (2015). "A case of successful treatment of post-traumatic frontal lobe brain abscess in patient during subacute period of penetrating craniocerebral trauma." New Armenian Medical Journal 9(4): 80-88.

Brain abscesses are dangerous complications of penetrating traumatic brain injury, where the mortality rate of inflammatory processes progression is up to 60%. Risk factors for this pathology are penetrating traumatic brain injury, purulent inflammation of the lungs, bacterial endocarditis, arteriovenous fistula in the pulmonary circulation. Brain abscesses as a result of gunshot craniocerebral traumas during military actions in World War II were developed in 7.5-27.6% cases, 84% of which were single abscesses, whereas in 16% - multiple, while during military actions in Chechnya and Afghanistan brain abscesses range decreased up to 7.5%, and during peace in case of weapon injuries up to 5%. Firstly such decreasing tendency can be explained with the improved quality of preliminary surgical debridement, secondly with the appearance of antibiotics' new generation and thirdly, with the improvement of drainage systems incorporated onto the wounds. Brain abscesses pathogens are streptococci and staphylococci in 33-50% of cases. In 80% of cases several microorganisms are identified including anaerobic forms. Despite the fact that traumatic brain abscess is a subject to a surgical treatment according to the classic rules, there are reports of successful conservative treatment in literature. The indications for conservative therapy are hard-to-reach location, multiple lesions less than 2.5 cm in diameter, associated meningitis, encephalitic stage of the brain abscesses. There are not so many supporters of conservative treatment. According to several authors, solely conservative treatment of the brain abscesses is not effective at all, or, if applied in the later stages, the formation of brain abscesses ends with persistent neurological deficit in more than a half of the patients. The article presents literature review about epidemiology, pathophysiology, diagnostics and the treatment of patients with brain abscesses, as well as a clinical case of successful treatment of post-traumatic abscess of the left frontal lobe of the patient in the subacute stage of open penetrating traumatic brain injury. This case is interesting in its dynamics. Encapsulated abscess was formed in the result of inefficient conservative therapy within 1 month after traumatic brain injury.

846. Cabano, F., et al. (1992). "[The surgery of liver trauma (clinical contribution)]." La chirurgia dei traumi epatici (contributo clinico). 44(3-4): 115-130.

Authors perform a retrospective review of all hepatic injuries operated on between 1974 and 1990 at Clinica Chirurgica II (ex Patologia Chirurgica II, ex Semeiotica Chirurgica) of Policlinico San Matteo (IRCCS) of Pavia. Thirteen patients were treated, 9 men and 4 women, with age ranged from 13 to 68 years and a mean age of 38 years. They were 21% of all patients operated on for abdominal trauma. Penetrating wounds were present in only two cases (15%), the other patients (85%) were affected by blunt trauma. The mechanisms of injuries were: road accidents (77%), fall at work (8%), gun shot wound (8%), stab wound (8%). All patients had associated injuries. The mortality was 31%: one patient died for haemorrhagic shock and the other three for craniocerebral injuries. After reviewing the several haemostatic techniques advocated for the various types of hepatic injuries, the authors stress that, although most lesions are minor and can be managed by simple technique of haemostasis, often the prognosis is severe for the associated injuries.

847. Cacciatori, A., et al. (2018). "Does Traumatic Brain Injury by Firearm Injury Accelerates the Brain Death Cascade? Preliminary Results." Transplantation proceedings 50(2): 400-404.

Brain death (BD) triggers a series of pathophysiological events similar to multiple-organ dysfunction. Traumatic brain injury (TBI) due to firearm injury (FAI) causes lesions that could lead to BD. Patients admitted to the ICU due to severe TBI that evolved to BD were studied, including those caused by FAI; the 2 groups were compared with the objective of demonstrating that the support of the deceased donor by TBI due to FAI is more unstable and of shorter duration than the one related to TBI by another cause. Preliminary results demonstrated that the individuals with TBI by FAI died in BD in a higher percentage than the individuals with TBI caused by accidents (83% vs 41%). The donor treatment period was lower in individuals who presented TBI by FAI. These individuals needed higher doses of noradrenaline as vasopressor support for their treatment, without showing a statistically significant difference (P = .15), compared with individuals whose BD cause was TBI caused by accident.

848. Cacciatori, A., et al. (2018). "Utility of Transcranial Doppler in the Coordination of Transplants: 10 Years of Experience." Transplantation proceedings 50(2): 408-411.

Transcranial Doppler (TCD) integrated to multimodal neuromonitoring of neurocritical patients is a useful tool in the clinical follow-up. A retrospective and descriptive study of 194 patients who were admitted into the intensive care unit (ICU) was carried out from December 2007 to February 2017. We analyzed the distribution of study frequencies with respect to the pathologies that motivated them, the characteristics of patients who evolved to brain death (BD), and most frequent patterns of cerebral circulatory arrest. Ninety-four of the patients that evolved to BD required 126 studies during their follow-up. The insonation of the 2 middle cerebral arteries and the basilar artery was the most frequent combination (30%). Most frequent reasons of request for a TCD included apnea test intolerance and reduction of waiting time and sedation analgesia. These 10 years of experience have enabled a deeper understanding of the cerebral hemodynamics and the identification of common patterns of high resistance to different pathologies (subarachnoid hemorrhage, severe skull trauma, anoxic ischemia, ammonia encephalopathy) that explain the severity of the acute brain injury, related to the increase of brain volume and its deleterious consequence: the elevation of intracranial pressure (ICP). In the same way, because invasive ICP monitoring is not available in all cases, with a tomographic scan of the skull we have been able to observe a correlation of some imaging signs suggestive of intracranial hypertension with patterns of high resistance obtained by the TCD in the pathologies mentioned. We recommend that each ICU that assists neurocritical patients should have TCD equipment and the skilled personnel to carry out the technique.

849. Cacic, K. and J. Bonomo (2021). "NeuroEthics and End of Life Care." Emergency medicine clinics of North America 39(1): 217-225.

The emergency department is where the patient and potential ethical challenges are first encountered. Patients with acute neurologic illness introduce a unique set of dilemmas related to the pressure for ultra-early prognosis in the wake of rapidly advancing treatments. Many with neurologic injury are unable to provide autonomous consent, further complicating the picture, potentially asking uncertain surrogates to make quick decisions that may result in significant disability. The emergency department physician must take these ethical quandaries into account to provide standard of care treatment. Copyright Published by Elsevier Inc.

851. Cadena, G., et al. (2012). "CT scan interpretation in TBI: Implications for resident training." Journal of neurotrauma 29(10): A41.

Introduction Resident interpretation of cranial CT scans has been reported in various subspecialties, but no such study exists in the neurosurgery literature. We compared neurosurgery resident trauma head CT interpretations with those of a faculty member, with emphasis on year of training and features comprising the Rotterdam and Marshall CT scores. Methods Data was prospectively collected from traumatic brain injury (TBI) patients at a level 1 trauma center between September 2010 and November 2011. Enrollment criteria included adult and pediatric patients with blunt or penetrating TBI and abnormal admission head CT scans, or persistent neurological deficit and a negative head CT. All patients were evaluated by the neurosurgery resident on call. Resident interpretations were entered into an electronic consult note that required responses to variables such as the presence of parenchymal hematoma, contusions, intraventricular hemorrhage (IVH), epidural hematoma (EDH), subdural hematoma (SDH), subarachnoid hemorrhage (SAH), midline shift, cisternal compression, and skull fractures. An attending neurosurgeon who was blinded to resident interpretations reviewed each CT scan and recorded his interpretations. Marshall and Rotterdam scores were assigned to each CT scan interpretation using data gathered from the consult notes. Members blinded to the final analysis entered the data into a secure centralized database. Results 615 patients were evaluated for TBI at our level 1 trauma center between September 2010 and November 2011. Twenty-nine patients were excluded from the study due to unavailability of their image, resulting in a final study population of 586 patients. This group had an average age of 37 years, was comprised of 414 men and 172 women, and 238 (40.6%) of them were transferred from an outside hospital. Junior residents saw the majority of consults: 40% by PGY1s, 32% by PGY2s, and 22% by PGY3s. There were significant differences between resident and faculty interpretations with regard to the presence of contusions, IPH, and SAH. When comparing junior residents (PGY1 and PGY2) to faculty, the residents recorded more IPH and SDH, whereas faculty recorded more contusions, IVH, and SAH. More senior residents (PGY3 and PGY4) did not differ significantly from faculty with regard to identifying the presence of IVH or SAH. The presence of EDH and midline shift was also not significantly different between residents and faculty. The effects of these differences on CT scoring systems were also investigated. Resident interpretations resulted in more patients with Rotterdam scores of 2 and less scores of 3 as compared to faculty. When stratified by year of training, this difference diminished with each successive year of training. Resident scores were nearly identical to that of faculty by PGY3. Marshall CT scores demonstrated an opposite trend, with resident interpretations yielding a higher rate of false positive interpretations when scans were actually normal. This became less significant with increasing year of training. Type 3 injuries became more similar with each training year. Conclusions Neurosurgery residents generally perform well with respect to interpreting key features of trauma head CTs; and they are often on par with that of faculty. Differences between resident and faculty interpretation highlight

the importance of targeted education, and may influence accurate patient prognostication and/or enrollment in clinical trials that are based on admission CT criteria. However, these differences in interpretation do not seem to affect acute clinical decision making, as even our junior-most residents were adept at identifying large extra-axial lesions and midline shift, features that may prompt immediate surgical intervention and triaging. This large blinded investigational study confirms neurosurgery residents' abilities to critically and accurately interpret trauma head CT scans.

852. Cage, T. A., et al. (2017). "Penetrating knife injury to the skull: A case report in pediatric neurosurgical care." Trauma (United Kingdom) 19(4): 302-307.

Isolated penetrating head injury in children is rare and is usually accidental. Each case is unique since the penetrating object and the trajectory through the brain parenchyma vary greatly among patients. We present a three-year-old girl who presented with a kitchen utility knife penetrating her left midface, skull, and brain abutting the anterior cerebral vasculature. Though the patient initially presented to a local trauma center, there were no pediatric nor vascular neurosurgeons on staff. Thus, she was transferred to our tertiary facility for definitive surgical management. A pediatric and vascular neurosurgeon worked together to remove the knife safely and the underlying vasculature remained intact. Postoperatively, the patient did well and was neurologically intact. Though penetrating cranial injury is rare in the pediatric population, such complex cases of brain injury can be properly managed with good outcome by an interdisciplinary team of specialists in tertiary care centers and can result in an excellent surgical and functional outcome for the patient.

853. Cai, Z., et al. (2020). "Study on behind Helmet Blunt Trauma Caused by High-Speed Bullet." Applied Bionics and Biomechanics 2020.

The mechanism of Behind Helmet Blunt Trauma (BHBT) caused by a high-speed bullet is difficult to understand. At present, there is still a lack of corresponding parameters and test methods to evaluate this damage effectively. The purpose of the current study is therefore to investigate the response of the human skull and brain tissue under the loading of a bullet impacting a bullet-proof helmet, with the effects of impact direction, impact speed, and impactor structure being considered. A human brain finite element model which can accurately reconstruct the anatomical structures of the scalp, skull, brain tissue, etc., and can realistically reflect the biomechanical response of the brain under high impact speed was employed in this study. The responses of Back Face Deformation (BFD), brain displacement, skull stress, and dura mater pressure were extracted from simulations as the parameters reflecting BHBT risk, and the relationships between BHBT and bullet-proof equipment structure and performance were also investigated. The simulation results show that the frontal impact of the skull produces the largest amount of BFD, and when the impact directions are from the side, the skull stress is about twice higher than other directions. As the impact velocity increases, BFD, brain displacement, skull stress, and dura mater pressure increase. The brain damage caused by different structural bullet bodies is different under the condition of the same kinetic energy. The skull stress caused by the handgun bullet is the largest. The findings indicate that when a bullet impacts on the bullet-proof helmet, it has a higher probability of causing brain displacement and intracranial high pressure. The research results can provide a reference value for helmet optimization design and antielasticity evaluation and provide the theoretical basis for protection and rescue.

855. Cairns, G. and A. Belshaw (2021). "Successful management of internal carotid artery transection secondary to a gunshot wound and subsequent malignant MCA syndrome." Case Reports in Neurology 13(2): 276-283.

There are over 100,000 strokes each year in the UK. A very small proportion of these can be attributed to gunshot wounds and subsequent surgical intervention. We present a rare case of a 24-year-old male patient admitted to the Emergency Department having sustained a gunshot wound to the left side of his neck. Initial imaging and surgical exploration revealed significant left-sided vertebral artery damage and a complete transection of the internal carotid artery. Following damage control surgery (DCS), the patient was admitted to ITU but had an acute neurological deterioration and was found to have suffered malignant middle cerebral artery (MCA) syndrome, requiring an urgent decompressive craniectomy. The patient's National Institutes of Health Stroke Scale (NIHSS) at this stage was 26. After a prolonged ITU stay and repatriation to a local stroke unit for intensive therapies input, the patient walked out of the hospital independently on day 106, with an improved NIHSS of 3. This case report aims to highlight the rarity of an ischaemic stroke, secondary to the DCS required for a near fatal gunshot wound, along with the importance of timely recognition of an acute deterioration following artery ligation. Additionally, it aims to examine the lifesaving surgical management of malignant MCA syndrome and in turn the significance of the shared decision-making process between clinicians, the patient, and family members, due to the high rate of poor functional outcomes following this major surgery.

Background and aims: Bizarre craniocerebral-penetrating injuries have been reported in the literature that were caused by nails, metal poles, ice picks, keys, pencils, chopsticks, and power drills. Aims: Our aims are to identify the early and late complications of intracranial injuries due to foreign bodies penetrating through the paranasal sinuses. Methods: We present a case of 6 years-old girl with menengitis after transnasal penetrating head injury with a pencil. Results: Transnasal penetrating foreign bodies may cause serious complications such as intracranial injury, intracranial hemorrhage and intracranial infections. Conclusions: This case illustruates the necessity of advanced imaging modalites and consultations of ENT and neurosurgery.

860. Calkins, C. M., et al. (2001). "Life-threatening dog attacks: a devastating combination of penetrating and blunt injuries." Journal of pediatric surgery 36(8): 1115-1117.

BACKGROUND/PURPOSE: Children often are the victims of dog attacks. Although bite injuries sustained in an attack characteristically are attributed to the penetrating component of the bite, the blunt nature of a bite may represent the most serious and devastating component of injury. The purpose of this study was to characterize a group of children suffering life-threatening dog bites and examine the predominant aspect of injury., METHODS: Thirty-nine children were admitted to the trauma service at a regional pediatric trauma center with the diagnosis of dog bite injury over a 6-year period (1994 through 1999). Patient demographics, site and description of injury, and surgical procedures performed were recorded from a chart review., RESULTS: Mean age of the 35 children included for analysis was 5.4 years (range, 0.8 to 17 years). Twenty-five (71%) injuries occurred in the head and neck region. Eight (23%) children sustained life-threatening injuries. Of these, blunt force was the predominant injury in 6. This resulted in 1 (20%) arterial occlusion requiring vascular reconstruction, 2 (40%) permanent neurologic injuries (stroke, spinal cord transection), and 1 (20%) death (exsanguination)., CONCLUSIONS: On evaluation of a dog attack, the focus generally is on the obvious penetrating aspect of the bite. Yet, we found the blunt component of injury can have devastating consequences reflected in acute arterial, brain, and spinal cord injury. Even in the absence of significant penetrating trauma, further evaluation should be considered to exclude occult blunt arterial or neurologic injury. Copyright 2001 by W.B. Saunders Company.

861. Callahan, C. D. and K. J. Hagglund (1995). "Comparing neuropsychological and psychiatric evaluation of competency in rehabilitation: a case example." Archives of physical medicine and rehabilitation 76(10): 909-912.

This report describes the case of a 20-year-old man who sustained a gunshot wound to the forehead, resulting in traumatic brain injury and C2 ventilator-dependent quadriplegia. Issues of personal control and autonomy typified his psychological adjustment. The question of competency to refuse medical treatment arose when he disallowed intervention for a suspected ear infection not confirmed by culture. Subsequently, the patient was alternately described as incompetent by a psychiatrist and competent by a medical ethics review panel. These decisions are interpreted within the context of existing medical-legal literature and historical precedent of competency in civil law. Central to competency evaluation is the patient's ability to recognize that a decision-making process is required, to review the pros and cons of various options, and to communicate a decision. Importantly, this decision need not be in accordance with the opinion of family or the health care team. Neuropsychological screening indicated the patient's cognitive abilities were within functional limits, and he subsequently agreed to treatment after experiencing pain and fever, and learning of a positive culture. It is concluded that a two-pronged neuropsychological evaluation of competency based on the patient's information processing capabilities is most appropriate in medical rehabilitation settings.

862. Callahan, N. and L. Moles (2021). "Posterior occipital gunshot wound causing orbital roof blow-in fracture with encephalocele." International journal of oral and maxillofacial surgery 50(12): 1603-1605.

Isolated orbital roof fractures are rare fractures that usually occur in conjunction with other facial bone fractures during high velocity trauma. This report concerns a patient with an isolated orbital roof fracture with encephalocele, including its diagnosis, surgical management, and clinical follow-up. This case required a multidisciplinary approach to safely repair the fracture, reduce the encephalocele, restore the orbital volume, and restore the patient's form and function.

863. Callcut, R. A., et al. (2019). "The why and how our trauma patients die: A prospective Multicenter Western Trauma Association study." The journal of trauma and acute care surgery 86(5): 864-870.

BACKGROUND: Historically, hemorrhage has been attributed as the leading cause (40%) of early death. However, a rigorous, real-time classification of the cause of death (COD) has not been

performed. This study sought to prospectively adjudicate and classify COD to determine the epidemiology of trauma mortality., METHODS: Eighteen trauma centers prospectively enrolled all adult trauma patients at the time of death during December 2015 to August 2017. Immediately following death, attending providers adjudicated the primary and contributing secondary COD using standardized definitions. Data were confirmed by autopsies, if performed., RESULTS: One thousand five hundred thirty-six patients were enrolled with a median age of 55 years (interquartile range, 32-75 years), 74.5% were male. Penetrating mechanism (n = 412) patients were younger (32 vs. 64, $p < 0.0001$) and more likely to be male (86.7% vs. 69.9%, $p < 0.0001$). Falls were the most common mechanism of injury (26.6%), with gunshot wounds second (24.3%). The most common overall primary COD was traumatic brain injury (TBI) (45%), followed by exsanguination (23%). Traumatic brain injury was nonsurvivable in 82.2% of cases. Blunt patients were more likely to have TBI (47.8% vs. 37.4%, $p < 0.0001$) and penetrating patients exsanguination (51.7% vs. 12.5%, $p < 0.0001$) as the primary COD. Exsanguination was the predominant prehospital (44.7%) and early COD (39.1%) with TBI as the most common later. Penetrating mechanism patients died earlier with 80.1% on day 0 (vs. 38.5%, $p < 0.0001$). Most deaths were deemed disease-related (69.3%), rather than by limitation of further aggressive care (30.7%). Hemorrhage was a contributing cause to 38.8% of deaths that occurred due to withdrawal of care., CONCLUSION: Exsanguination remains the predominant early primary COD with TBI accounting for most deaths at later time points. Timing and primary COD vary significantly by mechanism. Contemporaneous adjudication of COD is essential to elucidate the true understanding of patient outcome, center performance, and future research., LEVEL OF EVIDENCE: Epidemiologic, level II.

865. Calvano, T. P., et al. (2010). "Central nervous system infections in patients with severe burns." Burns : journal of the International Society for Burn Injuries 36(5): 688-691.

BACKGROUND: Central nervous system (CNS) infections develop in 3-9% of neurosurgical ICU patients and 0.4-2% of all patients hospitalized with head trauma. CNS infection incidence in burn patients is unknown and this study sets out to identify the incidence and risk factors associated with CNS infections., METHODS: A retrospective electronic chart review was performed from 1 July 2003 to 30 June 2008 evaluating inpatient medical records along with cerebrospinal fluid (CSF) microbiological results for the presence of CNS infection. The presence of facial and head injuries and burns, along with intracranial interventions were reviewed for association with CNS infections., RESULTS: There were 1964 admissions with 2 patients (0.1%) found to have CNS infection; 1 each with MRSA and Acinetobacter baumannii. Both patients had facial burns and trauma to their head that required intracranial surgery. Of note, both patients had bacteremia with the same microorganisms isolated from their CSF and both survived. Of all patients, 29% had head or neck trauma and burns; 0.35% of those had a CNS infection. Scalp harvest for grafts or debridement of burned scalp was performed on 125 patients of which 9 had an invasive surgical procedure that involved penetration of the skull. The 2 infected patients were from these 9 intracranial surgical patients revealing a 22% infection rate., CONCLUSION: The incidence of CNS infections in patients with severe burns is extremely low at 0.1%. This rate was low even with head and face burns with trauma unless the patient underwent an intracranial procedure.

866. Calvo-Rubal, A., et al. (2006). "[Cranial wounds of the skull caused by a fencing-foil]." Lesion intracraneal transorbitaria por florete. Caso clinico. 17(6): 550-554.

UNLABELLED: Penetrating stab cranial wounds of the skull by fencing-foil are rare in western countries., CASE REPORT: This 46-year-old man suffered a penetrating stab wound of the skull through the right orbital region. As a consequence he developed an intracranial hematoma requiring surgical evacuation., DISCUSSION AND CONCLUSIONS: Damage of intracranial contents due to transorbital penetrating objects other than missiles is a rare event.

867. Calzolari, F., et al. (1994). "Magnetic Resonance Imaging of strange body: Considerations of intracranial strange body." Rivista di Neuroradiologia 7(2): 286-288.

We report a case of a child presenting an intracranial foreign body. Child's mother told a history of headache. MR performed at first showed a rough artifact in frontal and parietal regions. Plain film x-rays of the skull and CT, performed afterwards, demonstrated a needle-shaped foreign body in the left frontal lobe; the eye of the needle was fixed in the cranial vault. Then, craniotomy was performed: a darning needle was removed. The manner of the needle penetration into the skull is still unknown; judicial authorities have been informed.

868. Çam, I., et al. (2014). "Endovascular treatment of travmatic vertebral artery arteriovenous fistula and pseudoaneurysm." Neuroradiology 56: 389.

PURPOSE: The purpose of this study was to describe the clinical and anjiographic findings and present endovascular treatment of vertebral arteriovenous fistula and pseudoaneurysm after vertebral artery injury with gunshot wounds MATERIAL AN METHODS:53 year old woman was admitted to our hospital with two gunshot wounds to her head and neck . She was eveluated with cranial-cervikal X-ray, computed tomography (CT) (Toshiba aquillion,64 slice), Brain 3T MR (Philips Achievea Intera Release Eindhoven, Netherlands) and angiography. Electrically detachable coils were used for endovascular treatment. RESULTS: CT examination revealed multiple fracture of left maxillofacial bones and foramen transversarium on C1 vertebral bone. Postcontrast scan showed pseudoaneurysm of left vertebral artery. Cranial MRI showed no ischemic lesion. After stabilization , selective left vertebral angiography demonstrated pseudoaneurysm and fistula at C1 level between distal segment vertebral artery of PICA with vertebral venous plexus. Therefore a catheter was advanced into the right vertebral artery from right brachial artery. micro catheter (Excelsior SL-10) and microguide (Radiofocus 0.012 90°) was advanced into left vertebral artery via right vertebral artery and basillary artery. Distal part of Arteriorvenous fistula and pseudoaneurysm was occluded with electrically detachable coils. Catheter was advanced into the left vertebral artery via right femoral artery. Proximal part of arteriovenous fistula and pseudoaneurysm was occluded with electrically detachable coils. Control anjography showed complete occlusion of the arteriorvenous fistula and pseudoaneurysm. CONCLUSION: An arteriovenous fistula and psedoaneurysm involving the vertebral artery is rare. These lesions can be of traumatic or spontaneous origin. Traumatic lesions are freuquently associated with penetrating neck injuries. Endovascular techniques are safe and effective method of treatment and is not associated with significant morbidity and mortality. (Figure Presented).

871. Cameron, D. and B. A. Lupton (1993). "Inadvertent brain penetration during neonatal nasotracheal intubation." Archives of disease in childhood 69(1 Spec No): 79-80.

During routine nasal intubation of a premature infant, the endotracheal tube penetrated the brain. Bloodstained cerebrospinal fluid and neural tissue was apparent. Initial cranial sonography was normal, but the infant later developed extensive intracranial haemorrhage. Rotation of an endotracheal tube to facilitate insertion angles the bevel at the tip upwards, increasing risk of brain penetration. Great care is required during nasal intubation; use of a small feeding tube over which to slide an endotracheal tube may be helpful.

872. Campbell, A. A., et al. (2015). "Spontaneous Resorption of a Penetrating Orbital Bone Fracture Fragment." Ophthalmic plastic and reconstructive surgery 31(5): e123-125.

The authors describe a 20-year-old man who sustained multiple facial fractures in a high-speed motor vehicle crash, including a bone fragment from a skull base fracture that penetrated the orbital soft tissues superomedially. Serial CT scans documented spontaneous resorption over a 6-month period. While it is known that autologous bone grafts used in craniofacial reconstruction exhibit variable amounts of bone resorption, the complete resorption of an intraorbital fracture fragment has not been documented in the literature. His clinical care and the report of his case were undertaken in a fashion in accordance with the principles of the Health Insurance Portability and Accountability Act regulations.

874. Campbell-Hewson, G., et al. (1997). "The use of air weapons in attempted suicide." Injury 28(2): 153-158.

The use of airguns in attempted suicide is uncommon. In such instances, the surface wounds caused by discharged pellets may be inconspicuous or appear deceptively trivial to the medical examiner. Airgun pellets however are easily capable of penetrating the skull or abdominal cavity when fired at the close ranges involved in suicide attempts. The destructive power of these weapons at close range should not be underestimated. We describe three cases of attempted suicide and review the other nine cases reported in the medical literature: of the 12 suicide attempts there were three fatalities. Seventeen out of a total of 19 pellets fired penetrated either the cranial or peritoneal cavity or damaged deep structures. Most of the victims were male. The majority of wounds were right sided. Four of the attempts were extremely determined, involving repeated discharge of the airgun or the use of other means to effect suicide.

875. Campbell-Malone, R., et al. (2008). "Gross and histologic evidence of sharp and blunt trauma in North Atlantic right whales (Eubalaena glacialis) killed by vessels." Journal of zoo and wildlife medicine : official publication of the American Association of Zoo Veterinarians 39(1): 37-55.

Vessel-whale collision events represented the ultimate cause of death for 21 (52.5%) of the 40 North Atlantic right whales (Eubalaena glacialis) necropsied between 1970 and December 2006. Injuries seen in vessel-struck whales fall into two distinct categories: 1) sharp trauma, often resulting from contact with the propeller, and 2) blunt trauma, presumably resulting from contact with a vessel's hull. This study analyzes four trauma cases that resulted from vessel-whale collisions, which together provide a framework for a more critical understanding of lethal blunt and sharp trauma resulting from vessel collisions with right whales. In case no. 1, contact with a propeller resulted in three deep lacerations. The animal survived acute trauma only to succumb nearly 14 years later when the lesions reopened and

became infected. In case no. 2, anecdotal reports linked the laceration of large arteries of the peduncle and histologic evidence of perimortem trauma at a bone fracture site to vessel-whale collision trauma. Case no. 3 had a laceration of the oral rete and a fracture of the rostrum. Both of the areas displayed histologic evidence of perimortem blunt trauma. Finally, in case no. 4, an antemortem mandibular fracture, two additional skull fractures, and widespread hemorrhage were consistent with severe blunt trauma. Evidence from each case, including the timing of trauma relative to the time of death and identifying characteristics of both trauma types, are presented. Before this study, no detailed comparative analysis of trauma pathology that resulted from lethal interactions between vessels and right whales had been conducted. This study demonstrates the importance of detailed gross and histologic examination in determining the significance and timing of traumatic events. This work represents a new paradigm for the differential diagnosis of lethal sharp and blunt trauma in right whales hit by ships and will enhance the present understanding of the impact of anthropogenic mortality on this critically endangered species.

---

877. Campos-Mollo, E., et al. (2007). "[Orbital penetrating wound by a bull horn]." Herida penetrante orbitaria por asta de toro. 82(10): 645-648.

INTRODUCTION: Bull horn injuries are severe lesions with a high risk of bacterial contamination, and are common in countries where people are fond of bullfighting and related spectacles., CASE REPORT: A 19-year-old man was referred with a penetrating wound in the superior left eyelid produced by a bull horn and resulting in a fracture of the orbital roof and a fat hernia. Prophylactic antibiotics and tetanus toxoid were administered and surgical reconstruction of the wound performed. Orbital cellulitis did develop, but this responded to systemic antibiotic therapy within a few days., DISCUSSION: Successful treatment of this type of lesion requires early diagnosis, meticulous surgical exploration and appropriate use of prophylactic antibiotics and tetanus toxoid.

---

878. Campos-Pires, R., et al. (2016). "Xenon provides short-term and long-term neuroprotection in a rodent model of traumatic brain injury." Brain injury 30(5-6): 653.

Background: Traumatic brain injury (TBI) is a leading cause of morbidity and mortality in western societies. Despite improvements in medical care, clinical TBI treatment is mainly supportive and no specific neuroprotective drugs are currently available. TBI results from external forces applied to the head, resulting in immediate and irreversible damage, known as primary injury and triggering early and long-lasting, secondary injury cascades. Over-activation of N-methyl-Daspartate (NMDA) receptors is thought to play a key role in secondary injury development. Xenon is a noble gas and general anaesthetic. Xenon is a competitive inhibitor of the NMDA receptor at the glycine binding site and it has been shown to be neuroprotective in models of brain ischaemia. Much less is known about the xenon effect in the context of traumatic brain injury. Objectives: Our work focused on evaluating xenon's neuroprotective efficacy in the reproducible controlled cortical impact model of blunt traumatic brain injury, mimicking elements found after moderate-to-severe TBI in humans, such as contusional lesion, brain oedema, elevated intracranial pressure and neurological impairment. Methods: Adult C57BL/6 male mice (n = 196) were fixed in a stereotactic frame under anaesthesia and underwent a right parietal cortical impact, delivered by a custom-made electropneumatic impactor with a 3 mm diameter tip perpendicular to the brain surface. An impact velocity of 8 m s-1, impact duration of 150 ms and brain penetration depth of 1.0 mm were used. Throughout the procedure, core body temperature was monitored and controlled. Animals were randomly assigned to control (75% nitrogen:25% oxygen) and xenon treated (30%, 50% or 75% xenon:25% oxygen, balanced with nitrogen) groups. Short-erm and long-term outcomes, both functional and histological, were measured by researchers blinded to

treatment. Statistical significance was assessed with one-way and two-way ANOVA with Bonferroni's posthoc test (SigmaPlot software). Results: Our study showed 75% xenon significantly ($p < 0.05$) reduced contusion volume 24 hours after injury and significantly ($p < 0.05$) improved neurologic outcome up to 4 days after injury and clinically relevant locomotor parameters 1 month after injury. Xenon treatment significantly ($p < 0.05$) reduced contusion volume when given up to 3 hours after injury and significantly ($p < 0.05$) improved neurologic outcome when given up to 1 hour after injury. Significant ($p < 0.05$) reductions in contusion volume and an improvement in neurologic outcome 24 hours after injury were also achieved with 30% and 50% xenon concentrations. Conclusions: Our results show for the first time in an animal model of TBI that xenon improves functional outcomes and reduces contusion volume. We demonstrate both a reduction in the development of secondary injury and improvement in functional neurological outcome. Our findings, including the demonstration of long-term neuroprotection and a clinically relevant therapeutic time window, support the idea that xenon may be of benefit as a neuroprotective treatment in TBI patients.

879. Can, C., et al. (2017). "The effect of brain tomography findings on mortality in sniper shot head injuries." Journal of the Royal Army Medical Corps 163(3): 211-214.

OBJECTIVES: Penetrating gunshot head injuries have a poor prognosis and require prompt care. Brain CT is a routine component of the standard evaluation of head wounds and suspected brain injury. We aimed to investigate the effect of brain CT findings on mortality in gunshot head injury patients who were admitted to our emergency department (ED) from the Syrian Civil War., METHODS: The study group comprised patients who were admitted to the ED with gunshot brain injury. Patients' GCS scores, prehospital intubations and brain CT findings were examined., RESULTS: 104 patients were included (92% male, mean age 25 years). Pneumocephalus, midline shift, penetrating head injury, patients with GCS scores <=6 and patients who had to be intubated in the prehospital period were associated with higher mortality ($p<0.05$)., DISCUSSION: The results of this study demonstrated that pneumocephalus, midline shift, a penetrating head injury, GCS scores <=6 and prehospital intubation are associated with high mortality, whereas patients with temporal bone fracture, perforating or single cerebral lobe head injury had a higher survival rates. The temporal bone has a relatively thin and smooth shape compared with the other skull bones so a bullet is less fragmented when it has penetrated the temporal bone, which could be a reason for the reduced cavitation effect. In perforating head injury, the bullet makes a second hole and so will have deposited less energy than a retained bullet with a consequent reduction in intracranial injury and mortality. Further studies are required to reach definitive conclusions.

881. Cannon, J. W., et al. (2021). "Use of Thromboelastography in the Evaluation and Management of Patients With Traumatic Brain Injury: A Systematic Review and Meta-Analysis." Critical care explorations 3(9): e0526.

Traumatic brain injury is associated with coagulopathy that increases mortality risk. Viscoelastic hemostatic assays such as thromboelastography (Haemonetics SA, Signy, Switzerland) provide rapid coagulopathy assessment and may be particularly useful for goal-directed treatment of traumatic brain injury patients. We conducted a systematic review to assess thromboelastography in the evaluation and management of coagulopathy in traumatic brain injury patients., DATA SOURCES: MEDLINE, PubMed Central, Embase, and CENTRAL., STUDY SELECTION: Clinical studies of adult patients with traumatic brain injury (isolated or polytrauma) who were assessed by either standard thromboelastography or thromboelastography with platelet mapping plus either conventional

coagulation assays or platelet function assays from January 1999 to June 2021., DATA EXTRACTION: Demographics, injury mechanism and severity, diagnostic, laboratory data, therapies, and outcome data were extracted for analysis and comparison., DATA SYNTHESIS: Database search revealed 1,169 sources; eight additional articles were identified by the authors. After review, 31 publications were used for qualitative analysis, and of these, 16 were used for quantitative analysis. Qualitative and quantitative analysis found unique patterns of thromboelastography and thromboelastography with platelet mapping parameters in traumatic brain injury patients. Patterns were distinct compared with healthy controls, nontraumatic brain injury trauma patients, and traumatic brain injury subpopulations including those with severe traumatic brain injury or penetrating traumatic brain injury. Abnormal thromboelastography K-time and adenosine diphosphate % inhibition on thromboelastography with platelet mapping are associated with decreased survival after traumatic brain injury. Subgroup meta-analysis of severe traumatic brain injury patients from two randomized controlled trials demonstrated improved survival when using a viscoelastic hemostatic assay-guided resuscitation strategy (odds ratio, 0.39; 95% CI, 0.17-0.91; p = 0.030)., CONCLUSIONS: Thromboelastography and thromboelastography with platelet mapping characterize coagulopathy patterns in traumatic brain injury patients. Abnormal thromboelastography profiles are associated with poor outcomes. Conversely, treatment protocols designed to normalize abnormal parameters may be associated with improved traumatic brain injury patient outcomes. Current quality of evidence in this population is low; so future efforts should evaluate viscoelastic hemostatic assay-guided hemostatic resuscitation in larger numbers of traumatic brain injury patients with specific focus on those with traumatic brain injury-associated coagulopathy.

882. Cantero, C. R. R. (2005). "Healthy years of life lost by traumatism in the Balbuena General Hospital." Medicina Interna de Mexico 21(5): 329-338.

Objective: To determine the healthy years of life lost by traumatism in the room of urgencies of the General Hospital Balbuena, from July 1 2003 to June 30 2004. Materials and methods: We included data of all the patients who entered in the room of urgencies of the General Hospital Balbuena, during the period from 1 July 2003 to June 30 2004, taking as inclusion approaches: a) patient who died due to traumatism in the room of urgencies of the General Hospital Balbuena, b) both sexes, c) any age; the exclusion approaches: a) lost file, b) patient that enter in cadaver quality. The hope of life considered was: men, 73.1 and women, 77.6, provided by the National Institute of Geography and Computer science in Mexico (INEGI). Results: During the period mentioned above, 104 patients died in the room of urgencies of the Hospital, of which 87 were male and 17 female. The days with the highest index of mortality were: Sunday (22 deaths), Monday, Thursday and Saturday (15 deaths). The months with the highest mortality were March and June (13 deaths), September and October (11 deaths). The age groups that had the biggest mortality were 30 to 44 years (28 deaths) and the one of the 15 to 29 years (24 deaths). The causes of mortality were: blunt traumatism (61 deaths) and penetrating traumatism (14 deaths). Brain injury traumatism accounted for 31 deaths in total, followed by the multiple traumatism with 26, and 26 cadavers were received. Traumatism originates 2,559.5 lost years of life, and the average for person of lost years of life due to traumatism is of 35.5. Conclusions: Traumatism is considered a cause of important mortality in the society that affects young people mainly, in reproductive and economically active age, which represents an important lost years of life, the lost healthy years of life. These results allow evaluating the impact (expressed in units of time) of different illnesses in a certain society, and offering a common metric for lost of health years for all the causes and all the ages.

883. Canturk, G., et al. (2009). "Autopsy findings of suicidal deaths committed by firearms in Ankara, Turkey." Medicine, science, and the law 49(3): 207-212.

The purpose of this study was to examine autopsy findings from suicidal deaths using firearms in Ankara, Turkey, and to compare the results with those reported from other studies. We retrospectively evaluated suicidal deaths by firearms referred for autopsy to the Morgue Department, Institute of Forensic Medicine, between 2002 and 2004. Results were subjected to discriminant analyses using SPSS 11.5 package program. One hundred and fifteen cases (83.3%) were male, the ratio of male to female was 5 to 1 and the mean age was 31.96 years (range:12-85 years). Forty cases were aged between 12 years and 20 years, 28 were aged between 0 and 18 (20.29%). One hundred and thirty-three cases (96.4%) had one bullet entry and five cases (3.6%) had two bullet entries. Out of 143 bullet entries, 116 (81.12%) were caused by gunshots fired from contact or near contact range. Regarding bullet entry sites, 103 (72.03%) were on the head with 56 (54.37%) located on the right temporal region. Gunshot related crimes are an increasing cause for concern in Turkey. However, a simple preventive measure may prevent the suicidal deaths of many young people.

887. Caplan, E. S., et al. (1983). "Response of traumatized splenectomized patients to immediate vaccination with polyvalent pneumococcal vaccine." The Journal of trauma 23(9): 801-805.

In recent years the syndrome of overwhelming post-splenectomy sepsis has been increasingly reported in adults. Since more than 50% of these infections are caused by pneumococcus these post-splenectomy patients are considered a suitable group to receive the pneumococcal vaccine. Previous studies of the response obtained in post-splenectomy patients have been conflicting and we found no study that looked at the response to immediate vaccination in this group of patients. Sixteen consecutive multitraumatized patients received polyvalent pneumococcal vaccine 0.5 ml IM within 72 hours of splenectomy and 10 normal controls were given 0.5 cc polyvalent pneumococcal vaccine. Patients received an average of 19.2 units of blood and blood products; seven were on steroids for concomitant head injury. Antibody was measured by the radioimmune assay. Most of the subjects of both groups responded to at least seven of the 12 measured antigens and no patient in the control group and only one in the splenectomized group responded to all 12 antigens. When rate of response to individual serotypes was compared no difference was found between the two groups. Comparison of geometric mean fold rise and fold rise between the two groups for each of the 12 serotypes revealed essentially no difference. We conclude the response to polyvalent pneumococcal vaccine among polytrauma splenectomized patients is similar to that of normal controls, and that the vaccine can be administered immediately post-splenectomy.

888. Carbonell, A. L. and J. Boya (1988). "Ultrastructural study on meningeal regeneration and meningo-glial relationships after cerebral stab wound in the adult rat." Brain research 439(1-2): 337-344.

Meningeal regeneration and meninges-glial relationships during the reparation of an experimental brain stab wound, are studied with the electron microscope. At 14 days after the wound, a

continuous newly formed basal lamina separates both nervous and meningeal tissues. Later, the astroglial processes of regenerated glia limitans showed very infolded surfaces and numerous filaments inside of them. Across the cavity left by the wound, filament-rich astroglial processes, forming bundles or glial cords of variable diameter, were seen. Each glial cord was surrounded by a basal lamina covered on the outside by a discontinuous sheet of meningocytic processes. Although regenerated meningocytes displayed interlacing processes forming a loose reticular network, large cellular meningocyte masses were also found.

889. Carbonell, W. S. and J. W. Mandell (2003). "Transient neuronal but persistent astroglial activation of ERK/MAP kinase after focal brain injury in mice." Journal of neurotrauma 20(4): 327-336.

Astrogliosis is a nearly ubiquitous response to a variety of insults to the central nervous system (CNS). This reaction is triggered rapidly, but can persist for years after the initial trauma. Little is known about the signaling mechanisms responsible for this activation and its chronic maintenance. Extracellular signal-regulated kinase/mitogen-activated protein kinase (ERK/MAPK) activation is implicated in several functions important to the reactive glial phenotype such as cellular proliferation and motility. Here we utilize immunohistochemistry with a phosphorylation state-specific antibody (pERK) to characterize the temporal and spatial pattern of ERK/MAPK activation in neurons and glia following a forebrain stab lesion (FSL) in mice. Early activation (1 h) was primarily in perilesional neuronal elements, particularly of the hippocampus. Occasional perilesional glia were also positive for pERK. Additionally, ependymal cells bilaterally stained prominently for pERK. These patterns of pERK immunoreactivity at 1 h were abolished by pretreatment with the selective MEK inhibitor, SL327. ERK/MAPK activation at later time points between 1 day (d) and 30 d was primarily restricted to perilesional astrocytes with maximum labeling at 3 d. However, pERK-positive astrocytes represented only a subset of total GFAP-positive cells and were found more proximal to the lesion suggesting specific functional activation of these cells. Finally, immunostaining for the phosphorylated form of cAMP response element-binding (CREB) protein, a downstream target of the ERK/MAPK cascade, was increased in perilesional glia 7 d after FSL. Sustained activation of the ERK/MAPK signaling pathway in perilesional reactive glia suggests a critical role for this cascade in astrogliosis.

890. Carew, R. M., et al. (2021). "Suitability of 3D printing cranial trauma: Prospective novel applications and limitations of 3D replicas." Forensic Science International: Reports 4.

3D printed reconstructions of skeletal material offer a novel, interactive and increasingly used tool to support courtroom testimony and aid juror interpretation of expert testimony. While research has begun to address the accuracy of 3D printed skeletal material, there has been little consideration of the diverse applications of prints to support trauma demonstrations, particularly in relation to gunshot trauma. This study explored the suitability of three printed human crania replicas exhibiting either gunshot trauma or blunt force trauma for identifying whether the prints were sufficiently accurate for the presentation of trauma wounds. The data indicate that metric measurement and qualitative assessment of trauma macromorphology was possible from the 3D printed reconstructions. The findings also offer an indication that it is possible to obtain data around the accuracy of 3D printing bullet wounds and for establishing a bullet path. However, some limitations of prints reconstructed from post-mortem computed tomography (PMCT) data were identified including the observation that not all fracture lines were successfully replicated which indicates that at present virtual models should be used concurrently with 3D prints in court.

891. Carey, M. E. (2000). "An overview of civilian brain wounds from bullets: 1963-1996." Neurosurgery Quarterly 10(1): 1-41.

The author reviews 34 clinical and 2 autopsy studies on civilian gunshot wounds (GSWs) of the brain from 1963 to 1996 to summarize evaluate, and interpret on what has been learned as increasingly

vigorous treatment has been applied to these injuries. Bullets injure tissue by trajectory and by energy deposit; the latter may cause damage at a distance from the bullet's path. Many who sustain a GSW die from apnea even though the bullet does not strike the respiratory centers. A few brain-wounded individuals may be helped by vigorous field resuscitation, but little evidence exists that rapid transport to a hospital will significantly lower overall brain GSW mortality. The Glasgow Coma Scale (GCS) and computed tomography scans are most often used to evaluate brain wound victims. Angiography should be strongly considered if a bullet passes near middle cerebral vessels because of possible pseudoaneurysm formation. Surgical mortality of brain GSWs is highly dependent on the GCS score of those operated on; overall mortality for patients with a GCS of 12-15 is low, and for those with GCS 3-5, it is 80% or higher. Operating on GCS 3-5 patients with penetrating brain wounds is controversial. The author concludes that GCS 3-5 patients with brain wounds should not be operated on. All GCS 6-8 patients deserve aggressive care, but because the surgical mortality of this group approaches 50%, surgical criteria for these patients may need to be refined.

892. Carey, M. E., et al. (1990). "Brain edema after an experimental missile wound." Advances in neurology 52: 301-305.

We have developed an experimental model to study cerebral pathophysiology associated with a missile wound to the brain. After wounding, vasogenic edema occurs about the missile wound track in the injured cerebral hemisphere. This edema is relatively mild, does not appear life-threatening, peaks at 48 hr after wounding, and spontaneously resolved in 1 week.

---

893. Carey, M. E., et al. (1984). "The correlation between surgical and CT estimates of brain damage following missile wounds." Journal of neurosurgery 60(5): 947-954.

The occurrence of distant brain damage following an apparent focal missile injury to the brain has not been well documented until computerized tomography scanning demonstrated this phenomenon. Mechanisms of additional or distant damage within the brain may include a high deposit of kinetic energy from the penetrating missile, additional vascular damage, and possibly neuronal and axonal degeneration. Widespread and distant brain changes may explain some instances of late neuropsychological and psychiatric dysfunction or rehabilitation failure following a brain wound. Brain imaging should be used to properly evaluate the full extent of brain damage following wounding.

894. Carey, M. E., et al. (1971). "A bacteriological study of craniocerebral missile wounds from Vietnam." Journal of neurosurgery 34(2 Pt 1): 145-154.

Bacteriological studies were performed on 45 craniocerebral missile wounds incurred in Vietnam within 2 to 4 hours of occurrence. All missiles had penetrated into the brain. Aerobic and anaerobic cultures were taken of the skin wound, brain, and indriven bone fragments. Forty-four of the skin wounds were contaminated, predominantly with staphylococcus. Only five brain wounds showed bacterial contamination 2 to 4 hours after wounding, indicating that many missile tracks within the brain are initially sterile. Of the patients who had early debridement, 45% had contaminated bone within the brain; possibly up to 75% of all indriven bone chips were sterile. The authors draw the following conclusions. Complete brain debridement with removal of all indriven bone is ideal. Accessible retained bone should be removed by reoperation. Multiple reoperations for an inaccessible retained fragment are inadvisable, however, as fatalities or severe neurologic residua may result. An individual indriven bone chip has a small likelihood of bacterial contamination provided initial debridement was done early. This knowledge may justify an expectant policy in certain individuals harboring an inaccessible retained bone fragment. The retained fragment would be removed only if untoward difficulties develop.

897. Carloni, R., et al. (2016). "Scalp Tissue Expansion Above a Custom-Made Hydroxyapatite Cranial Implant to Correct Sequelar Alopecia on a Transposition Flap." World neurosurgery 95: 616.e611-616.e615.

BACKGROUND: Resection of cranial tumors involving both bone and scalp tissue may require the recruitment of soft tissue using a flap above the bone reconstruction. When a transposition flap has been chosen, the alopecia zone on the donor site may be difficult to treat afterward. Scalp expansion is the gold standard in these situations, but this has never been described above cranial implants. We report the first case of a patient who underwent a scalp tissue expansion above a custom-made hydroxyapatite cranial implant to correct sequelar alopecia., CASE DESCRIPTION: A 30-year-old man presented with a dermatofibrosarcoma of the scalp with bone invasion. A cranioplasty with a custom-made hydroxyapatite implant and a transposition flap were performed. Although healing was achieved, the donor site of the transposition flap left a 9 x 13 cm sequelar alopecia area on the vertex. To correct it, a rectangular 340-cm3 expander was partially placed above the cranial implant and under the transposition flap. A second 120-cm3 expander was put on the contralateral temporal region. The expansion was successful. No expander infection, cranial implant displacement, or fracture on imaging performed during the follow-up period was detected. The alopecia zone was entirely excised. The patient was very satisfied with the cosmetic result., CONCLUSIONS: Tissue expansion above hydroxyapatite implants may be of concern to the physician because of the risk of infection and rupture of the cranial implant. With this clinical case, we emphasize some precautions to prevent these issues.

898. Carneiro, J. T., Jr., et al. (2011). "Orbitoethmoidal impacted injury by kitchen knife causing abducens nerve palsy." Oral and maxillofacial surgery 15(2): 107-108.

INTRODUCTION: Impacted knife injuries in the maxillofacial region are rare and infrequently reported. In cases of injury involving orbit or eye, these reports are even rarer., DISCUSSION: Damage to the orbital contents may result in a rupture of the globe, extraocular muscle injury, lacrimal gland damage, and others. Orbital foreign bodies are not only difficult to detect, and clinical features vary according to its size, characteristics, shape, penetrating method, and site. In this report, a case of abducens nerve palsy after orbitoethmoidal knife injury is presented.

899. Carneiro, T., et al. (2019). "Neurobehçet presenting with sympathetic ophthalmia and pseudotumoral brainstem lesion in afro-american patient." Neurology 92(15).

Objective: NA Background: Neurological involvement in Behçet disease (BD) has been reported to be 5%. Although common in Eurasia, BD is extremely rare in afro-american population in which presentation is typically severe with negative HLA B51. Design/Methods: NA Results: 37 year-old afro-american male with history of perforating trauma to the left eye in childhood, developed recurrent episodes of bilateral panuveitis when he was diagnosed with sympathetic ophtalmia at age 27. Patient was then started on systemic immunosuppression but had multiple relapses throughout the years due to poor compliance. At age 37, patient presented with subacute headaches, fatigue, nausea, vomiting and gait instability. Physical exam notable for dysarthria, mild upper extremity dysmetria and wide-based gait. Brain MRI demonstrated diffuse T2 and FLAIR hyperintensity in brainstem with multifocal nodular enhancements concerning for malignancy or inflammatory lesion. CSF demonstrated

lymphocytic pleocytosis (32 total cells) and elevated protein (69 md/dl). Cytology and flow cytometry were negative for malignancy. Infectious, paraneoplastic and sarcoidosis work-up were negative. Patient was started on methylprednisolone for 3 days with partial recovery and was discharged. Two weeks later, patient was readmitted with same symptoms with interval MRI showing improvement of prior lesions and development of new enhancing lesions in midbrain. Systemic inflamatory markers were elevated. General exam was revealing for oral ulcers and lower extremitiy sterile pustules and a clinical diagnosis of BD was made. There was no evidence of genital ulcers or scars. HLA B51 and pathergy test were negative. Patient was started on infliximab with improvement of lesions. Conclusions: Behçet's disease is rare in afro-american population and diagnosis can be delayed due to atypical presentation and negative HLA B51. Sympathetic ophthalmia is a devastating bilateral panuveitis that may represent the spectrum of uveitis in BD. Neurobehçet remains a challenging diagnosis and must be considered in patients with brainstem lesions and systemic inflammatory signs.

900. Carpenter, H., et al. (2018). "Penetrating trauma causing cerebrospinal fluid leak without nerve root damage." BMJ case reports 2018.

A 19-year-old man with a stab injury to the lower back presented with no focal neurology or haemodynamic instability. He complained of a headache that was improved by lying flat and underwent imaging to look for damage to local structures. He was found to have air in his intraspinal space. Initially this case was managed conservatively; however, 2 weeks after discharge, he presented with cerebrospinal fluid leak from his wound. This was managed with neurosurgical intervention and watertight closure of fascia. There were no further complications.

901. Carpenter, K. L., et al. (2012). "A microdialysis study of oral vigabatrin administration in head injury patients: preliminary evaluation of multimodality monitoring." Acta neurochirurgica. Supplement 114: 271.

BACKGROUND: We assessed the feasibility of administering a neuroprotective drug, vigabatrin (VGB; gamma-vinyl-gamma-aminobutyric acid) with multimodality monitoring, including cerebral microdialysis, in severe head injury patients, to measure surrogate endpoints and blood-brain barrier (BBB) penetration., METHODS: Patients (n = 20) were randomised to VGB (0.5 g twice-daily, enteric) or control. ICP, ABP, CPP and cerebrovascular pressure reactivity index (PRx) were monitored. Microdialysate glucose, lactate, pyruvate, glutamate, glycerol, amino acids, VGB and GABA were analysed., RESULTS: Preliminary evaluation of results (five VGB-treated patients) showed that VGB levels rose in brain microdialysates, followed by a modest increase in GABA. VGB and GABA increased more in abnormal brain than in sites further from lesions, and were higher after multiple VGB doses. Highest VGB and GABA microdialysate levels were 75 and 4 &mgr;mol/L respectively. Microdialysate glucose and glycerol sometimes decreased, and glutamate and tyrosine sometimes increased, following VBG administration; causation unproven. VGB did not overtly affect ICP, ABP, CPP, PRx, or microdialysate lactate, pyruvate and lactate/pyruvate ratio., CONCLUSION: Multimodality monitoring, including cerebral microdialysis, is feasible for studying surrogate endpoints following drug administration. VGB crosses the BBB, leading to modest increases in extracellular GABA. Further analyses are ongoing. Microdialysis may assist the development of neuroprotective agents by determining penetration into extracellular fluid of the brain.

903. Carr, R. M. and R. H. Mathog (1997). "Early and delayed repair of orbitozygomatic complex fractures." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons 55(3): 253-259.

PURPOSE: The goal of this study was to review experience with early and delayed repair of orbitozygomatic complex fractures and develop guidelines for repair based on timing and extent of injury., PATIENTS AND METHODS: Records of patients with orbitozygomatic complex fractures over a 10-year period were reviewed for cause of injury, signs and symptoms, length of time from injury to repair, and method of repair. Results were evaluated by office examination and telephone interviews at least 6 months to 10 years after surgery., RESULTS: Seventy-eight patients who had undergone 81 surgical procedures were analyzed. The series consisted of 49 primary repairs (1 to 22 days postinjury), 10 delayed repairs using osteotomies at 21 days to 5 months postinjury, and 22 delayed repairs requiring onlay bone grafting from 4 months to 16 years postinjury. Forty patients (43 procedures) were available for follow-up. Early surgical intervention dramatically improved esthetic and functional outcomes, whereas late repair was less satisfactory. Hypoesthesia was not improved by surgery. Osteotomy and onlay grafting techniques were necessary for delayed treatment., CONCLUSION: Orbitozygomatic fractures can be repaired up to 21 days postinjury using primary reduction and fixation techniques. Osteotomies are required after 21 days and can be used successfully up to 4 months postinjury. After 4 months, successful repair requires onlay bone grafting.

904. Carrau, R. L., et al. (1994). "Computer-assisted frontal sinusotomy." Otolaryngology--head and neck surgery : official journal of American Academy of Otolaryngology-Head and Neck Surgery 111(6): 727-732.

An osteoplastic frontal sinus flap with flat obliteration is the "gold" standard for the management of chronic frontal sinus inflammatory disease caused by obstruction of the nasofrontal duct. Frontal sinusotomy, with an osteoplastic technique, call for osteotomies, guided by a template obtained from a Caldwell radiographic view taken at a distance of 6 feet. The reliability of the template depends on the position of the patient, distance at which the radiograph is taken, penetration of the x-rays, and other technical aspects. Therefore the template is a potential source of error. We present the use of a computer-assisted frontal sinusotomy as a method to corroborate the shape and margins of the frontal sinus in six patients undergoing obliterative frontal sinus surgery. In our hands, this technique has proved more reliable than the radiographic template to corroborate the positioning of the osteotomies.

905. Carrel, M., et al. (1994). "[Prehospital air ambulance and systemic secondary cerebral damage in severe craniocerebral injuries]." Medicalisation prehospitaliere heliportee et agressions cerebrales secondaires d'origine systemique chez les traumatises craniocerebraux graves. 13(3): 326-335.

Advanced supportive therapy at the site of the accident, associated with direct transfer to a trauma centre increases survival and reduces morbidity rates. Patients with severe head injury, especially those with multiple injuries, often arrive in the emergency department with potentially causes of serious secondary systemic insults to the already injured brain, such as acute anemia (Hematocrit < or = 30%), hypotension (systolic arterial pressure (Pasys) or = 45 mmHg, 6 kPa) and/or hypoxemia (Pao2 < or = 65 mmHg, 8.7 kPa). The incidence of such insults and their impact on mortality were studied in a group of 51 consecutive adults suffering from non penetrating severe head injury (Glasgow score < or = 8, mean age 31 +/- 17 yrs) rescued by a medicalized helicopter. Each patient received medical care on the site of the accident by an anaesthesiologist of a university hospital (UH) complying with an advanced trauma life support protocol including intubation, hyperventilation with FiO2 = 1, restoration of an adequate Pasys and direct transportation to the UH. Mean delay from call to arrival of the rescue team on the site was 15 +/- 5 min. Mean scene time was 32 +/- 10 min in cases not requiring extrication. Nineteen patients (Group I) were admitted without secondary systemic insults to the brain, 13 with isolated head injury, and 6 with multiple injuries, with a low Glasgow Outcome Score (GOS 1-3) of 42% at 3 months. In 32 patients (Group II), despite advanced supportive measures at the scene of the accident and during transportation, one or more secondary systemic insults to the brain were detected upon arrival at the emergency room, one with isolated head injury, 31 with multiple injuries, with a bad GOS of 72% at 3 months. We conclude that: 1) advanced trauma life support prevents from secondary systemic insults in the great majority of isolated severe head injured patients. 2) secondary systemic insults to the already injured brain are frequent in patients with multiple injuries and are difficult to avoid despite rapid aeromedical trauma care, 3) secondary systemic insults to the brain have a catastrophic impact on the outcome of severely head injured patients.

---

906. Carreon, L. Y., et al. (2004). "Pediatric spine fractures: a review of 137 hospital admissions." Journal of spinal disorders & techniques 17(6): 477-482.

OBJECTIVE: The anatomy and biomechanics of the growing spine produce failure patterns different from those in adults. Spinal injury in the pediatric patient is a concern as prevention of further neurologic damage and deformity and the good potential for recovery make timely identification and appropriate treatment of such injury critical. A retrospective clinical case series was conducted to present data from a large series of pediatric patients with spine injuries from a single regional trauma center., METHODS: One hundred thirty-seven children with spine injuries were seen over 10 years and were divided into three age groups: 0-9, 10-14, and 15-17 years. Analysis of variance and chi2 were used to analyze differences between groups., RESULTS: There were 36 patients aged 0-9, 49 aged 10-14, and 52 aged 15-17. Spine injury incidence increased with age. Motor vehicular accidents were the most common cause in this series. There were 36% cervical, 34% thoracic, 29% lumbar, 34% multilevel contiguous, and 7% multilevel noncontiguous involvement. Nineteen percent had spinal cord injury. Thirteen of 21 complete neurologic injuries and all 3 incomplete injuries improved. Cord injury was more common in the 0-9 age group. Four of five patients with spinal cord injury without radiographic abnormality (SCIWORA) were in the 0-9 age group and had complete neurologic injuries. Young children with cervical injuries were more likely to die than older children. Fifty-three percent had associated injuries. Eighteen percent underwent decompression, fusion, and instrumentation. Two patients developed scoliosis. The complication rate in surgical patients was higher than in patients treated nonsurgically and in polytrauma patients. This may be related to the severity of the initial injury., CONCLUSIONS: Our results suggest age-related patterns of injury that differ from previous work. The incidence of cord injury is 20% with higher frequencies in the young child. Potential for neurologic recovery is good. Young children have a higher risk for death than older children. There was no

predominance of cervical injuries in the young child. The incidence of SCIWORA was low. Higher complication rates were seen in polytrauma and surgical patients.

---

907. Carrick, M. M., et al. (2016). "Intraoperative hypotensive resuscitation for patients undergoing laparotomy or thoracotomy for trauma: early termination of a randomized prospective clinical trial." The journal of trauma and acute care surgery 80(6): 886.

BACKGROUND: Hemorrhagic shock is responsible for one third of trauma related deaths. We hypothesized that intraoperative hypotensive resuscitation would improve survival for patients undergoing operative control of hemorrhage following penetrating trauma., METHODS: Between July 1, 2007, and March 28, 2013, penetrating trauma patients aged 14 years to 45 years with a systolic blood pressure of 90 mm Hg or lower requiring laparotomy or thoracotomy for control of hemorrhage were randomized 1:1 based on a target minimum mean arterial pressure (MAP) of 50 mm Hg (experimental arm, LMAP) or 65 mm Hg (control arm, HMAP). Patients were followed up 30 days postoperatively. The primary outcome of mortality; secondary outcomes including stroke, myocardial infarction, renal failure, coagulopathy, and infection; and other clinical data were analyzed between study arms using univariate and Kaplan-Meier analyses., RESULTS: The trial enrolled 168 patients (86 LMAP, 82 HMAP patients) before early termination, in part because of clinical equipoise and futility. Injuries resulted from gunshot wounds (76%) and stab wounds (24%); 90% of the patients were male, and the median age was 31 years. Baseline vitals, laboratory results, and injury severity were similar between groups. Intraoperative MAP was 65.5 ± 11.6 mm Hg in the LMAP group and 69.1 ± 13.8 mm Hg in the HMAP group ($p = 0.07$). No significant survival advantage existed for the LMAP group at 30 days ($p = 0.48$) or 24 hours ($p = 0.27$). Secondary outcomes were similar for the LMAP and HMAP groups: acute myocardial infarction (1% vs. 2%), stroke (0% vs. 3%), any renal failure (15% vs. 12%), coagulopathy (28% vs. 29%), and infection (59% vs. 58%) ($p > 0.05$ for all). Acute renal injury occurred less often in the LMAP than in HMAP group (13% vs. 30%, $p = 0.01$)., CONCLUSION: This study was unable to demonstrate that hypotensive resuscitation at a target MAP of 50 mm Hg could significantly improve 30-day mortality. Further study is necessary to fully realize the benefits of hypotensive resuscitation., LEVEL OF EVIDENCE: Therapeutic study, level II.

---

908. Carrillo, E. H., et al. (1998). "Embolization therapy as an alternative to thoracotomy in vascular injuries of the chest wall." The American surgeon 64(12): 1142-1148.

Hemothorax and persistent thoracic bleeding is frequently an indication for thoracotomy after trauma. Unfortunately, the source of the hemorrhage is often not identified. Presently, selective arteriography and transcatheter embolization (SATE) offers a good and safe alternative to localize and control hemorrhage from arterial injuries in selected patients. The records of eight patients who underwent SATE were reviewed. There were six blunt and two penetrating chest injuries. Four patients had significant preexisting medical comorbidities. Three patients with blunt injuries had undergone exploratory thoracotomy, but continued to bleed postoperatively. In three patients, angiography was indicated for associated thoracic and pelvic injuries, and five patients had SATE specifically due to thoracic hemorrhage. In all patients, SATE was effective to diagnose and control the hemorrhage. There were no complications related to the SATE procedure. Two patients died secondary to severe cerebral injuries. Given hemodynamic stability, SATE can be considered in patients who have already had a thoracotomy, have significant associated medical conditions, or those in need of other angiographic studies. Careful technique and a readiness to abandon SATE in unstable patients or when a suitable catheter position cannot be achieved are important technical points.

909. Carrillo-Ruiz, J. D., et al. (2013). "Skull stab wound from a metal railroad nail perforating the right frontal lobe." Brain injury 27(7-8): 973-977.

STUDY DESIGN: Case report and review of literature., OBJECTIVE: To present the rare case of a 70-year-old man with a punctured cranial lesion, who was treated with surgery and had a positive recovery., SUMMARY OF BACKGROUND DATA: Cerebral trauma as the serious consequence of urban aggressiveness., METHOD: Clinical and imagery review of a cranial puncture trauma caused by a metal railroad nail, which penetrated the cranium, dura mater, frontal cerebral parenchyma and deep structures, lodging itself next to the midline, without damaging the superior sagittal sinus., RESULTS: The patient underwent a frontal craniotomy to remove the metal nail. He was hospitalized 2 weeks post-surgery and discharged. During external consultations, he manifested no neurologic deficit. A post-surgical CT ruled-out a brain abscess or other complications., CONCLUSIONS: Skull and brain stab wound lesions are highly infrequent, but evaluating the mechanism of injury and the successful medical and surgical treatment employed is illustrative of how post-traumatic recovery of this severe head injury can be achieved. The site of the injury and the position of the object were decisive for establishing an adequate diagnosis and prognosis. The patient reported an exemplary recovery without any secondary complications.

910. Carson, H. J. (2010). "Dyads of father and son suicide separated by time and circumstances." The American journal of forensic medicine and pathology 31(1): 80-82.

We encountered 2 dyadic suicides among fathers and sons. In the first dyad, the father was a 64-year-old man with complications of heart surgery. He committed suicide with a shotgun. The decedent's son was a 38-year-old man. Five years after his father's death, the son had an argument with his wife. That morning, he drove to the house where his father had lived and inflicted a handgun wound to his head. In the second dyad, the son was a 22-year-old man whose girlfriend left him. He inflicted a shotgun injury to the head. His blood alcohol level was 294 mg/dL. The father of this decedent was a 43-year-old man who 1 year later was despondent after a fight with his girlfriend. He was found dead at home with a single handgun wound to the chest. His blood alcohol level was 173 mg/dL. All 4 suicides appear to have been premeditated and all 4 men used guns. Suicide in a family tends to cause depression and complicate bereavement in survivors more than other types of death. Copycat suicide is well-documented in high-profile cases. The effect of father-son relationships is likely closer and more influential than celebrity suicides.

911. Cartagena, C. M., et al. (2016). "Subacute Changes in Cleavage Processing of Amyloid Precursor Protein and Tau following Penetrating Traumatic Brain Injury." PloS one 11(7): e0158576.

Traumatic brain injury (TBI) is an established risk factor for the development of Alzheimer's disease (AD). Here the effects of severe penetrating TBI on APP and tau cleavage processing were investigated in a rodent model of penetrating ballistic-like brain injury (PBBI). PBBI was induced by stereotactically inserting a perforated steel probe through the right frontal cortex of the anesthetized rat and rapidly inflating/deflating the probe's elastic tubing into an elliptical shaped balloon to 10% of total rat brain volume causing temporary cavitation injury. Separate animals underwent probe injury (PrI) alone without balloon inflation. Shams underwent craniectomy. Brain tissue was collected acutely (4h, 24h, 3d) and subacutely (7d) post-injury and analyzed by immunoblot for full length APP (APP-FL) and APP beta c-terminal fragments (betaCTFs), full length tau (tau-FL) and tau truncation fragments and at 7d for cytotoxic Beta amyloid (Abeta) peptides Abeta40 and Abeta42 analysis. APP-FL was significantly decreased at 3d and 7d following PBBI whereas APP betaCTFs were significantly elevated by 4h post-injury and remained elevated through 7d post-injury. Effects on betaCTFs were mirrored with PrI, albeit to a lesser extent. Abeta40 and Abeta42 were significantly elevated at 7d following PBBI and PrI. Tau-FL decreased substantially 3d and 7d post-PBBI and PrI. Importantly, a 22 kDa tau fragment (tau22), similar to that found in AD, was significantly elevated by 4h and remained elevated through 7d post-injury. Thus both APP and tau cleavage was dramatically altered in the acute and subacute periods post-injury. As cleavage of these proteins has also been implicated in AD, TBI pathology shown here may set the stage for the later development of AD or other tauopathies.

912. Cartagena, C. M., et al. (2013). "Delayed decreases in aquaporins after penetrating brain injury in rats." Journal of neurotrauma 30(15): A110.

Introduction Brain edema is a primary factor in the morbidity and mortality of traumatic brain injury (TBI). The various isoforms of aquaporin 4 (AQP4) and aquaporin 9 (AQP9) are important factors influencing edema following TBI. Others have reported that these AQPs are regulated by the transcription factor hypoxia inducible factor (HIF) 1a. Methods In the penetrating ballistic-like brain injury (PBBI) model, a temporary cavity and resultant injury was formed by the rapid inflation/ deflation (i.e. < 40 msec) of an elastic balloon attached to the end of the custom probe, injuring 10% of total brain volume. Tissue from the ipsilateral core and perilesional injury zones was collected. Total RNA was isolated at 4, 12, and 24 hr, 3 and 7 days post-injury (sham and PBBI, n = 6 per group). cDNA was synthesized using oligodT primers. Quantitative real time PCR was performed using Taqman expression assays for aqp4 (recognizing all isoforms), aqp9, and hif1a. Using separate animals, tissue lysate was collected at 4 and 24 hr, 3 and 7 days post-injury and analyzed by immunoblot for protein expression of multiple isoforms of AQP4, the single known isoform of AQP9 and for expression of transcription factor HIF1α (sham, probe only control, and PBBI, n = 8-10 per group). Results 24 hr post injury aqp4 mRNA levels were decreased. Three of the four known isoforms of AQP4 were detected by immunoblot, M1 (34kDa), M23 (32 kDa) and isoform 3 (30 kDa). In injured animals AQP4 M1 decreased significantly at 3 and 7 days post-injury. AQP4 M23 levels were highly variable but showed no significant changes. AQP4 isoform 3 levels were stable and were significantly decreased 3 days post-injury. From 4 through 24 hr aqp9 mRNA levels were significantly decreased in injured animals whereas AQP9 protein levels were significantly decreased at 3 and 7 days. At 12 and 24 hr post-PBBI hif1a mRNA levels increased but at 3 and 7 days mRNA levels significantly decreased. From 24 hr through 7 days HIF1α protein levels were significantly decreased. Unlike the AQP4 M1 and AQP9 acute response to injury, these aquaporins are decreased at delayed timepoints following PBBI when HIF1α is also suppressed. Conclusions PBBI is characterized by a loss of AQP4 M1 and AQP9 at delayed time-points temporally corresponding with suppression of HIF1α. The severity of the injury (PBBI versus probe control) increased these effects. Therefore, AQP9 and the AQP4 M1 isoform may be regulated by HIF1α, but not AQP4 isoform 3. This delayed loss of aquaporins may markedly reduce the ability of the brain to efflux water, contributing to the protracted edema that is characteristic following severe penetrating TBI. Factors contributing to edema differ with different types and severities of TBI. For example, cellular based edema is more prominent in diffuse non-penetrating TBI whereas vasogenic edema is more prevalent with TBI involving hemorrhage. Molecular regulation leading to edema will likely also differ, such that treatments which have been suggested for non-hemorrhagic moderate TBI, such as the suppression of aquaporins, may be detrimental in more severe forms of TBI.

---

913. Cartagena, C. M., et al. (2013). "Mechanism of action for NNZ-2566 anti-inflammatory effects following PBBI involves upregulation of immunomodulator ATF3." Neuromolecular medicine 15(3): 504-514.

The tripeptide glycine-proline-glutamate analogue NNZ-2566 (Neuren Pharmaceuticals) demonstrates neuroprotective efficacy in models of traumatic brain injury. In penetrating ballistic-like brain injury (PBBI), it significantly decreases injury-induced upregulation of inflammatory cytokines including TNF-alpha, IFN-gamma, and IL-6. However, the mechanism by which NNZ-2566 acts has yet to be determined. The activating transcription factor-3 (ATF3) is known to repress expression of these inflammatory cytokines and was increased at the mRNA and protein level 24-h post-PBBI. This study investigated whether 12 h of NNZ-2566 treatment following PBBI alters atf3 expression. PBBI alone significantly increased atf3 mRNA levels by 13-fold at 12 h and these levels were increased by an additional fourfold with NNZ-2566 treatment. To confirm that changes in mRNA translated to changes in protein expression, ATF3 expression levels were determined in vivo in microglia/macrophages, T

cells, natural killer cells (NKCs), astrocytes, and neurons. PBBI alone significantly increased ATF3 in microglia/macrophages (820%), NKCs (58%), and astrocytes (51%), but decreased levels in T cells (48%). NNZ-2566 treatment further increased ATF3 protein expression in microglia/macrophages (102%), NKCs (308%), and astrocytes (13%), while reversing ATF3 decreases in T cells. Finally, PBBI increased ATF3 levels by 55% in neurons and NNZ-2566 treatment further increased these levels an additional 33%. Since increased ATF3 may be an innate protective mechanism to limit inflammation following injury, these results demonstrating that the anti-inflammatory and neuroprotective drug NNZ-2566 increase both mRNA and protein levels of ATF3 in multiple cell types provide a cellular mechanism for NNZ-2566 modulation of neuroinflammation following PBBI.

---

914. Cartagena, C. M., et al. (2014). "Prolonged increases in 22 kDa tau fragment following penetrating TBI." Journal of neurotrauma 31(12): A72.

Tau is a protein involved in stabilizing microtubules in axons. Here we determine whether there are changes in levels of tau or tau fragments within the acute and subacute time frames following penetrating ballistic-like brain injury (PBBI). PBBI involves the rapid inflation/deflation of a custom probe causing a temporary cavity that in this case equaled 10% of total brain volume. Brain tissue was collected ipsilaterally within the injury tract at 4 and 24 hr, 3 and 7 days post-injury (n = 8-10). Tau levels and tau fragmentation was analyzed by immunoblot and normalized to beta-actin levels. Tau levels during PBBI are compared to probe only (no temporary cavity) and sham controls. Full length tau levels (55 kDa) were not altered 4 hr post-injury. By 24 hr post-injury, probe and PBBI tau levels were decreased 39% and 42%, respectively. At 3 days post-injury 73% and 89%, respectively; and at 7 days post-injury 87% and 96%, respectively. A 40 kDa fragment showed similar temporal decreases: 35% (probe, $p < 0.05$) and 45% (PBBI, $p < 0.05$) at 24 hr, 78% (probe, $p < 0.001$) and 94% (PBBI, $p < 0.001$) at 3 days, and 80% (probe, $p < 0.001$) and 93% (PBBI, $p < 0.001$) at 7 days. In contrast, a 22 kDa tau fragment, known for its involvement in tauopathies, including Alzheimer's disease, increased dramatically following injury: 544% (probe, $p < 0.01$) and 1541% (PBBI, $p < 0.001$) at 4 hr and 893% (probe, $p < 0.05$) and 2367% (PBBI, $p < 0.01$) at 24 hr. At 3 and 7 days post-injury PBBI levels again were significantly increased 1541% and 2424%, respectively Changes in tau levels and tau fragment levels are clearly influenced by injury severity (probe vs PBBI). Ongoing studies will determine if the dramatic increases in the 22 kDa tau fragment can be detected at more chronic time-points (i.e. month post-PBBI). Collectively, these early changes in tau fragmentation may be useful as prognostic indicators of neurodegenerative tauopathies utilizing in vivo neuroimaging such at positron emission tomography, and as early markers of therapeutic efficacy.

915. Cartner, S. C., et al. (2007). "Loss of cortical function in mice after decapitation, cervical dislocation, potassium chloride injection, and CO2 inhalation." Comparative medicine 57(6): 570-573.

Electroencephalograms (EEG) and visual evoked potentials (VEP) in mice were recorded to evaluate loss of cortical function during the first 30 s after euthanasia by various methods. Tracheal cannulae (for positive-pressure ventilation, PPV) and cortical surface electrodes were placed in mice anesthetized with inhaled halothane. Succinylcholine was used to block spontaneous breathing in the mice, which then underwent continuous EEG recording. Photic stimuli (1 Hz) were presented to produce VEPs superimposed on the EEG. Anesthesia was discontinued immediately before euthanasia. Compared with that obtained before euthanasia, EEG activity during the 30-s study period immediately after euthanasia was significantly decreased after cervical dislocation (at 5 to 10 s), 100% PPV-CO2 (at 10 to 15 s), decapitation (at 15 to 20 s), and cardiac arrest due to KCl injection (at 20 to 25 s) but not after administration of 70% PPV-CO2. Similarly, these euthanasia methods also reduced VEP amplitude, although 100% PPV-CO2 treatment affected VEP amplitude more than it did EEG activity. Thus, 100% PPV-CO2 treatment significantly decreased VEP beginning 5 to 10 s after administration, with near abolition of VEP by 30 s. VEP amplitude was significantly reduced at 5 to 10 s after cervical dislocation and at 10 to 15 s after decapitation but not after either KCl or 70% PPV-CO2 administration.

The data demonstrate that 100% PPV-CO2, decapitation, and cervical dislocation lead to rapid disruption of cortical function as measured by 2 different methods. In comparison, 70% PPV-CO2 and cardiac arrest due to intracardiac KCl injection had less rapid effects on cortical function.

916. Cartotto, R. and R. M. Zuker (1988). "An unusual facial injury highlighting the basics of diagnosis in maxillofacial trauma: a case report." Canadian journal of surgery. Journal canadien de chirurgie 31(5): 349-352.

The authors present an unusual and bizarre missile type of maxillofacial injury in a 7-year-old girl, who was struck in the middle of her face by an iron hook. The area between her forehead and upper lip was obliterated, making a clinical and radiologic diagnosis impossible. The authors review the current diagnostic methods used in maxillofacial trauma, including standard and computed tomography, to emphasize the importance of a correct preoperative diagnosis in the management of maxillofacial injuries.

917. Cartwright, M. J., et al. (1995). "Intraorbital wood foreign body." Ophthalmic plastic and reconstructive surgery 11(1): 44-48.

It is frequently difficult to identify and localize organic intraorbital foreign bodies despite modern day high-resolution imaging studies. Although there can be grave complications associated with retention of organic intraorbital foreign bodies, many believe that removal of such bodies in most cases is unwarranted. A high clinical suspicion, proper choice of imaging studies, and removal by a skilled orbital surgeon probably make the risk of surgical exploration and foreign body removal less than the risk of foreign body retention. We present a case of an intraorbital wood foreign body that required two separate explorations for retrieval. An initial intraconal exploration failed to locate the foreign body. Although the clinical suspicion was high, the imaging studies were equivocal, complicating the management. A second exploration yielded a large intraorbital wooden foreign body in the inferior extraconal space. The patient fully recovered and regained visual acuity of 20/20. The evaluation of such patients and details of management strategy are discussed.

918. Casey, A. T. and A. J. Moore (1994). "A traumatic giant posterior cerebral artery aneurysm mimicking a tentorial edge meningioma." British journal of neurosurgery 8(1): 97-99.

Traumatic intracranial aneurysms due to non-penetrating trauma are rare. Commonly they are associated with an overlying fracture or secondary to trauma against the falcine edge in the case of the distal anterior cerebral artery. To date, only one case of traumatic posterior cerebral artery aneurysm has been reported associated with a comminuted depressed occipital fracture and lacerated transverse sinus. We report a case of a giant traumatic aneurysm of the posterior cerebral artery P2 branch directly associated with the tentorial edge. Its mechanism of formation is analogous to the falcine distal anterior cerebral artery aneurysms.

919. Casey-Trott, T. M., et al. (2014). "Effectiveness of a nonpenetrating captive bolt for euthanasia of 3 kg to 9 kg pigs." Journal of animal science 92(11): 5166-5174.

The objective of this study was to determine the effectiveness of a nonpenetrating captive bolt, Zephyr-E, for euthanasia of suckling and weaned pigs from 3 to 9 kg (5-49 d of age) using signs of insensibility and death as well as postmortem assessment of traumatic brain injury (TBI). The Zephyr-E was used by 15 stock people to euthanize 150 compromised pigs from 4 farrowing and nursery units from commercial farms and 2 research stations. Brainstem reflexes, convulsions, and heartbeat were used to assess insensibility, time of brain death, and cardiac arrest following Zephyr-E application. Skull fracture displacement (FD) was quantified from computed tomography (CT) scans (n = 24), macroscopic scoring was used to assess brain hemorrhage and skull fracture severity (n = 150), and

microscopic scoring was used to assess subdural hemorrhage (SDH) and parenchymal hemorrhage within specific brain regions that are responsible for consciousness and vital function (n = 32). The Zephyr-E caused immediate, sustained insensibility until death in 98.6% of pigs. On average, clonic convulsions (CC) ceased in 82.2 s (+/- 3.4 SE), brain death was achieved in 144.9 s (+/- 5.4 SE), and cardiac arrest occurred in 226.5 s (+/- 8.7 SE). Time of brain death and cardiac arrest differed significantly among stock people (P = 0.0225 and P = 0.0369). Age was positively related to the duration of CC (P = 0.0092), time of brain death (P = 0.0025), and cardiac arrest (P = 0.0068) with shorter durations seen in younger pigs. Average FD was 8.3 mm (+/- 1.0 SE). Macroscopic scores were significantly different among weight classes for subcutaneous (P = 0.0402) and subdural-ventral (P = 0.0037) hemorrhage with the lowest severity hemorrhage found in the 9-kg weight category. Microscopic scores differed among brain sections (P = 0.0070) for SDH with lower scores found in the brainstem compared to the cerebral cortex and midbrain. Parenchymal hemorrhage differed among brain sections (P = 0.0052) and weight categories (P = 0.0128) with the lowest scores in the midbrain and brainstem and the 7- and 9-kg weight categories. The Zephyr-E was highly effective for the euthanasia of pigs up to 9 kg (49 d) based on immediate insensibility sustained until death. Postmortem results confirmed that severe skull fracture and widespread brain hemorrhage were caused by the Zephyr-E nonpenetrating captive bolt.

---

920. Casey-Trott, T. M., et al. (2013). "Effectiveness of a nonpenetrating captive bolt for euthanasia of piglets less than 3 d of age." Journal of animal science 91(11): 5477-5484.

The objective of this study was to determine the effectiveness of a nonpenetrating captive bolt (NPCB), the Zephyr-Euthanasia (Zephyr-E), for euthanasia of neonatal piglets<72 h of age using signs of insensibility and death, as well as postmortem assessment of traumatic brain injury (TBI). The Zephyr-E was used by 10 stock people to euthanize 100 low viability neonatal piglets from 3 commercial farrowing units and 1 research farm. Brainstem reflexes, convulsions, and heartbeat were used to assess insensibility, time of brain death, and cardiac arrest after Zephyr-E application. Hemorrhage severity and skull fracture displacement (FD) were quantified from computed tomography scans (n=10), macroscopic scoring was used to assess brain hemorrhage and skull fracture (SK) severity (n=100), and microscopic scoring was used to assess subdural (SDH) and parenchymal (PH) hemorrhage within specific brain regions that are responsible for consciousness and vital function (n=10). All 100 piglets were rendered immediately insensible without return to sensibility. On average, clonic convulsions (CC) ceased in 101 s (+/-7.4 SE), brain death was achieved in 229 s (+/-9.18 SE), and cardiac arrest occurred in 420 s (+/-13.57 SE). Time of cardiac arrest differed significantly among stock people when either body weight (BW: P=0.0053) or body mass index (BMI: P=0.0059) was used as a covariate. The BMI was inversely related to the duration of CC (P=0.0227). Moderate to severe hemorrhage severity was reported in 9 of 10 piglets. There was no relationship between FD and BW (P=0.8408) or BMI (P=0.6439). Macroscopic analyses indicated moderate to severe hemorrhage and SK in all piglets. No differences were found among brain sections for SDH (P=0.2302); PH was greater in the cerebral cortex than in the midbrain and brainstem (P=0.0328). The Zephyr-E NPCB reliably caused immediate, sustained insensibility followed by death in neonatal piglets. Postmortem assessment confirmed that application of the Zephyr-E caused widespread, irreversible brain damage.

922. Castelão, M., et al. (2021). "The epidemiology of pediatric polytrauma and orthopedic injuries: 12-year analysis of a level-1 trauma center (2007-2019)." Pediatric Critical Care Medicine 22(SUPPL 1): 129.

AIMS & OBJECTIVES: We present a retrospective study of pediatric polytrauma patients admitted to the pediatric Intensive Care Unit (ICU) of a tertiary university hospital in Europe. METHODS: Data retrieved from 2007 to 2019 included mechanism and site of injury, pre-hospital and in-hospital trauma care, ICU length-of-stay (LOS), and in-hospital mortality. RESULTS: 217 patients were included (age 10,7 ± 4,86 years; 66% male). Motor vehicle accidents (MVA) (44,4%) and car-pedestrian accidents (25,9%) were the leading mechanisms of injury, followed by falls from height (21,8%; 4,2% sports-related), penetrating trauma (3,3%) and suicide attempts (2,3%). On pre-hospital assessment, 60% of children had documented loss of consciousness; of these, more than half had severe brain injury (GCS<9). The most frequent injury sites were brain (74%) and skeleton (73%). Vertebral fractures were the most common orthopedic injury (19%), followed by pelvic (16,6%) and femur (15,2%) fractures. Patients with orthopedic trauma had significantly longer ICU LOS (5,1 ± 2,76 vs 3,1 ± 1,16; p=0,007); those with 3 or more fracture sites had greater needs for blood transfusion (20 vs 4 mL/kg; p=0,016). MVA were associated with highest incidence of orthopedic severe injuries (p<0,001). Most children involved in MVA were completely unrestrained (37,5%) or using a restraint system inappropriately (6,3%). Overall ICU trauma-related mortality was 1,8% (three cases of severe brain injury and one cervical spine injury). CONCLUSIONS: The great majority of polytrauma children suffer orthopedic injuries, requiring longer ICU admission and higher transfusion volumes. Road traffic accidents remain the leading cause of severe polytrauma. Education-oriented programs are still of crucial importance for prevention.

923. Castellani, R. J., et al. (2020). Neuropathology in Consecutive Forensic Consultation Cases with a History of Remote Traumatic Brain Injury. 7: 167-175.

Traumatic brain injury (TBI) is widely assumed to be causal in neurodegenerative disease, based on epidemiological surveys demonstrating an increased risk of Alzheimer disease (AD) following TBI, and on recent theories surrounding repetitive head movement. We tested this assumption by evaluating 30 consecutive forensic examinations in which neuropathology consultation was sought, and in which a history of remote TBI was uncovered during the course of the investigation. In this series, there was a high frequency of psychiatric co-morbidities (100%), remote contusion (90%), and seizures (63%). Extent of proteinopathy showed no differences with age-matched controls. A subset of the cases showed focal geographic tauopathy that correlated with older age at autopsy, but had no correlation with clinical signs, and was minimal in comparison with the encephalomalacia secondary to trauma. The results suggest that cerebral contusion and post-traumatic epilepsy may be over-represented in civilian TBI, while structural brain damage from trauma is the predominant cause of morbidity following TBI. We found no evidence that TBI initiates a progressive proteinopathy.

924. Castellarin, A., et al. (2004). "Iatrogenic open globe eye injury following sinus surgery." American journal of ophthalmology 137(1): 175-176.

PURPOSE: To report a case of iatrogenic open globe eye injury occurring during endoscopic sinus surgery., DESIGN: Case report and literature review., METHODS: A 10-year-old boy presented with periorbital swelling and subconjunctival hemorrhage of the left eye following bilateral nasal adenoidectomy. Funduscopic examination showed evidence of a full-thickness open globe injury at the equator in the inferior nasal midperiphery., RESULTS: The injury most likely was secondary to inadvertent perforation of the lamina papiracea with entrance into the orbit and subsequent penetration of the globe., CONCLUSION: Sinus surgery has been reported previously in association with severe orbital complications. We are unaware of previous reports of open globe injury following sinus surgery.

925. Castillo-Rangel, C., et al. (2010). "Cranio-thoracic bullet migration over a period of 27 years: case report." Neurocirugia (Asturias, Spain) 21(4): 326-329.

We report the case of a 36 year old woman that was hurt in the head with a lost bullet while walking through the street when she was 9 years old. On admission, the patient was fully conscious with no neurological deficits. Skull radiography showed the intracranial bullet but she was dispatched after 24 hours of observation without neurological deterioration. Six months later she suddenly presented quadriplegia and after one year of rehabilitation she recovered the mobility and strength in all her limbs. 25 years latter she began with thoracic pain (dermatomal sensory changes), constipation, paresthesias and weakness in the lower extremities; the X-Ray showed a bullet caliber 9 mm in the thoracic canal at T4 level. The bullet was removed via posterior laminectomy and dorsal midline mielotomy. 12 hours after surgery, the patient presented signs of medullar shock. The post-operatory MRI showed the trajectory of the bullet through the brain to the spinal cord in FLAIR, and spinal cord edema as well. The patient received steroids as treatment for the spinal cord edema, and with the help of rehabilitation she recovered movement in the lower extremities 30 days after the surgery.

926. Castro, C., et al. (1989). "[Non-fatal firearm injuries of the head and neck]." Heridas por arma de fuego no mortales a nivel de cabeza y cuello. 16(3): 257-270.

There is depicted the evolutive course of 6 men with gunshot wounds of the neck and head, fortunately not threatening their lives. All victims were men between 18 and 67 years of age. Three times the gun fired a single projectile, whereas the other 3 were multiple projectiles. The latter cases resulted in heavier damages. Etiologically the events were classified as: 3 cases as suspected murder, 2 as attempted suicide and in the last case, an accident. The management has been both medical and surgical under general anesthesia, in order to repair the disorders and/or remove the bullets in 5 occasions. The sixth case did not allow removal of the bullet because of expected risk. All the cases did seemingly well, in spite of 2 who had postoperative complications which delayed healing.

927. Catapano, J. S., et al. (2021). "Pediatric intracranial arterial injuries by penetrating gunshot wounds: an institutional experience." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery 37(4): 1279-1283.

PURPOSE: Pediatric intracranial injuries due to penetrating gunshot wounds are a rare entity that is often fatal. A subset of patients may experience an intracerebral arterial injury; however, literature on the pediatric population is limited. This study analyzes a large institution's experience with pediatric head gunshot wounds and intracranial arterial injuries., METHODS: All pediatric patients <= 18 years of age who presented to our institution with a penetrating gunshot wound from 2008 to 2018 were retrospectively analyzed., RESULTS: Thirty-seven patients presented with an intracerebral penetrating gunshot injury. There were 18 deaths (49%) in the cohort. A total of 20 patients (54%) had vascular imaging. Of the remaining 17 patients with no vascular imaging, 13 (35%) died before any vascular studies were obtained. Four (20%) of the 20 patients with vascular imaging experienced an intracerebral arterial injury. Three of these 4 patients died before treatment could be administered. One patient with a firearm injury underwent embolization of a distal middle cerebral artery pseudoaneurysm and was discharged home with a Glasgow Outcome Scale score of 5 on follow-up., CONCLUSION: Pediatric patients with penetrating intracranial gunshot wounds often die before vascular imaging can be obtained.

928. Cato, M. A., et al. (2004). "Assessing the elusive cognitive deficits associated with ventromedial prefrontal damage: a case of a modern-day Phineas Gage." Journal of the International Neuropsychological Society : JINS 10(3): 453-465.

Cognitive deficits following ventromedial prefrontal damage (VM-PFD) have been elusive, with most studies reporting primarily emotional and behavioral changes. The present case illustrates the utility of a process approach to assessing cognitive deficits following VM-PFD. At age 26, C.D. acquired bilateral VM-PFD, more so in the left frontal region, following a penetrating head injury.

Despite exemplary premorbid academic and military performances, his subsequent history suggests dramatic occupational and social changes, reminiscent of Phineas Gage. In fact, lesion analysis revealed similar structural damage to that estimated of Gage. C.D.'s scores on the vast majority of neuropsychological measures were average to superior (e.g., Verbal IQ = 119). However, on several new process measures, particularly those that quantify error rates on multilevel executive function and memory tasks, C.D. exhibited marked impairments. From his pattern of deficits, C.D. appeared to sacrifice accuracy for speed and to adopt liberal response strategies, implicating problems with cognitive inflexibility, impulsivity, and disinhibition. The current findings suggest that VM-PFD may be associated with a wider spectrum of cognitive deficits than previously characterized.

---

929. Cato-Addison, W. B., et al. (2007). "Near lethal art--transorbital brain injury." Orbit (Amsterdam, Netherlands) 26(4): 279-281.

Penetrative transorbital injuries put intracranial structures in peril. We present one such case where a low velocity transorbital injury resulted in traumatic temporal lobe injury, but with full recovery. Clinicians should be vigilant of intracranial complications of transorbital injuries.

930. Caudle, K. L., et al. (2016). "Neuroprotection and anti-seizure effects of levetiracetam in a rat model of penetrating ballistic-like brain injury." Restorative neurology and neuroscience 34(2): 257-270.

PURPOSE: We assessed the therapeutic efficacy of FDA-approved anti-epileptic drug Levetiracetam (LEV) to reduce post-traumatic nonconvulsive seizure (NCS) activity and promote neurobehavioral recovery following 10% frontal penetrating ballistic-like brain injury (PBBI) in male Sprague-Dawley rats., METHODS: Experiment 1 anti-seizure study: 50 mg/kg LEV (25 mg/kg maintenance doses) was given twice daily for 3 days (LEV3D) following PBBI; outcome measures included seizures incidence, frequency, duration, and onset. Experiment 2 neuroprotection studies: 50 mg/kg LEV was given twice daily for either 3 (LEV3D) or 10 days (LEV10D) post-injury; outcome measures include motor (rotarod) and cognitive (water maze) functions., RESULTS: LEV3D treatment attenuated seizure activity with significant reductions in NCS incidence (54%), frequency, duration, and delayed latency to seizure onset compared to vehicle treatment. LEV3D treatment failed to improve cognitive or motor performance; however extending the dosing regimen through 10 days post-injury afforded significant neuroprotective benefit. Animals treated with the extended LEV10D dosing regimen showed a twofold improvement in rotarod task latency to fall as well as significantly improved spatial learning performance (24%) in the MWM task., CONCLUSIONS: These findings support the dual anti-seizure and neuroprotective role of LEV, but more importantly identify the importance of an extended dosing protocol which was specific to the therapeutic targets studied.

931. Cavalcanti, A. L., et al. (2011). "Violent deaths and maxillofacial injuries in children and adolescents in campina grande, PB, brazil." Acta Stomatologica Croatica 45(4): 268-275.

Objective: In this study, mortality by external causes of children and adolescents and the occurrence of maxillofacial injuries was evaluated in the city of Campina Grande, PB, Brazil in 2003. Methods: 837 forensic medical reports were reviewed, 115 (13.7%) of them belonging to victims aged from 0 to 18 years. The causes were classified according to the Chapter XX of the International Classification of Diseases - CID 10. Data were organized using Epi-Info 3.4.1 software. The association of the variables: type of cause and maxillofacial injuries as dependent variables and sex and age as independent variable was performed by the chi-square and Fisher's exact tests ($p<0.05$). Results: Higher mortality was observed among boys (70.4%) and in the 14-18-year-old age group (50.3%), although without statistically significant difference between the age groups and the genders ($p=0.149$). There was a predominance of traffic accidents (32.2%), most involving pedestrians (37.8%). Males had a 4.6 times greater chance of being victims of firearms than females. Most of the victims had multiple injuries, with predominance of abrasions (39.4%) and wounds (24.5%). The prevalence of injuries to the head and

face was 22.5% and 20.4%, respectively. Maxillofacial injuries were identified in 41.7% of the victims. Six victims (12.5%) exhibited fractures, mainly in the mandible (37.5%). Victims of traffic accidents had a 2.9 times greater chance of suffering injuries to the maxillofacial region. Conclusion: Boys aged between 14 and 18 years were the main victims of fatalities due to external causes, mainly traffic accidents, and the occurrence of multiples injuries to the head and face was frequent.

---

933. Cecchi, R., et al. (2012). "Pulmonary embolisation of bone fragments from penetrating cranial gunshot wounds." International journal of legal medicine 126(3): 473-476.

Bone embolism is a very rare event that usually occurs in trauma-induced septic bone lesions, after bone surgery or after bone marrow transplantation, and normally remains silent. To our knowledge, there are no previous reports of bone embolism after a gunshot to the head. We describe a case of pulmonary embolism associated with bone fragments after a gunshot to the head in which bone fragments surrounded by leukocytes, interstitial and intra-alveolar oedema and haemorrhage around the embolised vessels, leukostasis and fat and bone marrow embolism suggest that the survival time from the gunshot was sufficiently long to allow changes in lung microcirculation and lung tissue.

934. Cecchini, M. J. and M. J. Shkrum (2019). "A Self-Inflicted Gunshot Wound With an Unusual Hand Injury." The American journal of forensic medicine and pathology 40(1): 47-48.

Self-inflicted gunshot wounds are a common cause of firearm-related deaths. The appearance and location of the entry wound, other concomitant findings at autopsy, and correlation with the scene and circumstances are critical in determining the manner of death. A case of a 72-year-old man with a self-inflicted gunshot wound with an unusual injury pattern is described. There was a contact range gunshot entry in the right temple, and an exit wound was seen in the left parietal region. There was a re-entry with an associated exit wound on the left hand.

935. Celix, J., et al. (2011). "The association between ICP monitoring and resource level and outcome from severe traumatic brain injury in Latin America." Journal of neurotrauma 28(6): A112.

PURPOSE: In many high-income countries (HICs), the use of invasive intracranial pressure (ICP) monitoring is common in severe traumatic brain injury (sTBI) patients. In most low- and middle-income countries (LMICs) there is unequal access to acute medical care and variable availability and utilization of medical resources to treat TBI, unlike HICs. TBI management guidelines developed in resourcerich settings may not be applicable in resource-limited settings. This study evaluates the association between resource availability and outcomes from sTBI in LMICs in South America. METHODS: We conducted a prospective observational study of 228 patients with severe non-penetrating TBI admitted to one of four metropolitan hospitals in Argentina, Brazil, Ecuador, and Colombia fromAugust 2008 through December 2009. Study hospitals were dichotomized to low (2) or high (2) resource based on the availability of invasive ICP monitoring. Demographic, injury, clinical, and outcome data were compared. RESULTS: Transportation to the hospital via ambulance occurred more frequently at high- than low-resource hospitals (95% vs. 64%). Between the two high resource hospitals, there were significant differences in the use of ICP monitors (74% vs. 14%). The lack of availability of an intensive care unit (ICU) bed was the primary determinant preventing ICP monitoring in the low utilization hospital. Based on this finding, outcomes were compared in patients with and without ICP monitoring as well as by level of resources. Functional outcome assessed by the 6 month Extended Glasgow Outcome Scale (GOS-E) differed by both ICP monitoring and by resource level. CONCLUSION: There are associations between outcomes from sTBI in Latin America and both the use

of ICP monitoring and level of resources; however, one must be concerned about likely confounding. We are optimistic that the ongoing ICP randomized controlled trial in Latin America will help resolve such confounding.

936. Cellini, L., et al. (2020). "Complex craniomaxillofacial gunshot wounds A step-by-step multidisciplinary approach." Annali italiani di chirurgia 91.

BACKGROUND: Gunshot injuries of the viscerocranium are rarely reported. Penetrating wounds to the cranio-maxillofacial region pose a significant challenge for surgeons as they often comprise serious soft tissue, bone and cerebral defects. We present a case report of a 42-year old female with a gunshot wound to the viscerocranium after suicidal attempt. Series of image of the disease course are available., CASE DESCRIPTION: A 42-year-old female presented with gunshot wound to the viscerocranium after a suicidal attempt. At the arrival GCS was 8/15 and general examination showed the inlet wound in the submental region whereas the outlet one in the left temporal skull area. After first rescue procedures, ICP was monitored before proceeding surgically. Due to massive hemorrhage, embolization of ianternal maxillary artery was performed. Afterwards, tracheostomy, surgical reduction of multiple maxillo-facial fractures and ocular avulsion were performed. In a second time, ICP monitoring and CT scan revealed ICH signs due to intraparenchimal injures. The patient underwent to a second surgical procedure, consisting of bifrontal decompressive craniectomy. The patient was discharged on 20th post-op day to a rehabilitation center. She returned to our department after 4 months to perform a craniomaxillofacial recostruction. She presented 15 in GCS, left ptosis, left VII cranial nerve deficit, decannulated, KPS 100%., CONCLUSION: A step-to-step multidisciplinary approach both with Neurosurgeons and Maxillo-facial surgeons is mandatory in Cranial Gunshot Injuries where extensive damage is linked to a higher mortality., KEY WORDS: Cranial gunshot inuuries, Cranial reconstruction, Maxillofacial reconstruction.

937. Cemil, B., et al. (2009). "Attempted suicide with screw penetration into the cranium." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES 15(6): 624-627.

Intracranial foreign bodies are usually secondary to penetrating injuries. Nails, knives, screwdrivers, sewing needles, bullets, and shrapnel have been described related to penetrating brain injury. In this report, we present a 34-year-old prisoner with an intracranial screw located in the right parietal lobe. The screw was used by prisoner in an attempted suicide. A right parietal craniectomy was performed, and the screw was removed successfully. It is important to know the type of penetrating brain injury preoperatively in order to determine the best surgical approach to remove the foreign body settled in the brain. A long-term radiological assessment should be performed to detect any future complications, such as a cerebral abscess.

939. Cernak, I. (2005). "Animal models of head trauma." NeuroRx : the journal of the American Society for Experimental NeuroTherapeutics 2(3): 410-422.

Animal models of traumatic brain injury (TBI) are used to elucidate primary and secondary sequelae underlying human head injury in an effort to identify potential neuroprotective therapies for developing and adult brains. The choice of experimental model depends upon both the research goal and underlying objectives. The intrinsic ability to study injury-induced changes in behavior, physiology, metabolism, the blood/tissue interface, the blood brain barrier, and/or inflammatory- and immune-mediated responses, makes in vivo TBI models essential for neurotrauma research. Whereas human TBI

is a highly complex multifactorial disorder, animal trauma models tend to replicate only single factors involved in the pathobiology of head injury using genetically well-defined inbred animals of a single sex. Although such an experimental approach is helpful to delineate key injury mechanisms, the simplicity and hence inability of animal models to reflect the complexity of clinical head injury may underlie the discrepancy between preclinical and clinical trials of neuroprotective therapeutics. Thus, a search continues for new animal models, which would more closely mimic the highly heterogeneous nature of human TBI, and address key factors in treatment optimization.

940. Cernak, I., et al. (1997). "Relations among plasma prolactin, testosterone, and injury severity in war casualties." World journal of surgery 21(3): 240-246.

Tissue trauma leads to a complex hormonal response of pituitary end-organ axis. This response can be recorded by determining parameters that represent the functional integrity of these systems. The concentrations of serum prolactin (PRL), serum testosterone, and plasma adrenocorticotropin (ACTH) were measured in 62 adult male casualties from the recent war in former Yugoslavia. Patients with brain injury were not included. Venous blood samples were taken as soon as possible (2-18 hours) after admission and at 1, 2, 5, and 14 days after injury. The severity of gunshot/missile wounds was assessed by the Injury Severity Score (ISS). The control group consisted of healthy blood donors. Uninjured subjects who had undergone great stress on the battlefield (explosion in the vicinity without injury) served as the sham-control group. Tissue trauma leads to a severity-dependent decrease in serum testosterone concentrations during the first 5 days following injury. Significant correlations were observed between ACTH, prolactin, and ISS during the first 18 hours after injury. A strong negative correlation between testosterone and prolactin serum concentrations was found during the first 18 hours. In patients with additional complications or unsatisfactory outcome, the prolactin concentrations remained elevated, whereas testosterone concentrations were reduced. Our results support the usefulness of recording hormonal changes for determining trauma severity and monitoring the clinical course. Such monitoring also helps assess the efficacy of therapeutic strategies. The relation between testosterone and prolactin might be helpful for predicting the clinical course and trauma outcome.

---

941. Cernak, I., et al. (2000). "Characterization of plasma magnesium concentration and oxidative stress following graded traumatic brain injury in humans." Journal of neurotrauma 17(1): 53-68.

Plasma magnesium, calcium, and oxidative status were investigated in 31 male casualties with traumatic brain injury (TBI) during a 7-day posttraumatic period. The study group consisted of eight patients with mild closed head injury (Glasgow Coma Scale score [GCS] of 13-15), 10 patients with extensive penetrating head injury (GCS 4-6), and 13 patients with blast injuries but without direct head trauma. The latter group was included since previous experimental and clinical data have confirmed the development of indirect brain trauma in patients with blast injuries. Patients with multiple injuries were not included. Significant declines in plasma divalent cations were found in GCS 4-6 patients immediately after TBI and persisting for the entire 7-day study period. Similar changes in magnesium, but not calcium, were present in the GCS 13-15 and the blast injury groups, but only up until day 3 after injury. Alterations in lipid peroxidation products and superoxide anions were also observed following TBI. Increased lipid peroxidation was noted in all three groups over the entire posttraumatic period while increases in superoxide anion generation occurred transiently immediately following TBI. Thereafter, in the GCS 13-15 and blast injury groups, superoxide anions subsequently normalized, whereas in extensive head injury (GCS 4-6), superoxide anion generation significantly declined. A negative correlation between magnesium balance and oxidative stress was observed in all patients immediately after injury persisting in GCS 4-6 patients to the end of the observation period. Our findings suggest an interrelationship between magnesium changes and blood oxidants/antioxidants after TBI, which could be of both diagnostic and prognostic value in patients with neurotrauma.

---

942. Cernak, I., et al. (1999). "Neuroendocrine responses following graded traumatic brain injury in male adults." Brain injury 13(12): 1005-1015.

In an effort to characterize thyroid, gonadal and adrenal function following neurotrauma, the present study determined serum concentrations of thyroid-stimulating hormone (TSH), total triiodothyronine (T3), thyroxine (T4), testosterone and cortisol over a 7 day period in 31 patients with traumatic brain injury. The study group consisted of eight patients with mild closed head injury (Glasgow Coma Scale--GCS 13-15), 10 patients with extensive penetrating head injury (GCS 4-6) and 13 patients with blast injuries but without direct head trauma. The latter group was included in the study because the development of indirect brain trauma has previously been implicated in blast injuries. Patients with multiple injuries were not included. Following mild injury (GCS 13-15), TSH was increased up until day 3 after injury. T3 levels were elevated on days 1, 5 and 7 after injury while T4 remained unchanged throughout. While testosterone was decreased over only the first 2 days post-trauma, cortisol was increased over these first 2 days after injury. In contrast, following severe penetrating injury (GCS 4-6), there were significant declines in TSH, T3 and testosterone over the 7 day observation period post-trauma. Serum cortisol also declined in these patients between 1-3 days after injury, before increasing again on days 5 and 7 after injury. Following indirect neurotrauma, TSH was slightly decreased immediately after trauma but increased to above normal levels on days 5 and 7 post-trauma. Similarly, T3 initially declined after injury, but then increased to above normal levels between 5 and 7 days after injury. T4 and testosterone remained unchanged over the entire post-traumatic period. Serum cortisol was significantly increased after indirect neurotrauma but only up to day 2 post-trauma. In summary, patients with both direct and indirect traumatic brain injury demonstrated endocrine alterations after trauma, the dynamics of which may be a reflection of the severity of brain damage.

---

943. Cernak, I., et al. (2014). "A novel mouse model of penetrating brain injury." Frontiers in neurology 5.

Penetrating traumatic brain injury (pTBI) has been difficult to model in small laboratory animals, such as rats or mice. Previously, we have established a non-fatal, rat model for pTBI using a modified air-rifle that accelerates a pellet, which hits a small probe that then penetrates the experimental animal’s brain. Knockout and transgenic strains of mice offer attractive tools to study biological reactions induced by TBI. Hence, in the present study, we adapted and modified our model to be used with mice. The technical characterization of the impact device included depth and speed of impact, as well as dimensions of the temporary cavity formed in a brain surrogate material after impact. Biologically, we have focused on three distinct levels of severity (mild, moderate, and severe), and characterized the acute phase response to injury in terms of tissue destruction, neural degeneration, and gliosis. Functional outcome was assessed by measuring bodyweight and motor performance on rotarod. The results showed that this model is capable of reproducing major morphological and neurological changes of pTBI; as such, we recommend its utilization in research studies aiming to unravel the biological events underlying injury and regeneration after pTBI.

944. Cetinkaya, E. A., et al. (2006). "Transnasal, intracranial penetrating injury treated endoscopically." The Journal of laryngology and otology 120(4): 325-326.

Intracranial penetrating injury through the nose is uncommon. We present the case of a four-year-old girl who sustained a transnasal, intracranial penetrating injury with a sharp wooden object. We performed endoscopic removal of the foreign body and repair of the associated cerebrospinal fluid fistula.

---

945. Cetira Filho, E. L., et al. (2019). "Early Reconstruction of Gunshot Mandible Fracture: A Modified Approach." The Journal of craniofacial surgery 30(7): e653-e655.

The management of victims of gunshot fractures is a challenge for surgeons, mainly due to the complexity of the injury itself and degree of bone comminution. The titanium functionally dynamic bridging plate has often been used in reconstructive surgery after mandibular fractures. The classic indication for bridge plate use is comminuted fractures with or without associated substance losses. The aim of this article is report the case of gunshot victim and to discuss the bridge plate technique utilized for treatment. A 21 years-old, melanoderma, male patient was victim of a firearm-related assault, with comminutive fracture of the mandibular body. The protocol for the bridging plate technique was performed. The patient is in postoperative follow-up of eight months, not present aesthetic or functional complaints, stable occlusion, satisfactory mouth opening and no clinical signs of infection.

---

946. Chae, R., et al. (2018). "The influence of presenting characteristics on outcomes in moderate to severe pediatric traumatic brain injury: Penetrating versus blunt mechanisms." Neurology 90(15).

Objective: 1) Evaluate whether the clinical presenting features of known prognostic value in adult traumatic brain injury (TBI) have prognostic value in pediatric TBI; 2) Assess for differences in how these clinical presenting features correlate with outcomes when comparing pediatric patients with blunt or penetrating TBI. Background: TBI is a leading cause of injury, death, and disability. Often, due to a lack of literature, the basis for guidelines on pediatric TBI have been drawn from adult studies including an overwhelming number of blunt injury patients. It is unknown if these guidelines are appropriate for penetrating TBI. Design/Methods: Patients 0-18 years with moderate to severe blunt or penetrating TBI presenting to the local level 1 trauma centers were included. Outcomes were mortality, Pediatric Functional Independence Measures (wee- FIM), and the Glasgow Outcome Scale- Extended Pediatric Version (GOS-E Peds) at 12-18 mo post-injury. Results: Records from 52 patients were reviewed. Patients with hypotension on arrival had a higher mortality rate (67% vs 6.9%; $p<0.0001$). They also had a higher mean GOS-E Peds score (7.7 vs 4.3; $p<0.0001$). Patients with coagulopathy on presentation had a higher mortality rate (76% vs none; $p=0.0002$). Patients without pupil reactivity on arrival had a mortality rate of 94.7% compared to 8% for those who had bilateral pupil reactivity ($p<0.0001$). Initial GCS scores were negatively correlated with GOS-E Peds ($p=0.002$) and Rotterdam scores were positively correlated with GOS-E Peds ($p=0.0003$). Penetrating TBI had a higher mortality rate than blunt TBI (56% vs 22%; $p=0.02$), but significantly higher mean wee-FIM scores on admission for rehabilitation (32.6 vs 19.3; $p=0.002$). Conclusions: This study supports the findings of previously published adult TBI literature that hypotension, lack of pupil reactivity and coagulopathy are associated with poor outcomes. The data also support that pediatric penetrating TBI has higher mortality, but the survivors have better functional status on admission for rehabilitation.

---

947. Chagnaud, C., et al. (2003). "[Imaging of paranasal sinus trauma]." Traumatismes des sinus de la face. 84(7-8 Pt 2): 923-940.

UNLABELLED: The role of imaging in the management of maxillofacial trauma is to describe anatomical lesions and to detect complications and associated injuries. Plain films are still useful for minimal trauma, but CT-scan is the gold standard for complex trauma. Helical CT and multidetector row CT simplify the emergency imaging of horizontal struts (skull base, orbital floor, alveolar ridge and palate). The diagnosis, and sometimes the treatment of complications may require CT cisternography, MRI and angiography., LEARNING OBJECTIVES: review mechanisms and classification of paranasal sinuses trauma; present the imaging techniques with special emphasis on CT; describe paranasal sinuses trauma features and pseudo-fracture patterns; describe complications and associated injuries.

---

948. Chahidi, A., et al. (2014). "Post traumatic epilepsy due to traumatic brain injury by traffic accidents in neurophysiological explorations laboratory of Marrakesh University Hospital." Clinical Neurophysiology 125: S260.

Introduction: Post traumatic epilepsy (PTE) is defined by two or more unprovoked seizures after a brain traumatic injury (BTI). PTE after TBI can be secondary to traffic accidents. Its prevalence of 4% increases after penetrating brain injury. Cortical lesions play a role of the genesis of the PTE. Morocco face a real" Road War" and Marrakesh city and its region is especially known by traffic accidents of motorcyclists. Aim of the study: Was to analyze some characteristics of PTE cases secondary to TBI caused by traffic accidents in the area of Marrakesh city. Patients and methods: Retrospective study on the cases of PTE registered over one year in the laboratory of neurophysiological explorations of Marrakesh university hospital. All cases had an electroencephalography (EEG) with selection of the cases associating epileptic seizure caused by TBI. Results: Among 385 patients with epilepsy who had an EEG, 11 cases were associated with a TBI caused by a traffic accident (Among a total of 20 cases with TBI). TBI was severe in 9 cases. The average age of patients was of 27.5 years (ranged from 17 to 72 years) with a male predominance (10 cases). PTE diagnostic delay was of 4 years after the accident. Epilepsy seizures were mainly partial (9 cases). The neurological examination was normal in 5 cases. Elsewhere we found confusion (2 cases), a limb motor paralysis (2 cases), pyramidal signs (1case) and multifocal lesions (1 case). The EEG confirmed partial paroxystic abnormalities in 8 cases and was normal in 3 cases. All patients have a cerebral CT scan showing hemorrhagic contusions (3 cases), depressed skull (2 cases), frontal hematoma (2 cases). Five patients were treated by valproate at the time of the realization of the EEG. Discussion: Traffic accidents constitute a significant cause of deaths and disabilities in Morocco with 3000 victims dying and almost 62 222 injuries every year. PTE caused by traffic accidents constitute 55% of all PTE secondary to TBI in our series over one year which is similar to rate of some other African countries less developed than Morocco (62% in Tanzania for example). The incidence is known to increase with the severity of the TBI and the presence of hemorrhagic contusions and depressed skulls. AED prophylaxis seems not to be effective in preventing the late unprovoked seizures and PTE. Most used AED are phenytoin, valproate and carbamazepine. Conclusion: PTE due to traffic accidents was seen in 55% of all TBI cases seen in our neurophysiologic laboratory. The majority of victims of this "road war" are young active males with severe consequences in Marrakesh region. In spite of the deployed efforts to decrease road deaths, more prevention is needed with an early diagnostic and treatment of the PTE victims.

949. Chalaye, J. C., et al. (1982). "[2 unusual intra-orbital, extra-ocular foreign bodies]." Deux corps etrangers "insolites" intra-orbitaires, extra-oculaires. 83(4): 226-231.

---

950. Chalkley, D., et al. (2008). ""I was stabbed in the head 11 days ago"." Emergency medicine journal : EMJ 25(8): 539.

A case is presented in which a knife wound to the head was initially assessed as inconsequential and later proved to be significant. This case illustrates the necessity of exploring scalp wounds to assess for possible skull fractures and of using the history to direct management. It also highlights the requirement for thorough guidelines for use by junior staff and for the staff to apply them with some degree of latitude.

951. Chaloupka, J. C., et al. (1999). "Recurrent carotid blowout syndrome: diagnostic and therapeutic challenges in a newly recognized subgroup of patients." AJNR. American journal of neuroradiology 20(6): 1069-1077.

BACKGROUND AND PURPOSE: To our knowledge, recurrent carotid blowout syndrome (rCBS) has not been well described. Our purpose was to review our institution's recent experience with patients who presented with multiple episodes of carotid blowout syndrome (CBS), and who were referred for emergent diagnostic angiography and endovascular therapy., METHODS: We retrospectively reviewed the last 46 consecutive patients who had a clinical diagnosis of CBS. All patients were examined and treated prospectively according to a standardized protocol. Most patients

(43 of 46) had undergone extensive primary and salvage radical surgery with intraoperative brachytherapy or external beam radiation or both. The remaining three patients had either traumatic or iatrogenic CBS., RESULTS: Twelve patients (26%) in our series had more than one episode of CBS in which a total of 32 (20 recurrent) events were observed (average 2.7, range 2-4). Intervals of rCBS ranged from 1 day to 6 years. Thirteen (65%) of 20 recurrent events were attributed to progressive disease (PD), and seven (35%) of 20 to treatment failures (TFs). In the PD group, seven (54%) of 13 had recurrent ipsilateral disease, and six (46%) of 13 had recurrent contralateral disease. Etiologies of rCBS were as follows: seven exposed carotids; seven carotid pseudoaneurysms; eight small-branch pseudoaneurysms; five tumor hemorrhages; three hyperemic/ulcerated wounds; and one aortic arch rupture. Twenty-seven of 32 events were treated with endovascular therapy, which included the following: nine carotid occlusions; 11 small-branch embolizations; three transarterial tumor embolizations; one carotid stent; and two direct-puncture embolizations. Four of six TFs were retreated successfully with endovascular therapy; the remaining two TFs were managed successfully by surgery. In the PD group, hemorrhagic complications of rCBS were managed successfully in all but one patient, who died. No permanent neurologic or ophthalmologic complications occurred., CONCLUSION: Recurrent CBS is a frequently encountered problem in which most cases are caused by PD resulting from both multifocal iatrogenic arteriopathy and occasional wound complications that are characteristic of aggressively managed head and neck surgical patients. Initial TFs are encountered often as well. Despite the diagnostic and therapeutic challenges of rCBS, most cases can be retreated effectively.

952. Chalya, P. L., et al. (2011). "Aetiological spectrum, injury characteristics and treatment outcome of head injury patients at Bugando Medical Centre in north-western Tanzania." Tanzania journal of health research 13(1): 74-81.

Head injury is considered as a major health problem that is a frequent cause of death and disability and makes considerable demands on health services. A cross-sectional study was conducted to determine the etiological spectrum, injury characteristics and treatment outcome of head injury patients at Bugando Medical Centre (BMC) in North-western Tanzania. Data were collected using a pre-tested, coded questionnaire and analyzed using SPSS programme. A total of 260 head injury patients (mean age=26.84 years) were studied. Males outnumbered females by a ratio of 1.5:1. Road traffic accidents (RTAs) were the most common cause of injury accounting for 49.2% of patients. Scalp injuries, cerebral concussion and skull fractures were the most common type of head injuries. Fifty-six (21.5%) patients had associated injuries of which musculoskeletal region (36.1%) was commonly affected. Most of patients (66.1%) sustained mild head injury. The majority of patients (75.8%) were treated conservatively and only 24.2% of patients needed surgical interventions. Most of patients (85.4%) had good recovery. The mean hospital stay (LOS) was 24.56 days and the mortality rate was 11.2%. Patients who had RTAs, penetrating head injuries, associated long bone fractures and those who were treated surgically were found to have significantly longer LOS (P< 0.001). Mortality was found to be significantly associated with extreme of age, presence of pre-morbid illness and associated injuries, admission Glasgow Coma Score < 9, systolic blood pressure < 90mmHg, injury severity core > or =16, longer duration of loss of consciousness, the need for intensive care unit admission and finding of space occupying lesion on computed tomography scan (P < 0.001). Head injuries resulting from RTAs remain a major public health problem in this part of Tanzania. Urgent preventive measures targeting at reducing the occurrence of RTAs is necessary to reduce the incidence of head injuries in this region.

---

953. Chambres, O., et al. (2003). "[A detailed examination of injuries to the head and neck caused by bullfighting, and of their surgical treatment; the role of the cervico-facial surgeon]." Specificites lesionnelles et chirurgicales des traumatismes de la tete et du cou en tauromachie. Role du chirurgien cervico-facial. 124(4): 221-228.

Bullfighting (corrida) dates back to the 13th century in France, especially in the Camargue and the South-West, even if this fight between man and wild bull had been described before in other

countries. The current modern bullfight, as an artistic interpretation, was codified in Spain during the 18th century into 3 tercios (parts): the tercio of the lance, of the bandillera, and of the muletta, which end with the death of the bull. Celebrated by our Spanish neighbours as a national fiesta, the corrida represents a confrontation between the intelligence of man and the power of the bull. Injuries are the heavy cost of this art paid by each bullfighter. Most of them have been injured seriously, or even gored to death inside the bullring. Goring is a single injury, a mix of wound, burn, contusion and infection. Its treatment calls for an expert, which makes this type of surgery highly specialised. Head and neck trauma represents 16% of the total wounds in bullfighting. Its not very often that this type of injury happens, but each time it is serious. This study is based on 1450 case reports, deals with causes and accident circumstances, together with the type of injuries and their early management in the bullring's infirmary. The seriousness of these wounds would justify a head and neck surgeon being part of the medical staff during the corrida.

---

954. Chan, B. S., et al. (1989). "Urban trauma: an analysis of 1,116 paediatric cases." The Journal of trauma 29(11): 1540-1547.

Over a 2-year period 1,116 children admitted to an urban teaching hospital were studied prospectively. The overall group was analysed as to the nature of the injury and a subgroup of seriously injured children was identified and further analysed. All deaths were examined as to their cause and possible preventable as well as salvageable factors. The predictive value of the Trauma Score (T.S.) and Method of Injury (M.O.I.) were evaluated for their prospective prediction of serious injury as determined by the Injury Severity Score and outcome. Most of the children were not seriously injured, with the most common injury being due to a fall (57%) and involving a single injury to the upper limb. With the subgroup of 143 children (13% of the total) who suffered serious injuries, the cranial cavity (90%) was the most common site of injury, occurring most often in pedestrians (31% of the total injured). There were 16 deaths in the series, representing 1.4% of all paediatric trauma admissions and 11% of the admissions who were seriously injured. All deaths were related to motor vehicle accidents and associated with serious head injury. A Trauma Score less than or equal to 12 accurately included all deaths but when correlated with the I.S.S., the Trauma Score had a specificity of 99% and a positive predictive value of 86%; its sensitivity was only 27%. The Method of Injury was associated with an overtriage rate of 300% in relation to the I.S.S.. Of children admitted following pedal cycle accidents only 9% were wearing helmets. Of car occupants injured, 39% were unrestrained.(ABSTRACT TRUNCATED AT 250 WORDS)

955. Chan, S. K., et al. (2014). "Transnasal penetrating intracranial injury with a chopstick." Hong Kong medical journal = Xianggang yi xue za zhi 20(1): 67-69.

We report the first case of a transnasal penetrating intracranial injury in Hong Kong by a chopstick. A 49-year-old man attempted suicide by inserting a wooden chopstick into his left nose and then pulled it out. The chopstick caused a transnasal penetrating brain injury, confirmed by contrast magnetic resonance imaging of the brain. He was managed conservatively. Later he developed meningitis without a brain abscess and was prescribed antibiotics for 6 weeks. He enjoyed a good neurological recovery. This case illustrates that clinician should have a high index of suspicion for penetrating intracranial injury due to a nasally inserted foreign body, even though it had already been removed. In such cases moreover, brain magnetic resonance imaging is the imaging modality of choice, as it can delineate the path of penetration far better than plain computed tomography.

957. Chandler, J. A., et al. (2017). "Online public reactions to fMRI communication with patients with disorders of consciousness: Quality of life, end-of-life decision making, and concerns with misdiagnosis." AJOB empirical bioethics 8(1): 40-51.

BACKGROUND: Recently, the news media have reported on the discovery of covert awareness and the establishment of limited communication using a functional magnetic resonance imaging (fMRI) neuroimaging technique with several brain-injured patients thought to have been in a vegetative state. This discovery has raised many ethical, legal, and social questions related to quality of life, end-of-life decision making, diagnostic and prognostic accuracy in disorders of consciousness, resource allocation, and other issues. This project inquires into the public responses to these discoveries., METHODS: We conducted a thematic analysis of online comments (n = 779) posted in response to 15 news articles and blog posts regarding the case of a Canadian patient diagnosed for 12 years as in a vegetative state, but who was reported in 2012 as having been able to communicate via fMRI. The online comments were coded using an iteratively refined codebook structured around 14 main themes., RESULTS: Among the most frequent public reactions revealed in the online comments were discussions of the quality of life of patients with disorders of consciousness, whether life-sustaining treatment should be withdrawn (and whether the fMRI communication technique should be used to ask patients about this), and misgivings about the accuracy of diagnosis in disorders of consciousness and brain death., CONCLUSIONS: These public perspectives are relevant to the obligations of clinicians, lawyers, and public policymakers to patients, families, and the public. Future work should consider how best to alleviate families' concerns as this type of research shakes their faith in diagnostic accuracy, to clarify the legal rules relating to advance directives in this context, and to address the manner in which public messaging might help to alleviate any indirect impact on confidence in the organ donation system.

958. Chandran, R., et al. (2013). "Serum microrna signatures as potential biomarkers of traumatic brain injury: A comparative study of three different rodent models of TBI." Journal of neurotrauma 30(15): A65.

Introduction Mild to moderate traumatic brain injury can often go undiagnosed due to the lack of reliable diagnostic markers. Diagnosis is further complicated by the heterogeneous nature of the cause and severity of injury. Circulating microRNAs found in serum are fast emerging as useful diagnostic biomarkers for various diseases. Methods In this study, three different rodent models of TBI ± weight drop injury model, controlled cortical impact (CCI) injury model and blast overpressure (BOP) injury model were used to replicate three different types of TBI ± closed head injury, penetrating TBI and blast TBI respectively. A weight-drop device was used to induce a single closed head injury (CHI) to the left parietal lobe in mice. Two different rod weights (246 and 333 g) and fall heights (2 and 3 cm) were used to simulate different injury severities within the mTBI spectrum. For the CCI model, a 1mm deep injury after craniotomy was performed on the left parietal lobe in mice. In the blast model, animals were exposed to three serial blasts of 120 kPa at an interval of 2 hours. Serum was collected at 3 hours following brain injury. MicroRNA expression profiles were carried out using TaqMan MicroRNA Array cards. Data analysis was done using RealTime StatMiner software. Results In the weight drop injury model, 7, 5, 10 and 20 microRNAs were significantly modulated in 246 g/2cm, 246g/3cm, 333g/2 cm and 333g/ 3 cm respectively. Five microRNAs (one up- and 4 down regulated) were significantly modulated in all the four injury groups. In the case of CCI model, 35 microRNAs were differentially expressed post injury and among them seven microRNAs were highly significant (2 up and 5 down regulated). In case of blast TBI model, 123 microRNAs were differentially modulated in serum at 3 hours post injury. Comparison of the microRNA expression profiles of the three TBI models showed that two microRNAs (mmu-miR-297c and mmu-miR-652) were common between the blast and CCI models whereas another two microRNAs (mmu-miR-875-5p and mmu-miR-450a-5p) were common between the blast and weight drop injury model. Further validation of the selected microRNAs and studies on their targets are in progress. Conclusions Serum microRNA signatures of the three different TBI models were found to be distinct and indicate that these may be useful in diagnosing mild to moderate TBI along with identifying the nature and cause of the injury. Common microRNAs between

the injury types can be an indication of the common molecular pathways being affected following the injury. Detailed studies on the selected micro- RNAs and their targets can also elucidate the pathophysiology of TBI.

960. Chang, C. C. and H. C. Wang (2021). "Emboli stroke following migration of carotid foreign body: A case report." eNeurologicalSci 22.

Foreign body embolization can cause intracranial artery occlusion with ischemic stroke. Reported etiologies include post cerebrovascular interventions, migration of esophageal foreign body and neck trauma. We reported a case with punctured wound at left neck, X-ray and computed tomography revealed a foreign body located in the carotid region. The patient eventually developed stroke symptoms in the next day after operation. Non-contrast brain Computer tomography at that time revealed that porcelain fragment located at the suprasellar area, and infarction of the left anterior basal ganglion. Our patient is the first reported case having an embolic stroke secondary to distal migration of a foreign body from the carotid artery after neck trauma. We call attention to this rare neurologic complication of neck trauma with foreign body retention. Appropriate and prompt identification of concurrent vascular injuries with retention of foreign body is strongly advised in neck trauma patients.

961. Chang, C.-J., et al. (2002). "Oral wooden stick injury complicated by meningitis and brain abscess." Chang Gung medical journal 25(4): 266-270.

Meningitis is rarely seen following oral injury. We describe a 3-year-old boy developing meningitis and brain abscess following a penetrating oral wooden stick injury. There was no cerebrospinal fluid rhinorrhea noted. A cerebrospinal fluid culture yielded viridans streptococcus. Brain magnetic resonance imaging and computed tomography revealed a multiloculated ring-enhancing mass. This patient underwent surgical drainage and completed 8-week antibiotic therapy. The patient demonstrated a late and dismal complication of a penetrating oral injury. At 2-year follow-up the patient was in good condition. A penetrating oral wooden stick inury should be regarded as potentially serious.

962. Chang, L., et al. (2003). "Persistent brain abnormalities in antiretroviral-naive HIV patients 3 months after HAART." Antiviral therapy 8(1): 17-26.

BACKGROUND: Proton magnetic resonance spectroscopy (1H-MRS) and neuropsychological tests may be useful for monitoring the effectiveness of highly active antiretroviral therapy (HAART) in HIV-associated brain injury. We aimed to evaluate whether brain abnormalities will improve 3 months after HAART., METHOD: Thirty-three HIV patients naive to antiretroviral medications were evaluated before and 3 months after HAART using 1H-MRS and neuropsychological tests; results were compared with those of 26 seronegative control subjects., RESULTS: Despite significant improvement in CD4 counts, and suppression of plasma and cerebrospinal fluid (CSF) viral loads, elevated brain metabolites (choline compounds and myoinositol in the frontal lobes) and neuropsychological tests abnormalities (including the computerized tests [CalCAP]) persisted after 3 months of HAART. In the basal ganglia, choline and myoinositol became elevated only after treatment. No interaction effect was observed between the number of CSF-penetrating drugs (one vs two) and changes (baseline vs 3 months) in any of the brain metabolites, cognitive performance or CSF viral load., CONCLUSIONS: The persistent brain abnormalities suggest ongoing repair or reactive inflammatory processes in the brain after 3 months of HAART. Regimens with two CSF-penetrating antiretroviral medications do not appear to be more effective than those with one CSF-penetrating drug in treating HIV brain injury at 3 months.

963. Chang, R., et al. (2020). "Characteristics of trauma mortality in patients with aortic injury in Harris County, Texas." Journal of Clinical Medicine 9(9): 1-9.

Background: The National Academies of Science have issued a call for zero preventable trauma deaths. The mortality characteristics in all patients with aortic injury are not well described. Methods: All prehospital and hospital medical examiner records for deaths occurring in Harris County, Texas in 2014 were retrospectively reviewed, and patients with traumatic aortic injury were selected. The level of aortic injury was categorized by zone (0 through 9) and further grouped by aortic region (arch, zones 0 to 2; descending thoracic, zones 3 to 5; visceral abdominal, zones 6 to 8; infrarenal, zone 9). Multiple investigators used standardized criteria to categorize deaths as preventable, potentially preventable, or non-preventable. Results: Of 1848 trauma deaths, 192 (10%) had aortic injury. There were 59 (31%) aortic arch, 144 (75%) descending thoracic, 19 (10%) visceral abdominal, and 20 (10%) infrarenal aortic injuries. There were 178 (93%) non-preventable deaths and 14 (7%) potentially preventable deaths, and none were preventable. Non-preventable deaths were associated with blunt trauma (69%) and the arch or thoracic aorta (93%), whereas potentially preventable deaths were associated with penetrating trauma (93%) and the visceral abdominal or infrarenal aorta (79%) (all $p < 0.05$). Half of potentially preventable deaths ($n = 7$) occurred at the scene, and half occurred at a trauma center. Conclusion: Potentially preventable deaths after aortic injury were associated with penetrating mechanism and injury to the visceral abdominal and/or infrarenal aorta. Optimal prehospital and ED treatment include temporizing hemorrhage control, hemostatic resuscitation, and faster transport to definitive treatment.

964. Chang, S. E., et al. (1998). "Successful removal of traumatic tattoos in Asian skin with a Q-switched alexandrite laser." Dermatologic surgery : official publication for American Society for Dermatologic Surgery [et al.] 24(12): 1308-1311.

BACKGROUND: Traumatic tattoos result from mechanical penetration of the skin by foreign-body particles associated with puncture, abrasive, or explosive trauma. Until the recent development of the Q-switched lasers, it was not possible to remove tattoo pigments without scar and pigmentary changes., OBJECTIVE: The objective of this study was to determine the effectiveness of the Q-switched alexandrite laser (wavelength, 755 nm; pulsewidth, 100 ns), in treating the 27 cases of Asian skin with 36 traumatic tattoos and to observe any side effects such as scarring or pigmentary change., METHODS: The results of treatments on 16 patients with 19 penetrant tattoos, 10 patients with 16 abrasive tattoos and 1 patient with bomb explosion were clinically analyzed., RESULTS: Greater than 76% removal of tattooed pigments required an average of 1.7 treatment sessions in penetrant tattoos in contrast with 2.4 sessions in abrasive tattoos. The excellent removal of traumatic tattoos required 7.5 J/cm2 except the scarred region of one explosive tattoo and one abrasive tattoo on soil. There were no permanent side effects such as scar or permanent pigmentary changes., CONCLUSION: In conclusion, the Q-switched alexandrite laser is a safe and highly effective modality for removal of various traumatic tattoos without scar or permanent pigmentary change in Asian skin.

966. Channar, K. A., et al. (2011). "Comparison of open reduction and internal fixation versus closed reduction and fixation of maxillomandibular joint for the treatment of gunshot injuries of mandible." Journal of the Liaquat University of Medical and Health Sciences 10(3): 168-173.

Objectives: To determine the early and late outcome of two treatment options by open reduction and internal fixation versus closed reduction and Maxillomandibular fixation (MMF) in treatment of gunshot injuries of Mandible. Study Design: Prospective descriptive study. Place and Duration:Department of Oral and Maxillofacial Surgery King Edward Medical University/ Mayo

hospital Lahore from November 2008 to November 2009. Methodology: Sixty patients of gunshot injury were randomly allocated in two groups. In group A, 30 patients were treated by open reduction and internal fixation and in group B, 30 patients were treated by closed reduction and Maxillomandibular fixation. Postoperative complications were evaluated fortnightly and the outcome between two group were assessed Postoperatively infection, malocclusion, nonunion/ malunion of fracture fragments, facial asymmetry, exposed plate and sequestration of devitalized bone were checked. Patients were discharged as the treatment completed and recalled for post operative follow up. Results: Patients treated by open reduction were having fewer complications as compared to closed reduction i.e. 36.6%, and 50%. P-value (P>0.05) is significant in nonunion, mal union and facial asymmetry. Conclusion: Based on this study open reduction and internal fixation is the best available method for the treatment of gunshot injuries to the mandibular fractures after gunshot injuries.

968. Chapman, A. J. and J. McClain (1984). "Wandering missiles: autopsy study." The Journal of trauma 24(7): 634-637.

Five cases of firearm missile emboli are reported. Three were not unusual arterial bullet emboli. One, however, was a single shotgun pellet embolus which produced death from cerebral infarction. The fifth case appears to be the first known to embolize within the portal system and was associated with a 'wandering bullet' within the pericardial space.

971. Charlier, P., et al. (2014). "Maori heads (mokomokai): the usefulness of a complete forensic analysis procedure." Forensic science, medicine, and pathology 10(3): 371-379.

Based on an analysis of 19 mummified Maori heads (mokomokai) referred to our forensic laboratory for anthropological analysis prior to their official repatriation from France to New Zealand, and data from the anthropological and medical literature, we propose a complete forensic procedure for the analysis of such pieces. A list of 12 original morphological criteria was developed. Items included the sex, age at death, destruction of the skull base, the presence of argil deposits in the inner part of the skull, nostrils closed with exogenous material, sewing of eyelids and lips, pierced earlobes, ante-mortem and/or post-mortem tattoos, the presence of vegetal fibers within nasal cavities, and other pathological or anthropological anomalies. These criteria were tested for all 19 mokomokai repatriated to New Zealand by the French authorities. Further complementary analyses were limited to fiberscopic examination of the intracranial cavities because of the taboo on any sampling requested by the Maori authorities. In the context of global repatriation of human artifacts to native communities, this type of anthropological

expertise is increasingly frequently requested of forensic anthropologists and other practitioners. We discuss the reasons for and against repatriating non-authentic artifacts to such communities and the role played by forensic anthropologists during the authentication process.

972. Charry, J. D., et al. (2016). "Damage control of civilian penetrating brain injuries in environments of low neuro-monitoring resources." British journal of neurosurgery 30(2): 235-239.

INTRODUCTION: Gunshot wounds to the head are more common in military settings. Recently, a damage control (DC) approach for the management of these lesions has been used in combat areas. The aim of this study was to evaluate the results of civilian patients with penetrating gunshot wounds to the head, managed with a strategy of early cranial decompression (ECD) as a DC procedure in a university hospital with few resources for intensive care unit (ICU) neuro-monitoring in Colombia., MATERIALS AND METHODS: Fifty-four patients were operated according to the DC strategy (<12 h after injury), over a 4-year period. Variables were analysed and results were evaluated according to the Glasgow Outcome Scale (GOS) at 12 months post injury; a dichotomous variable was established as 'favourable' (GOS 4-5) or 'unfavourable' (GOS 1-3). A univariate analysis was performed using a chi(2) test., RESULTS: Forty (74.1%) of the patients survived and 36 (90%) of them had favourable GOS. Factors associated with adverse outcomes were: Injury Severity Score (ISS) greater than 25, bi-hemispheric involvement, intra-cerebral haematoma on the first CT, closed basal cisterns and non-reactive pupils in the emergency room., CONCLUSION: DC for neurotrauma with ECD is an option to improve survival and favourable neurological outcomes 12 months after injury in patients with penetrating traumatic brain injury treated in a university hospital with few resources for ICU neuro-monitoring.

---

973. Chatrath, V., et al. (2015). "Fluid management in patients with trauma: Restrictive versus liberal approach." Journal of Anaesthesiology Clinical Pharmacology 31(3): 308-316.

Trauma is a leading cause of death worldwide, and almost 30% of trauma deaths are due to blood loss. A number of concerns have been raised regarding the advisability of the classic principles of aggressive crystalloid resuscitation in traumatic hemorrhagic shock. Some recent studies have shown that early volume restoration in certain types of trauma before definite hemostasis may result in accelerated blood loss, hypothermia, and dilutional coagulopathy. This review discusses the advances and changes in protocols in fluid resuscitation and blood transfusion for treatment of traumatic hemorrhage shock. The concept of low volume fluid resuscitation also known as permissive hypotension avoids the adverse effects of early aggressive resuscitation while maintaining a level of tissue perfusion that although lower than normal, is adequate for short periods. Permissive hypotension is part of the damage control resuscitation strategy, which targets the conditions that exacerbate hemorrhage. The elements of this strategy are permissive hypotension, minimization of crystalloid resuscitation, control of hypothermia, prevention of acidosis, and early use of blood products to minimize coagulopathy.

974. Chattha, A., et al. (2018). "An Algorithmic Approach to the Management of Ballistic Facial Trauma in the Civilian Population." The Journal of craniofacial surgery 29(8): 2010-2016.

Annual incidence of non-fatal ballistic civilian has been increasing for the last decade. The aim of the present study was to clarify the optimal reconstructive management of civilian ballistic facial injuries. A systematic review of PubMed was performed. Articles were evaluated for defect type and site, reconstructive modality, complications, and outcomes. A total of 30 articles were included. Most common region of injury was mandibular with a 46.6% incidence rate. All-cause complication rate after reconstruction was 31.0%. About 13.3% of patients developed a postoperative infection. Gunshot wounds had overall lower complication rates as compared with shotgun wounds at 9.0% and 17.0%. By region, complications for gunshot wounds were 35% and 34% for mandible and maxilla, respectively. Immediate surgical intervention with conservative serial debridement is recommended. However, for

patients with pre-existing psychiatric disorders, secondary revisions should be delayed until proper psychiatric stabilization. When there is extensive loss of soft tissue in the midface, aesthetic outcomes are achieved with a latissimus dorsi or anterolateral thigh free flap. Radial forearm flap is favored for thin lining defects. Open reduction is suggested for bony-tissue stabilization. The fibula flap is recommended for bony defects >5 cm in both midface and mandible. For bony defects, <5 cm bone grafting was preferred. Delaying bone grafting does not worsen patient outcomes. Surgical treatment of ballistic facial trauma requires thorough preparation and precise planning. An algorithm that summarizes the approach to the main decision points of surgical management and reconstruction after ballistic facial trauma has been presented in this study.

975. Chattopadhyay, S. (2008). "Accidental low velocity atypical missile injury to the head." The American journal of forensic medicine and pathology 29(4): 334-336.

Missile injuries on the head are mostly due to firearms. Atypical missiles may be encountered in case of shrapnel of bomb explosions but rarely because of stones. The present case is a rare case where a stone propelled by the pressure from the rear wheel of a speeding truck on the highway, struck the head of a 7-year-old girl resulting in fatality. Reconstruction of the incident on the basis of history and postmortem findings throws some light on the mechanism. The case is unique as it is the first reported case of an accidental missile injury to the head resulting in fatality without any direct human involvement for propulsion of the projectile.

---

976. Chattopadhyay, S., et al. (2013). "Fatal crocodile attack." Journal of forensic and legal medicine 20(8): 1139-1141.

Attacks on human beings by various animals leading to varied types of injuries and even death in some cases are not uncommon. Crocodile attacks on humans have been reported from a number of countries across the globe. Deaths in such attacks are mostly due to mechanical injuries or drowning. Bites by the crocodiles often cause the limbs to be separated from the body. The present case refers to an incident of a fatal attack by a crocodile on a 35 years old female where only the mutilated head of the female was recovered. Multiple lacerated wounds over the face and scalp along with fracture of the cranial bones was detected on autopsy. Two distinct bite marks in the form of punched in holes were noted over the parietal and frontal bones. Injuries on the head with its traumatic amputation from the body were sufficient to cause death. However, the presence of other fatal injuries on the unrecovered body parts could not be ruled out.

---

977. Chattopadhyay, S., et al. (2009). "Fatal transorbital head injury by bicycle brake handle." Journal of forensic and legal medicine 16(6): 352-353.

Accidental transorbital head injuries are quite rare. Penetrating head injuries by blunt objects are possible when the site of penetration is through the orbit or the thin temporal bone. The present case is a rare case of transorbital penetrating head injury by a blunt object - bicycle brake handle. Minor external wounds may be misleading and fatal consequences may ensue if cerebral damage is missed on diagnosis. Proper antibiotic coverage to prevent meningitis and neurosurgical intervention can reduce mortality in such cases.

978. Chau, A., et al. (2015). "The effect of claustrum lesions on human consciousness and recovery of function." Consciousness and cognition 36: 256-264.

Crick and Koch proposed that the claustrum plays a crucial role in consciousness. Their proposal was based on the structure and connectivity of the claustrum that suggested it had a role in coordinating a set of diverse brain functions. Given the few human studies investigating this claim, we decided to

study the effects of claustrum lesions on consciousness in 171 combat veterans with penetrating traumatic brain injuries. Additionally, we studied the effects of claustrum lesions and loss of consciousness on long-term cognitive abilities. Claustrum damage was associated with the duration, but not frequency, of loss of consciousness, indicating that the claustrum may have an important role in regaining, but not maintaining, consciousness. Total brain volume loss, but not claustrum lesions, was associated with long-term recovery of neurobehavioral functions. Our findings constrain the current understanding of the neurobehavioral functions of the claustrum and its role in maintaining and regaining consciousness.

979. Chaudhary, R., et al. (2015). "The role of computerised tomography in predicting visual outcome in ocular trauma patients." Eye (London, England) 29(7): 867-871.

PURPOSE: Ocular blast injuries in the military setting are particularly associated with significant maxillofacial trauma and/or brain injury. The opportunity to perform a comprehensive ophthalmic evaluation is frequently limited in the acute multiple trauma scenario. We aim to describe the relationship between the clinical effects of acute ocular and orbital blast trauma with the findings on computerised tomography (CT)., METHODS: This was a retrospective consecutive case series of all soldiers with facial and/or suspected ocular injuries. A total of 80 eyes that had suffered blast injuries of varying severity were studied. Assessment of orbital and ocular CT images were performed by military consultant radiologists. A comparison was made with actual clinical findings. Statistical analysis was performed using Fisher's exact test., RESULTS: No pathological findings were described in 37 of the 80 eyes imaged by orbital and ocular CT scans. Clinically, these eyes and orbits were all found to be intact, or had minor trauma. All foreign bodies and penetrating eye injuries were successfully diagnosed by CT. Absence of an orbital fracture did not rule out a globe injury. However, a corneal or scleral defect was less likely when an orbital fracture was absent., CONCLUSION: The eye is a delicate structure prone to injury that requires urgent repair if breached. It is difficult to assess thoroughly in the unconscious or distressed patient. In this context, CT imaging is invaluable to be able to make a relatively confident prediction of clinical findings and decide upon the necessity for acute ophthalmic surgical intervention.

980. Chaudhri, K. A., et al. (1994). "Penetrating craniocerebral shrapnel injuries during "Operation Desert Storm": early results of a conservative surgical treatment." Acta neurochirurgica 126(2-4): 120-123.

A follow-up study is presented of the initial neurosurgical treatment of 20 patients who sustained penetrating craniocerebral injuries during "Operation Desert Storm". Fifteen of these patients had received intracranial debridement through a craniectomy and five patients had received care of scalp wounds only. Following treatment and stabilisation in a frontline hospital, these patients were transferred to the Riyadh Armed Forces Hospital for further evaluation and management. On admission, all the patients received a computerised tomographic scan which revealed shrapnel fragments inside their brain. No attempt had been made to remove the metal fragments. A patient with an infected scalp wound was treated with a course of appropriate antibiotics and the wound dressed. Dexamethasone was not used. Anticonvulsants were used only in one patient who had been treated for a presumed cerebral abscess. The neurological status of the patients improved along with the reduction of oedema and the swelling of the brain as shown in the follow-up CT scans. No patient died or developed a seizure disorder. These results suggest that re-operation for removal of retained fragments is unnecessary. It is concluded that the initial treatment of shrapnel wounds of the brain should be to preserve maximal cerebral tissue and function either by limiting the wound debridement performed through a craniectomy or by care of scalp wounds only.

---

981. Chaudhry, H., et al. (2017). "Sagittal sinus stenosis as a cause of increased intracranial pressure." Neurology 88(16).

Objective: To report a case of medical therapy for elevated intracranial pressure (ICP) secondary to venous sinus stenosis. Background: Venous sinus injury has been described after trauma, often in the setting of surgical intervention following failed medical management for venous sinus thrombi. Venous sinus stenosis following depressed occipital skull fracture is a rare but described phenomenon. Although successful surgical management has been reported, successful medical management has not. Design/Methods: Case report. Literature review (PubMed). Results: A 41 year-old male presented with a gunshot wound to the back of the head. CT head showed bullet fragments in the occipital bone with multiple depressed skull fractures with minimal surrounding edema and extraaxial hemorrhage. Initial CT venogram revealed a distorted posterior superior sagittal sinus but both proximal and distal flow were patent. Patient was discharged home day 6 with reportedly normal neurologic exam. Day 14 posttrauma, patient reported worsening of his headache, blurry vision and new binocular diplopia. Formal ophthalmologic exam showed 20/40 visual acuity bilaterally with complete color vision loss in his left eye, bilateral 6th nerve palsies and 2+ bilateral papilledema. Patient also was noted to have a mild left facial droop and left lower extremity weakness. Repeat CT venogram was again stable but limited. Conventional angiogram revealed severe stenosis in the superior sagittal sinus without thrombosis. Patient was medically managed with acetazolamide 250mg BID and symptoms improved. On follow-up 2 weeks later, subtle improvement was noted in his color vision, visual acuity and papilledema as well as facial droop. Patient was started on aspirin 81mg to help prevent the formation of thrombi with plan to follow up again in 3 months. Conclusions: In cases of traumatic superior sagittal sinus stenosis, increased ICP may present remotely from initial injury and medical management may be an option.

---

982. Chaudhry, I. A., et al. (2005). "Severe ocular injuries from pointed door handles in children." Ophthalmology 112(10): 1834-1837.

OBJECTIVE: To report severe ocular injuries caused by pointed door handles in children., DESIGN: Noncomparative, interventional, retrospective case series., METHODS: Clinical records of 15 patients who sustained severe ocular injuries from door handles were reviewed for place of trauma, presenting symptoms and signs, surgical procedures performed, and final outcome., MAIN OUTCOME MEASURES: Trauma caused by complications from the door handle injury, such as loss of vision and ocular and adnexal injuries, and treatment rendered., RESULTS: There were 12 boys and 3 girls with an average age of 7.8 years (range, 6-10 years). Place of trauma was at home in 12 children and in school in 3 children. Presenting visual acuity (VA) was 4/200 in 1 patient, light perception (LP) in 5 patients, and no light perception (NLP) in 9 patients. There were 9 eyelid or canalicular lacerations, 4 ruptured globes, and 14 optic nerve avulsions. All ruptured globes were repaired initially and eyelid and canalicular lacerations were repaired primarily within 24 hours of presentation. Average follow-up was 21 months (range, 1 month-8 years). Final VA was 20/30 in 1 patient, LP in 1 patient, and NLP in 13 patients. Eight eyes required enucleation for painful blind eye or to achieve optimal cosmesis., CONCLUSIONS: Pointed door handles installed at current heights may pose a significant risk of ocular and periocular injuries among young children.

984. Chauhan, R., et al. (2018). "Anesthesia for Emergency Preservation and Resuscitation (EPR) for Traumatic Cardiac Arrest: a Brief Review." Current Anesthesiology Reports 8(1): 59-62.

Purpose of Review: We present the anesthesia management protocol currently in development at our institution for those patients enrolled into the Emergency Preservation and Resuscitation for Cardiac Arrest from Trauma (EPR-CAT) Clinical Trial. Recent Findings: Emergency preservation and resuscitation (EPR) utilizing saline and deep hypothermia is a novel approach for management of trauma patients who present with life threatening non-compressible hemorrhage. This pioneering technique has transitioned from laboratory animal studies to human clinical trials. Summary: Patients who experience witnessed cardiac arrest from penetrating trauma and fail conventional therapy are eligible for enrollment in the EPR-CAT trial. This concept involves replacing the patient's blood volume with cold saline to rapidly induce hypothermia and drastically reduce the metabolic rate of the heart, brain, and other vital organs. It is expected that this approach should give surgeons up to 1 hour to operate and gain surgical hemostasis before hypoxic brain damage would otherwise occur. After surgical control of hemorrhage, patients are reperfused via cardiopulmonary bypass (CPB) with balanced blood products and rewarmed back to near normal temperatures. During cooling and CPB, the patients are anticoagulated with heparin with the goal of restoring normal coagulation after liberation from CPB. The primary outcome measure is survival to hospital discharge with minimal neurologic deficits.

988. Chedid, M. K., et al. (1989). "Major cerebral vessels injury caused by a seatbelt shoulder strap: case report." The Journal of trauma 29(11): 1601-1603.

Major cerebral arterial injury may result from penetrating or blunt trauma. In blunt trauma, clinical suspicion of such injury may not be raised, especially if the cranial CT scan is negative. We report a case of a seatbelt shoulder strap to the neck resulting in injury to three major cerebral vessels as demonstrated by cerebral angiography. Although the initial cranial CT scans were negative, a cerebral infarction ultimately developed. The patient was managed conservatively and recovered most of her functions. The importance of clinical suspicion and cerebral angiography is stressed.

989. Chedid, M. K., et al. (2001). "Delayed appearance of a traumatic intracranial aneurysm. Case report and review of the literature." Journal of neurosurgery 94(4): 637-641.

Giant traumatic intracranial aneurysms are rare, and thus their incidence and clinical behavior are poorly understood. In most cases, traumatic aneurysms develop and become symptomatic within months

following injury. The authors present the case of a 46-year-old war veteran, in whom a giant internal carotid artery aneurysm developed as a result of a penetrating cranial shrapnel injury sustained 25 years earlier during the Vietnam war. The aneurysm had not been evident on previous imaging studies. At surgery, a piece of shrapnel was found embedded in the dome of the aneurysm. The presentation, diagnosis, management, and treatment options related to this lesion are discussed.

990. Cheema, A., et al. (2020). "A CASE OF AN EMBOLIZING BULLET." Chest 158(4): A905.

SESSION TITLE: Medical Student/Resident Critical Care Posters SESSION TYPE: Med Student/Res Case Rep Postr PRESENTED ON: October 18-21, 2020 INTRODUCTION: Pulmonary bullet embolism arising from gunshot wounds are relatively rare and therefore have no clear guidelines for treatment. Management options include removal of the bullet fragments through endovascular approach or thoracotomy versus conservative approach with anticoagulation. We present a case of bullet embolism in bilateral lungs with hemorrhagic complication requiring emergent surgery. CASE PRESENTATION: 19 years old African American male was admitted to the trauma service following a gunshot wound (GSW) to the right upper chest. On presentation, the gunshot wound was not bleeding and the patient was hemodynamically stable. CT angiography showed bullet fragments within the segmental pulmonary arteries within the left upper lobe and right lower lobe. These fragments entered through the injured superior vena cava and embolized to pulmonary arteries. Upper GI endoscopy was done to rule out oesophagal injury. Post-procedure, patient coughed resulting in dislodgement of the clot and subsequent bleeding from the wound site. He was rushed emergently to the OR to control the bleeding. The patient underwent median sternotomy with the repair of vessels injured by the bullet. During the procedure, the patient had a cardiac arrest that was successfully resuscitated with open heart massage. He was transiently placed on cardiopulmonary bypass. He was subsequently transferred to the critical care unit (CCU) where targeted temperature management was initiated to minimize post-cardiac arrest brain injury. He was extubated 2 days following admission to CCU. The decision was made not to remove the bullet fragments and treat patient conservatively with observation and anticoagulation. Warfarin was therefore started with goal INR of 2-3. The patient was discharged to rehab in stable condition. After 1 year, the patient remains asymptomatic and compliant to therapy. DISCUSSION: Pulmonary embolism arising from GSWs is a rare occurrence with less than 200 case reports in the literature1. In our case, it is presumed that the fragments travelled from the right subclavian area, superior vena cava, right heart and to the pulmonary arteries. Fragmented venous bullet emboli are usually managed with retrieval or conservative management. Risks of leaving the bullet fragment emboli include pulmonary infarct, dislodgement and vascular damage, haemorrhage and death. Risks of emboli removal include thrombus formation, vessel damage and complications related to the surgery2 CONCLUSIONS: Although consensus on management of bullet emboli remains unclear, our case argues that conservative management with anticoagulation should take precedence over surgical/invasive approach in the management of bilateral or multiple bullet emboli. 992. Chegini, S., et al. (2014). "5 year review of a tertiary multispecialty craniofacial trauma unit. The oxford experience." British Journal of Oral and Maxillofacial Surgery 52(8): e46-e47.

Introduction: There is a trend towards care in multispecialty tertiary centres with evidence of improved outcomes. The Oxford University Hospitals Craniofacial Trauma unit was set up 5 years ago as a joint Oral & Maxillo-facial and Neurosurgical service. We present our experience to date in the treatment of patients with Frontal Sinus (FS) and Nasoorbito- ethmoid fractures (NOE). Method: The study included 97 patients (average followup time 8 years) with a 83% data capture rate which was collected from a prospective database and retrospectively from medical records using a pre-designed proforma. Recorded data included method of treatment and clinical and radiological outcomes. Results: Data (60% FS, 3% NOE, 19% FS & NOE) showed male:female ratio 7:1 with mean admission age of 35. Data included mechanisms of injury (36% RTA, 25% fall from a height, 11% assault, 4% gunshot), 14% presented with GCS<8 and 15% required preoperative ITU admission. Patients commonly presented with other injuries (18% Le Fort fractures, 18% skull fracture, 25% intra-cranial haemorrhage, 13% thoracic, 27% limb, 6% spine). FS fractures were treated conservatively (44%), by cranialisation (44%) or ORIF with sinus preservation (13%) with mean time to theatre of 8 days.We report treatment outcomes on CSF leak & duration, infections, late contour irregularity and need for further surgery. Conclusion: There are no agreed national guidelines for the treatment of FS/NOE. We present outcomes from one dedicated multi-specialist Craniofacial Trauma Unit in the UK which may inform benchmarking for care of patients with this specific group of injuries.

993. Chegini, S., et al. (2016). "Outcomes of treatment of fractures of the frontal sinus: review from a tertiary multispecialty craniofacial trauma service." The British journal of oral & maxillofacial surgery 54(7): 801-805.

There are no agreed national guidelines for the treatment of fractures of the frontal sinus and the naso-orbitoethmoid complex. The Oxford University Hospitals Craniofacial Trauma unit was set up five years ago as a joint oral and maxillofacial, ENT, and neurosurgical service, and we present our experience to date in the treatment of patients with such fractures. The study includes 91 patients with data collected from a prospective database. Patients underwent cranialisation if they met the criteria of persistent leak of cerebrospinal fluid (CSF), displaced fracture of the posterior wall or obstruction of the nasofrontal outflow tract. The mean follow-up time was 42 months (range 1-10 years). Three groups of patients were analysed. Group 1 met the criteria for, and were treated by, cranialisation (n=50). Group 2 met the criteria for cranialisation, but were treated conservatively because of coexisting conditions (n=8). Group 3 did not match the criteria for treatment, and were managed conservatively (n=33). The numbers of patients with complications or who required further operation were: group 1 (4/50), group 2 (3/8), and group 3 (3/33). There were significantly fewer complications among those patients who met the operative criteria and were treated by cranialisation than among those treated conservatively (p=0.04). These outcomes from one dedicated multispecialist craniofacial trauma unit in the UK may help surgeons who care for patients with this specific group of injuries. Our morbidity was in keeping with published figures.

A thyroid abscess is a rare condition, and it is so infrequently encountered. A migrated fish bone is a rare otolaryngologic emergency indicated when the foreign body penetrates through the esophageal mucosa into the thyroid gland space of the neck after several weeks of swallowing. We present the case of a 50-year-old woman who had fever and anterior neck painful mass. An intrathyroid abscess was diagnosed; and she underwent thyrotomy with transcervical approach. A foreign body, which proved to be a fish bone and which fortunately did not cause any adverse effects, was removed.

998. Chen, J. W. Y., et al. (2009). "Posttraumatic epilepsy and treatment." Journal of rehabilitation research and development 46(6): 685-696.

Posttraumatic epilepsy (PTE) is a major long-term complication of traumatic brain injury (TBI). PTE usually develops within 5 years of head injury. The risk for developing PTE varies with TBI type. Both Korean and Vietnam war veterans with penetrating TBI had a 53% risk of developing PTE. The risk of developing PTE is between 10% and 25% in combat-associated closed-head trauma with positive brain imaging and about 5% in moderately severe closed-head injury without imaging finding. We do not know the risk of PTE among Operation Iraqi Freedom/Operation Enduring Freedom veterans with minimal TBI because of blast exposure.Partial seizures may manifest with subtle behavioral alterations that can be mistaken for manifestations of posttraumatic stress disorder and improperly treated. Accidents and medical complications commonly occur during seizures. Sudden unexpected death in epilepsy is most frequent among 20- to 40-year-olds. Seizures increase the likelihood of refractory seizures years after TBI. Seizures are also a social stigma that compromise veterans' reintegration into society. People with uncontrolled epilepsy are not allowed to drive and have difficulty obtaining or maintaining employment. Optimal seizure control is essential to the physical and emotional health of veterans with TBI and to their ability to lead productive lives.

999. Chen, L., et al. (2007). "Retransplantation of fetal olfactory ensheathing cells for chronic spinal cord injury in 1 case." Journal of Clinical Rehabilitative Tissue Engineering Research 11(33): 6690-6692.

Aim: To explore the efficacy of olfactory ensheathing cell (OEC) on neural function after intraspinal retransplantation on the treatment of chronic spinal cord injury (SCI). Methods: 1 One 27-year-old man of Kazakstan with chronic complete spinal cord injury at thoracic vertebrae 12 (T12), who had suffered from paraplegia, urinary and fecal incontinence, and severe pain in right lower limb following a emergency operation due to a gunshot wound on September 20th, 2001, was selected as subject. It was A-level injury according to the standard of America Spinal Injury Association. The subject was treated with two OEC intraspinal transplantations in September 30th, 2002 and February

5th, 2007, respectively. Therapeutic scheme was known by the patient. 2 Olfactory bulb of 4-month aborted fetus was obtained with the agreement of pregnant women and their family members and trypsinized to single OECs, and then cultured for 2 weeks with concentration of 2×1010 L-1. A keyhole with the diameter of 3 cm was made on T11. 100 μL(the first operation) and 50 μL (the second operation) OEC suspension were injected into avascular area along median line of juncture between injured spinal cord and normal spinal cord with No. 4.5 fine needle (1×106 each time), respectively. Donor and receptor HLA zygosity was done before the second transplantation. The patient took orally FK506 capsule 2 mg, twice a day for 42 days after operation. Results: 1 The patient was able to control his urination well for 6 hours at month 3 after the first transplantation. His both ankles moved freely and his sexual function involved penis erection ameliorated. The pain relieved. 2 10.days after the second transplantation, the sweating in his both feet increased, the pain in his lower limb reduced, skin of abdomen was better and the sensation to pin prick improved from absent to decreased at the dermatome of T10. The findings of paraspinal somatosensory evoked potentials (PSSEPs) showed that the sensory level declined from T10 to T12, bilaterally. Conclusion: The patient achieved some new improvements of neurologic function after OEC retransplantation. The issues on the amount and volume of the transplanted cells and injection site need to be further studied.

1000. Chen, L. L. K., et al. (2014). "Posttraumatic epilepsy in Operation Enduring Freedom/Operation Iraqi Freedom veterans." Military medicine 179(5): 492-496.

Penetrating traumatic brain injury (TBI) is a well-established risk factor for post-traumatic epilepsy (PTE). However, many veterans in Operation Enduring Freedom (OEF) and Operation Iraqi Freedom (OIF) who suffer from TBI do so from blast injury, and its consequences are not fully known. Two neurologists performed a chart review to describe patterns of injury and health care among all 16 OEF/OIF veterans at the VA Greater Los Angeles Healthcare System who were assigned an outpatient diagnosis of both epilepsy and TBI in 2008-2009. All Veterans were male, and the mean age was 30 years. Blast exposure was the most common mechanism of TBI (81%). Although all Veterans were assigned a diagnosis code of seizures, the diagnosis of PTE was clinically confirmed in only 3 veterans. On the other hand, the diagnosis of post-traumatic stress disorder was confirmed in 81% of the sample and a diagnosis of nonepileptic seizures was suspected in 44% of the sample. Researchers who study PTE among the OEF/OIF population using administrative data also should perform chart reviews to account for the prevalence of psychogenic nonepileptic seizures. 1001. Chen, P., et al. (2010). "Penetrating cranionasal injury in a child caused by a bicycle spoke." Pediatric emergency care 26(11): 837-839.

Penetrating cranionasal injuries are relatively rare, usually occur in young children, and can be caused by a variety of unusual objects. The mortality and disability rates are high without appropriate treatment. We report a penetrating cranionasal injury caused by a bicycle spoke. Some fundamental principles in the diagnosis and treatment of penetration injuries are emphasized from this case and the surrounding literature reviewed.

1002. Chen, P. C., et al. (2014). "Post-traumatic cerebral infarction following low-energy penetrating craniocerebral injury caused by a nail." Journal of Korean Neurosurgical Society 55(5): 293-295.

Post-traumatic cerebral infarction (PTCI) is a secondary insult which causes global cerebral hypoxia or hypoperfusion after traumatic brain injury, and carries a remarkable high mortality rate. PTCI is usually caused by blunt brain injury with gross hematoma and/or brain herniation. Herein, we present the case of a 91-year-old male who had sustained PTCI following a low-energy penetrating craniocerebral injury due to a nail without evidence of hematoma. The patient survived after a decompressive craniectomy, but permanent neurological damage occurred. This is the first case of

profound PTCI following a low-energy penetrating craniocerebral nail injury and reminds clinicians of possibility this rare dreadful complication for care of head-injured patients.

1003. Chen, P. Y., et al. (2014). "A shocking craniofacial penetrating injury by a steel bar." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES 20(5): 382-384.

Owing to the diversity in cause and damage, there is no standard surgical treatment method for a complicated penetrating craniofacial injury. The treatment of a complicated penetrating head injury caused by a steel bar is presented here. A 66-year-old woman fell onto a steel bar at a construction site and it penetrated the mandible, entered the sinus and orbital cavities, and reached the base of the frontal bone. A multi-disciplinary team including a neurosurgeon, otolaryngologist, and plastic surgeon was involved in removing the steel bar. The patient survived without sequelae except for blindness in the right eye. Despite the lack of standardized surgical treatment for a complicated penetrating craniofacial injury, aggressive treatment by a multidisciplinary team can result in good outcomes.

1004. Chen, T., et al. (2009). "The CT characteristics of orbital blowout fracture and its medicolegal expertise." Journal of forensic and legal medicine 16(1): 1-4.

To explore the CT characteristics of orbital blowout fracture, we reviewed 76 cases with orbital blowout fracture and analyzed their clinical forensic characteristics. The missed diagnosis rate of cranial CT was 26.3%, and plain X-ray was 47.4%. The orbital CT examination has advantages in diagnosing orbital blowout fracture. In 42 cases fractures were simple medial orbital wall fracture, 30 cases were inferior orbital fractures. Loss of clinical signs included local haematoma, bone continuity, and displacement of bone fragments were mostly seen in CT image. Clinical signs and symptoms included local haematoma, whilst diplopia as the most common clinical symptom. Visual acuity was rarely affected after fracture. It is concluded that orbital blowout fracture may be misdiagnosed if only cranial CT and plain X-ray are used. Diagnose the orbital blowout fracture only by craniocerebral CT and head X-ray. Orbital CT should be done if the clinical signs are suggestive of orbital blowout fracture Visual acuity was affected and diplopia may be present.

1005. Chen, T. A., et al. (2018). "Bioengineered dermal substitutes for the management of traumatic periocular tissue loss." Orbit (Amsterdam, Netherlands) 37(2): 115-120.

PURPOSE: Traumatic periocular injuries occasionally result in significant soft tissue loss, for which there are limited management options that provide satisfactory cosmetic and functional outcomes. The authors describe the use of a bioengineered dermal substitute (Integra R Dermal Regeneration Template [DRT], Integra LifeSciences, Plainsboro, NJ) as an alternative to immediate flap reconstruction or skin grafting., METHODS: Retrospective interventional case series of patients who underwent DRT placement for periocular tissue loss at the time of trauma. In each case, primary closure or immediate flap reconstruction was deemed impractical or undesirable due to the size and location of the primary and associated secondary defects. One to four weeks later, the outer silicone layer was removed and healing assessed. Additional reconstructive techniques were performed as needed., RESULTS: Three patients were treated at Bascom Palmer Eye Institute and one at Byers Eye Institute at Stanford. The defects healed completely in two patients, and by 79.2% in a third, with no need for additional reconstructive surgery. In the remaining patient, the defect was significantly downsized by 56.1%, allowing for a simpler flap reconstruction., CONCLUSIONS: Bioengineered dermal substitutes should be considered as a viable alternative to traditional reconstructive techniques for large periocular defects resulting from trauma. The outer silicone layer prevents desiccation and serves as a protective barrier, while the inner collagen matrix organizes the growth of neo-dermis and minimizes wound contraction. The dimensions of cutaneous defects can therefore be reduced dramatically, potentially eliminating the need for skin grafting and/or reducing the ultimate complexity of flap reconstruction.

1006. Chen, Y. and M. J. DeVivo (2005). "Epidemiology of extraspinal fractures in acute spinal cord injury: Data from the model spinal cord injury care systems, 1973-1999." Topics in Spinal Cord Injury Rehabilitation 11(1): 18-29.

Because of the high-energy force of the event, injuries to the spinal cord are often associated with fractures of bone. Analyzing data on 18,087 patients with spinal cord injury (SCI) receiving initial hospital care from the 24 Model SCI Care Systems from 1973 through 1999, we documented that the incidence of extraspinal fractures was 27.8 per 100 patients, with rib/sternum being the most common site of fractures. Injury etiology and level of neurologic deficit were the most important factors determining the presence and location of fractures. The incidence varied by age, gender, race, injury year, and completeness of neurologic deficit. This study establishes a baseline for future investigations.

1007. Chen, Z., et al. (2013). "Characterizations of post-traumatic epilepsy in experimentalmodels of penetrating ballisticlike brain injury." Journal of neurotrauma 30(15): A131.

Introduction Patients suffering severe traumatic brain injury experience increased risk of post-traumatic epilepsy (PTE). There is currently no drug proven clinically-effective for reducing the risk or effects of PTE, underscoring the need for pre-clinical research focused on developing PTE animal models that can be used to screen potential therapeutics. Methods Rats were randomly assigned to one of 6 groups categorized by: (1) the PBBI injury track (frontal or lateral PBBI), (2) injury severity (10% or 12.5% PBBI) and (3) survival time (3 or 6 months post-injury). At three weeks post-PBBI, all rats received skull EEG electrodes for seizure detections. Continuous EEG monitoring (5 consecutive days) was performed at 12, and 24 weeks post PBBI. At the end of EEGrecording time, each rat was subjected to a “seizure threshold” test induced by a single intraperitoneal injection of 30mg/kg pentylenetetrazole (PTZ). Seizure susceptibility was visually monitored for 30 min after PTZ injection and PTZ-induced convulsive behaviors were scored: 0 = no symptoms; 1 = body jerk; 2 = generalized seizure; 3 = “pop-corn” convulsion; and 4 = death following convulsion. For control purposes, a separate group of naïve (non-injured) rats were exposed to the PTZ challenge. Results Sporadic nonconvulsive seizure was detected by EEG in < 10% of all PBBI rats, regardless of injury severity, tract, or post-injury survival time. However, 38-100% of the animals across all PBBI groups displayed significant increases in their susceptibility to the PTZ challenge as compared to naïve animals. The degree of increased seizure susceptibility was positively correlated with PBBI severity, anatomical orientation, and survival time. In naïve rat group, only 14% displayed increased seizure sensitivity to PTZ challenge. At 3 months post-injury, PTZ induced seizures were detected in 38% of animals receiving 10% frontal PBBI, 67% of rats exposed to 10% lateral PBBI, and 100% of rats exposed to 12.5% PBBI (both frontal and lateral). At 6 months post injury, PTZ-induced seizures were detected in 83-100% of PBBI rats, indiscriminative of injury severity or orientation. The severity of PTZinduced seizures also correlated with PBBI severity, injury orientation, and post-injury duration. Mean seizure scores were: naïve rats = 0.2 ± 0.2; at 3 month, 10% frontal PBBI = 1.0 ± 0.5; 10% lateral PBBI = 1.7 ± 0.5; 12.5% frontal PBBI = 3.0 ± 0.5; 12.5% lateral PBBI = 2.5 ± 0.5. At 6 month, 10% frontal PBBI = 2.5 ± 2.1; 10% lateral PBBI = 2.2 ± 0.4; 12.5% frontal PBBI = 2.4 ± 0.3; 12.5% lateral PBBI = 2.0 ± 0.4. Conclusions Previously we reported that 10% and 12.5% frontal PBBI triggered NCS in 60-70% of animals during the acute 72 h post-injury period. These NCS were only detected by continuous EEG monitoring and occurred spontaneously without being challenged by PTZ. In this study, although intermittent EEG recording confirmed sporadic occurrence of spontaneous NCS, the intensity of seizure activities appeared to be subsiding during the much later recovery phases of PBBI. However, PBBI significantly lowered seizure threshold to the PTZ challenge at 3-6 months post PBBI. Interestingly, this increased seizure susceptibility was positively associated not only with the injury severity, but also with the anatomical orientation of the injury as well as the post-injury duration.

1008. Chen, Z., et al. (2011). "Synergism of human amnion-derived multipotent progenitor (AMP) cells and a collagen scaffold in promoting brain wound recovery: pre-clinical studies in an experimental model of penetrating ballistic-like brain injury." Brain research 1368: 71-81.

One of the histopathological consequences of a penetrating ballistic brain injury is the formation of a permanent cavity. In a previous study using the penetrating ballistic-like brain injury (PBBI) model, engrafted human amnion-derived multipotent progenitor (AMP) cells failed to survive when injected directly in the injury tract, suggesting that the cell survival requires a supportive matrix. In this study, we seated AMP cells in a collagen-based scaffold, injected into the injury core, and investigated cell survival and neuroprotection following PBBI. AMP cells suspended in AMP cell conditioned medium (ACCS) or in a liquefied collagen matrix were injected immediately after a PBBI along the penetrating injury tract. Injured control rats received only liquefied collagen matrix. All animals were allowed to survive two weeks. Consistent with our previous results, AMP cells suspended in ACCS failed to survive; likewise, no collagen was identified at the injury site when injected alone. In contrast, both AMP cells and the collagen were preserved in the injury cavity when injected together. In addition, AMP cells/collagen treatment preserved some apparent brain tissue in the injury cavity, and there was measurable infiltration of endogenous neural progenitor cells and astrocytes into the preserved brain tissue. AMP cells were also found to have migrated into the subventricular zone and the corpus callosum. Moreover, the AMP cell/collagen treatment significantly attenuated the PBBI-induced axonal degeneration in the corpus callosum and ipsilateral thalamus and improved motor impairment on rotarod performance. Overall, collagen-based scaffold provided a supportive matrix for AMP cell survival, migration, and neuroprotection. Copyright Published by Elsevier B.V.

1009. Chen, Z., et al. (2009). "Synergism of human Amnion-derived Multipotent Progenitor (AMP) cells and a collagen scaffold in promoting brain wound recovery: Pre-clinical studies in an experimental model of PBBI." Journal of neurotrauma 26(8): A60.

One of the histopathological consequences of a penetrating ballistic-like brain injury (PBBI) is the formation of a permanent brain cavity that becomes unsalvageable once it develops. In a previous study, when AMP cells were injected directly in the injury tract and observed 2 weeks post injury, they failed to survive in the brain cavity, suggesting that the cells survival require a supportive matrix. In this study, we suspended undifferentiated AMP cells in a collagen-based scaffold and investigated cell survival and neuroprotection in the rat PBBI model. AMP cells, labeled with the fluorescent dye PKH26, were suspended in AMP Cell Conditioned Medium (Spell out ACCS) or in a fluorescein labeled liquefied collagen matrix and were injected immediately after injury (2× 106 cells/150µ1/rat, n = 5/grp) along the injury tract (from the frontal cortex through the dorsal striatum). Injured control rats received only the fluorescein liquefied collagen matrix (150µ1/rat, n = 5). All animals survived two weeks after surgery. Serial brain sections were collected. Consistent with our previous results, AMP cells suspended in ACCS alone failed to survive at the injury site; likewise, collagen alone, which normally solidifies at 37°C, was not identified at the injury site in control rats. In contrast, aggregated AMP cells suspended in the collagen survived in the lesion cavity, and the fluorescein-labeled collagen was preserved in the injury cavity. Critically, the labeled AMP cells were also found to have migrated into the subventricular zone of the lateral ventricle and into the corpus callosum. Moreover, similar to i.c.v. injections of AMP cells without collagen support, the AMP cell/collagen treatment in this study also significantly attenuated the PBBI-induced axonal degeneration (silver staining) measured in the corpus callosum and ipsilateral thalamus. In conclusion, a solidified collagen-based scaffold provided a supportive matrix for AMP cell survival, migration, and neuroprotection when injected into the injury tract immediately after the PBBI trauma.

1010. Chen, Z., et al. (2009). "Human amnion-derived multipotent progenitor cell treatment alleviates traumatic brain injury-induced axonal degeneration." Journal of neurotrauma 26(11): 1987-1997.

To identify a viable cell source with potential neuroprotective effects, we studied amnion-derived multipotent progenitor (AMP) cells in a rat model of penetrating ballistic-like brain injury (PBBI). AMP cells were labeled with fluorescent dye PKH26 and injected in rats immediately following right hemispheric PBBI or sham PBBI surgery by ipsilateral i.c.v. administration. At 2 weeks post-injury, severe necrosis developed along the PBBI tract and axonal degeneration was prominent along the corpus callosum (cc) and in the ipsilateral thalamus. Injected AMP cells first entered the subventricular zone (SVZ) in both sham and PBBI rats. Further AMP cell migration along the cc only occurred in PBBI animals. No significant difference in injury volume was observed across all treatment groups. In contrast, treatment with AMP cells significantly attenuated axonal degeneration in both the thalamus and the cc. Interestingly, PKH26-labeled AMP cells were detected only in the SVZ and the cc (in parallel with the axonal degeneration), but not in the thalamus. None of the labeled AMP cells appeared to express neural differentiation, as evidenced by the lack of double labeling with nestin, S-100, GFAP, and MAP-2 immunostaining. In conclusion, AMP cell migration was specifically induced by PBBI and requires SVZ homing, yet the neuroprotective effect of intracerebral ventrical treatment using AMP cells was not limited to the area where the cells were present. This suggests that the attenuation of the secondary brain injury following PBBI was likely to be mediated by mechanisms other than cell replacement, possibly through delivery or sustained secretion of neurotrophic factors.

1011. Chen, Z. Y., et al. (2014). "Application of an active avoidance task in detecting cognitive deficits following penetrating ballistic-like brain injury." Journal of neurotrauma 31(12): A43.

In this study we used a modified active avoidance (AA) task to characterize cognitive deficits associated with emotional distress in rats following penetrating ballistic-like brain injury (PBBI). The AA device consists of a revolving arena covered by shock pads that are electrically charged only when rotating into a designated shock zone (SZ) (1/6 of the arena area). The goal of AA is for animals to learn to use environmental cues to avoid entering the SZ. Anaesthetized rats received PBBI (5% or 10% injury severity) or sham surgery. At 7 days post-injury (DPI), each rat was habituated to the arena (10-min) with the SZ turned off. On post-injury days 8 and 9, the rats received two avoidance acquisition trials per day (5 min/trial; 1 h ITI) in the revolving arena with the SZ turned on. At 10 DPI, the SZ was shifted 180 and the animals were exposed to a reversal learning test (4 trials; 5 min/trial; 1 h ITI). No significant injury-induced alterations in spontaneous locomotor behavior were detected during the habituation trial. However, results of AA acquisition trials and reversal tasks revealed significant injury-severity dependent deficits. More specifically, compared to sham controls, PBBI animals made more entries into the SZ (Sham: 1.9 ± 1.1; 5% PBBI: 3.5 ± 2.1; 10% PBBI: 9.9 ± 2.9) and displayed significantly longer escape latencies (Sham: 2.1 ± 1.5s; 5% PBBI 10.9 ± 8.7s, 10% PBBI: 22.9 ± 8.8s) on the last day of acquisition. Similar deficits associated with injury severity were also detected on the reversal test for entry frequency: (Sham: 2.0 ± 0.8; 5% PBBI: 7.0 ± 3.1; 10% PBBI: 10.8 ± 3.6), and escape latency (Sham: 20.6 ± 6.8s; 5% PBBI: 31.8 ± 6.9s; 10% PBBI: 42.0-12.6s). Overall, these results indicate that the AA task provides a sensitive measure for detecting cognitive dysfunction in the PBBI model. While ongoing work will determine whether this task would be sensitive to mild TBI, the current results suggest this may provide a useful measure for detecting efficacy of promising pharmacotherapeutics in the PBBI model.

1012. Cheng, A. L. and E. S. Lang (2014). "Pseudopancreatitis on computed tomography in a patient with isolated blunt head trauma: A case report." Journal of medical case reports 8(1).

Introduction. Computed tomography is commonly used to exclude occult injuries in patients with trauma, but imaging can reveal findings that are of uncertain etiology or clinical significance. We present a case of unsuspected pancreatic abnormality in a female patient with trauma who sustained an isolated blunt head injury. Case presentation. A 25-year-old female Caucasian patient sustained massive blunt and penetrating head trauma, secondary to a large object penetrating through the vehicle windshield. Based on the mechanism of injury and clinical evaluation, it was felt to be an isolated head

injury. However, computed tomography of her abdomen revealed an occult, intra-abdominal finding of significant pancreatic enlargement and peripancreatic fluid. There was no computed tomography evidence of parenchymal pancreatic laceration. The appearance of her pancreas on computed tomography was identical to that of acute pancreatitis or low-grade pancreatic injury, but her clinical history and laboratory values were not consistent with this, hence the term 'pseudopancreatitis'. Later surgery for organ donation confirmed diffuse pancreatic and peripancreatic edema, but no hematoma, contusion or other evidence for direct traumatic injury. This was an isolated intra-abdominal abnormality. Conclusion: The routine use of computed tomography in patients who have sustained trauma has led to increasing detection of unexpected findings. Clinical information such as mechanism of injury and blood work, along with careful evaluation of ancillary imaging findings (or lack of), is important for the provision of an appropriate differential diagnosis. We discuss the possible mechanism and differential diagnosis of an isolated pancreatic abnormality in the setting of non-abdominal trauma, which includes shock pancreas, overhydration, traumatic pancreatic injury and pancreatitis secondary to other etiologies.

1013. Cheng, D. Y. (1980). "[Management of 91 cases of penetrating craniocerebral injuries due to missiles (author's transl)]." Zhonghua wai ke za zhi [Chinese journal of surgery] 18(6): 536-538.

1014. Cheng, J., et al. (2017). "Long-term outcome of allogeneic cultivated limbal epithelial transplantation for symblepharon caused by severe ocular burns." BMC ophthalmology 17(1): 8.

BACKGROUND: The therapeutic effects of allogeneic cultivated limbal epithelial transplantation (CLET) for symblephara at different degrees caused by ocular burns were evaluated in this study., METHODS: A series of interventional cases were involved in this retrospective study. Eighty eyes (80 patients) with symblephara underwent CLET and the success rates of surgical treatment as well as corneal conditions and risk factors for recurrent symblepharon were analyzed., RESULTS: The average age of patients was 32.4 +/- 13.7 years (ranged from 4 to 60 years). The average follow-up time was 26.4 +/- 13.6 months (ranged from 12 to 60 months). Symblepharon cases were caused by chemical burns (36 eyes) or thermal burns (44 eyes). The first surgical intervention achieved complete success in 40 eyes (50%), partial success in 25 eyes (31.3%), and failure in 15 eyes (18.8%). The rate of complete success was 85.0% in eyes with grade I/II symblephara, 51.5% in eyes with grade III eyes and 22.2% in eyes grade IV symblephara (P = 0.001). The treatment was completely successful in 23.1% of eyes with moderate or severe preoperative inflammatory action and 63.0% of eyes with mild or no inflammation (P = 0.000). The corneal conditions were improved in 43 eyes (53.8%), of which 21 eyes had improved visual acuity. The recurrence of symblepharon after the first CLET was positively correlated with symblepharon length (P = 0.003), preoperative inflammatory activity (P = 0.016) as well as postoperative cicatricial entropion and trichiasis (P = 0.038)., CONCLUSIONS: CLET was effective on the recovery of anatomically deep fornixes in eyes caused by symblephara and corneal surface condition could be improved simultaneously. The success of surgical treatment was dependent on the effective control of inflammation and timely management of eyelid abnormalities.

1015. Cheng, J. S., et al. (2012). "Delayed acute spinal cord injury following intracranial gunshot trauma: case report." Journal of neurosurgery 116(4): 921-925.

The authors report the case of a patient who presented with a hoarse voice and left hemiparesis following a gunshot injury with trajectory entering the left scapula, traversing the suboccipital bone, and coming to rest in the right lateral medullary cistern. Following recovery from the hemiparesis, abrupt quadriparesis occurred coincident with fall of the bullet into the anterior spinal canal. The bullet was retrieved following a C-2 and C-3 laminectomy, and postoperative MR imaging confirmed signal change in the cord at the level where the bullet had lodged. The patient then made a good neurological recovery. Bullets can fall from the posterior fossa with sufficient momentum to cause an acute spinal

cord injury. Consideration for craniotomy and bullet retrieval should be given to large bullets lying in the CSF spaces of the posterior fossa as they pose risk for acute spinal cord injury.

1016. Cherednichenko, T. V. and A. V. Popov (2012). "[Optimization of medical-diagnostic process in patients with traumatic brain injury during early rehabilitation]." Likars'ka sprava(7): 194-197.

The problem of cardiovascular disease and cancer, the effects of traumatic brain injury is now one of the major health and social problems. Every year in Ukraine registered 200 thousand cases of the victims of traumatic brain injury. Of these, 30% of people then have persistent signs of disability that results in a disability, sometimes painful existence the patient and his relatives. Therefore, in order to bring man back into society after a traumatic brain injury, to the rehabilitation phase of treatment, immediately after the stabilization of the patient.

1017. Chermisin, V. M., et al. (2002). "[Significance of computer tomography and diagnosis of gunshot craniocerebral injuries at the stage of specialized medical care]." Znachenie komp'iuternoi tomografii v diagnostike ognestrel'noi cherepno-mozgovoi travmy na etape okazaniia spetsializirovannoi meditsinskoi pomoshchi. 323(1): 28-31.

1018. Cherry, R. A., et al. (2010). "Outcome assessment of blunt trauma patients who are undertriaged." Journal of Surgical Research 158(2): 421.

Objectives: Factors leading to undertriage (UT) include insufficient or inaccurate prehospital information, failure to upgrade care upon arrival, physician experience with triage protocols, and medical judgment. We investigated the outcomes of UT patients and compared them with those who met criteria for a full TTA at our Level 1 trauma center. Methods: Blunt trauma patients were retrospectively identified who met full or partial TTA from 7/02-1/08 using the trauma registry. Patients who met the criteria for a full TTA and had a partial TTA were considered UT. Data was collected on demographics (age, gender), injury severity, delays to OR, resource utilization (hospital and ICU LOS, ventilator days), and outcomes (complications, mortality, disposition, and functional independence measure score or FIM). Excluded: penetrating trauma, interfacility transfers, burn patients, age < 18 years old. Statistical analysis: chi square, $p< 0.05$, mean ± SD. Results: There were 1,424 full TTA with 318 (22.3%) in the UT group (UTG) and 1,106 in the correctly triaged group (CTG). The CTG was 70.4% male with a mean age of 41.5 years 6 19.8. The UTG was 67.1% male with a mean age of 45.8+ 20.5. The CTG had a higher ISS (24.7 vs 17.0, $p < 0.0001$). The CTG was more likely to undergo intubation upon arrival to the ED (34.9% vs 8.2%, $p < 0001$) and require ICU admission (49.0% vs 37.1%, $p <0.0001$). There were no differences in delay to OR for laparotomies, craniotomies, or open fractures between groups. The CTG group had a longer ICU and hospital LOS and spent more days on the ventilator ($p < 0.0001$). There was a higher incidence of ARDS, pneumonia, and infectious complications in the CTG ($p < 0.03$). The UTG had a lower mortality rate (6.0% vs 16.7%, $p < 0.0001$) and was more likely to be discharged home (65.3% vs 52.2%, $p = 0.02$). FIM scores were better among the UTG ($p < 0.01$). Conclusions: The UTG had a lower ISS and improved outcomes compared to the CTG with no differences in delays to OR. Despite the inherent challenges in TTA protocols, patients who were UT at our institution appear to have satisfactory outcomes.

1019. Cherry, R. L., et al. (2019). "Migration of retrobulbar wooden foreign body between diagnostic imaging and surgical extraction in a German shepherd dog." Veterinary ophthalmology 22(3): 353-359.

A 2-year-old, male castrated German shepherd dog was presented to the University of Tennessee Veterinary Medical Center (UTVMC) with periorbital swelling and conjunctival mucopurulent discharge 2 days following removal of a twig from the medial canthus by the owner. Diagnostic imaging was pursued due to the suspicion of a retrobulbar foreign body (FB). A cylindrical FB approximately 3.0

cm in length and 1.0 cm in diameter with concentric rings, suspected to be wooden material, was identified on computed tomography (CT) imaging. An attempt to remove the FB via a stab incision using ultrasound guidance was unsuccessful, and postmanipulation ultrasound confirmed the FB position was unchanged. An exploratory orbitotomy was performed, using the acquired CT images for guidance in locating the FB; however, the FB was not present at the predicted site. The CT imaging was repeated and showed that the FB had migrated rostrally approximately 3.0 cm, compared to the originally acquired study and its same location during attempted ultrasound-guided removal. A combination of CT-guided needle placement and contrast injection was then used with repeat imaging in an attempt to better localize the FB and its soft tissue tract. The dog was taken back into the operating room, and the wooden FB was successfully removed.

1021. Chibbaro, S. and L. Tacconi (2006). "Orbito-cranial injuries caused by penetrating non-missile foreign bodies. Experience with eighteen patients." Acta neurochirurgica 148(9): 937-932.

BACKGROUND: Penetrating non-missile orbito-cranial injuries are uncommon civilian injuries which have some special features. Only limited case-reports are available in the international literature., METHOD: We present a retrospective review of 18 such in presumed trivial orbital injury. Early identification and removal of retained foreign body fragments was achieved within 36 hours., FINDINGS: Patients were operated on and followed up for at least of 3 years. The final clinical outcome was excellent: 16 had a Glasgow Outcome Scale (GOS) of 5 while in the remaining 2 it was 4., CONCLUSION: The present report indicates that good results, in managing such injuries, can be achieved by a high index of suspicion and early diagnosis of intracranial injury in presumed trivial wounds and by the removal of every possible retained foreign body.

1022. Chiquet, C., et al. (2002). "[Risk factors for secondary retinal detachment after extraction of intraocular foreign bodies]." Facteurs de risque de decollement de retine apres extraction de corps etrangers intraoculaires. 37(3): 168-176.

BACKGROUND: Better identification of patients at risk for retinal detachment after intraocular foreign body removal would guide management as well as help prevent this complication. We performed a study to identify risk factors for secondary retinal detachment in eyes with retained intraocular foreign bodies., METHODS: We reviewed the records of 102 consecutive patients (95 males and 7 females with a mean age of 31.6 years) seen between 1990 and 1995 at one ophthalmology service for intraocular foreign body after penetrating ocular injury. All eyes underwent primary surgical repair and foreign body removal (via electromagnet or vitrectomy). The mean length of follow-up was 2 years (range 6 months to 6 years). Survival analysis (Kaplan-Meier, Cox regression) was performed to determine predictors of retinal detachment., RESULTS: The foreign body was metallic in 95% of cases and magnetic in 60%. The largest diameter was 3 mm or more in 35% of cases (range 1 mm to 25 mm, mean 3.6 mm). The foreign body was preretinal or intraretinal in 24 patients (24%), intravitreal in 47 (46%), located in the sclera in 16 (16%) and located in the anterior segment in 15 (15%). A secondary retinal detachment developed in 25 patients (24%) after foreign body removal, with a mean delay of 4.6 (standard deviation 7.6) months (range 7 days to 31 months). The posterior pole was detached in 15 patients (60%). The retinal detachment was total in 13 patients (52%). Proliferative vitreoretinopathy was noted in 13 cases (grade B in 3, grade CI in 3, grade CI in 1, grade C3 in 1, and grade C4 in 5). Univariate analysis using Kaplan-Meier survival showed that firearm injuries, visual acuity less than 20/200, presence of hyphema, presence of tissue prolapse and presence of vitreous hemorrhage at the initial examination were significantly associated with the occurrence of secondary retinal detachment. On multivariate analysis (Cox regression), two independent and combined factors were predictive of

retinal detachment: initial visual acuity less than 20/200 (odds ratio 5.5, p = 0.02) and presence of vitreous hemorrhage (odds ratio 2.2, p = 0.05)., INTERPRETATION: Patients at risk for secondary retinal detachment after penetrating ocular injury with retained intraocular foreign body can be identified at the initial examination.

1023. Chirichella, T. J., et al. (2011). "Lingual artery pseudoaneurysm with arteriovenous fistula formation following a gun shot wound." Journal of Surgical Radiology 2(2): 166-169.

1024. Chiu, R. G., et al. (2019). "Gunshot wounds to the head: racial disparities in inpatient management and outcomes." Neurosurgical focus 47(5): E11.

OBJECTIVE: Several studies have indicated that racial disparities may exist in the management and outcomes of acute trauma care. One segment of trauma care that has not been as extensively investigated, however, is that of cranial trauma care. The goal of this study was to determine whether significant differences exist among racial and ethnic groups in various measures of inpatient management and outcomes after gunshot wounds to the head (GWH)., METHODS: In this study, the authors used the Nationwide (National) Inpatient Sample (NIS) to investigate all-cause mortality, receipt of surgery, days from admission to initial intervention, discharge disposition, length of hospital stay, and total hospital charges of those with GWH from 2012 to 2016. A 1:1 propensity score-matched analysis was conducted to evaluate the effect of race on these endpoints, while controlling for baseline demographics and comorbidities., RESULTS: A total of 333 patients met the inclusion and exclusion criteria: 148 (44.44%) white/Caucasian, 123 (36.94%) black/African American, 54 (16.22%) Hispanic/Latinx, and 8 (2.40%) Asian. African American patients were sent to immediate care and rehabilitation significantly less often than Caucasian patients (RR 0.17 [95% CI 0.04-0.71]). There were no significant differences in mortality, length of stay, rates of surgical intervention, or total hospital charges among any of the racial groups., CONCLUSIONS: The authors' findings suggest that racial disparities in inpatient cranial trauma care and outcomes may not be as prevalent as previously thought. In fact, the disparities seen were only in disposition. More research is needed to further elucidate and address disparities within this population, particularly those that may exist prior to, and after, hospitalization.

1025. Cho, M. J., et al. (2019). "Rapidly growing pediatric trampoline-related injuries in Korea: A 10-year single center retrospective study." Korean Journal of Pediatrics 62(3): 90-94.

Purpose: Several published policy statements have warned against the risks associated with trampoline use and recommended safety guidelines. However, few studies have focused on trampoline-related injuries in Korea. This study aimed to assess the incidence and characteristics of pediatric trampoline-related injuries presented to Ulsan University Hospital. Methods: We retrospectively reviewed the medical records of children aged <16 years with trampoline-related injuries who visited our Emergency Department between 2008 and 2017. Results: Over the 10-year period, 178 trampoline-related injuries were reported, which represented a significant increase (P=0.016). Most (87.6%) of the injuries occurred during the last 5 study years, and a rapid increase in injuries was observed in children aged <6 years. Lower extremity injuries (62.4%) were the most common, followed by injuries of the upper extremities, head and face, and trunk, including injuries to the neck and spine. Sixty-seven children (37.6%) had fractures, and proximal tibia fractures were the most common. Fractures were significantly more common in younger children (<6 years old) than in older children (P=0.026). Conclusion: In Korea, the mechanism of trampoline injury is similar to that of injuries incurred in indoor trampoline parks but is characterized by smaller spaces and multiple users. Trampoline use and the incidence of trampoline-related injuries in children aged <6 years are increasing rapidly. Prohibiting the use of trampolines for children aged <6 years, restricting simultaneous use by multiple children, and

ensuring adult supervision should be strictly emphasized. Public awareness and policy guidelines are needed to reduce the incidence of trampoline-related injuries.

1026. Cho, R. A., et al. (2019). "Diagnostic Yield of Computed Tomography Angiography in Mandibular Fractures Caused by Blunt Force Trauma: A 10-Year Retrospective Study." Journal of oral and maxillofacial surgery 77(9): e19-e20.

Background: Mandibular fracture is the second most common (17.1%) maxillofacial fracture observed in the emergency departments (ED) in the US followed by nasal fracture (58.6%)1. Although computed tomography angiogram (CTA) has been indicated for penetrating head and neck (H&N) injury and for any suspicion of blunt vascular injury, there has been no studies on its diagnostic yield on blunt force trauma2. The purpose of this study is to examine diagnostic yield of CTA in the evaluation of patients presenting to the ED with acute mandible fracture due to blunt force trauma and to propose practical and rational guideline for proper usage of CTA. Methods: An IRB approved (4269) retrospective study was conducted of 1204 consecutive patients who presented to our hospital ED with acute mandible fractures over a period of 9 years. Medical records were reviewed for mechanism of injury (MOI) and demographics. Inclusion Criteria: Patients with mandible fractures due to acute blunt H&N trauma that obtained panorex and CT scan with or without CTA. Exclusion Criteria: Certain MOI with penetrating injuries such as stab and gunshot wounds and pediatric patients under the age of 18. Descriptive statistics were used to describe sample injury characteristics. Unadjusted odds ratios with 95% confidence intervals were performed to identify independent predictors of an increased risk of H&N vascular injury. Results: Total of 1086 patients, ages 18 to 96 years were included in this study (mean age 37.16 ± SD 18.75). In total, 919 patients obtained CT and orthopantomogram (panorex) while 167 patients obtained additional CTA. Among those patient that has obtained CTA, only 6.6% (11/167) revealed positive findings with H&N vascular injuries. Among those with positive CTA findings the following results were observed: the majority (45%) were motorcycle crashes, followed by motor vehicle crash (27%), assault (18%), and 1 from a fall (9%). Further analysis of mandibular fracture patterns failed to demonstrate statistical significance when compared to positive findings in CTA except for bilateral fractures: Bilateral (82%; p = 0.03), coronoid (27%; p = 0.06), ramus (27%; p = 0.12), symphyseal (18%; p = 0.34), condylar/subcondylar (27%; p = 0.36), parasymphyseal (27%; p = 0.57), angle (27%; p = 0.71), and body (18%; p = 0.74) fractures. Maxillary and mandibular edentulation status failed to demonstrate statistical significance (p = 0.15 and p = 0.25, respectively). The following vascular injuries were noted in the 11 patients with positive CTA findings: internal carotid artery (55%), common carotid artery (27%), internal jugular vein (9%), and lingual artery (9%). When looking at other H&N injuries, 2 patients had isolated cervical spine fractures, 2 had tracheal injury and cervical spine fractures, 1 had skull base fractures, 1 had occipital bone fracture, and 1 patient had frontal bone, temporal bone, and skull base fractures. When looking at other maxillofacial injuries, 1 patient suffered palatal fracture (9%), 1 patient suffered zygomatic fracture (9%), 1 patient suffered Le Fort type I fracture (9%), 2 patients suffered nasal fractures (18%), 2 patients suffered Le Fort type III fractures (18%), and 3 patients suffered orbital floor fractures (27%). Conclusions: Positive CTA findings were 4.9 times more likely to be bilateral (95% CI 1.05-22.80) versus unilateral fractures. Positive CTA findings were 4.01 times more likely to be with coronoid fractures (95% CI 1.05-15.36) versus without coronoid fractures. A similar pattern was observed in patients with ramus fractures: 11.3% (122/1075) without CTA versus 27% (3/11) with CTA. The findings of this study provides an opportunity to reexamine the current protocol at each hospital of ordering CTA for patients with mandibular fractures to provide effective and financially responsible care for the patients. 1028. Cho, W.-K., et al. (2017). "Orbital and Orbitocranial Trauma From Pencil Fragments: Role of Timely Diagnosis and Management." American journal of ophthalmology 180: 46-54.

PURPOSE: To emphasize the importance of early detection and radiologic evaluation of retained organic foreign bodies (FBs) in orbital or orbitocranial penetrating injuries by pencil., DESIGN: Retrospective case series., METHODS: A retrospective chart review of patients who had penetrating orbital or orbitocranial trauma at 2 tertiary hospitals was conducted. Patients whose mechanism of injury was penetrating trauma by pencil were included. The patients' demographics, time between initial trauma and detection of foreign body, radiologic images, and resulting sequelae were reviewed., RESULTS: Four patients were included in this study. All patients were male; 3 were less than 2 years of age and 1 was 34 years old. Accidents were witnessed in 2 cases, and initial detections of FBs were delayed in 3 cases, from 2 days to 7 weeks. Three cases involved the right orbit. Computed tomography (CT) imaging of the head demonstrated penetration of the orbital walls in 3 cases. Three-dimensional CT scans were used to differentiate the penetrating graphite pencil fragments from the orbital wall, and catheter angiography was used in 1 case of suspected orbital apex penetration. Vision was lost in 1 patient while other severe neurologic deficits were fully recovered after removal of FB., CONCLUSIONS: Penetrating injury by pencils to the periorbital structures and delayed detection of retained pencil fragments can result in threat to life and vision. Radiologic examinations are essential to the detection of these retained FBs. Prompt detection and removal of the FBs within 48 hours and treatment with antibiotics can save vision and life.

1029. Choi, C. S., et al. (1994). "The missing link. An unusual case of embolization." The American journal of forensic medicine and pathology 15(3): 211-212.

Embolization is a well-recognized phenomenon in medicine and forensic pathology and generally involves formed blood elements, bone, air, amniotic fluid, or more exotic items such as bullets. We report the embolization of a chain-saw link. The case demonstrates how, without complete autopsy and investigation, a penetrating sharp-force injury could be misdiagnosed and a false conclusion as to the commission of a crime could occur. Although the forensic literature is replete with examples of bizarre emboli, from bullets to suspected crystals of methylmethacrylate, a literature review failed to find a single case of penetrating chain-saw-link injury as a cause of traumatic death. Most reports of chain-saw incidents cite accidental injuries to hands and arms or dramatic facial injuries due to entrapment and recoil (1,2). One fatality occurred from a skull fracture and cerebral injury when a 19-year-old man fell onto a saw.

1030. Choi, E., et al. (1994). "Deaths due to firearms injuries in children." Journal of forensic sciences 39(3): 685-692.

There has been a marked increase in firearms-related deaths in this country over the past several decades. Especially in urban areas this increase has been correlated with a greater availability of handguns. Children have become more common victims of gunfire. Both accidental and homicidal shooting deaths have increased in the lower age groups. We examined deaths due to gunfire in children ten years and younger in Cook County, Illinois, which contains the large city of Chicago. Homicidal shootings predominated in this age group with the most common circumstances being a child struck by a stray bullet. Accidental shooting deaths always occurred when one or more children were playing with a gun they found in the home.

1031. Choi, I. (2020). "Awareness and expectations of the role of the neurotrauma society about child abuse: Abusive head traumas in 4 infants, case series." Korean journal of neurotrauma 16(2): 111-112.

1032. Choi, J. J., et al. (2011). "Paradoxical herniation in wartime penetrating brain injury with concomitant skull-base trauma." The Journal of craniofacial surgery 22(6): 2163-2167.

A case of the syndrome of the trephined progressing to paradoxical herniation is presented in a patient with a penetrating brain injury, postdecompressive craniectomy, and a delayed cerebral spinal fluid leak from a skull base defect. The patient had a penetrating head trauma from a high-velocity ballistic projectile during military wartime operations. The patient's clinical course, which demonstrates a rare presentation of central sleep apnea syndrome or Ondine's curse, is reviewed. Radiographic imaging includes sequential computed tomography (CT) scans with and without intrathecal contrast. Medical management was directed at increasing the intracranial pressures (ICPs) by placing the patient into Trendelenburg position and increasing hydration. Surgical intervention involved correction of the skull base defect by intranasal endoscopic repair. A literature review of paradoxical herniation and delayed neurologic decline in postcraniectomy patients is conducted, and the surgical and neurocritical care management is discussed.

1033. Choi, K. J., et al. (2017). "Penetrating Craniomaxillofacial Injury Caused by a Pneumatic Nail Gun." Craniomaxillofacial Trauma and Reconstruction 10(2): 159-161.

Craniomaxillofacial injuries can be complex, requiring a multidisciplinary approach. The primary survey is always the first step in trauma management prior to proceeding with further evaluation and treatment. A 26-year-old man presented with a penetrating nail gun injury through the oral and nasal cavities. He did not present in extremis but required elective endotracheal intubation for intraoperative assessment and treatment. Airway management was enhanced by the use of lingual nerve and inferior alveolar nerve blocks via the Vazirani-Akinosi technique to maintain spontaneous respiration while the tongue was distracted from the palate. The nail was removed and rapid sequence induction initiated for orotracheal intubation. Local nerve blocks can be an effective tool in the armamentarium of the craniomaxillofacial trauma surgeon in managing blunt and penetrating injuries. We demonstrate its utility in airway management when a penetrating foreign body in the upper airway precludes orotracheal or nasotracheal intubation.

1034. Choi, M., et al. (2012). "A 10-year review of frontal sinus fractures: clinical outcomes of conservative management of posterior table fractures." Plastic and reconstructive surgery 130(2): 399-406.

BACKGROUND: Frontal sinus cranialization is commonly indicated for posterior table fractures with significant comminution, displacement, or cerebrospinal fluid leaks. This study assessed the clinical outcomes of conservative management., METHODS: A 10-year retrospective review of all frontal sinus fractures treated at a level 1 trauma center was performed using medical records and radiographic images., RESULTS: A total of 875 patients with frontal sinus fractures were identified, and 68 had posterior table involvement. Nine died within the first 48 hours from other injuries. The remaining 59 patients constituted the study population. Average follow-up approached 1 year (342 days). The more common mechanisms of injury were blunt interpersonal violence (29 percent) and motor vehicle accidents (27 percent). Concurrent central nervous system injury was common (73 percent), and the average Glasgow Coma Scale score was 12.7. Posterior wall fracture pattern was nondisplaced and noncomminuted in 33 patients (54 percent) and comminuted and/or displaced in 27 (46 percent). Cerebrospinal fluid leak was recorded in 11 patients (19 percent). Conservative management was the more common strategy (78 percent), followed by open reduction and internal fixation with sinus preservation (12 percent), obliteration (8 percent), and cranialization (2 percent). Of the 27 patients with comminuted and/or displaced fractures, 16 (59 percent) underwent conservative management, and 11 (41 percent) underwent surgical management, but only one patient (2 percent) underwent cranialization. There was no incidence of intracranial infection, except for one patient who died from encephalitis secondary to a gunshot wound to the head., CONCLUSION: The vast majority of

frontal sinus fractures involving the posterior table, including those with comminution, displacement, or cerebrospinal fluid leaks, can be safely managed without cranialization., CLINICAL QUESTION/LEVEL OF EVIDENCE: Therapeutic, IV.

1035. Choi, W. C., et al. (2016). "The Efficacy of Bioabsorbable Mesh in Craniofacial Trauma Surgery." Archives of craniofacial surgery 17(3): 135-139.

BACKGROUND: The ultimate goal of craniofacial reconstructive surgery is to achieve the most complete restoration of facial functions. A bioabsorbable fixation system which does not need secondary operation for implant removal has been developed in the last decade. The purpose of this study is to share the experience of authors and to demonstrate the efficacy of bioabsorbable mesh in a variety of craniofacial trauma operations., METHODS: Between October 2008 and February 2015, bioabsorbable meshes were used to reconstruct various types of craniofacial bone fractures in 611 patients. Any displaced bone fragments were detached from the fracture site and fixed to the mesh. The resulting bone-mesh complex was designed and molded into an appropriate shape by the immersion in warm saline. The mesh was molded once again under simultaneous warm saline irrigation and suction., RESULTS: In all patients, contour deformities were restored completely, and bone segments were fixed properly. The authors found that the bioabsorbable mesh provided rigid fixation without any evidence of integrity loss on postoperative computed tomography scans., CONCLUSION: Because bioabsorbable meshes are more flexible than bioabsorbable plates, they can be molded and could easily reconstruct the facial bone in three dimensions. Additionally, it is easy to attach bone fragments to the mesh. Bioabsorbable mesh and screws is effective and can be easily applied for fixation in various craniofacial trauma reconstructive scenarios.

1036. Chong, C. L., et al. (1998). "Is cervical spine imaging indicated in gunshot wounds to the cranium?" The Journal of trauma 44(3): 501-502.

BACKGROUND, MATERIALS AND METHODS: Because there is no consensus regarding the necessity of imaging the cervical spine of patients who sustain a gunshot wound to the cranium, the cervical spinal radiographs of 53 consecutive patients with gunshot wounds to the cranium admitted to Hermann Hospital, a Level I trauma center, from January of 1993 to January of 1996, were reviewed., RESULTS: The cervical spine radiographs of all 53 patients were negative., CONCLUSIONS: Cervical spine injury is not associated with gunshot wound to the cranium. Therefore, patient management decisions/procedures, including endotracheal intubation, should not be delayed pending cervical spine imaging.

1037. Chong, S. G., et al. (2014). "A deceptive pneumothorax." Archivos de bronconeumologia 50(11): 496.

1038. Chopra, N., et al. (2017). "Ophthalmic outcomes following gunshot wound to head." Investigative Ophthalmology and Visual Science 58(8).

Purpose: There has been limited research on gun trauma over the past two decades, despite the fact that firearm injuries in the U.S. account for a significant percentage of all injury deaths each year (16.8% in 2014). In particular, there have been few studies on ophthalmic outcomes following gunshot wounds to the head. The purpose of this retrospective cohort study was to assess how often patients who survive gunshot wounds to the head suffer permanent visual loss. Methods: The Elmhurst City Hospital Trauma Registry and Mount Sinai Data Warehouse were queried for International Classification of Diseases, Ninth Revision (ICD-9) and Tenth Revision (ICD-10) codes for gun trauma resulting in ocular injury, and paper charts were obtained to evaluate ophthalmology notes. Between January 1, 2000 and May 8, 2016, we identified 31 patients who suffered a gunshot wound to the head and resultant ocular

trauma, including orbital fracture, ruptured globe, foreign body, and optic nerve injury. Gun types included all firearms, air guns, and explosives. Of the 31 patients queried, four patients were excluded due to incorrect coding upon chart review, and five patients were excluded because their charts were missing. Data from the 22 remaining patients were then assessed. Results: Of 915 patients presenting to the Elmhurst and Mount Sinai Hospital Emergency Departments with injuries due to gun trauma, 27 (3.0%) sustained ocular injuries. Of the 22 patients whose records were accessible, four were noted to have ocular injury on presentation but then died in the operating room. Of the surviving 18 patients, 2 (11%) were shot directly in the eye, 5 (28%) were shot in the orbit, and 11 (61%) were shot elsewhere in the head. Neither location of injury (p =.243) nor type of gun used (p =.296) predicted visual loss outcome. Eight of the 18 surviving patients (44%) suffered permanent visual loss, defined as open globe injury requiring enucleation/evisceration or loss of vision due to traumatic optic neuropathy. Conclusions: Loss of life from gun trauma is an issue that continues to attract national attention. However, even if one survives a gunshot wound to the head, we find that there is a high likelihood of suffering permanent visual loss. Though our dataset was limited, we found that visual loss outcome is not predicted by the location of gunshot wound or gun type used. Further research is needed to understand the full impact of gun trauma on ophthalmic outcomes.

1039. Chopra, N., et al. (2018). "Gun trauma and ophthalmic outcomes." Eye (London, England) 32(4): 687-692.

Purpose This retrospective cohort study assesses the visual outcomes of patients who survive gunshot wounds to the head. Methods The Elmhurst City Hospital Trauma Registry and Mount Sinai Data Warehouse were queried for gun trauma resulting in ocular injury over a 16-year period. Thirty-one patients over 16 years of age were found who suffered a gunshot wound to the head and resultant ocular trauma: orbital fracture, ruptured globe, foreign body, or optic nerve injury. Gun types included all firearms and air guns. Nine patients were excluded due to incorrect coding or unavailable charts. Statistical analysis was performed using a simple bivariate analysis (chi2). Results Of the 915 victims of gun trauma to the head, 27 (3.0%) sustained ocular injuries. Of the 22 patients whose records were accessible, 18 survived. Eight of the 18 surviving patients (44%) suffered long-term visual damage, defined as permanent loss of vision in at least one eye to the level of counting fingers or worse. Neither location of injury (P=0.243), nor type of gun used (P=0.296), nor cause of gun trauma (P=0.348) predicted visual loss outcome. The Glasgow Coma Scale eye response score on arrival to the hospital also did not predict visual loss outcome (P=0.793). Conclusion There has been a dearth of research into gun trauma and even less research on the visual outcomes following gun trauma. Our study finds that survivors of gun trauma to the head suffer long-term visual damage 44% of the time after injury.

1040. Chou, C. K., et al. (1993). "Management of windshield facial injuries." Gaoxiong yi xue ke xue za zhi = The Kaohsiung journal of medical sciences 9(3): 153-161.

Between Jan. 1986 and Dec. 1990, 99 patients with automobile windshield facial injuries were hospitalized in Kaohsiung Medical College hospital. All patients were injured by old type windshields in car accidents. Seventy-three patients (74%) were male and twenty-six (26%) were female. Ages ranged from 6 to 62 years (mean age 31 years). Fifty-seven patients (58%) were car drivers and forty-two (42%) were front seat passengers. All patients had typical multiple U-shaped lacerations on the face. The major injury sites were localized to the upper one third of the face. The wounds were repaired immediately after careful debridement. A total of 21 facial bone fractures were noted. All were open fractures with large, deep avulsion wounds. Displaced and comminuted fractures received reduction and fixation before wound closure. Three patients had cranial bone fracture with no displacement. Brain edema and subarachnoid hemorrhage were found by brain CT scan in two and one patients respectively. They were treated conservatively. In one patient with frontal sinus fracture the glass pieces penetrated into the brain. The foreign bodies were removed from the brain and frontal sinus. Eyeball rupture was found in 16 patients, including two patients in whom both eyes were involved. Eight eyeballs needed immediate

evisceration and ten eyeballs received reparation. Blindness occurred in all these patients. Of the 99 patients in this study, 15% sustained additional injury. Most were wounds on the extremities. Because serious injuries can be caused by the old type of windshields, it should be abandoned. Driving with the seat belt fastened is the best way to insure safety.

1041. Chou, E.-K., et al. (2009). "Epistaxis as the only initial symptom in pediatric naso-orbital-ethmoid fracture complicated with meningitis." The Journal of craniofacial surgery 20(3): 953-955.

Epistaxis is a frequent finding in patients with facial trauma. Herein, we report an unusual presentation of pediatric naso-orbital-ethmoid (NOE) fracture with epistaxis as the only initial symptom. The course of the patient's condition was later complicated by meningitis, related in part to the delay in diagnosis. A 3-year-old girl with preexisting upper respiratory symptoms was involved in a traffic accident, sustaining blunt trauma to the right side of her face. During the initial examination, only right-sided epistaxis was noted. Five days later, she developed febrile convulsion and was admitted to the intensive care unit with other signs of meningitis such as mental status change and neck stiffness. Her craniofacial computed tomographic scan showed a right-sided NOE fracture with minimal displacement and without dura tear. The cerebrospinal fluid culture grew Streptococcus pneumoniae, which may be due to ascending infection as a result of cribriform plate fracture. Intravenous antibiotic therapy was initiated with good response, and she was discharged from the hospital after 2 weeks. The presence of epistaxis and periorbital bruise, together with other symptoms and signs, helps in the identification of NOE and cribriform plate fracture. A high index of suspicion with repetitive computed tomographic scans is necessary to achieve correct early diagnosis. Parental antibiotic therapy is indicated if ascending cerebrospinal fluid infection develops.

1042. Choudhary, D. S. and N. Agrawal (2018). "New Surgical Modality for Management of Corneal Perforation Using Bowman Membrane." Cornea 37(7): 919-922.

PURPOSE: To describe a new surgical modality, "Bowman membrane tuck-in," for management of small to medium sized corneal perforation of a noninfectious etiology., METHODS: Two patients with corneal perforation of a noninfectious etiology and less than 4 mm in size underwent Bowman membrane tuck-in, a new surgical procedure. In this technique, Bowman membrane harvested from the donor cornea was tucked inside the stromal pocket of host tissue, which was prepared by 360-degree anterior stromal lamellar dissection. Patients were followed up for 6 months and were examined for best-corrected visual acuity, epithelialization time, anterior chamber stability, and graft-related complications., RESULTS: During 6-month follow-up, best-corrected visual acuity improved from PL+ (positive) to 20/120 and 20/200 in patient 1 and patient 2, respectively, and epithelialization was completed within a 2-week period in both patients. Surgery was uneventful in both cases; however, anterior chamber re-formation and graft repositioning were performed in patient 1. None of the patients showed signs of rejection or graft failure at 6-month follow-up., CONCLUSIONS: Bowman membrane tuck-in is an effective sutureless and glueless technique for management of corneal perforation of a noninfectious etiology, which may be used in emergency settings for the management of noninfectious corneal perforation of size less than 4 mm.

1043. Choulakian, A., et al. (2011). "Emergent cavernous carotid stenting for iatrogenic and skull base injuries." Skull Base 21.

Objective: Traumatic injury to the cavernous carotid artery (CCA) may be difficult to manage because it often requires emergent treatment due to the potential for life-threatening hemorrhage. Because this segment of the artery is difficult to access surgically, endovascular treatment by either parent artery occlusion or stent grafting is frequently necessary. Methods: This is a prospective case series of 29 patients who had traumatic CCA injury or spontaneous hemorrhage who had placement of one or more stent grafts in the CCA for treatment. Patients were loaded with either 300 mg or 600 mg of

clopidogrel and 325 mg of aspirin either a few hours before the endovascular procedure or via an oral gastric tube at the time of the procedure. Patients also received intraprocedural intravenous heparin. They were then maintained on clopidogrel and aspirin for 6 months, then aspirin alone from then on. Follow-up imaging was performed at 6 months postintervention, and patients were then followed up clinically on an annual basis. Results: Of the 29 patients who had treatment, 14 had a traumatic direct carotid cavernous fistula, 10 had iatrogenic injury to the CCA from surgery resulting in epistaxis, and 2 had epistaxis or subarachnoid hemorrhage from a gunshot wound. Three patients had prior malignant skull base tumor resection with subsequent radiation therapy that developed acute epistaxis in a delayed manner. Two patients developed thromboembolic events within the first 30 days of treatment. With an average imaging follow-up of 2.7 years, two patients had asymptomatic occlusion of their stent grafts, 22 patients had patent stent grafts, and 5 patients had no imaging follow-up. Conclusion: Stent grafts provide a safe alternative to deliberate parent artery occlusion in patients with spontaneous hemorrhage or trauma to the CCA. With aggressive antiplatelet therapy, a long-term symptomatic thromboembolic rate of 7% was seen.

1044. Chovanes, G. and R. M. Richards (2013). "Pressure is only part of the story in traumatic brain injured patients; Focal cerebral blood flow goes to zero in some patients with adequate cerebral perfusion pressure." Clinical neurosurgery 60: 176.

INTRODUCTION: The pathophysiology of traumatic brain injury (TBI) is still not clearly understood. Recently, a decompressive craniec-tomy trial (1) and a trial of intracranial pressure (ICP) treatment with ICP monitoring vs no monitoring (2) failed to support the concept that increases in ICP are exclusively responsible for TBI mortality and morbidity. To analyze the role ICP, cerebral perfusion pressure (CPP = BP-ICP), and cerebral blood flow (CBF) play in head injury, we monitored brain injured patients' ICP, blood pressure (BP), CPP, and focal cerebral blood flow (fCBF), recording the real-time data for computer analysis. METHODS: 20 patients with severe brain injury were monitored with recordings of ICP, BP, CPP, and fCBF every minute. 17 patients had severe closed TBI, 1 gunshot wound, and 2 intracerebral hemorrhages. 13 patients lived (GCS 3-9, average 5), 7 died (GCS 3-7, average 5). Of the 7 patients who died, 5 had technically adequate recordings before and as death supervened. Graphs were prepared of time vs CPP, ICP and fCBF and reviewed for the time course of fCBF deterioration vs CPP elevation. If CPP obviously and substantially decreased before fCBF decreased, that was termed a pressure death. However, if CPP stayed adequate and fCBF still decreased to zero, that was termed a non-pressure death. RESULTS: Three patients had a pressure death (Fig 1), and 2 patients had a non-pressure death (Fig 2). CONCLUSION: This may be the first real-time documentation of non-CPP dependent brain death as expressed by fCBF. There are pathological processes in the injured brain that do not directly involve increases in ICP and decreases in CPP. Heretofore clinical treatment efforts in brain injury have focused on ICP: other mechanisms are also extant and should be further investigated so as to more successfully treat brain injury.

1045. Chow, F. (2018). "Brain and Spinal Epidural Abscess." Continuum (Minneapolis, Minn.) 24(5, Neuroinfectious Disease): 1327-1348.

PURPOSE OF REVIEW: Brain abscesses and spinal epidural abscesses are serious, potentially life-threatening infections of the central nervous system. This article outlines the clinical presentation, evaluation, and management of brain abscesses and spinal epidural abscesses, with a specific focus on bacterial infections., RECENT FINDINGS: The overall incidence of brain abscesses has declined, in part because of fewer brain abscesses associated with otogenic infections. However, emerging patient populations at high risk for brain abscess include those with a history of penetrating head trauma, neurosurgery, or immunodeficiency. Improved mortality rates for brain abscess are attributable to modern diagnostic imaging, stereotactic-guided aspiration, and newer antimicrobials that readily penetrate into the central nervous system and abscesses. Brain MRI is more sensitive than CT for brain abscess, particularly in the early stages, but CT remains more widely available and can adequately

identify potential abscesses and confirm response to treatment. With the advent of minimally invasive neurosurgical techniques, surgical excision is often employed only for posterior fossa, multiloculated, or superficial well-circumscribed abscesses. In select clinical scenarios, conservative medical management may be a safe alternative to a combined surgical and medical approach. Unlike brain abscess, the incidence of spinal epidural abscess is on the rise and has been attributed to higher prevalence of predisposing factors, including spinal procedures and instrumentation., SUMMARY: Successful diagnosis and management of brain abscess and spinal epidural abscess requires a collaborative approach among neurologists, neurosurgeons, radiologists, and infectious disease physicians. The foundation of management of brain abscess includes surgical intervention for diagnostic purposes if a pathogen has not been identified or for decompression of larger abscesses or those with mass effect and significant surrounding edema; appropriate dosing and adequate duration of an antimicrobial regimen tailored to the presumptive source of infection and available culture data, and eradication of the primary source of infection. For spinal epidural abscesses, neurologic status at the time of presentation is directly related to outcomes, underscoring the importance of prompt recognition and intervention.

1046. Chow, L. Q., et al. (2015). "Ceritinib in patients (PTS) with anaplastic lymphoma kinase (ALK)-rearranged (ALK+) non-small cell lung cancer (NSCLC) metastatic to the brain and/or leptomeninges: The phase II ascend-7 study." Annals of Oncology 26: i42.

Background: Although the ALK inhibitor (ALKi) crizotinib (CRZ) achieves high responses in pts with ALK+ NSCLC, disease progression within 1 year often occurs, with the brain/central nervous system (CNS) as a common site of progression and relapse. Ceritinib is a novel oral ALKi with 20-fold greater potency than CRZ in enzymatic assays that crosses the blood-brain barrier with good CNS penetration in preclinical studies. In the pivotal phase I study (NCT01283516), ceritinib was highly active in ALK+ NSCLC pts (regardless of prior CRZ exposure) and achieved intracranial responses in 7 of 14 pts with measurable baseline brain lesions. The adverse events profile in these pts was similar to that of the full study population. Trial design: This international prospective phase II open-label study is designed to evaluate the antitumor activity of ceritinib in pts with ALK+ NSCLC metastatic to the brain or leptomeninges (ASCEND-7; CLDK378A2205). Eligible pts must have centrally assessed ALK+ NSCLC metastatic to the brain and ≥1 extracranial measurable lesion using Response Evaluation Criteria in Solid Tumors (RECIST) version 1.1. Pts must be neurologically stable ≥1 week prior to study drug and will be allocated to 1 of 5 cohorts depending on prior treatment:.

1047. Chow, L. Q., et al. (2015). "Ceritinib in ALK+ NSCLC metastatic to brain and/or leptomeninges: The ASCEND-7 study." Journal of Thoracic Oncology 10(9): S550-S551.

Background: Although the anaplastic lymphoma kinase inhibitor (ALKi), crizotinib achieves high responses in patients with ALK-rearranged (ALK+) non-small cell lung cancer (NSCLC), disease progression within 1 year can occur, with the brain/central nervous system (CNS) as a common site of progression and relapse. Ceritinib is a novel oral ALKi with 20-fold greater potency than crizotinib in enzymatic assays and crosses the blood-brain barrier with good CNS penetration in preclinical studies. In the pivotal phase 1 study (NCT01283516), ceritinib was highly active in ALK+ NSCLC patients (regardless of prior crizotinib exposure) and achieved intracranial responses in 7 of 14 patients with measurable baseline brain lesions. The adverse events profile in these patients was similar to that of the full study population. Methods: This international, prospective, phase 2, open-label study is designed to evaluate the antitumor activity of ceritinib in patients with ALK+ NSCLC metastatic to the brain or leptomeninges (ASCEND-7; CLDK378A2205). Eligible patients must have ALK+ (centrally assessed) NSCLC metastatic to the brain and ≥ 1 extracranial measurable lesion using Response Evaluation Criteria in Solid Tumors (RECIST) version 1.1. Patients must be neurologically stable ≥ 1 week prior to study drug administration and will be allocated to 1 of 5 arms depending on prior treatment: ∗Lesion free of local treatment (stereotactic or WBRT) or lesions in unequivocal progression after radiotherapy. Oral ceritinib 750 mg/d will be dosed on a continuous schedule and study assessments are consistent

across arms. The primary and key secondary objectives are to evaluate overall response rate and disease control rate, respectively. Other secondary objectives include assessment of intracranial and extracranial responses for all patients and for each of arms 1-4; overall survival and safety for all patients and for each of arms 1-5; and ceritinib pharmacokinetics in all patients. Enrollment is ongoing. Results: This study is in the activation phase. Conclusion:This study will demonstrate the efficacy of ceritinib in ALK+ NSCLC brain metastases and leptomeningeal metastases, in both WBRT-naive patients and prior irradiated patients. (Table Presented).

1048. Chowdhury, F. H., et al. (2016). "Nonmissile Penetrating Injury to the Head: Experience with 17 Cases." World neurosurgery 94: 529-543.

BACKGROUND: Penetrating nonmissile injuries to the head are far less common than missile penetrating injuries. Here we describe our experience in managing 17 cases of nonmissile injury to the head, likely the largest such series reported to date. We also highlight the surgical steps and techniques used to remove in situ objects (including weapons) in the penetrating wounds that have not been described previously., METHODS: We conducted a retrospective study of cases of nonmissile, low-velocity penetrating injuries of the head managed in our department. The recorded data of patients with penetrating head injuries were studied for the cause of the injury, type of object, type and extent of penetration, Glasgow Coma Scale score on admission, other clinical issues, evaluation and assessment, interval from penetration to operation, surgical steps and notes, difficulty during the operation, major and minor complications, follow-up, and ultimate outcome., RESULTS: Our 17 cases included 6 cases of accidental penetration and 11 cases of penetration as the result of violence. Weapons and other foreign objects causing injury included a teta (a pointed metal weapon with a wooden handle and a barb near the tip, used for hunting and fishing) in 4 cases, a dao (a sharp metal cutting instrument with a wooden handle used for cutting vegetables, fish, meat, bamboo, wood, etc.) in 3 cases, a bamboo stick in 3 cases, a metal rod in 2 cases, a knife in 2 cases, a sharp stone in 1 case, a metal steam chamber cover in 1 case, and a long peg in 1 case. GCS on admission was between 13 and 15 in 15 cases. Only 1 patient exhibited limb weakness. Four patients with an orbitocranial penetrating injury had 1-sided vision loss; 2 of these patients had orbital evisceration, and 1 of these patients died. In 14 patients, the foreign object was in situ at presentation and was removed surgically. Computed tomography scan and plain X-ray of the head were obtained in all patients. Postoperatively, 2 patients (11.7%) needed support in the intensive care unit but died early after surgery. One patient developed late osteomyelitis. The remaining patients were doing well at the most recent follow-up., CONCLUSIONS: The presenting picture of nonmissile penetrating injury to head may be daunting, but these cases can be managed with very good results with proper (clinical and radiologic) evaluation and simple neurosurgical techniques.

1049. Chowdhury, R. K., et al. (2009). "An unusual case of total ophthalmoplegia." Indian journal of ophthalmology 57(5): 389-391.

An eight-year-old male child presented with drooping of the left eyelid with a history of penetrating injury of hard palate by an iron spoon seven days ago, which had already been removed by the neurosurgeon as the computed tomography scan revealed a spoon in the left posterior ethmoid and sphenoid bone penetrating into the middle cranial fossa. On examination, visual acuity was 20/20 in each eye and left eye showed total ophthalmoplegia. Oral cavity revealed a hole in the left lateral part of the hard palate. We managed the case with tapering dose of systemic prednisolone. The total ophthalmoplegia was markedly improved in one month. Cases of foreign bodies in the orbit with intracranial extension are not unusual, but the path this foreign body traveled through the hard palate without affecting the optic nerve, internal carotid artery or cavernous sinus makes an interesting variation.

1050. Chrcanovic, B. R. (2012). "Open versus closed reduction: mandibular condylar fractures in children." Oral and maxillofacial surgery 16(3): 245-255.

PURPOSE: The purpose of the study was to review the literature regarding the evolution of current thoughts on management of mandibular condylar fractures (MCFs) in children., METHODS: An electronic search in PubMed was undertaken in May 2012. The titles and abstracts from these results were read to identify studies within the selection criteria. Eligibility criteria included studies published in English or German from the last 20 years (from 1992 onwards) reporting clinical series of MCFs in children and adolescents until the age of 18., RESULTS: The search strategy initially identified 542 studies. The references from 1992 onwards totaled 339 articles. Twenty-seven studies were identified without repetition within the selection criteria. Additional hand-searching yielded two additional papers., CONCLUSIONS: Pediatric MCFs require thoughtful consideration in management to avoid significant growth disturbance. Early treatment is indicated in order to improve the chances for favorable development. Long-term follow-up is required, in order to properly treat late complications that may appear. Coronal computed tomography is helpful in substantiating the correct final diagnosis. Many studies show that conservative treatment (CTR) has satisfactory long-term outcome of jaw function, occlusion, and facial esthetics, despite a high frequency of radiological aberrations. Surgery before puberty should be reserved for exceptional cases such as missile injuries, in cases with extensive dislocation and lack of contact between the fragments, in cases with multiple midfacial fractures, in which the mandible has to serve as a guide to reposition the midfacial bones, and in cases which the dislocation of the fractured stump creates a functional impediment that cannot be resolved by CTR. As the craniofacial skeleton becomes more adult-like in its form at about 12 years of age, the decreased remodeling capacity in the adolescents may occasionally result in abnormally shaped condylar heads or shortened ramus heights that may lead to persistent malocclusion. Thus, the indication of open reduction and internal fixation increases with age.

1051. Chrcanovic, B. R., et al. (2009). "Migration of tip knife blade through middle-third facial tissues." Oral and maxillofacial surgery 13(1): 41-44.

PURPOSE: The aim of this paper is to report a case of knife aggression with a spontaneous migration of a tip blade lodged in deep tissues 6 months after trauma., PATIENT: An 18-year-old woman that was a victim of impalement injury with a knife by her boyfriend on the glabella region with a blade fracture and tip lodging into middle-third facial tissues., RESULTS: After conservative management of a knife tip, a spontaneous migration occurred with its exposition on the zygomatic area, possibly due to a functional treatment to improve mouth opening., CONCLUSION: Fracture of knife blade with a tip retained deeply into the tissues is considered foreign body, and its removal must be considered. Nevertheless, the basis for this removal takes account the cost-benefit ratio, and if a conservative management was chosen, the clinical and radiological accompanying is mandatory to prevent and to treat its possible complications.

1052. Christensen, J., et al. (2015). "High-Energy Traumatic Maxillofacial Injury." The Journal of craniofacial surgery 26(5): 1487-1491.

High-energy blunt or penetrating impact leads to great variability in facial injury patterns. Although the mechanism, pattern, and distribution of forces vary, the resultant damage to hard and soft tissues requires dedicated planning and execution of debridement and reconstructive procedures. This article evaluates the initial management of patients sustaining high-energy facial impact injuries resulting in one or more comminuted or displaced facial fractures, with accompanying severe facial lacerations and/or soft tissue defects and avulsion injuries. Seventy-three patients met the criteria for high-energy traumatic injuries at Jackson Memorial/University of Miami Medical Center between 2003 and 2013 and are included in this article. Thirty-nine patients sustained one or more gunshot wounds to the face, and 34 patients were involved in high-speed motor vehicle collisions; all patients met our criteria for high-energy trauma. The treatment protocol for these injuries involves meticulous surgical

exploration and assessment, aggressive debridement, early definitive reduction/fixation, and reconstruction as necessary.

1053. Christopherson, L. K. and D. T. Lunde (1971). "Heart transplant donors and their families." Seminars in psychiatry 3(1): 26-35.

1054. Chu, A. and M. R. Levine (1989). "Gunshot wounds of the eye and orbit." Ophthalmic surgery 20(10): 729-736.

Gunshot wounds to the globe and orbit require careful evaluation and management. This article highlights five cases of penetrating gunshot injuries, each demonstrating different points to consider when managing the severely traumatized patient. Immediate and late complications are described. Missile velocities of different weapons are detailed, and the mechanism of injury is discussed. Careful preoperative evaluation is stressed as a means of avoiding complications.

1056. Chun, H., et al. (2022). "Inhibition of monoamine oxidase B prevents reactive astrogliosis and scar formation in stab wound injury model." Glia 70(2): 354-367.

Reactive astrocytes manifest molecular, structural, and functional alterations under various pathological conditions. We have previously demonstrated that the reactive astrocytes of the stab wound injury model (STAB) display aberrant cellular gamma-aminobutyric acid (GABA) content and tonic GABA release, whereas the active astrocytes under enriched environment (EE) express high levels of proBDNF. However, the role of monoamine oxidase B (MAO-B) in reactive astrogliosis and hypertrophy still remains unknown. Here, we investigate the role of MAO-B, a GABA-producing enzyme, in reactive astrogliosis in STAB. We observed that the genetic removal of MAO-B significantly reduced the hypertrophy, scar formation, and GABA production of reactive astrocytes, whereas the MAO-B overexpression under glial fibrillary acidic protein (GFAP) promoter enhanced the levels of GFAP and GABA. Furthermore, we found that one of the by-products of the MAO-B action, H2 O2 , but not GABA, was sufficient and necessary for the hypertrophy of reactive astrocytes. Notably, we identified two potent pharmacological tools to attenuate scar-forming astrogliosis-the recently developed reversible MAO-B inhibitor, KDS2010, and an H2 O2 scavenger, crisdesalazine (AAD-2004). Our results implicate that inhibiting MAO-B activity has dual beneficial effects in preventing astrogliosis and scar-formation under brain injury, and that the MAO-B/H2 O2 pathway can be a useful therapeutic target with a high clinical potential.

1057. Chunhua, Q. and W. Qun (2014). "A late-onset seizure due to a retained intracranial foreign body--pencil lead: a case report and review." The Journal of craniofacial surgery 25(2): e109-110.

A 40-year-old man presented with recent recurrent seizures. He was operated on to resect the right temporal mass with a foreign body, a pencil lead. The foreign body had entered the brain parenchyma for an accident in a child without apparent head injury, sustained for 30 years. He was asymptomatic for the intervening 30 years. It is rare that a pencil lead totally penetrated with an inapparent transtemporal closed head injury. The case may caution neurosurgeons to make the complete diagnosis of retained intracranial foreign bodies and thinking of need for early surgical exploration, to avoid chronic and potentially life-threatening neurological complications.

1058. Churojana, A., et al. (2011). "Cerebro-facial vascular injury: Outcome of endovascular management." Interventional Neuroradiology 17: 93.

Purpose: To review endovascular treatment outcome in patients with cerebro-facial vascular injury. Method: Excluding carotid-cavernous fistulas, forty-four patients with vascular injury in the head and neck region during 2000-2010 at Siriraj Hospital, Thailand, were retrospectively reviewed. A variety of devices including detachable balloons, coils, arylic glue and stents were used for interventional neurovascular treatment with the goal to eradicate the lesions completely. Result: Mechanisms of injury were motor vehicle accident 52.3%, penetrating injury 18.2%, falling 6.8%, blunt injury 13.6% and iatrogenic 9.1%. These resulted to extracranial vascular injury at 68.2% and intracranial at 31.8%. The injuries were classified angiographically as the followings; arteriovenous fistula 34.1%, false aneurysm 45.5%. dissection 15.9% and arterial tear 4.5%. Treatments were achieved by intervention at 75%, surgery at 9.1% (due to large intracranial hematoma) and conservation at 15.9%. By mean of endovascular technique, 90.9% had parent artery sacrifice and 9.1% had parent artery preservation. Endovascular treatment was successful in 97% without procedure-related complication. Seven selected patients for conservative treatment, included 6 arterial dissections and one small non-bleed cavernous false aneurysm. Five deaths occurred because of primary brain injury. Conclusion: Endovascular procedure is effective and safe in bleeding and symptom control of patients with cerebro-facial vascular injury. Parent artery occlusion should not be reluctant in life threatening hemorrhage or impending rupture false aneurysm. However, stent is eligible in selected patients.

1059. Chute, D. J., et al. (2017). "Case Report of a Migrating Bullet: An Unusual Cause of Postmortem Confusion." Journal of forensic sciences 62(5): 1386-1388.

Migrating bullets are rare sequelae of penetrating gunshot wounds. Such cases have been described in the neurosurgical literature because they can produce complications in the management of patients such as decline in neurologic status, delays in rehabilitation, and difficulties in bullet removal. In contrast, few postmortem reports have described this phenomenon. We report a case of a gunshot wound in which the projectile entered the left side of the head and traversed to the right frontal area as documented by CT scan on hospital admission. At autopsy, the bullet was noted to have migrated back to the left side of the head from where it was recovered. Medical examiners need to be aware of this unusual phenomenon of retained intracranial projectiles.

1060. Cianchetti, J. A. and G. F. Carroll (1980). "Traumatic pneumomediastinum resulting from facial trauma." Annals of emergency medicine 9(4): 218-221.

Pneumomediastinum is an uncommon complication of blunt or penetrating trauma to the head, neck, thorax, or abdomen. Air in the mediastinum can indicate a serious penetrating injury but may also represent a benign finding associated with relatively insignificant neck or facial trauma. We present a case demonstrating the correlation between facial trauma and pneumomediastinum. Echocardiographic and phonocardiographic data are offered as adjuncts in the diagnosis, and were utilized by us. Treatment is directed toward the factors responsible for leakage of air. Only in the rare instance of tension pneumomediastinum are invasive procedures warranted. Our patient, who was treated only with antibiotics, improved.

1062. Cifu, D. X., et al. (1996). "Functional outcomes of older adults with traumatic brain injury: a prospective, multicenter analysis." Archives of physical medicine and rehabilitation 77(9): 883-888.

OBJECTIVE: To investigate improvement rates and medical services costs in older brain injured adults relative to younger patients., DESIGN: Descriptive statistics were computed in a prospective comparative study of 50 patients 55 years and older and 50 patients 18 to 54 years old matched for gender and injury severity (number of days in coma, admission Glasgow Coma Score, intracranial pressure). Independent t tests were performed to examine differences between the two samples on specific variables., SETTING: Five medical centers in the federally sponsored Traumatic Brain Injury Model Systems Project that provide emergency medical services, intensive and acute medical care, inpatient rehabilitation, and a spectrum of community rehabilitation services., PARTICIPANTS: Patients were selected from a national database of 531 rehabilitation inpatients admitted to acute care within 8 hours of traumatic brain injury between 1989 and 1994., MAIN OUTCOME MEASURES: Disability Rating Scale, Functional Independence Measure, Rancho Los Amigos Levels of Cognitive Functioning Scale, length of stay, acute care and rehabilitation charges, and discharge disposition., RESULTS: Older persons averaged a significantly longer rehabilitation length of stay, higher total rehabilitation charges, and a lower rate of change on functional measures. No significant differences between groups were found for acute care length of stay, daily rehabilitation charges, acute care charges (daily or total), or discharge disposition., CONCLUSIONS: Although older persons demonstrated functional changes, the cost of change was substantially higher than for younger patients, coincident with longer lengths of stay. These higher overall charges and slower rates of change may effect changes in referral and management patterns.

1063. Cikatricis, P., et al. (2008). "Iatrogenic lateral rectus transection secondary to dental implantation surgery." Orbit (Amsterdam, Netherlands) 27(4): 305-307.

A 48-year-old patient noted right subconjunctival hemorrhage and double vision immediately following dental implant surgery. CT scan confirmed implant screw misplaced into the right orbit, and exploration revealed transection of right lateral rectus muscle belly. Diagnostic and management challenges are discussed.

1064. Cina, S. J., et al. (1995). "A rock in a hard place. A brief case report." The American journal of forensic medicine and pathology 16(4): 333-335.

Radiographs are often of assistance in locating foreign bodies, particularly bullets, at autopsy. It must be remembered, however, that all bullet-shaped radioopacities that appear to be within the skull are not necessarily projectiles. Described is a radiographic conundrum caused by a piece of gravel that pierced the scalp when the victim of a gunshot wound to the head fell to the ground. The stone, although bullet shaped, differed in radiodensity to metal and could have been recognized for what it was prior to much consternation on the part of the prosecutors. This case serves as a reminder of two pitfalls in the interpretation of gunshot wounds to the head. First, the radiodensity of a foreign body must be considered as important as its shape. Second, a foreign body outside of the convex surface of the skull may appear intracranial on both anteroposterior and lateral radiographs. Last, the prosecutor is encouraged to remain open minded and not to simply "see what he/she wants to see."

1065. Cinar, K., et al. (2015). "Outcomes and demostration of cranial firearm injuries: A multicenter retrospective study." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES 21(4): 291-296.

BACKGROUND: Cranial firearm injuries (CFAI) are associated with significant morbidity and mortality. This study was aimed to determine the factors affecting mortality of CFAI cases managed in our institution by a retrospective analysis of CT scans and clinical data., METHODS: This multicenter retrospective study examined two hundred and nineteen patients presenting to neurosurgery clinics after CFAI between January 2012 and November 2014. Age, sex, Glasgow Coma Score (GCS), CT findings, and mortality and morbidity rates of the patients were analyzed to determine the factors affecting

mortality., RESULTS: Mean age of the study population was 24.19+/-12.25 years, 85.8% of them were male. The most common CT findings were fracture (100%), intracranial hemorrhage (61.2%), and an intracranially located foreign body (44.3%). A cranial operation was performed in 64.8% of the victims. Mean GCS on admission was 8+/-3.9, which increased in survivors ($p<0.05$)., CONCLUSION: CFAIs are associated with increased mortality and morbidity. We determined that many factors affected morbidity and mortality rates, and patient age, presence of intracranial hemorrhage, GCS, and treatment protocols were significantly associated with mortality.

1066. Ciocca, L., et al. (2011). "Computer-aided design and manufacturing construction of a surgical template for craniofacial implant positioning to support a definitive nasal prosthesis." Clinical oral implants research 22(8): 850-856.

AIM: To design a surgical template to guide the insertion of craniofacial implants for nasal prosthesis retention., MATERIALS AND METHODS: The planning of the implant position was obtained using software for virtual surgery; the positions were transferred to a free-form computer-aided design modeling software and used to design the surgical guides. A rapid prototyping system was used to 3D-print a three-part template: a helmet to support the others, a starting guide to mark the skin before flap elevation, and a surgical guide for bone drilling. An accuracy evaluation between the planned and the placed final position of each implant was carried out by measuring the inclination of the axis of the implant (angular deviation) and the position of the apex of the implant (deviation at apex)., RESULTS: The implant in the glabella differed in angulation by 7.78degree, while the two implants in the premaxilla differed by 1.86 and 4.55degree, respectively. The deviation values at the apex of the implants with respect to the planned position were 1.17 mm for the implant in the glabella and 2.81 and 3.39 mm, respectively, for those implanted in the maxilla., CONCLUSIONS: The protocol presented in this article may represent a viable way to position craniofacial implants for supporting nasal prostheses.

1067. Cipriani, R., et al. (1998). "Mandibular reconstruction with revascularized free flap." Rivista Italiana di Chirurgia Plastica 30(1): 19-26.

Microsurgery has revolutionized the problem of mandibular reconstruction after segmental resection for endo-oral carcinoma. Revascularized flaps not only ensure the best possible functional results, but also allow for an ample choice adapt to the single patient's needs. Nowadays, there are five or six sites with suitable bone structure, from which a free flap may be removed for this type of reconstruction. Therefore, thanks to specific anatomic studies carried out by various authors, these flaps are now the first choice. They allow for immeidate reconstruction as they eliminate the common complications of the past and give functional results that can improve patients' quality of life. This applies to the cases involving resectioning of the anterior mandibular arch, whilst, for lateral resectioning (ascending corner and branch) the choice is to be evaluated according to each single case, depending on age, motivation and prognosis. The indications for a marginal resectioning (conservative approach) or segmental (demolitive approach) of the mandible or the immediate reconstruction after segmental resectioning, bearing in mind the various solutions available with osteo-myo-cutaneous revascularized free flaps are to be evaluated for each individual case. Over the past four years, (at time of writing), we have carried out, in collaboration with the E.N.T., Clinic of our Hospital, 87 revascularized free flaps in complex reconstruction cases of the head. Mandibular reconstruction, with a revascularized osteo-myo-cutaneous flap, was carried out in 11 patients. Surgery was performed for neoplastic pathologies in most cases where reconstruction was immediate, whilst a small percentage underwent surgery on various lateral parts of the mandiboular after firearm injures.

1068. Cirak, B., et al. (2000). "[Cranial gunshot injuries and treatment approaches]." Kranyal atesli silah yaralanmalari ve tedavi yaklasimlari. 6(4): 241-243.

21 patients with gunshot wounds were retrospectively evaluated. They were 19 male and 2 female, age range was 9-24. All of the patients underwent a plain x-ray and computed tomography evaluation. 9 patients had intracerebral hematoma, 4 had subdural hematoma, 1 had epidural hematoma and 1 had intraventricular hematoma. 9 patients were observed to have bullet in the cranium. All the patients with glasgow coma scale 3-5 at the admittance died. 15 patients underwent surgical treatment. 3 patients had cerebrospinal fluid fistula postoperatively and underwent reoperation. Extensivity of the lacerated brain, localization of the lesion and the glasgow coma scale at the admittance affect the outcome in gunshot wounds.

1069. Cirak, B., et al. (2004). "Spinal injuries in children." Journal of pediatric surgery 39(4): 607-612.

BACKGROUND/PURPOSE: Traumatic spinal injury (TSI) is an uncommon source of morbidity and mortality in children. The aim of this study was to describe childhood TSI in a single level 1 urban pediatric trauma center., METHODS: The authors retrospectively analyzed all children younger than 14 years with TSI, treated at a level I pediatric trauma center between 1991 and 2002 (n = 406, 4% total registry). All children were stratified according to demographics, mechanisms, type and level of injury, radiologic evaluations, associated injuries, and mortality., RESULTS: The mean age was 9.48 +/- 3.81 years. The most common overall mechanism of injury was motor vehicle crash (MVC; 29%) and ranked highest for infants. Falls ranked highest for ages 2 to 9 years. Sports ranked highest in the 10 to 14 year age group. Paravertebral soft tissue injuries were 68%. The most common injury level was the high cervical spine (O-C4). The incidence of spinal cord injury without radiologic abnormality (SCIWORA) was 6%. Traumatic brain injury (37%) was the most common associated injury. Overall mortality rate was 4% in this urban catchment., CONCLUSIONS: TSI in children requires a different preventive and therapeutic logarithm compared with that of adults. The potential devastating nature of TSI warrants that the health care team always maintains a high index of suspicion for injury. Future prospective studies are needed to further elucidate injury patterns.

1070. Ciurea, A. V., et al. (2011). "Traumatic brain injury in infants and toddlers, 0-3 years old." Journal of medicine and life 4(3): 234-243.

OBJECT: Children 0-3 years old present a completely different neurotraumatic pathology. The growing and the development processes in this age group imply specific anatomical and pathophysiological features of the skull, subarachnoid space, CSF flow, and brain. Most common specific neurotraumatic entities in children 0-3 years old are cephalhematoma, subaponeurotic (subgaleal) hematoma, diastatic skull fracture, grow skull fracture, depressed ('ping-pong') skull fracture, and extradural hematoma., METHODS: We present our 10 years experience in neuropediatric traumatic brain injuries, between 1999 and 2009, in the First Department of Neurosurgery and Pediatric Intensive Care Unit. Including criteria were children, 0-3 years old, presenting only traumatic brain injury. We excluded patients with politrauma, who require a different management., RESULTS: We present the incidence of these specific head injuries, clinical and imagistic features, treatment, and outcome. We found 72 children with diastatic skull fracture, 61 cases with depressed ('ping-pong') skull fracture, 22 cases with grow skull fracture, 11 children harboring intrusive skull fracture, 58 cephalhematomas, 26 extradural hematomas, and 7 children with severe brain injury and major posttraumatic diffuse ischemia ('black-brain'). Usually, infants and toddlers present with seizures, pallor, and rapid loss of consciousness. First choice examination, in all children was cerebral CT-scan, and for follow-up, we performed cerebral MRI. We emphasize on the importance of seizure prevention in this age group. Children presenting with extensive diffuse ischemia ('black-brain') had a poor outcome, death occurring in all 7 cases., CONCLUSION: Children 0-3 years old, present with a total distinctive pathology than adults. Children with head injury must be addressed to a pediatric department of neurosurgery and pediatric intensive care unit. Prophylaxis pays the most important role in improving the outcome.

1071. Civelek, E., et al. (2006). "[Penetrating transorbital intracranial foreign body]." Penetran transorbital uzanimli intrakraniyal yabanci cisim. 12(3): 245-248.

We report a seven year-old boy who suffered left orbital penetration of an industrial sewing machine needle. The needle passing through the left orbit and sphenoid bone at the posterior was extending into the layers of the dura of the left temporal lobe. In this patient, we preferred surgical approach and there was no complication after surgery. Penetrating intraorbital foreign materials with intracranial extension may lead to complications such as intracerebral hematoma, brain abscess, CSF fistula, proptosis of the eye, diplopia, orbital cellulitis and periorbital abscess. They have to be removed by surgical approach to prevent potential complications.

1072. Civil, I. D., et al. (1987). "Major trauma in an urban New Zealand setting: resource requirements." The Australian and New Zealand journal of surgery 57(8): 543-548.

Patients with severe injuries, place significant demands on an institution's facilities and staff if these patients are to be treated adequately. In the USA, requirements for institutions managing patients with major injuries have been outlined and 'trauma centres' designated. In New Zealand, the requirements for care of patients with severe injuries have not been documented. One hundred and fourteen patients who presented to the Accident and Emergency Department at Auckland Hospital over a 6 month period were prospectively evaluated. All patients had Injury Severity Scores greater than or equal to 16 and the majority were young males. The greatest number of patients presented at night and during the weekend. Radiographic studies and resuscitation room procedures were commonly required and 54% of patients required surgery within the first 24 h after presentation. Management of patients required involvement by a large variety of specialties with general surgery, intensive care, anaesthetics, neurosurgery and orthopaedics more commonly involved. Sixty per cent of patients required intensive care admission and the overall group had a 30% mortality rate. This study confirms that major trauma in New Zealand patients places similar demands on resources to that experienced in the USA. Although health resources are currently limited, appropriate allocation of these resources must be considered to best treat patients suffering severe injuries.

1073. Claiborne, S. T., et al. (2017). "Non-union rates in fibula free-flap reconstruction of head and neck oncologic defects." Journal of oral and maxillofacial surgery 75(10): e335.

Objective: The microvascular free tissue transfer of the fibula is a well-established and predictable method of providing reconstruction for mandibular and maxillary defects that arise from the resection of benign and malignant disease or traumatic injury. The purpose of this study is to evaluate our experience with the fibula free flap in 20 cases and describe the rate of non-union after reconstruction. Patients and Methods: From 2012 to 2017, the senior author and 3 reconstructive surgeons performed osseous fibula free flaps on a total of 30 patients. Five patients were excluded due to lack of adequate length followup. Minimum acceptable follow-up was imaging at least 8 weeks postoperatively with either CT scan or panoramic radiograph, at which time the most recent radiographic examination was evaluated for evidence of a continuous clear gap between bony segments, indicating non-union. Five more patients were excluded due to complete flap failure. Therefore, 20 fibula flap patients were considered for retrospective review. Within these 20 patients, there were a total of 11 males and 9 females, with an age range of 25-81 years. Sixteen involved mandibular reconstruction and 4 were maxillary cases. A wide variety of both benign and malignant disease provided the indication for surgical therapy. Ten patients had malignant disease (7 SCC, 1 clear cell odontogenic carcinoma, 1 ameloblastic carcinoma, 1 mucosal melanoma) and 4 had benign pathology (3 ameloblastomas, 1 keratocystic odontogenic tumor). Two patients had osteoradionecrosis and 2 had osteomyelitis. Post-traumatic deformities existed in 2 patients after gunshot wounds to the face. Complications of reconstruction included flap failure in 5/30 patients, who were therefore excluded from the study. Postoperative wound infection was the most frequent complication in 4/20 patients, and 3 of these patients were treated with hardware exchange as part of the goal of eliminating source of infection,

in addition to systemic antibiotics and surgical drainage. Reconstruction plates were used in all cases as the primary method of fixation. Cases involving exchanged hardware during a subsequent operation utilized single mini-plate fixation across all osteotomies. Results: A total of 54 osteotomies were bridged by plate fixation in the 20 fibula reconstructions. Of these 54 gaps, bony union was ultimately found in 39 or 72%. Maxillary rates (50%) were lower than mandibular cases (80%), but there were only 4 involving the maxilla compared to 16 mandibular. In the 20% non-unions found in the mandible, the majority were located in the posterior mandible. The overall non-union rate was 28% despite a fairly even split between heavy reconstruction plates (11 cases) and mini-plates (9 cases). Conclusions: The fibula free flap is a reliable and versatile reconstruction for head/neck oncologic defects, with a higher than expected rate of bony non-union. This may be more clinically significant in the case of implant reconstruction than in cases where the patient does not undergo dental rehabilitation.

1074. Clark, W. C., et al. (1986). "Analysis of 76 civilian craniocerebral gunshot wounds." Journal of neurosurgery 65(1): 9-14.

A retrospective analysis of 76 civilian craniocerebral gunshot wounds treated over a 20-month period is presented. The authors report a 62% mortality rate and conclude that the admission Glasgow Coma Scale (GCS) score is a valuable prognosticator of outcome. Other important findings were: patients with a GCS score of 3 invariably died, with or without surgical intervention; and the presence of intracranial hematomas, ventricular injury, or bihemispheric wounding was associated with a poor outcome. Standardized methods of data reporting should be adopted in order to allow multicenter trials or comparisons that might lead to management practices that could improve results.

1075. Clarke, W. E., et al. (2001). "Coordination of fibroblast growth factor receptor 1 (FGFR1) and fibroblast growth factor-2 (FGF-2) trafficking to nuclei of reactive astrocytes around cerebral lesions in adult rats." Molecular and cellular neurosciences 17(1): 17-30.

Traumatic injury to the adult central nervous system initiates a cascade of cellular and trophic events, culminating in the formation of a reactive gliotic scar through which transected axons fail to regenerate. Levels of fibroblast growth factor-2 (FGF-2), a potent gliogenic and neurotrophic factor, together with its full-length receptor, FGF receptor 1 (FGFR1) are coordinately and significantly increased postinjury in both nuclear and cytoplasmic fractions of extracted cerebral cortex biopsies after a penetrant injury. FGFR1 is colocalized with FGF-2 in the nuclei of reactive astrocytes, and here FGF-2 is associated with nuclear euchromatin. This study unequivocally demonstrates coordinate up-regulation and trafficking of FGF-2 and full-length FGFR1 to the nucleus of reactive astrocytes in an in vivo model of brain injury, thereby implicating a role in nuclear activity for these molecules. However, the precise contribution of nuclear FGF-2/FGFR1 to the pathophysiological response of astrocytes after injury is undetermined.

1077. Clarot, F., et al. (2003). "Lethal head injury due to tear-gas cartridge gunshots." Forensic science international 137(1): 45-51.

We report a fatal head injury caused by a tear-gas cartridge and point out the underestimated potential injury of this type of weapon. Gas pressure wounds and the death mechanisms are also described. A review of the literature and forensic considerations of head injury without projectile are presented.

1078. Claussen, C. D., et al. (1977). "Computed tomography of trauma involving brain and facial skull (craniofacial injuries)." Journal of computer assisted tomography 1(4): 472-481.

Among head injuries, frontobasal fractures play an important role due to frequently concomitant intracranial complications. Intracranial hematomas, cerebral contusions, depressed fractures, and intracranial air are readily detected by computed tomography (CT). Traumatization of intraorbital structures often associated with blowout fractures and herniation of cerebral parenchyma into the ethmoidal, frontal, or sphenoidal sinuses are best demonstrated by CT. In assessing soft tissue structures, CT is superior to multidirectional tomography, which tends to be more suitable for fine detail study of bony structures. Furthermore, CT is helpful for diagnosing inflammatory processes due to bacterial invasion not infrequently following traumatic communication between the paranasal sinuses and the cranial cavity. Sequelae of head trauma such as posttraumatic porencephaly are clearly demonstrated by CT.

1079. Clayton, N. A., et al. (2019). "Ablative Fractional Resurfacing in Acute Care Management of Facial Burns: A New Approach to Minimize the Need for Acute Surgical Reconstruction." Journal of burn care & research : official publication of the American Burn Association 40(3): 368-372.

Current evidence suggests awaiting for scars to fully mature before engaging surgical reconstruction unless acute indications to prevent secondary damage, such as microstomia and eyelid ectropion are apparent. To evaluate the efficacy of ablative fractional CO2 laser intervention early in the acute treatment of panfacial burn injury. A 39-year-old Asian male with 60% TBSA flame burns including panfacial involvement was developing microstomia and upper and lower eyelid ectropion early proceeding epithelialization. At 6-weeks postinjury, ablative fractional CO2 laser treatment was commenced while still in the intensive care unit, and subsequently delivered at regular intervals. Nonsurgical scar contracture management was provided concurrently as per site specific standard protocols. Measurements and photographic data relative to deficits in eye and mouth competence were obtained at rest, as well as maximal opening at baseline and routinely until scar stabilization was reached. The outcomes were subsequently compared with facial burn patient historical data within our facility. No significant difference was identified in the functional ROM for mouth and eye regions; treatment duration was, however, shorter and aesthetic outcomes were considered superior to their surgical reconstruction counterparts in the historical cohort. This case report reveals that early ablative fractional CO2 resurfacing treatment, coalesced with nonsurgical scar management is an efficacious interventional approach to abate contractures to the face, accelerates and enhances scar maturation processes and may alleviate the need for surgical scar reconstructions. Moreover, optimal aesthetic outcomes may be achieved compared with traditional reconstructive methods.

1080. Clemedson, C. J., et al. (1973). "Head injuries caused by small-calibre, high velocity bullets. An experimental study." Zeitschrift fur Rechtsmedizin. Journal of legal medicine 73(2): 103-114.

1081. Clifton, G. L., et al. (2011). "Very early hypothermia induction in patients with severe brain injury (the National Acute Brain Injury Study: Hypothermia II): a randomised trial." The Lancet. Neurology 10(2): 131-139.

BACKGROUND: The inconsistent effect of hypothermia treatment on severe brain injury in previous trials might be because hypothermia was induced too late after injury. We aimed to assess whether very early induction of hypothermia improves outcome in patients with severe brain injury., METHODS: The National Acute Brain Injury Study: Hypothermia II (NABIS: H II) was a randomised, multicentre clinical trial of patients with severe brain injury who were enrolled within 2.5 h of injury at six sites in the USA and Canada. Patients with non-penetrating brain injury who were 16-45 years old

and were not responsive to instructions were randomly assigned (1:1) by a random number generator to hypothermia or normothermia. Patients randomly assigned to hypothermia were cooled to 35degreeC until their trauma assessment was completed. Patients who had none of a second set of exclusion criteria were either cooled to 33degreeC for 48 h and then gradually rewarmed or treated at normothermia, depending upon their initial treatment assignment. Investigators who assessed the outcome measures were masked to treatment allocation. The primary outcome was the Glasgow outcome scale score at 6 months. Analysis was by modified intention to treat. This trial is registered with ClinicalTrials.gov, NCT00178711., FINDINGS: Enrolment occurred from December, 2005, to June, 2009, when the trial was terminated for futility. Follow-up was from June, 2006, to December, 2009. 232 patients were initially randomised a mean of 1.6 h (SD 0.5) after injury: 119 to hypothermia and 113 to normothermia. 97 patients (52 in the hypothermia group and 45 in the normothermia group) did not meet any of the second set of exclusion criteria. The mean time to 35degreeC for the 52 patients in the hypothermia group was 2.6 h (SD 1.2) and to 33degreeC was 4.4 h (1.5). Outcome was poor (severe disability, vegetative state, or death) in 31 of 52 patients in the hypothermia group and 25 of 56 in the normothermia group (relative risk [RR] 1.08, 95% CI 0.76-1.53; p=0.67). 12 patients in the hypothermia group died compared with eight in the normothermia group (RR 1.30, 95% CI 0.58-2.52; p=0.52)., INTERPRETATION: This trial did not confirm the utility of hypothermia as a primary neuroprotective strategy in patients with severe traumatic brain injury.

1082. Close, J. K., et al. (2009). "Percutaneous ultrasound-guided intraorbital foreign body removal." Ophthalmic plastic and reconstructive surgery 25(4): 335-337.

Percutaneous ultrasound-guided intraorbital foreign body removal was successfully performed for removal of an intraorbital wooden foreign body. A 13-month-old boy presented with left periorbital cellulitis, which developed 3 days after a fall from an all-terrain vehicle. Orbital CT showed preseptal and postseptal orbital cellulitis, and an 11 x 2 mm linear foreign body in the medial compartment of the left eye. Surgical exploration of the left eye was performed, with no foreign body identified. Following surgery, diagnostic sonography demonstrated a linear foreign body adjacent to the medial rectus muscle, with sonographic characteristics compatible with wood. The percutaneous procedure was performed with intravenous deep sedation. With sonographic guidance, a Hartmann forceps was advanced in the medial soft tissues of the orbit, and the foreign body was removed intact. Ophthalmologic follow-up over 6 months revealed no evidence of visual loss, nerve injury, or impairment of extraocular muscle function.

1083. Cobb, S. R., et al. (1985). "Computed tomographic evaluation of ocular trauma." Computerized radiology : official journal of the Computerized Tomography Society 9(1): 1-10.

The CT scans of 10 traumatized patients with demonstrable ocular injuries were reviewed. The CT findings were correlated with the clinical findings in each case. CT manifestations of a variety of ocular and orbital injuries are reported and a systematic approach to the CT evaluation of ocular trauma is presented.

1084. Cocanour, C. S., et al. (1995). "Does the potential for organ donation justify scene flights for gunshot wounds to the head?" The Journal of trauma 39(5): 968-970.

OBJECTIVE: The goal of this study was to evaluate helicopter transport to an urban level I trauma center from the scene of injury for patients with self-inflicted gunshot wounds to the head., DESIGN: This study is a retrospective review of the prehospital, hospital, and billing records., MEASUREMENTS AND MAIN RESULTS: Despite the fact that 10 of 28 patients (36%) had an airway established by the medical flight crews, scene flights did not enhance survival. Twenty-seven of 28 patients (96%) died. The remaining patient's survival could not be attributed to the scene flight. We

estimated that 27 of 28 patients would have arrived at the trauma center sooner if they had been transported by the first-responder emergency medical services ground unit. Flight service charges were approximately one-third of the hospital charges. As a group, patients with a self-inflicted gunshot wound to the head had the highest rate of organ donation in this trauma center (26%). Twenty-nine organs were harvested from the seven donors., CONCLUSIONS: The use of helicopter scene flights from the scene of injury for patients with a self-inflicted gunshot wound to the head provides no medical advantage to the victims, but provides a high-yield source of desperately needed organs. The prompt establishment of an airway in the field may prolong patient survival long enough to allow evaluation for organ donation. Helicopter transport of these patients is justified only as a means of rapidly delivering the personnel capable of providing advanced airway skills to the scene. Patients requiring CPR in the field after isolated gunshot wounds to the head will not live long enough to become organ donor candidates; therefore, there is no benefit to helicopter transport for these patients.

1085. Coe, C. D., et al. (2010). "Effect of blast trauma and corneal foreign bodies on visual performance." Optometry and vision science : official publication of the American Academy of Optometry 87(8): 604-611.

PURPOSE: To evaluate the effect of non-penetrating corneal foreign bodies secondary to explosive blasts on the visual performance of soldiers., METHODS: In a prospective, non-interventional study subjective visual performance and objective optical quality of 11 injured eyes with retained corneal foreign bodies were compared with that of 11 normal controls. Visual performance measures consisted of best spectacle-corrected high-contrast visual acuity (HCVA), low-contrast (5%) visual acuity (LCVA), and contrast sensitivity (CS). LCVA was evaluated in two luminance levels (photopic and mesopic) and two glare conditions (with and without glare). Acuity measurements were scored using logMAR notation. Objective optical quality was assessed comparing total root mean square wavefront error (WFE) and percent higher order aberrations. Modulation transfer functions calculated from the wavefront maps were used to predict the results of the psychophysical contrast testing., RESULTS: HCVA of injured eyes (M = -0.03) did not differ significantly ($t(20) = 1.56$, $p = 0.13$) when compared with controls (M = -0.09). However, visual performance of injured eyes (M = 0.33) was significantly worse than control eyes (M = 0.11) on photopic LCVA ($t(20) = 4.16$, $p < 0.001$), mesopic LCVA(M = 0.44 vs. M = 0.21, $t(20) = 3.85$, $p = 0.001$), mesopic LCVA with glare (M = 0.49 vs. M = 0.21, $t(20) = 3.66$, $p = 0.002$), and small letter CS (M = 0.25 vs. M = 0.90, $t(20) = -6.6$, $p < 0.001$). For a 6-mm pupil, mean absolute WFE attributed to higher order aberrations for the injured eyes was 0.86 microm and 0.59 microm for the control eyes. This difference was significant ($t(20) = -2.15$, $p = 0.044$)., CONCLUSIONS: Although HCVA was no different than the normal controls, visual performance of the injured eyes was significantly worse in terms of LCVA and CS. On average, visual performance can be broadly predicted by the modulation transfer function derived from the subjects' wavefront aberration map.

1086. Cogbill, T. H. and H. G. Sullivan (1995). "Carotid artery pseudoaneurysm and pellet embolism to the middle cerebral artery following a shotgun wound of the neck." The Journal of trauma 39(4): 763-767.

Arterial missile embolism is a rare complication of penetrating vascular trauma. We report a case of middle cerebral artery pellet embolism and delayed appearance of a carotid artery pseudoaneurysm following a shotgun wound of the neck. The pseudoaneurysm was repaired. Because the patient had no associated neurologic deficits, the pellet embolus was left within the patient middle cerebral artery. He remains well 4 years after injury. A selective approach to the management of a pellet embolus to the middle cerebral artery based on clinical signs or symptoms and status of arterial patency is recommended. In addition, several principles are suggested to improve the reliability of arteriography for shotgun wounds of the neck.

1087. Cohen, J. E., et al. (2008). "Results of endovascular treatment of traumatic intracranial aneurysms." Neurosurgery 63(3): 476-476.

OBJECTIVE: To present results of early angiographic diagnosis and endovascular treatment of traumatic intracranial aneurysms (TICA)., METHODS: From June 2002 to December 2006, diagnostic angiography was performed on patients with moderate to severe traumatic brain injury that involved a cranial base fracture or a penetrating brain injury with a tract from the penetrating agent that entered at the pterional area, went through the middle cerebral artery candelabra, and crossed the midline. TICAs were treated by various endovascular techniques during the same angiographic procedure., RESULTS: Thirty-four patients with traumatic brain injury underwent angiography (25 penetrating brain injuries, nine blunt injuries); 13 TICAs were diagnosed (10 penetrating brain injuries, three blunt injuries). The Glasgow Coma Scale score at diagnosis ranged from 5 to 15. Angiography was performed for screening in eight patients and for clinical indications in five patients; 11 TICAs were diagnosed before rupture. Seven aneurysms were located on branches of the middle cerebral artery, two on pericallosal branches of the anterior cerebral artery, and four on the internal carotid artery. No recanalization was detected in 12 patients. One patient treated with a bare stent and coiling had a growing intracavernous pseudoaneurysm; therefore, internal carotid artery occlusion with extracranial-intracranial microvascular bypass was performed. Six patients refused angiographic follow-up, but computed tomographic angiography has failed to show recanalization. No patient presented with delayed bleeding (mean follow-up, 2.6 yr). There were no procedure-related complications or mortality., CONCLUSION: Early angiographic diagnosis with immediate endovascular treatment provided an effective approach for TICA detection and management. Endovascular therapy is versatile and offers a valuable alternative to surgery, allowing early aneurysm exclusion with excellent results.

1088. Cohen, J. E., et al. (2005). "Endovascular management of traumatic and iatrogenic aneurysms of the pericallosal artery. Report of two cases." Journal of neurosurgery 102(3): 555-557.

Traumatic intracranial aneurysms are rare complications of closed and penetrating head injuries and may also be related to a variety of neurosurgical procedures. The primary goals in the treatment of patients harboring these lesions are early identification and intervention to prevent bleeding. Traumatic aneurysms are fragile, prone to rupture, and represent a challenging subset of vascular lesions for either surgery or endovascular therapy. Surgical approaches to aneurysms located at the pericallosal arteries are associated with higher rates of morbidity and mortality than approaches to other supratentorial aneurysms. Current endovascular treatment most often involves occlusion of the parent artery with the potential of added morbidity. The authors present their experience in the endovascular management of traumatic and iatrogenic aneurysms of the pericallosal artery achieved by primary coil embolization with parent vessel preservation. For patients harboring traumatic pericallosal aneurysms with favorable anatomical characteristics, in which the morbidity caused by parent vessel occlusion is not acceptable, endosaccular coil placement may be a valuable option.

1089. Cohen, M. A., et al. (1986). "Low velocity hand-gun injuries of the maxillofacial region." Journal of maxillofacial surgery 14(1): 26-33.

In contrast to the number of reports in the literature describing high velocity injuries of the maxillo-facial region, there are relatively few which deal with civilian type gunshot injuries. The purpose of this study was to undertake a retrospective analysis of 40 cases of low-velocity hand-gun injuries of the maxillo-facial region. The majority of cases were due to assault followed by accidental shootings and failed suicide attempts. Injuries ranged from mild soft tissue damage without fractures to severe, comminuted fractures of the facial bones. In some cases, soft tissue damage was severe. Rarely were injuries life threatening. Entrance wounds were characteristically small and well circumscribed. In 60 per cent of cases the bullet did not exist and was retained within the tissues. The floor of the mouth and tongue were the soft tissues most commonly injured. Other structures injured were major blood

vessels, nerves and the eye. Mandibular fractures occurred in 58 per cent of cases, followed in frequency by maxillary complex fractures. Twenty per cent of fractures simultaneously involved bones of the upper, middle and lower-thirds of the facial skeleton. The above injuries are discussed and a classification of low-velocity hand-gun injuries of the maxillo-facial region is proposed.

1090. Cohen, M. J., et al. (2009). "Early release of high mobility group box nuclear protein 1 after severe trauma in humans: role of injury severity and tissue hypoperfusion." Critical care (London, England) 13(6): R174.

INTRODUCTION: High mobility group box nuclear protein 1 (HMGB1) is a DNA nuclear binding protein that has recently been shown to be an early trigger of sterile inflammation in animal models of trauma-hemorrhage via the activation of the Toll-like-receptor 4 (TLR4) and the receptor for the advanced glycation endproducts (RAGE). However, whether HMGB1 is released early after trauma hemorrhage in humans and is associated with the development of an inflammatory response and coagulopathy is not known and therefore constitutes the aim of the present study., METHODS: One hundred sixty eight patients were studied as part of a prospective cohort study of severe trauma patients admitted to a single Level 1 Trauma center. Blood was drawn within 10 minutes of arrival to the emergency room before the administration of any fluid resuscitation. HMGB1, tumor necrosis factor (TNF)-alpha, interleukin (IL)-6, von Willebrand Factor (vWF), angiopoietin-2 (Ang-2), Prothrombin time (PT), prothrombin fragments 1+2 (PF1+2), soluble thrombomodulin (sTM), protein C (PC), plasminogen activator inhibitor-1 (PAI-1), tissue plasminogen activator (tPA) and D-Dimers were measured using standard techniques. Base deficit was used as a measure of tissue hypoperfusion. Measurements were compared to outcome measures obtained from the electronic medical record and trauma registry., RESULTS: Plasma levels of HMGB1 were increased within 30 minutes after severe trauma in humans and correlated with the severity of injury, tissue hypoperfusion, early posttraumatic coagulopathy and hyperfibrinolysis as well with a systemic inflammatory response and activation of complement. Non-survivors had significantly higher plasma levels of HMGB1 than survivors. Finally, patients who later developed organ injury, (acute lung injury and acute renal failure) had also significantly higher plasma levels of HMGB1 early after trauma., CONCLUSIONS: The results of this study demonstrate for the first time that HMGB1 is released into the bloodstream early after severe trauma in humans. The release of HMGB1 requires severe injury and tissue hypoperfusion, and is associated with posttraumatic coagulation abnormalities, activation of complement and severe systemic inflammatory response.

1091. Cohen, O., et al. (2007). "Donor brain death mechanisms and outcomes after heart transplantation." Transplantation proceedings 39(10): 2964-2969.

We sought to explore whether the cause of donor brain death influenced recipient outcomes after cardiac transplantation. In retrospect, 358 consecutive donors provided cardiac allografts to adult patients undergoing orthotopic heart transplantation at a single urban US medical center from January 2000 through December 2005. Alternate recipients were excluded. Mechanism and cause of donor brain injury and death were divided into five categories: anoxia (nontraumatic) (n=36), blunt head trauma (n=220), penetrating head trauma (n=83), brain tumor/infection (n=7), and cerebrovascular event (n=12). The five subgroups were categorized as traumatic or nontraumatic. The end points of the study were causes of early and late mortality, survival, and rejection rate. There were 59 deaths in the 6-year period. Total and short-term recipient mortality were found to be statistically higher among heart transplant recipients when the donors suffered from traumatic brain death compared to those whose brain death etiology was nontraumatic (P=.045, P=.033, respectively). Rejection rate was similar in all groups (P=.497). In conclusion, donor traumatic brain death was found to be a valid risk factor for recipient mortality after heart transplantation. Caution should be used when evaluating such donors, particularly in the presence of other risk factors.

1092. Cohen-Zimerman, S., et al. (2020). "Neural underpinning of a personal relationship with God and sense of control: A lesion-mapping study." Cognitive, affective & behavioral neuroscience 20(3): 575-587.

A strong personal relationship with God is theoretically and empirically associated with an enhanced sense of control. While a growing body of research is focused on understanding the neural mechanisms underlying religious belief, little is known about the brain basis of the link between a personal relationship with God and sense of control. Here, we used a sample of patients with focal brain lesions (N = 84) and matched healthy controls (N = 22) to determine whether damage to the ventromedial prefrontal cortex (vmPFC)-a region associated with emotionally meaningful religious experiences and with sense of control-will modulate self-reports of a personal relationship with God and sense of control. We also examined potential mediators for these associations. Voxel-based lesion symptom mapping revealed that damage to the right vmPFC resulted in a stronger personal relationship with God, and patients with damage to this region demonstrated an increased sense of control relative to patients with damage to posterior cortex and healthy controls. Moreover, the association between vmPFC damage and greater perceived sense of control was mediated by a stronger personal relationship with God. Collectively, these results suggest that a strong personal relationship with God can serve an important psychological function by affecting sense of control, with both enhanced following damage to the right vmPFC.

1093. Cohen-Zimerman, S., et al. (2019). "Childhood Socioeconomic Status Predicts Cognitive Outcomes Across Adulthood Following Traumatic Brain Injury." Archives of physical medicine and rehabilitation 100(10): e16.

Objective: To examine the association between childhood socioeconomic status and the level and rate of change in intelligence scores throughout adulthood following traumatic brain injury. Design: This longitudinal study included data collected for the Vietnam Head Injury Study between 1960s and 2012 (follow-up, 5-22 years). Assessment of intelligence score was done by observers blind to patient' childhood SES. Setting: Outpatient multidisciplinary reevaluation of brain-injured veterans and controls. Participants: 186 combat male veterans with a penetrating brain injury and 54 male veterans without a brain injury volunteered to participate in this study. The groups were matched on age, childhood SES and pre-injury intelligence. Interventions: Not applicable. Main Outcome Measure(s): Childhood SES was determined for each participant based on parental educational attainment and occupational prestige. General intelligence was initially assessed pre-injury upon induction into the military, and again 15, 35 and 42 years post-injury. Total brain volume loss and lesion laterality were determined based on CT scans. Results: For both participants with and without TBI, childhood SES accounted for a significant portion of the variance in intelligence scores pre-injury and in all three post-injury evaluations, however, it was not associated with the rate of cognitive change. Moreover, childhood SES predicted cognitive outcome among patients with left hemisphere damage better than it did for right hemisphere damage patients. Conclusions: These findings provide the first evidence indicating the persistent effects of childhood SES on intelligence scores later in adulthood following a TBI. Childhood SES should be considered when predicting and assessing cognitive recovery following TBI, even when the injury occurred in adulthood. Author(s) Disclosures: All the authors report no conflict of interests. Key Words: Socioeconomic Status, Traumatic Brain Injury, Intelligence, Longitudinal Study

1094. Cohen-Zimerman, S., et al. (2021). "The neural basis for mental state attribution: A voxel-based lesion mapping study." Human brain mapping 42(1): 65-79.

The ability to infer other persons' mental states, "Theory of Mind" (ToM), is a key function of social cognition and is needed when interpreting the intention of others. ToM is associated with a network of functionally related regions, with reportedly key prominent hubs located in the dorsolateral prefrontal cortex (dlPFC) and the temporoparietal junction (TPJ). The involvement of (mainly the right)

TPJ in ToM is based primarily on functional imaging studies that provide correlational evidence for brain-behavior associations. In this lesion study, we test whether certain brain areas are necessary for intact ToM performance. We investigated individuals with penetrating traumatic brain injury (n = 170) and healthy matched controls (n = 30) using voxel-based lesion-symptom mapping (VLSM) and by measuring the impact of a given lesion on white matter disconnections. ToM performance was compared between five patient groups based on lesion location: right TPJ, left TPJ, right dlPFC, left dlPFC, and other lesion, as well as healthy controls. The only group to present with lower ToM abilities was the one with lesions in the right dlPFC. Similarly, VLSM analysis revealed a main cluster in the right frontal middle gyrus and a secondary cluster in the left inferior parietal gyrus. Last, we found that disconnection of the left inferior longitudinal fasciculus and right superior longitudinal fasciculus were associated with poor ToM performance. This study highlights the importance of lesion studies in complementing functional neuroimaging findings and supports the assertion that the right dlPFC is a key region mediating mental state attribution.

1095. Cohen-Zimerman, S., et al. (2018). "Intelligence across the seventh decade in patients with brain injuries acquired in young adulthood." Trends in neuroscience and education 13: 1-7.

In this longitudinal study, we examined intelligence in a group of Vietnam veterans in their 60 s who suffered combat-related penetrating traumatic brain injuries (pTBI) in their 20 s (n = 120), as well as matched veterans with no brain damage (n = 33). Intelligence was evaluated using the Armed Forces Qualification Test (AFQT) administered before the injury occurred and then again at three points in time over the following 45 years. We tested for potential predictors and correlates of late midlife intelligence score, as well as the recent change in score over the seventh decade. The pTBI group had lower intelligence scores than the control group when currently evaluated. Pre-injury intelligence and the presence of a pTBI were the most consistent predictors of current intelligence scores. While exacerbated intellectual decline occurs following a young-adulthood pTBI and affects everyday life, no evidence for late midlife accelerated cognitive decline or dementia was found.

1096. Coker, N. J. (1991). "Management of traumatic injuries to the facial nerve." Otolaryngologic clinics of North America 24(1): 215-227.

Penetrating and nonpenetrating trauma to the head and neck produces myriad injuries to the facial nerve. This article presents a rationale of management of neural injury, emphasizing extracranial and intratemporal trauma and techniques of neurorrhaphy.

1097. Coker, N. J., et al. (1987). "Traumatic intratemporal facial nerve injury: management rationale for preservation of function." Otolaryngology--head and neck surgery : official journal of American Academy of Otolaryngology-Head and Neck Surgery 97(3): 262-269.

A retrospective review of 29 cases of intratemporal facial nerve injuries included 18 temporal bone fractures, 7 gunshot wounds, and 4 iatrogenic complications. Surgical exploration confirmed involvement of the fallopian canal in the perigeniculate region in 14 longitudinal and 3 transverse or mixed fractures of the petrous pyramid. Gunshot and iatrogenic injuries usually occurred within the tympanic and vertical segments of the facial canal and at the stylomastoid foramen. When hearing is salvageable, the middle fossa approach provides the best access to the perigeniculate region of the facial nerve. In the presence of severe sensorineural hearing loss, the transmastoid-translabyrinthine approach is the most appropriate for total facial nerve exploration. Grade I to III results can be anticipated in timely decompression of lesions caused by edema or intraneural hemorrhage. Undetectable at the time of surgery, stretch and compression injuries with disruption of the endoneural tubules often lead to suboptimal results. Moderate-to-severe dysfunction (Grade IV), with slight weakness and synkinesis, is the outcome to be expected from the use of interpositional grafts.

1098. Colbachini, P. C. M., et al. (2022). "Air Rescue for Pediatric Trauma in a Metropolitan Region of Brazil: Profiles, Outcomes, and Overtriage Rates." Frontiers in Pediatrics 10.

Besides ensuring a quick response and transport of trauma victims, helicopter support also involves risks to patients and professionals and has higher operational costs. Studying prehospital triage criteria and their relationship with patient overtriage and outcomes is important, particularly in newly established services and in developing countries with limited health budgets. This could help improve the use of the helicopter rescue and provide better management of the costs and risks related to it. The objective of this study was to determine the epidemiologic and severity profiles of pediatric victims of trauma attended by helicopter in a Brazilian Metropolitan Area to evaluate the outcomes and overtriage rates related to pediatric air rescue in the region. We conducted an observational and retrospective study using 49 hospital and prehospital records from victims of trauma aged <18 years old (yo) assisted by helicopter and then transferred to a tertiary University Hospital. Of the 49 patients, 39 (79.6%) individuals were male, and the mean age was 11.3 yo. Vehicular collisions accounted for 15 (30.6%) of the traumas, and traumatic brain injuries occurred in 28 (57.1%) cases. A total of 29 (59.1%) individuals had severe trauma (Injury Severity Score; ISS >15), and 34 (69.4%) required admission to the intensive care unit. Overtriage varied from 18.4 to 40.8% depending on the criteria used for its definition, being more frequent in individuals aged between 1 and 5 yo. Death occurred in 10 (20.4%) patients. On prehospital evaluation, we classified 29/32 (90.6%) patients with severe trauma according to the Pediatric Trauma Score (PTS ≤8) and 18/25 (72%) according to the Revised Trauma Score (RTS ≤11). Of these, 7/29 (24.1%) and 6/18 (33.3%), respectively, presented ISS <15 at in-hospital evaluation. None of the patients with PTS >8 and 3/7 (42.8%) of those with RTS >11 presented ISS >15. In conclusion, air rescue of pediatric trauma victims was used mainly for critically ill individuals, resulting in rates of overtriage compatible with that found in the literature. PTS showed the lowest rates of overtriage within excellent rates of undertriage.

1100. Coldwell, D. M. (2007). "The role of interventional radiology in trauma." Journal of Interventional Radiology 16(3): 213-215.

1101. Cole, R. D., et al. (1994). "Gunshot wounds to the mandible and midface: evaluation, treatment, and avoidance of complications." Otolaryngology--head and neck surgery : official journal of American Academy of Otolaryngology-Head and Neck Surgery 111(6): 739-745.

As American society becomes progressively violent, an ever-increasing number of gunshot wounds are being seen across the United States. Particularly challenging are injuries that involve the mandible and midface, not only because of problems with reconstructing bone and soft-tissue defects but also because of emergent problems with airway obstruction and neurovascular compromise. We present 40 cases of gunshot wounds to the mouth, mandible, and maxilla treated at Wake Forest University Medical Center during the past 7 years. The focus of this retrospective analysis is on emergency evaluation and treatment, complications encountered, and operative techniques used for reconstruction. Special emphasis is placed on recognizing and avoiding the complications of these injuries.

1102. Coleman, D. M., et al. (2013). "Contemporary outcomes after distal vertebral reconstruction." Journal of vascular surgery 58(1): 152-157.

INTRODUCTION: Flow-limiting lesions or embolic phenomena can produce vertebrobasilar ischemia. This study aims to differentiate the pathophysiology of vertebral ischemia and examine contemporary outcomes after distal vertebral reconstruction., METHODS: Between February 2005 and November 2011, 41 consecutive distal vertebral artery (VA) reconstructions were performed in 34 patients, including bypass to the third portion of the VA (V3) at the C1-2 level (n = 24) or the C0-1 level (n = 7); transposition of the external carotid artery or its occipital branch onto V3 (n = 6); transposition of V3 onto the internal carotid artery (n = 3); and bypass from the ipsilateral subclavian artery to V3 (n = 1). Six patients required a concomitant carotid intervention, and nine patients required a partial resection of the C1 transverse process. Symptoms, present in 91% of patients, were attributed to a flow-limiting lesion in 16 (52%), to embolization in nine (29%), and to a mixed etiology in six (19%)., RESULTS: Intraoperatively, five patients required graft revision or conversion of a transposition to a bypass, and two patients required vertebral ligation. Median blood loss was 260 mL. Median hospital length of stay was 1 day. Postoperatively, one patient (2%) required re-exploration for bleeding, a stroke occurred in one patient (2%), and cranial nerve injury occurred in three patients (7%). There were no perioperative deaths. Survival analysis showed that primary patency at 1, 2, and 5 years, respectively, was 74%, 74%, and 54%. Secondary patency was 80% at 1 year and remained so through the end of follow-up at 80 months. A statistically significant difference in patency was noted favoring arterial transposition over vertebral bypass of 100%, 100%, and 83% at 1, 2, and 5 years, respectively, vs 65%, 65%, and 39% (P = .018). Considering successful redo bypass grafting for late failure, 97% of patients demonstrated preserved patency at their last follow-up. There were two late deaths of unknown etiology and no late strokes., CONCLUSIONS: Distal VA reconstruction for flow-limiting or embolic lesions provides excellent stroke protection and symptomatic relief with acceptable perioperative risk in selected patients.

1104. Collins, K. A. (2010). "Adolescent Russian roulette deaths." The American journal of forensic medicine and pathology 31(1): 4-6.

Adolescence, between the ages of 10 and 19 years, is a unique period both physically and emotionally. During this time of life, individuals are known to experiment and engage in risky behavior, sometimes with unforeseen morbidity and mortality. We also see suicide emerge as a manner of death in this age group. The most common method is gunshot wound and sometimes in the form of Russian roulette. Few studies have looked at deaths by Russian roulette, the victims, and scenarios. In particular, no study examines the adolescent victim of Russian roulette. To better understand and classify this entity, adolescent Russian roulette autopsy cases over a 20-year period were examined looking at the victims, scenarios, autopsy findings, cause and manner of death, and the weapons. All victims were males, ages 13 to 19 years, with a Black-to-White ratio of 1:1. No victim had a previous psychiatric history. Toxicology was positive for alcohol and/or marijuana in 50% of the victims. Friends were present when the victim shot himself which occurred in the home the majority of the time. In all but 1 case, premeditation of the game was involved as the victim provided the weapon for the roulette. The cause of death was gunshot wound to the head (6 to the right side, 1 to the mouth, 1 to the forehead), and the manner of death was suicide in 6 cases and accident in 2 cases. A review of the literature discusses the adolescent victim, suicide, and Russian roulette.

1105. Colombage, S. M. and S. R. Hulathduwa (2011). "Death of a driver due to an atypical missile." Journal of forensic and legal medicine 18(1): 23-25.

A road traffic accident of an unusual nature is presented. The driver of a pickup cab sustained fatal injuries by a large piece of concrete (missile) set in motion consequent to a car crashing onto the centre island of a highway.

1106. Colombo, F., et al. (1997). "[Clinical and therapeutic aspects of stab and gunshot wounds]." Aspetti clinici e terapeutici delle ferite d'arma bianca e da fuoco. 52(9): 1087-1093.

In the last three years (1992-1995) 130 stab (114) and gunshot (16) wounds were observed at and admitted to the Emergency Surgical Department of Fatebenefratelli Hospital of Milan. We observed a high incidence of non-EEC patients (62%). Imaging devices (US and CT scan) and surgical minimally invasive procedures have reduced open surgery rate with a remarkable reduction in drawbacks and mortality.

1107. Colombo, J., et al. (2008). "Noninvasive monitoring of the autonomic nervous system and hemodynamics of patients with blunt and penetrating trauma." The Journal of trauma 65(6): 1364-1373.

BACKGROUND: To describe early effects of sympathetic (SNS) and parasympathetic nervous system (PSNS) activities measured by heart rate (HR) and respiratory rate variabilities simultaneously with noninvasive hemodynamic patterns in patients with blunt and penetrating trauma., METHODS: Descriptive study of 168 monitored trauma patients in a level I university-run trauma service. We studied HR and respiratory rate variability by spectral analysis as a measure of autonomic nervous system (ANS) activity in severe blunt and penetrating injuries beginning shortly after their admission to the emergency department. The low frequency area is the area under the HR spectral analysis curve within the frequency range of 0.04 Hz to 0.10 Hz. This area primarily reflects the tone of the SNS as mediated by the vagus nerve. The respiratory frequency area, sometimes referred to as the high frequency area, is a 0.12 Hz-wide frequency range centered around the fundamental respiratory frequency defined by the peak mode of the respiratory activity power spectrum. It is indicative of vagal outflow reflecting PSNS activity. The low frequency area/respiratory frequency area, or L/R ratio, reflects the balance of the SNS and the PSNS. ANS was studied simultaneously with noninvasive hemodynamic patterns after blunt and penetrating thoracic or abdominal injury beginning shortly after admission. We measured cardiac index by bioimpedance, HR, and mean arterial pressure (MAP) to evaluate cardiac function, pulse oximetry (SapO2) to reflect changes in respiratory function, and transcutaneous oxygen indexed to fractional inspired oxygen (PtcO2/FIO2) to reflect tissue perfusion., RESULTS: ANS activity markedly increased especially in the nonsurvivors at 12 hours to 24 hours after admission. Compared with survivors, the nonsurvivors had lower MAP, CI, and PtcO2/FIO2 values associated with increased ANS activity., CONCLUSIONS: In the nonsurvivors, low flow, low MAP, and reduced tissue perfusion were associated with pronounced increases in PSNS and lesser increases in SNS activity. In the survivors, higher CI, MAP, and PtcO2/FIO2 values were associated with lesser increases in both PSNS and SNS activities.

1108. Como, J. J., et al. (2009). "Practice management guidelines for identification of cervical spine injuries following trauma: Update from the eastern association for the surgery of trauma practice management guidelines committee." Journal of Trauma - Injury, Infection and Critical Care 67(3): 651-659.

Background: Injury to the cervical spine (CS) is common after major trauma. The Eastern Association for the Surgery of Trauma first published its Practice Management Guidelines for the evaluation of CS injury in 1998. A subsequent revision was published in 2000. Since that time a large volume of literature has been published. As a result, the Practice Management Guidelines Committee set out to develop updated guidelines for the identification of CS injury. Methods: A search of the National Library of Medicine and the National Institutes of Health MEDLINE database was performed using

PubMed (www.pubmed.gov). The search retrieved English language articles regarding the identification of CS injury from 1998 to 2007. The questions posed were: who needs CS imaging; what imaging should be obtained; when should computed tomography, magnetic resonance imaging, or flexion/extension radiographs be used; and how is significant ligamentous injury excluded in the comatose patient? Results: Seventy-eight articles were identified. From this group, 52 articles were selected to construct the guidelines. Conclusion: There have been significant changes in practice since the previous CS injury guidelines. Most significantly, computed tomography has supplanted plain radiography as the primary screening modality in those who require imaging. Clinical clearance remains the standard in awake, alert patients with trauma without neurologic deficit or distracting injury who have no neck pain or tenderness with full range of motion. Cervical collars should be removed as soon as feasible. Controversy persists regarding CS clearance in the obtunded patient without gross neurologic deficit.

1109. Congiusta, D. V., et al. (2021). "Epidemiology of orthopaedic fractures due to firearms." Journal of Clinical Orthopaedics and Trauma 12(1): 45-49.

The majority of firearm injuries involve the extremities and have concomitant orthopaedic injuries. National data on the epidemiology of wounds caused by firearms may better inform physicians and identify areas of public health intervention. We conducted an analysis of a national database to describe the epidemiology of orthopaedic firearm injuries in the United States. The Nationwide Inpatient Sample 2001–2013 database was queried for adult patients with fractures excluding those of the skull using injury billing codes. Characterization of injury was determined using External Cause of Injury billing codes. Sociodemographic and geographic variables were reported. Chi square and multinomial logistic regression analyses were performed to identify predictors of type of firearm implicated in injury. 334,212 firearm injuries were reported in the database and about half had concomitant orthopaedic fractures. Most patients were between the ages 19 and 29, were African American, and were male. The most frequent circumstance of injury was assault/homicide, the most common firearm used was a handgun, and the most common fracture site was the femur. Patients without insurance and patients of lower income were most commonly afflicted. Knowing this distribution of the burden of this class of injury provides the opportunity to identify and intervene on behalf of at-risk populations, potentially reducing injuries by promoting firearm safety to these groups and advocating sensible practices to reduce inequitable outcomes caused by these injuries.

1110. Conner, W. C., 3rd, et al. (1998). "Traumatic aneurysms of the face and temple: a patient report and literature review, 1644 to 1998." Annals of plastic surgery 41(3): 321-326.

The branches of the external carotid artery are protected from injury in most locations by an adequate buffer of soft tissue. On occasion, the vessels approach the surface to cross bone structures, and in these key areas they become vulnerable to blunt trauma. The facial, superficial temporal, and terminal branches of the internal maxillary arteries are the branches most often affected via this mechanism of injury. In addition, damage to deeper branches of the internal maxillary artery and to the subparotid portion of the superficial temporal artery has been reported secondary to maxillary fractures and craniofacial surgery. A brief patient report illustrates the highlights of clinical examination, diagnostic study, and surgical management of an aneurysm of the facial artery. A review of the world literature since 1644 has revealed 386 patients with traumatic aneurysms of the face and temple.

1111. Conradi, S. E. (1982). "New aluminum-jacketed ammunition: the case of the "invisible" jacket." The American journal of forensic medicine and pathology 3(2): 153-155.

The recovery of the metallic jacket fired from higher-velocity weapons is crucial for ballistics testing. Therefore, even when exit wounds are present, radiographs should routinely be made. The use of the new Winchester Western Silvertip ammunition may present a problem to the forensic pathologist

because of the use of aluminum-jacketed bullets. Aluminum is only faintly radiopaque and may easily be overlooked on x-ray. An illustrative case is reported.

1112. Conroy, C. and J. F. Kraus (1988). "Survival after brain injury. Cause of death, length of survival, and prognostic variables in a cohort of brain-injured people." Neuroepidemiology 7(1): 13-22.

Injuries are the leading cause of death in the United States for those between 1 and 44 years of age and brain injuries are a major component of trauma. This report examines survival in a cohort of San Diego County, California, residents who incurred a brain injury in 1981. Cumulative risk of death over time, using the Cox Proportional Hazards Model, and predictors of death (determined by logistic regression) are used to evaluate survival. The results showed that about half of all brain-injured people who died, died in less than 2 h. Severe overall body damage and severe brain injury are the greatest causes of prehospital death. Even if they survived to the hospital, most people who die have brain injury as their underlying cause of death. Age as well as nature and severity of brain injury are the important predictors of in-hospital death. People who are discharged alive from the hospital have survival comparable to that of the population they came from. However, more die from trauma-related causes than would be expected.

1113. Consunji, R. J., et al. (2011). "A profile of deaths among trauma patients in a university hospital: the Philippine experience." Journal of injury & violence research 3(2): 85-89.

BACKGROUND: The Philippine General Hospital (PGH) is the pioneer in trauma care in the country, being the first to create a dedicated Trauma Service in 1989. The service has not conducted a review of its admissions and mortalities since 1992. The purpose of this study is to describe the mortality patterns of this service., METHODS: A descriptive and retrospective 3-year review, covering January 2004 June 2007, was conducted using an electronic patient database. Review of patient records included: population demographics, mechanism of injury, length of stay prior to death, and the cause of death., RESULTS: Of the 4947 patients admitted to the Division of Trauma during the study period, there were 231 (4.7%) deaths. The most common mechanisms of injuries were stab wounds (32.9 %), vehicular crashes (28.6 %), and gunshot wounds (25.5 %). Multiple organ failure/Sepsis (37.7 %) was the most frequent causes of death, followed by Exsanguinations (27.7 %), Central Nervous System failure (18.6 %) and other causes (10.8%). Forty four (66.7 %) of the 66 patients who died within the first 24 hours died from Exsanguinations, while 66 (61.1 %) of the 8 patients who died after 72 hours died from Multiple organ failure/Sepsis., CONCLUSIONS: Intentional causes of injury (i.e. penetrating interpersonal violence) caused the majority of trauma deaths in this series from the Philippine General Hospital. This highlights the need for prioritizing a public health approach to violence prevention in the Philippines. Further research must be conducted to identify risk factors for interpersonal violence. Early identification of lethal injuries that may cause exsanguinations and definitive control of hemorrhage should be the primary focus to prevent acute deaths, within 24 hours of admission. Further adjuncts to the definitive treatment of hemorrhage, the critical care of TBI and MOF/Sepsis are needed to reduce deaths occurring more than 72 hours after admission.

1114. Cook, S., et al. (2018). "Crosstalk between Estrogen Withdrawal and NFkappaB Signaling following Penetrating Brain Injury." Neuroimmunomodulation 25(4): 193-200.

OBJECTIVES: Characterized by neuroinflammation, traumatic brain injury (TBI) induces neuropathological changes and cognitive deficits. Estrogens are neuroprotective by increasing cell survival and this increase is mediated by a decrease in neuroinflammation. To further explore the relationship between estrogens, brain injury, and neuroinflammation, we examined the expression of the IKK/NFkappaB complex. The IKK/NFkappaB complex is a pleiotropic regulator of many cellular signaling pathways linked to inflammation, as well as three major cytokines (IL-1beta, IL-6, and TNF-alpha). We hypothesized that NFkappaB expression would be upregulated following injury and that this

increase would be exacerbated when circulating estrogens were decreased with fadrozole (aromatase inhibitor)., METHODS: Using adult zebra finches, we first determined the expression of major components of the NFkappaB complex (NFkappaB, IkappaB-alpha, and IkappaB-beta) following injury using qPCR. Next, male and female finches were collected at 2 time points (2 or 24 h after injury) and brain tissue was analyzed to determine whether NFkappaB expression was differentially expressed in males and females at either time point. Finally, we examined how the expression of NFkappaB changed when estrogen levels were decreased immediately after injury., RESULTS: Our study documented an increase in the expression of the major components of the NFkappaB complex (NFkappaB, IkappaB-alpha, and IkappaB-beta) following injury. Decreasing estrogen levels resulted in a surprising decrease in the NFkappaB complex studied here., DISCUSSION: These data further expand the model of how estrogens and other steroid hormones interact with the inflammatory pathways following injury and may prove beneficial when developing therapies for treatment of TBI. 1115. Cooke, C. T. and D. J. Pounder (1988). "Spinocerebral faecal migration in a shotgun injury." The American journal of forensic medicine and pathology 9(2): 166-168.

Migration of foreign material within the subarachnoid space is a rare event, seldom reported in the medical literature. We report a unique case in which spinocerebral migration of faecal material occurred as a direct consequence of a shotgun injury to the pelvis.

1116. Cooper, J. A. and C. J. Hunter (2013). "Jael's syndrome: Facial impalement." Western Journal of Emergency Medicine 14(2): 158-160.

1117. Cooper, P. R., et al. (1979). "Computerized tomographic scan and gunshot wounds of the head: indications and radiographic findings." Neurosurgery 4(5): 373-380.

The authors document their experience with the computerized tomographic (CT) scanner for evaluating gunshot wounds of the head. Only those patients who were considered to be operative candidates and who were neurologically stable were scanned. In the postoperative period, patients who were not scanned preoperatively and those whose condition did not improve were also scanned. In the preoperative period the CT scanner is useful for identifying and localizing missile tracks, bony and metallic fragments, intra- and extraparenchymal hematomas, intracranial air, and brain swelling. In the postoperative period the CT scanner may demonstrate retained bone fragments, edema, brain abscess, and intracranial air. The limitations of the CT scan in evaluating gunshot wounds include an inability to define vascular lesions suchas traumatic aneurysms and post-traumatic spasm. Metallic scatter from missile fragments may render certain CT cuts uninterpretable. In addition, the CT scan may appear minimally abnormal in spite of immediate and irreversible injury caused by a shock wave transmitted to brain stem structures. The CT scanner has superceded angiography as a diagnostic tool for evaluating gunshot wounds of the head because it is noninvasive and rapid, allows visualization of the entire head, can resolve very small lesions that produce little or no mass effect, can help to determine the nature of intracranial lesions and may quantitate the amount of hemorrhage and edema. Because it enables physicians to visualize intracranial structures in three dimensions, the CT scan may precisely define missile tracks and contiguous lesions in a manner not heretofore possible with other diagnostic modalities. Thus, it is invaluable for the rational planning of surgical therapy.

1118. Copcu, E., et al. (2003). "Reconstruction of facial gunshot wound by the cervicopectoral flap." European Journal of Trauma 29(1): 54-57.

Background: Reconstruction of large facial defects secondary to shotgun blast to the face is a very difficult task in surgery. Case Study: We report on a 34-year-old female patient with suicidal

shotgun injury to her face delivered by a hunting rifle at close range into her mouth. She showed a large right cheek defect and a mandibular fracture. The defect was closed by a cervicopectoral fasciocutaneous flap; the mandibular fracture was managed with a titanium reconstruction plate. Good aesthetic and functional results were achieved 1 year after reconstruction. Conclusion: Early definitive reconstruction of shotgun injuries is still controversial. The cervicopectoral flap has many advantages. It is easy and secure to harvest and possesses skin properties similar to the face. The flap is quite thin allowing soft tissue coverage without a bulky view. This is the first study in the literature using a cervicopectoral flap for closure of a facial gunshot wound. We conclude that in patients with facial gunshot wounds, early reconstruction with a cervicopectoral flap offers a very important alternative.

1119. Copcu, E., et al. (2004). "Trauma and Fracture of the Mandible: Effects of Etiologic Factors on Fracture Patterns." European Journal of Trauma 30(2): 110-115.

Background: The mandible is one of the most frequently fractured bones. The objective of this prospective study was to determine and illustrate fracture patterns of the mandible in relation to various etiologic factors. Patients and Methods: A total of 218 patients with mandibular fractures were included in this study. Data regarding age, gender, causes and anatomic sites of fractures and treatment modalities were collected. Conventional plain radiographs of the mandible were obtained in all patients. The plain radiographs included such projections as Towne and Waters in patients suspected of having subcondylar fractures or associated facial fractures. Radiographs were scanned using a high-resolution scanner, and fracture lines were marked. The lines were copied and pasted to a graphic image of the mandible. All fracture lines were confirmed on surgical explorations of the fractures when the patients were under general anesthesia. Results: Traffic accidents (67%) were the most frequent cause of mandibular fractures. 51% of the patients had multiple fractures including fractures of the parasymphysis and angle, which were the most commonly affected sites (33.3%). 49% of the patients had a single fracture. The body of the mandible was the most frequently affected site in these patients (26.2%). Conclusion: Weak points of the mandible and etiologic factors were the determinants of mandibular fracture sites. We speculate that the main determinants of fracture sites were characteristics of the mandible in those fractures caused by motor vehicle accidents, while the other etiologic factors themselves determined the fracture sites for the other types of trauma.

1120. Copeland, A. R. (1989). "Suicide among nonwhites. The Metro Dade County experience, 1982-1986." The American journal of forensic medicine and pathology 10(1): 10-13.

Suicide among nonwhites was studied using the case files of the office of the Medical Examiner of Metropolitan Dade County in Miami, Florida. A total of 116 cases, during the years 1982-1986, were analyzed as to the age, sex, cultural background, cause of death, blood alcohol content at autopsy, and reason for the suicide of the victim. By analyzing the ethnic/cultural backgrounds of the victims, it was noted that the overall rate of suicide among nonwhites in Dade County was 5 per 100,000 population per year. However, the rate varies within the overall group such that black-Hispanics, American Indians, and Haitians have suicide rates of 13.9, 11, and 3.1 per 100,000 population per year, respectively. Some of these rates are higher than the U.S. national nonwhite suicide rate of 7 per 100,000 population. Interestingly, while suicide rates are variable, the reasons listed for the suicide and the high frequency of young adult victims are similar to those for whites. A discussion ensues concerning this similarity and what future work in the field remains to be done.

1121. Copley, I. B. (1990). "Remarkable recovery after a cranio-cerebral injury produced by an impacted hot missile fragment: apparent 'regeneration' of the temporal lobe." British journal of neurosurgery 4(6): 523-527.

A facio-cranio-cerebral injury due to a large piece of shrapnel causing direct and heat damage to the temporal lobe is described. It was managed by initial dural repair which was followed by sloughing

and repeated wound debridement, leaving an open cerebral wound communicating with a facial wound. Auto-rotation of the temporal lobe occurred, allowing split-skin grafting onto arachnoid mater to obtain dural closure. Further treatment of the facial wound by skin-grafting the cavity and prosthetic reconstruction allowed early return to society and a full rehabilitation programme.

1122. Copley, I. B. (1991). "Cranial tangential gunshot wounds." British journal of neurosurgery 5(1): 43-53.

The effects of high velocity missiles are described. A series of cases of craniocerebral tangential gunshot wounds over a 6 year period is presented with unsuspected cerebral contusion shown by CT. Tangential wounds are defined and classified into four groups. The associated brain damage, often unsuspected prior to CT, and in some cases without radiographic changes, of the four groups is compared. The short- and long-term sequelae and the extent of cerebral damage belie the innocent appearance of the scalp wound. This influences the management of this unusual type of head injury.

1125. Cordelier, P. and D. S. Strayer (2006). "Using gene delivery to protect HIV-susceptible CNS cells: inhibiting HIV replication in microglia." Virus research 118(1-2): 87-97.

Antiretroviral chemotherapy penetrates the CNS poorly. CNS HIV, thus sheltered, may injure the brain and complicate control of systemic HIV infection. Microglial cells play a major role in HIV persistence in the CNS but are rarely targeted for gene delivery. Because recombinant SV40 vectors (rSV40s) transduce other phagocytic cells efficiently, we tested rSV40 delivery of anti-HIV genetic therapy to microglial cells. Microglia prepared as enriched cultures from human fetal brain, were transduced with marker vectors, SV(RFP) and SV(Nef/FLAG), respectively, carrying DsRed and HIV-1 Nef bearing a FLAG epitope. By immunostaining and FACS, 95% of unselected cells expressed the transgenes, without detectable toxicity. Microglia were transduced with SV(AT), carrying human alpha1-antitrypsin (alpha1AT), which blocks Env and Gag processing. SV(AT)-treated microglia strongly resisted challenge with HIV-1BaL, even when microglia were transduced with SV(AT) following HIV challenge. Thus, rSV40s effectively transduce microglia and protect them from HIV.

1127. Corkin, S., et al. (1984). "Prognostic factors for life expectancy after penetrating head injury." Archives of neurology 41(9): 975-977.

Survival curves were made for 190 World War II veterans with penetrating head injuries, and for 106 WW II veterans with peripheral nerve injuries who matched the subjects with head injuries with respect to age at injury, years of formal education, and preinjury intelligence-test score. The results indicated that penetrating head injury coupled with posttraumatic epilepsy shortened life expectancy in subjects who survived the early postinjury period, but that head injury alone did not. Educational level was also a significant variable independent of seizures: subjects with more education survived longer than those with less education. Age at injury and the difference between preinjury and postinjury intelligence-test scores did not predict survival status.

1129. Cornetta, S., et al. (2009). "Unusual death of a transvestite: identification of crime weapon and survival time*." Journal of forensic sciences 54(5): 1149-1151.

The authors report a case of a transvestite found murdered near his automobile with several lacerated contused wounds to the face and cranial fractures. Autopsy revealed that the cause of death was a serious head trauma with subdural and subarachnoidal hemorrhages. In order to identify the crime weapon, a scanning electron microscopy (SEM) was used which revealed metallic residue on the skin fragments with the same molecular composition of the car paint. As for survival time, antibody anti-beta-amyloid precursor protein (APP) was applied to brain fragments and brainstem tissue, allowing for axonal varicosities (which form 2 to 3 h following death) to be observed under the optic microscope. So, by using SEM we understood that the fatal cranial-encephalic lesions were the result of the victim's head being repeatedly struck against the car door while anti-betaAPP led to the understanding that the time elapsed between injury and death was less than 2 to 3 h.

1130. Cornford, E. M., et al. (1996). "Glut1 glucose transporter activity in human brain injury." Journal of neurotrauma 13(9): 523-536.

The principal glucose transporter at the blood-brain barrier (BBB) is the Glut1 isoform, and transporter density is believed to be an index of cerebral metabolic rate. In the present study, glucose transporter expression was studied in tissue resected 7-8 h after acute traumatic brain injuries in 2 patients. Light microscopic immunochemistry indicated a zone of complete loss of the Glut1 glucose transporter isoform in microvessel endothelial cells adjacent to sites of small vessel injury, concentrically surrounded by a narrow zone of variable Glut1, and distally surrounded by capillaries with typically immunoreactive endothelia in nondisrupted parenchyma. Variably reactive capillaries displayed alternating sectors of greatly reduced and highly reactive Glut1 density, suggesting a high density and low density of transporter activity in contiguous endothelial cells. Quantitative electron microscopic immunogold analyses demonstrated that the transporter was predominantly localized to the luminal and abluminal endothelial membranes, with lesser reactivity in cytoplasm; pericyte Glut1 was minimally above background levels. In endothelial sectors with reduced Glut1 transporter immunoreactivity, the luminal:abluminal ratio of Glut1 epitopes was less than unity; while it is greater than unity in highly reactive endothelial cells. The number of Glut1-immunoreactive sites per micrometer of capillary membrane was not significantly different from previous reported Glut1 density in seizure resections, and about 2- to 3-fold higher than in human red cells. In the same tissue samples, qualitative immunogold electron microscopy of human serum albumin indicated leakage of this protein (MW 65,000) from the vascular space into pericapillary regions. Thus the high Glut1 density observed in capillaries from acutely injured brain occurs concomitantly with compromised barrier function.

1131. Coronado, V. G., et al. (2011). "Surveillance for traumatic brain injury-related deaths--United States, 1997-2007." Morbidity and mortality weekly report. Surveillance summaries (Washington, D.C. : 2002) 60(5): 1-32.

PROBLEM/CONDITION: Traumatic brain injury (TBI) is a leading cause of death and disability in the United States. Approximately 53,000 persons die from TBI-related injuries annually. During 1989-1998, TBI-related death rates decreased 11.4%, from 21.9 to 19.4 per 100,000 population. This report describes the epidemiology and annual rates of TBI-related deaths during 1997-2007., REPORTING PERIOD: January 1, 1997-December 31, 2007., DESCRIPTION OF SYSTEM: Data were analyzed from the CDC multiple-cause-of-death public-use data files, which contain death

certificate data from all 50 states and the District of Columbia., RESULTS: During 1997-2007, an annual average of 53,014 deaths (18.4 per 100,000 population; range: 17.8-19.3) among U.S. residents were associated with TBIs. During this period, death rates decreased 8.2%, from 19.3 to 17.8 per 100,000 population (p = 0.001). TBI-related death rates decreased significantly among persons aged 0-44 years and increased significantly among those aged >=75 years. The rate of TBI deaths was three times higher among males (28.8 per 100,000 population) than among females (9.1). Among males, rates were highest among non-Hispanic American Indian/Alaska Natives (41.3 per 100,000 population) and lowest among Hispanics (22.7). Firearm- (34.8%), motor-vehicle- (31.4%), and fall-related TBIs (16.7%) were the leading causes of TBI-related death. Firearm-related death rates were highest among persons aged 15-34 years (8.5 per 100,000 population) and >=75 years (10.5). Motor vehicle-related death rates were highest among those aged 15-24 years (11.9 per 100,000 population). Fall-related death rates were highest among adults aged >=75 years (29.8 per 100,000 population). Overall, the rates for all causes except falls decreased., INTERPRETATION: Although the overall rate of TBI-related deaths decreased during 1997-2007, TBI remains a public health problem; approximately 580,000 persons died with TBI-related diagnoses during this reporting period in the United States. Rates of TBI-related deaths were higher among young and older adults and certain minority populations. The leading external causes of this condition were incidents related to firearms, motor vehicle traffic, and falls., PUBLIC HEALTH ACTIONS: Accurate, timely, and comprehensive surveillance data are necessary to better understand and prevent TBI-related deaths in the United States. CDC multiple-cause-of-death public-use data files can be used to monitor the incidence of TBI-related deaths and assist public health practitioners and partners in the development, implementation, and evaluation of programs and policies to reduce and prevent TBI-related deaths in the United States. Rates of TBI-related deaths are higher in certain population groups and are primarily related to specific external causes. Better enforcement of existing seat belt laws, implementation and increased coverage of more stringent helmet laws, and the implementation of existing evidence-based fall-related prevention interventions are examples of interventions that can reduce the incidence of TBI in the United States.

1132. Corradino, G., et al. (1988). "Traumatic carotid-cavernous fistula." Southern medical journal 81(5): 660-663.

Carotid-cavernous fistulas are uncommon, although not rare, complications of trauma to the base of the skull; they may result in cranial nerve palsies, blindness, and occasionally in devastating subarachnoid hemorrhage. We have presented a case of carotid-cavernous fistula in a 17-year-old boy, treated successfully with balloon embolization. Although surgical treatment was advocated in the past, the low morbidity and high success rate of percutaneous balloon embolization currently make this the procedure of choice.

1133. Coruh, A. (2019). "High Voltage Electric Burn Repair of the Forehead by Reverse Flow Temporalis Muscle Flap." Journal of burn care & research : official publication of the American Burn Association 40(3): 373-376.

Repairing soft tissue defects of the forehead which exposes the bare bone is a dilemma with few reconstructive techniques for plastic surgeons. Forehead is an important aesthetic unit of the face which is covered with the glabrous skin. Due to the relative lack of similar mobile tissue locally, reconstruction of large soft tissue defects of the forehead region by local flaps is demanding. Temporalis muscle flap does not reach to the midline of the forehead region because of the insufficient length of the deep temporal vascular system. During the transfer of the muscle, only a small volume and size of the muscle can reach to the defect, remaining most of the muscle bulk in the pedicle and a relatively limited arc of rotation, thus a small volume of usable tissue at the distal portion of the flap. We successfully used reverse flow temporalis muscle flap for the purpose of eliminating the above-mentioned disadvantage of temporalis muscle flap in a 23-year-old male patient who sustained a high-voltage electrical burn

resulting 12 x 8 cm left forehead defect exposing the bare bone.

1134. Cosan, T. E., et al. (2006). "Peripheral seventh nerve palsy due to transorbital intracranial penetrating pontine injury." European archives of oto-rhino-laryngology : official journal of the European Federation of Oto-Rhino-Laryngological Societies (EUFOS) : affiliated with the German Society for Oto-Rhino-Laryngology - Head and Neck Surgery 263(4): 327-330.

The case of a child injured by a knitting needle penetrating transorbitally and intracranially, resulting in carotid cavernous fistula and pontine injury, is reported. After receiving medical and endovascular treatment, the only remaining abnormal neurological manifestation was right peripheral facial nerve palsy. The clinical sequences of events and the demonstration of a pontine lesion leading to peripheral facial palsy are presented. Facial nuclear injury with a penetrating trauma is an extremely rare condition. It is important to identify the anatomical regions injured in penetrating traumas. The lesions must be identified by computerized tomography, magnetic resonance imaging, clinical and laboratory investigation.

1135. Cosan, T. E., et al. (2001). "Injury caused by deeply penetrating knife blade lodged in infratemporal fossa." European journal of emergency medicine : official journal of the European Society for Emergency Medicine 8(1): 51-54.

Knife-inflicted, deeply penetrating head and neck trauma is an uncommon life-threatening injury and a challenging problem. An examination of the neurovascular and systemic physical status is a first requirement and the decision as to which approach to adopt for the removal of the blade is of critical importance. Here we report a rare case of a pre-auricular stab wound with the knife blade deeply lodged in the extracranial infratemporal fossa. Radiological investigations showed that the knife blade had entered from the temporomandibular joint and become lodged through the anterior margin of foremen magnum below the petrosal bone. Minimal left vocal cord paresis, left palatal weakness and a slight deviation of the tongue towards the left side were observed. The other neurological and systemic physical evaluations were normal. Simple withdrawal of the blade in the operating room did not cause serious neurovascular injury. Here we discuss and compare the expanded exposure of anatomical structures for blade removal and simple withdrawal in similar injuries.

1136. Cosar, A., et al. (2005). "Craniocerebral gunshot wounds: results of less aggressive surgery and complications." Minimally invasive neurosurgery : MIN 48(2): 113-118.

Four hundreds patients who suffered from cranial gunshot wounds injuries were analyzed. Surgical therapy, primary and secondary debridement, including repair of dural defects and removal of retained intracranial bone and metal fragments were applied. Central nervous system infections were mostly observed in cases with cerebrospinal fluid (CSF) fistulas. In 130 of 400 patients, bone and metal fragments were determined on control CT scans. Most of the deaths in this group of patients were attributed to the influence of brain injury and occurred within the first month after injury. Fragments retained after first debridement were followed periodically by CT scans. Surgery was not performed until the infection developed. Retained fragments did not increase the infection risk but high rates of infection did occur in cases with CSF fistulas. The presence of diffuse brain damage, brainstem injury, CNS infection, or ventricular injury was associated with a poor outcome. The prognostic importance of complications such as intracranial haemorrhage, epileptic seizures, hydrocephalus, was also investigated.

1137. Coscia, A., et al. (2019). "Use of the sports concussion assessment tool 3 in emergency department patients with psychiatric disease." Academic emergency medicine 26: S91.

Background: There are no assessments of concussion specialized for the ED setting. One commonly used tool is the Sports Concussion Assessment Tool 3 (SCAT3) Concussion Symptom Severity Score (CSSS). The SCAT3 has not been validated for use in non-athlete populations. We aimed to determine the relationship between psychiatric history, and SCAT3 CSSS score. We hypothesized that subjects with a history of psychiatric disorders would have a higher CSSS score compared to those without. Methods: This was an analysis from a prospective, non-randomized, non-blinded, multicenter study of adults with suspected concussion (BrainPulseTM Jan Medical) from three US EDs. Subjects with a penetrating injury to the brain, Glasgow Coma Score (GCS) < 13, or medical device in the head were excluded. Demographic data, a BrainPulse device recording, the SCAT3, a neurologic exam, and a cognitive test were obtained. Subjects with depression, anxiety, bipolar disease, post-traumatic stress disorder, schizophrenia, and/or taking medications for psychiatric disease were classified as having pre-injury psychiatric history. The association between SCAT3 CSSS score and psychiatric disorder was analyzed using multivariable median regression. Bivariate associations between CSSS and potential predictors were first explored via a Mann-Whitney U test. Stepwise backward elimination was used to develop a final model. Results: Of 305 adult subjects, 262 had no missing data. Mean age was 44 (SD 19), the median CSSS score was 32.5 (IQR 15-62), 133 (51%) were female, 206 (79%) were Caucasian. A total of 174/262 (66%) were diagnosed with concussion and 151/262 (58%) had psychiatric history. Psychiatric history (ppp<0.05) were all independently associated with higher CSSS. Subjects with psychiatric history scored 16.8 points (95 CI 6.73, 26.79) higher on the CSSS after controlling for age, sex, race, and concussion diagnosis. A subject with a concussion diagnosis in the ED scored 19.5 points (95 CI 8.54, 30.46) higher on the CSSS after controlling for psychiatric history, age, sex, and race. Conclusion: Subjects with a history of psychiatric disorders had a higher CSSS compared to those without. These data suggest the CSSS component of the SCAT3 may need to be tailored for use in an ED population with psychiatric comorbidities.

1138. Costa, S. T., et al. (2017). "Systematic review of finite element analysis utilisation in craniofacial gunshot wounds." Australian Journal of Forensic Sciences 49(4): 369-378.

The study of wound ballistics should include biomechanical science for better results in diagnosis, treatments and prognosis. Finite Element Analysis can provide interesting tools when human head injuries need to be evaluated. This work is the first step in a systematic study of the use of finite element analysis in craniofacial gunshot wounds. The study aimed to systematically: (1) review the use of Finite Element Analysis on heads injuries, especially gunshot wounds; (2) review the safety of using standard patterns of Finite Element Analysis; and (3) analyse and discuss the advantages and deficiencies of finite element models. Electronic research databases, Pubmed, Scopus and Web of Knowledge, were searched using the restricted key words: finite element gunshot. Studies were included if they reported finite element analysis in heads, simulating gunshot injuries. Excluded studies were those that did not clearly describe their methods and results, had significant discrepancies, were not published in the English language or were not published yet. There were 30 references identified by the bibliographic search strategy. Fourteen manuscripts were eligible for inclusion and were fully critically appraised. The collected data were able to furnish details about the simulations as well as some variables that may affect the predictive accuracy of the simulation.

1139. Costanzo, C., et al. (2011). "Brain abscess in seven cats due to a bite wound: MRI findings, surgical management and outcome." Journal of feline medicine and surgery 13(9): 672-680.

UNLABELLED: PRESENTATION AND LESION LOCALISATION: Seven adult domestic shorthair cats were presented with a 1- to 6-day history of progressive neurological signs. A focal skin puncture and subcutaneous swelling over the dorsal part of the head were detected on physical examination. Neurological examination indicated lesion(s) in the right forebrain in four cats, multifocal forebrain in one cat, left forebrain in one cat, and multifocal forebrain and brainstem in the remaining cat. In all cats, magnetic resonance imaging revealed a space-occupying forebrain lesion causing a

severe mass effect on adjacent brain parenchyma. CLINICAL APPROACH AND OUTCOME: All cats were managed with a combination of medical and surgical treatment. At surgery a small penetrating calvarial fracture was detected in all cats, and a tooth fragment was found within the content of the abscess in two cats. The combination of surgical intervention, intensive care and intravenous antimicrobials led to a return to normal neurological function in five cats., PRACTICAL RELEVANCE: As this series of cases indicates, successful resolution of a brain abscess due to a bite injury depends on early recognition and combined used of antimicrobials and surgical intervention. A particular aim of surgery is to remove any skull and foreign body (tooth) fragments that may represent a continuing focus of infection.

1140. Costello, B. J., et al. (2000). "Distraction osteogenesis for the reconstruction of traumatic defects." Journal of Cranio-Maxillofacial Trauma 6(2): 47-52.

Background and Objectives. Distraction osteogenesis has become popular in recent years as a means to reconstruct congenital defects and deformities. These techniques may also be used to reconstruct traumatic deformities. The distraction techniques offer volumetric expansion of a deficient site that may be difficult to reconstruct using any other method. Method and Materials. The basic concepts, indications, and application of distraction osteogenesis are reviewed. Two clinical cases are presented in which distraction osteogenesis was utilized to reconstruct traumatic defects and deformities. The advantages of distraction osteogenesis for defect reconstruction are discussed. Results and/or Conclusions. Distraction osteogenesis techniques afford the clinician the ability to overcome obstacles that render traditional reconstructive methods difficult and/or unpredictable. They obviate the need for a donor site and provide improved soft tissue coverage by volumetric tissue expansion. The application of these new devices and techniques provides the reconstructive surgeon numerous options for traumatic defect repair. In some cases, these options may offer significant advantages over the traditional techniques.

1141. Cote, M. N., et al. (2011). "Nutritional support in severe traumatic brain injury." Critical Care 15: S133.

Introduction: Clinical guidelines recommend full caloric replacement within 7 days after severe traumatic brain injury (TBI) since it may improve clinical outcomes. However, enteral feeding is often poorly tolerated in this population. We hypothesized that most patients with severe TBI do not receive adequate caloric and protein intake. Methods: We performed a retrospective cohort study of randomly selected patients with severe TBI (GCS ≤8) identified with ICD-10 codes and admitted to a 24-bed ICU of a Canadian level 1 trauma center between January 2005 and December 2006. We excluded patients <16 years old, with penetrating TBI or mechanically ventilated for <48 hours. Using a standardized pretested case report form, we collected daily kilocalories and proteins (ordered and received), sedation, use of prokinetic drugs and post-pyloric access. The primary endpoint was achievement of ≥90% of caloric and protein requirement within 7 days. Secondary endpoints were factors associated with achievement of nutritional goals and with gastric intolerance (one episode of residuals ≥250 ml/4 hours). A sample size of 100 patients was required to obtain a margin of error of 9%. Student t and chi-square tests were used to compare continuous data and proportions. We obtained ethics approval. Results: Among the 109 patients included, 82.6% were men (mean age 40.5 ± 20.5 years, GCS 3.7 ± 1.3 and BMI 25.3 ± 5.1 kg/m2). Patients had 1,204 potential feeding days. Ninety-six patients (88.1%) were fed by day 3. Mean caloric and protein orders were 32.6 ± 4.8 kcal/kg and 1.4 ± 0.2 g/kg, respectively. Two patients never received enteral nutrition. Nutrition was started at a mean rate of 32.6 ± 9.3% of the nutritional goal using the stomach as the initial access in 97.2%. The achievement of caloric, protein and both requirements was successful in 48 (44.0%, 95% CI = 34.7 to 53.4%), 64 (58.7%, 95% CI = 49.5 to 68.0%) and 42 (38.5, 95% CI = 29.4 to 47.7%) patients during the first week. The most associated factor with unsuccessful nutrition was gastric intolerance (RR = 1.40. 95% CI = 1.11 to 1.88, P <0.01), which occurred in 49.5% patients. Factors associated with gastric intolerance were young age (P <0.001),

increased intracranial pressure (P <0.001), high opioid doses (P = 0.004) and nonuse of prokinetic drugs (P = 0.05). Conclusions: Most patients with severe TBI did not achieve nutritional goals within 7 days, partially due to high gastric residuals. Although we identified factors associated high gastric residuals, improving feeding tolerance is unlikely to be the only intervention to significantly improve nutritional intakes.

1142. Cotner, B., et al. (2017). "Quality of sleep in caregivers of service members and veterans with traumatic brain injury." Archives of physical medicine and rehabilitation 98(10): e97-e98.

Research Objectives: To examine sleep quality in persons who provide care to Service Members and Veterans (SMV) with traumatic brain injury (TBI).DesignA mixed method study. Setting: Focus group participants were recruited through community outreach initiatives and multiple Department of Defense medical treatment facilities nationwide. Focus groups were held at Walter Reed National Military Medical Center. Participants: 31 caregivers of SMVs who had sustained a TBI participated in one of six focus groups (approx. 90 mins). Participant were female (90.3%), spouses (71%) with spouse; Age: M=39.8 years, SD=10.6). Interventions: Not applicable.Main Outcome Measure(s)Quality of sleep of caregivers of persons with TBI. Results: Almost half (45.2%) of the caregivers reported having sleep problems. Caregivers described four types of sleep issues: 1) Cannot sleep, and in some cases, using medication to assist; 2) Cannot fall asleep due to being “wound up” 3) Waking up often during the night due to SMV being awake and/or worrying; and 4) Waking up tired from poor quality of sleep in general.Conclusion/DiscussionThese results suggest that there is a high incidence of caregivers of SMVs with TBI experiencing sleep problems. While caregivers of SMVs with moderate-severe and penetrating TBIs were the most prevalent group to report sleep issues, caregivers of SMVs with equivocal mild and mild TBIs also reported sleep issues indicating that inadequate sleep is common for this population of caregivers. The main limitation to this study is that the case examples rely on a small number of focus group interviews. Given this limitation, results should be considered preliminary.

1143. Coughlan, A. K. and E. K. Warrington (1978). "Word-comprehension and word-retrieval in patients with localized cerebral lesions." Brain : a journal of neurology 101(1): 163-185.

1144. Coughlan, M. D., et al. (2003). "Craniocerebral gunshot injuries in children." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery 19(5-6): 348-352.

INTRODUCTION: Despite the worldwide increase in the incidence of gunshot injuries, there are few large published series on craniocerebral gunshot injuries in children., MATERIALS AND METHODS: The records of 30 consecutive children who were treated for craniocerebral gunshot injuries at the Red Cross War Memorial Children's Hospital from 1989 to 2002 were reviewed retrospectively. The circumstances of the injury, clinical status, CT findings, complications, and outcome were assessed., RESULTS: The median age was 7 years. Seventy-seven percent of the victims were boys. The majority of the children were injured in the crossfire of civilian violence. The initial management consisted of debridement under local anesthesia in 16 children and neurosurgical procedures under general anesthesia were performed in 14. Sixteen children sustained transhemispheric injuries, 5 bihemispheric injuries, 5 tangential injuries, and 4 transventricular injuries. All 3 children with a GCS <4 died within 72 h of admission. Three of the 7 children with GCS 4-7 died but there were no deaths in those children whose GCS was >7 post-resuscitation. Motor deficits, cranial nerve palsies, and visual field defects were very common. Early post-traumatic seizures were the commonest complication (18%)., CONCLUSION: Children with higher post-resuscitation GCSs fared better than adults in terms of mortality but not necessarily morbidity. As in the case with adults, the GCS after resuscitation is a very good prognostic indicator of mortality.

1145. Couper, G. W., et al. (2000). "Unguarded electric plugs cause penetrating head injuries in children." Journal of accident & emergency medicine 17(1): 55.

1146. Coupland, R. M. and P. E. Pesonen (1992). "Craniocerebral war wounds: non-specialist management." Injury 23(1): 21-24.

The non-specialist management of 28 craniocerebral war wounds is described. Of these, 26 were operated upon of which three died. Two of the survivors developed wound abscesses in the early postoperative period. None developed epilepsy while in hospital. Aspects of the operative management are discussed.

1147. Courtney, A. and M. Courtney (2015). "The Complexity of Biomechanics Causing Primary Blast-Induced Traumatic Brain Injury: A Review of Potential Mechanisms." Frontiers in neurology 6: 221.

Primary blast-induced traumatic brain injury (bTBI) is a prevalent battlefield injury in recent conflicts, yet biomechanical mechanisms of bTBI remain unclear. Elucidating specific biomechanical mechanisms is essential to developing animal models for testing candidate therapies and for improving protective equipment. Three hypothetical mechanisms of primary bTBI have received the most attention. Because translational and rotational head accelerations are primary contributors to TBI from non-penetrating blunt force head trauma, the acceleration hypothesis suggests that blast-induced head accelerations may cause bTBI. The hypothesis of direct cranial transmission suggests that a pressure transient traverses the skull into the brain and directly injures brain tissue. The thoracic hypothesis of bTBI suggests that some combination of a pressure transient reaching the brain via the thorax and a vagally mediated reflex result in bTBI. These three mechanisms may not be mutually exclusive, and quantifying exposure thresholds (for blasts of a given duration) is essential for determining which mechanisms may be contributing for a level of blast exposure. Progress has been hindered by experimental designs, which do not effectively expose animal models to a single mechanism and by over-reliance on poorly validated computational models. The path forward should be predictive validation of computational models by quantitative confirmation with blast experiments in animal models, human cadavers, and biofidelic human surrogates over a range of relevant blast magnitudes and durations coupled with experimental designs, which isolate a single injury mechanism.

1148. Covelli, E., et al. (2006). "Unknown posttraumatic foreign body in facial region." The Journal of craniofacial surgery 17(1): 191-194.

This study emphasizes the importance of scrupulous diagnostic first aid procedures to avoid the consequences of trauma due to a foreign body. Two patients were examined, both with facial trauma showing nonspecific symptoms. Through objective internal and external oral examination complete with clinical and radiographic examinations Three dimensional computed tomography (TC3D), foreign bodies unknown at the time of the trauma were identified. When the foreign bodies had been removed, the ache symptoms disappeared, restoring functionality and the patient's facial appearance. This study shows the need for detailed early diagnosis to achieve correct monitoring and therefore proper treatment for these patients.

1149. Cowley, R. A., et al. (1979). "The subcellular pathology of shock in trauma patients: studies using the immediate autopsy." The American surgeon 45(4): 255-269.

In summary, our immediate autopsy program provides a new tool for investigating the pathophysiologic effects of shock and trauma at the cellular and subcellular levels. By minimizing the time delay between death and tissue sampling with this technique, we have demonstrated the feasibility of validly applying the refinements of electron microscopy, histochemistry and analytical biochemistry

to human tissue. Qualitative, semi-quantitative and quantitative data with these techniques have been integrated with clinical, physiologic and chemical studies on these patients during life. Cell injury produces an altered steady state of metabolism within the cell, evidence of which is seen in altered ultrastructure. If the injury is too severe, the cell will pass the "point-of-no-return," at which time the changes in the cell are no longer compatible with life and the cell dies and undergoes necrosis. Although the initiating injury and the patterns of the altered steady state may vary, once the cell has passed the "point-of-no-return," the patterns of cell injury regardless of the initial insult, are similar. We believe that the cellular patterns seen in patients dying from shock and trauma are remarkably similar to those produced by hypoxic tissue injury in experimental systems. Tissue from control patients in whom ischemic injury due to episodes of hypotension did not occur show good morphologic preservation with normal mitochondria and other cell organelles. Tissue from patients who have experienced acute shock consisting of a period of hypotensive ischemia show changes in the mitochondria and ER compatible with the experimental picture of hypoxia: i.e., dilated ER, with loss of ribosomes, swelling of mitochondria and the appearance of flocculent densities in the mitochondria. Tissues taken from the patients who had experienced repeated episodes of shock, whom we designated as those in "chronic shock," showed changes paralleling the acute changes, but also showed much evidence of autophagocytosis as a) the cells attempted to achieve a lower metabolic requirement in order to survive, and b) they attempted to "clean-up" and remove altered and damaged organelles and debris from previous bouts with sublethal ischemic injury. We hope that the increased knowledge of tissue and cellular injury obtained by the immediate autopsy will provide a means of integration, hypothesis formation and testing of the vast knowledge of cell biology and pathology, and the opportunity for developing in the human the potential for testing new hypotheses in model systems resulting in immediate and innovative feedback for the patient in terms of diagnosis, functional monitoring and treatment.

1150. Cox, M. W., et al. (2007). "Traumatic pseudoaneurysms of the head and neck: early endovascular intervention." Journal of vascular surgery 46(6): 1227-1233.

BACKGROUND: Trauma to the head and neck with military munitions often presents with complex multisystem injury patterns. Vascular evaluation typically focuses on the carotid and vertebral arteries; however, trauma to branches of the external carotid artery may also result in devastating complications. Pseudoaneurysms are the most frequent finding on delayed evaluation and can result in life-threatening episodes of rebleeding., METHODS: Patients evacuated from the Afghanistan and Iraq conflicts with penetrating injury to the face and neck were evaluated by the vascular surgery service to determine the potential for unsuspected vascular injury. Patients with significant penetrating injury underwent computed tomography angiography (CTA) as the initial evaluation and subsequent arteriography in cases where injuries were suspected or metallic fragments produced artifacts obscuring the vasculature. Data on all vascular evaluations were entered prospectively into a database and retrospectively reviewed., RESULTS: Between February 2003 and March 2007, 124 patients were evaluated for significant penetrating trauma to the head and neck. Thirteen pseudoaneurysms of the head and neck were found in 11 patients: two in the internal carotid artery, one of the vertebral artery, and 10 involving branches of the external carotid. Seven pseudoaneurysms were symptomatic, of which two presented with episodes of massive bleeding and airway compromise. Seven pseudoaneurysms were treated with coil embolization, 1 with Gelfoam (Upjohn, Kalamazoo, Mich) embolization, 2 with stent grafts, 2 with open repair, and 1 with observation alone. None of the patients undergoing embolization had complications; however, a stent graft of the internal carotid artery occluded early, without stroke. All of the pseudoaneurysms had resolved on follow-up CTA or angiogram., CONCLUSIONS: Pseudoaneurysms are a common finding in patients with high-velocity gunshot wounds or blast injuries to the head and neck. Most involve branches of the external carotid artery and can be treated by embolization. CTA should be performed on all patients with high-velocity gunshot wounds or in cases of blast trauma with fragmentation injuries of the head and neck.

1151. Crandon, I. W., et al. (2004). "Civilian cranial gunshot wounds: a Jamaican experience." The West Indian medical journal 53(4): 248-251.

Gunshot injuries are an escalating social and medical dilemma in many Western and some developing countries. Of 40 patients arriving at the University Hospital of the West Indies (UHWI), Jamaica, from 1993 to 1998, with gunshot wounds of the head, 30 were admitted. Six of those admitted died within 24 hours, five with poor Glasgow Coma scores. Ten patients had surgery, two of whom died. Six complications occurred: two patients each developed an infection, cerebrospinal fluid fistula or seizures. All patients were victims of an assault and all had intracranial penetration, the most common sites of which were facial and frontal. Median hospital stay was eleven days. The Glasgow Coma Score on admission was a good prognostic indicator. Fourteen patients had associated injuries, four of which were in the neck. Surgery was considered inappropriate for moribund patients and those with inaccessible bone and bullet fragments. Young males were the most common victims of this devastating form of assault.

1152. Crane, J. K. (2018). "Intrathecal spinal abscesses due to Candida albicans in an immunocompetent man." BMJ case reports 2018.

Infections of the central nervous system due to Candida albicans are uncommon and are usually only observed in special circumstances, such as following neurosurgery or penetrating head trauma, in immunosuppressed patients, premature infants or in patients with ventriculoperitoneal shunts. The author reports a case of an immunocompetent man who presented with a thoracic intraspinal abscess due to C. albicans Despite surgical drainage and 6 weeks of high-dose fluconazole therapy, the abscess extended and recurred in the cervical spine, requiring a second operation to arrest the infection.

1153. Crawford, T. C., et al. (2018). "Traumatically Brain-Injured Donors and the Impact on Lung Transplantation Survival." The Annals of thoracic surgery 106(3): 842-847.

BACKGROUND: Concern has been raised over inferior lung transplantation survival associated with traumatic brain injury (TBI) organ donors. Our purpose was to explore the relationship between TBI donors and lung transplantation survival in the lung allocation score (LAS) era., METHODS: We queried the United Network for Organ Sharing Scientific Registry of Transplant Recipients and identified all adult (>=18 years) lung transplantations performed from May 4, 2005, to December 31, 2015. Recipients were dichotomized based on donor cause of death, TBI versus non-TBI, propensity score across eight variables (final LAS, intensive care unit admission before transplantation, extracorporeal membrane oxygenation before transplantation, donor age 50 years or older, cytomegalovirus antibody recipient-/donor+, ischemia time, annual center transplantation volume, single versus double lung transplantation), and matched 1:1 without replacement. Our primary outcomes were survival at 1, 3, and 5 years by Kaplan-Meier method., RESULTS: A total of 17,610 patients underwent isolated lung transplantation over the study period at 75 different transplantation centers. TBI was the leading cause of death in the donor population: 47% of all donors. Propensity score matching generated 6,782 well-matched donor TBI versus non-TBI pairs (all covariate $p > 0.2$). Risk-adjusted survival was similar between recipients of TBI donors versus non-TBI donors at 1 year (86% versus 86%, log-rank $p = 0.27$), 3 years (68% versus 68%, log-rank $p = 0.47$), and 5 years (55% versus 54%, log-rank $p = 0.40$)., CONCLUSIONS: In the largest analysis of TBI donors and the impact on lung transplantation survival to date, we found similar survival out to 5 years in lung transplant recipients of TBI versus non-TBI donors, alleviating concerns over continued transplantation with this unique donor population.

1154. Crevenna, R., et al. (1999). "Unusual treatment of slaughterer's gun injury." Injury 30(8): 537-538.

1155. Crevenna, R., et al. (1999). "Is there an obligation for neurosurgical intervention in Slaughterer's gun injuries?" Acta Chirurgica Austriaca 31(SUPPL. 156): 165-167.

Backeground: Slaughterer's guns ('humane killers') are powder-activated cattle skull impacting tools. Today mechanical stunning is typical for countrylike regions, because in the municipal slaughter-houses electrical stunning of pigs and ruminants is preferred. In very rare cases these weapons are used for suicide. They then cause penetrating brain lesions and if the victim survives the brain-damage, an encephalitis caused by the impacted material results in the case of no neurosurgical intervention. Methods: The aim of this short report is to describe this rare and special type of injury especially the wounding mechanism in a forensic point of view. Additional we discuss the clinical course of a patient who attempted suicide by a slaughterer's gun, and survived the injury without neurosurgical intervention. Results: Although these injuries are very rare events today, it is important for involved physicians to know the wounding mechanism, the consequences and potential complications of injuries caused by slaughterer's guns. It is possible to survive such an injury without neurosurgical intervention. Conclusions: In our opinion such penetrating head-injuries should be treated by revision of the gunshot canal and by removal of foreign bodies (brain debris, impacted bone fragments and contaminated skin) under antibiotic treatment.

1156. Crevenna, R., et al. (2003). "[Therapy of head injuries caused by animal slaughter guns]." Therapie bei Kopfverletzungen durch Schlachtschussapparate. 153(1-2): 37-39.

Slaughterer's guns ("humane killers") are powder-activated cattle skull impacting tools. Today mechanical stunning is typical for country like regions, because in the municipal slaughter-houses electrical stunning of pigs and ruminants is preferred. In rare cases these weapons are used for suicide. They then cause penetrating brain lesions and if the victim survives the brain-damage, an encephalitis caused by the impacted material results. The neurosurgical treatment is to revise the gunshot canal and to remove impacted fragments of bone and contaminated skin (imprimat) under antibiotic cover. A psychiatric treatment of the mostly underlying depression and a rehabilitative treatment should complete therapy. So treatment of slaughterer's gun injury should have a multidisciplinary approach.

1157. Cripps, M. W., et al. (2009). "The number of gunshot wounds does not predict injury severity and mortality." The American surgeon 75(1): 44-48.

It is presumed that as the number of gunshot wounds (GSWs) increases, so do the Injury Severity Score (ISS) and mortality risk. We hypothesized that the number of bullet wounds relates to ISS and death; however, a single GSW to the head is ominous. We reviewed the charts of all GSW patients admitted to a trauma center from 2004 to 2006 (n = 531). We analyzed patient demographics, ISS, and mortality. There was no correlation with the number of GSWs with either ISS or mortality. There was only a 0.3 per cent increased risk of death for each additional GSW (r2 = 0.12). Patients with a single GSW versus multiple GSWs had no difference in mortality (9.1 vs 8.4%, P = 0.8). A single GSW to the head carried a 50 per cent mortality risk. For those who sustained both head and body GSWs, each additional GSW did not increase mortality (r2 = 0.007). Our study shows that the number of GSWs has no affect on mortality or ISS. Internal triage and management of gunshot victims should not be affected by the categorization of patients as having a single versus multiple GSWs.

1158. Cristofori, I., et al. (2016). "Neural correlates of mystical experience." Neuropsychologia 80: 212-220.

Mystical experiences, or subjectively believed encounters with a supernatural world, are widely reported across cultures and throughout human history. Previous theories speculate that executive brain

functions underpin mystical experiences. To evaluate causal hypotheses, structural studies of brain lesion are required. Previous studies suffer from small samples or do not have valid measures of cognitive functioning prior to injury. We investigated mystical experience among participants from the Vietnam Head Injury Study and compared those who suffered penetrating traumatic brain injury (pTBI; n=116) with matched healthy controls (HC; n=32). Voxel-based lesion-symptom mapping analysis showed that lesions to frontal and temporal brain regions were linked with greater mystical experiences. Such regions included the dorsolateral prefrontal cortex (dlPFC) and middle/superior temporal cortex (TC). In a confirmatory analysis, we grouped pTBI patients by lesion location and compared mysticism experiences with the HC group. The dlPFC group presented markedly increased mysticism. Notably, longitudinal analysis of pre-injury data (correlating with general intelligence and executive performance) excludes explanations from individual differences. Our findings support previous speculation linking executive brain functions to mystical experiences, and reveal that executive functioning (dlPFC) causally contributes to the down-regulation of mystical experiences.

1159. Cristofori, I., et al. (2019). "The lonely brain: evidence from studying patients with penetrating brain injury." Social neuroscience 14(6): 663-675.

Loneliness is perceived as social isolation and exclusion. The neural substrate of loneliness has been investigated with functional neuroimaging; however, lesion-based studies and their associated outcomes are needed to infer causal involvement between brain regions and function. Here, we applied voxel-based lesion-symptom mapping (VLSM) analyses to investigate the causal role of brain lesions on self-report of loneliness (UCLA Loneliness Scale) in a unique sample from the Vietnam Head Injury Study, including veterans with penetrating traumatic brain injuries (pTBI) (n = 132) and healthy controls (HCs) (n = 35). Our results revealed that the right anterior insula (AI) and right prefrontal cortex (PFC) are key brain regions underpinning loneliness perception. Individuals with selective lesions to the right AI and right PFC were less likely to report loneliness compared to patients with selective lesions to the posterior cortex and HCs. Therefore, it appears that lesions to key regions involved in processing social pain act to lower the perception of loneliness. Reporting loneliness was associated with executive dysfunction, apathy, disinhibition, and lower life satisfaction. In conclusion, the reported findings broaden our understanding of how loneliness is processed in the social brain, and how behavioral and cognitive factors can influence this perception.

1160. Cristofori, I., et al. (2015). "The neural bases for devaluing radical political statements revealed by penetrating traumatic brain injury." Social cognitive and affective neuroscience 10(8): 1038-1044.

Given the determinant role of ventromedial prefrontal cortex (vmPFC) in valuation, we examined whether vmPFC lesions also modulate how people scale political beliefs. Patients with penetrating traumatic brain injury (pTBI; N = 102) and healthy controls (HCs; N = 31) were tested on the political belief task, where they rated 75 statements expressing political opinions concerned with welfare, economy, political involvement, civil rights, war and security. Each statement was rated for level of agreement and scaled along three dimensions: radicalism, individualism and conservatism. Voxel-based lesion-symptom mapping (VLSM) analysis showed that diminished scores for the radicalism dimension (i.e. statements were rated as less radical than the norms) were associated with lesions in bilateral vmPFC. After dividing the pTBI patients into three groups, according to lesion location (i.e. vmPFC, dorsolateral prefrontal cortex [dlPFC] and parietal cortex), we found that the vmPFC, but not the dlPFC, group had reduced radicalism scores compared with parietal and HC groups. These findings highlight the crucial role of the vmPFC in appropriately valuing political behaviors and may explain certain inappropriate social judgments observed in patients with vmPFC lesions.

1161. Cristofori, I., et al. (2015). "White and gray matter contributions to executive function recovery after traumatic brain injury." Neurology 84(14): 1394-1401.

OBJECTIVE: We investigated the association between regional white and gray matter volume loss and performance on executive functions (EFs) in patients with penetrating traumatic brain injury (pTBI)., METHODS: We studied 164 pTBI patients and 43 healthy controls from the Vietnam Head Injury Study. We acquired CT scans for pTBI patients and divided them according to lesion localization (left and right prefrontal cortex [PFC]). We administered EF tests (Verbal Fluency, Trail Making, Twenty Questions) and used voxel-based lesion symptom mapping (VLSM) and group-based correlational and multiple regression analyses to examine the relative influence of gray and white matter lesions on EF recovery., RESULTS: The VLSM analysis revealed that white and gray white matter lesions were associated with impaired EFs. In the left PFC lesion group, damage to the PFC gray matter, anterior corona radiata, and superior longitudinal fasciculus (SLF) were most correlated with functional recovery. Verbal Fluency, which involves a broad fronto-temporo-parietal network, was best predicted by SLF lesion volume. Trail Making and Twenty Questions, which is associated with more focal left frontal damage, was better predicted by PFC lesions., CONCLUSIONS: Our results indicated that white matter volume loss can be a superior predictor of recovery and a crucial factor driving clinical outcome in functions involving a broad network such as Verbal Fluency. White matter damage may place additional burden on recovery by deteriorating signal transmission between cortical areas within a functional network. Copyright © 2015 American Academy of Neurology.

1162. Cristofori, I., et al. (2016). "Brain Regions Influencing Implicit Violent Attitudes: A Lesion-Mapping Study." The Journal of neuroscience : the official journal of the Society for Neuroscience 36(9): 2757-2768.

Increased aggression is common after traumatic brain injuries and may persist after cognitive recovery. Maladaptive aggression and violence are associated with dysfunction in the prefrontal and temporal cortex, but such dysfunctional behaviors are typically measured by explicit scales and history. However, it is well known that answers on explicit scales on sensitive topics--such as aggressive thoughts and behaviors--may not reveal true tendencies. Here, we investigated the neural basis of implicit attitudes toward aggression in humans using a modified version of the Implicit Association Task (IAT) with a unique sample of 112 Vietnam War veterans who suffered penetrating brain injury and 33 healthy controls who also served in combat in Vietnam but had no history of brain injury. We hypothesized that dorsolateral prefrontal cortex (dlPFC) lesions, due to the crucial role of the dlPFC in response inhibition, could influence performance on the IAT. In addition, we investigated the causal contribution of specific brain areas to implicit attitudes toward violence. We found a more positive implicit attitude toward aggression among individuals with lesions to the dlPFC and inferior posterior temporal cortex (ipTC). Furthermore, executive functions were critically involved in regulating implicit attitudes toward violence and aggression. Our findings complement existing evidence on the neural basis of explicit aggression centered on the ventromedial prefrontal cortex. These findings highlight that dlPFC and ipTC play a causal role in modulating implicit attitudes about violence and are crucially involved in the pathogenesis of aggressive behavior., SIGNIFICANCE STATEMENT: Maladaptive aggression and violence can lead to interpersonal conflict and criminal behavior. Surprisingly little is known about implicit attitudes toward violence and aggression. Here, we used a range of techniques, including voxel-based lesion-symptom mapping, to examine the causal role of brain structures underpinning implicit attitudes toward aggression in a unique sample of combat veterans with traumatic brain injury. We found that damage to the dorsolateral prefrontal cortex (dlPFC) led to a more positive implicit attitude toward violence that under most normal situations would be considered inappropriate. These results suggest that treatments aimed at increasing cognitive control using cognitive behavioral therapies dependent on the intact dlPFC could treat aggressive and violent behavior. 1163. Croca, M., et al. (2013). "Complex neuropsychiatric symptoms after suicidal attempt by double gunshot to the head." European Psychiatry 28.

Cranioencephalic trauma and resulting traumatic brain injury are sometimes associated with hard to manage psychiatric symptoms, requiring interpretation from an integrated neuropsychiatric perspective. We present the case of a 49-year-old man with no known psychiatric history who attempted suicide by gunshot to the head resulting in severe cranioencephalic trauma (GCS=7) and subsequent admission to our hospital's Neurosurgery ward. Brain-CT showed two intracranial projectiles, in left temporal and right occipital topography, as well as multiple haemorragic foci. He was transferred to our Psychiatry ward, as there was no neurosurgical indication and he repeatedly attempted suicide. At admission, he presented with level of consciousness fluctuations, temporospatial disorientation, anosognosia and difficult to assess depressive symptoms. Brief neuropsychological evaluation showed deficits on visual-perceptive abilities, executive functions, logical reasoning, and immediate verbal memory, with a MoCA (Montreal Cognitive Assessment) total score under the normative values. Some language capacities (i.e. naming and repetition) were found to be preserved. Neuroophthalmological evaluation evidenced damage to the anterior left optic tract and a right campimetric defect. The EEG revealed no epileptic activity. At the 34th day of hospitalization, after accidental choking, he began to exhibit delirium with accompanying psychotic symptoms. Presently, two-and-a-half months after admission, we observe remission of delirium, coherent and organized speech, an alexithymic pattern of response, ideative perseverance and no suicidal ideation. The noteworthiness of this case resides on the scarcity of published reports and on the difficulty it presents in terms of therapeutic and post-discharge management, originating from the hard-to-interpret symptoms and uncertain prognosis.

1164. Crockard, H. A. (1974). "Bullet injuries of the brain." Annals of the Royal College of Surgeons of England 55(3): 111-123.

Experience gained with a wide variety of missile injuries of the brain is presented. Clinical signs and intracranial pressure (ICP) studied in the early post-injury period have been correlated with survival and treatment. Stress is laid on fluid requirements and the importance of controlled ventilation in the management of the labile clinical condition of such patients. Coughing and struggling caused extrusion of blood and brain from the wound, and this was reduced considerably with endotracheal intubation and mechanical ventilation. Post-operatively high ICP could be controlled in potential survivors with continued ventilation.

1166. Crockard, H. A., et al. (1977). "Somatosensory evoked potentials, cerebral blood flow and metabolism following cerebral missile trauma in monkeys." Surgical neurology 7(5): 281-287.

Somato sensory evoked potentials (SEP), cerebral blood flow and cerebral metabolism were studied in seven rhesus monkeys before and after a right occipito-frontal missile injury with an air rifle. The sensory evoked potential was present shortly after injury though markedly altered in shape. There was a very close correlation (r2 equal to 0.83) between SEP and cerebral blood flow on the uninjured side five minutes after injury. On the injured side, this was also noted but the amplitude of the SEP was much smaller, perhaps due to direct injury. If the flow in either hemisphere fell below 15-20 mls/100 gm/min, the evoked response disappeared, but in several animals a subsequent increase in flow was associated with a return of electrical activity. There was no correlation with cerebral perfusion pressure or cerebral metabolic rates for oxygen or lactate production, though it is likely that this is not due to physiological reasons but rather methodological. It might be inferred from these results that adequate flow is vital for the preservation and return of electrical activity following brain injury.

1168. Crocker, K. L., et al. (2021). "Neurogenesis in the adult Drosophila brain." Genetics 219(2).

Neurodegenerative diseases such as Alzheimer's and Parkinson's currently affect ~25 million people worldwide. The global incidence of traumatic brain injury (TBI) is estimated at ~70 million/year. Both neurodegenerative diseases and TBI remain without effective treatments. We are utilizing adult Drosophila melanogaster to investigate the mechanisms of brain regeneration with the long-term goal of identifying targets for neural regenerative therapies. We specifically focused on neurogenesis, i.e., the generation of new cells, as opposed to the regrowth of specific subcellular structures such as axons. Like mammals, Drosophila have few proliferating cells in the adult brain. Nonetheless, within 24 hours of a penetrating traumatic brain injury (PTBI) to the central brain, there is a significant increase in the number of proliferating cells. We subsequently detect both new glia and new neurons and the formation of new axon tracts that target appropriate brain regions. Glial cells divide rapidly upon injury to give rise to new glial cells. Other cells near the injury site upregulate neural progenitor genes including asense and deadpan and later give rise to the new neurons. Locomotor abnormalities observed after PTBI are reversed within 2 weeks of injury, supporting the idea that there is functional recovery. Together, these data indicate that adult Drosophila brains are capable of neuronal repair. We anticipate that this paradigm will facilitate the dissection of the mechanisms of neural regeneration and that these processes will be relevant to human brain repair.

1169. Crockett, A., et al. (2013). "A rare case of a penetrating,life-threatening injury to the oropharynx." Journal of Laryngology and Otology 127(4): 8.

Case report A six-year-old child presented to the accident and emergency department after he had been found in the street apnoeic and cyanosed with a broken pencil embedded in his mouth and a Glasgow Coma Score of 3. In the accident and emergency department, the child's Glasgow Coma Score fluctuated between 8 and 13. A penetrating injury of the soft palate was noted, and a provisional diagnosis of penetrating intracranial injury was made. Antibiotics were given and the child was intubated and ventilated. Computed tomography (CT) showed no evidence of brain or spinal cord injury. Examination under anaesthesia revealed a small penetrating wound in the nasopharynx with cerebrospinal fluid (CSF) leakage. The child was transferred, intubated, to Great Ormond Street Hospital. Attempted extubation after 72 hours failed because of a poor gag reflex and aspiration. Magnetic resonance imaging (MRI) and magnetic resonance angiography showed an ill-defined lesion in the right side of the medulla and upper spinal cord. Antibiotics were continued. After 9 days, a tracheostomy was fashioned. The child's level of consciousness subsequently improved, but there was evidence of a partial bulbar palsy together with left facial and upper and lower limb weakness. The CSF leak ceased spontaneously within 72 hours. Further management consisted of nasogastric tube feeding and rehabilitation, including swallowing therapy and physiotherapy. After six months, there was still a mild left-sided limb weakness. Conclusion This unusual penetrating injury of the brain stem was diagnosed on clinical grounds and correct management instituted despite a normal CT scan. Suspicions were subsequently confirmed by MRI scanning, together with the development of focal neurological signs which became apparent following extubation.

1170. Croezen, D. H. and T. L. Van Natta (2001). "Presentation and outcomes for organ donation in patients with cerebral gunshot wounds." Clinical transplantation 15 Suppl 6: 11-15.

This study was undertaken to examine the presentation and outcomes relative to solid organ donation in patients with fatal cerebral gunshot wounds at a level I trauma center over a 7-year period. A retrospective chart review of patients with such wounds over the years 1993-99 was completed. Eighty (80) patients were considered potential solid organ donors. Of these, 28 (35%) became organ donors, yielding 97 transplantable organs. Ninety-six percent presented with a GCS of less than 6. Mean SBP on presentation was 130, ranging from 48 to 225. Median time from presentation to death was 18 hours. Intravenous fluids given over the first 6 hours averaged 4.3 liters. Pressors were required in 68% of cases, blood products in 34%. Consent rate for donation was 32% when requested by a physician and 59% when requested by an organ procurement organization (OPO) co-ordinator. No request was made in 15 cases. Patients with fatal cerebral gunshot wounds, but with solid organ donor potential, have a characteristic presentation. Those with hemodynamic stability and those whose hypotension responds promptly to treatment can be expected to have a donor potential despite their devastating brain injury. Minimal time and resources are required to support such patients. Additional organs may have been obtained if the request for donation was consistently separated from the families' notification of brain death, and if the request was initiated by an OPO coordinator rather than a physician. Further, all patients admitted with cerebral gunshot wounds and poor neurologic function should have local OPO referral, potential survival notwithstanding.

1171. Crokard, H. A., et al. (1977). "Physiological consequences of experimental cerebral missile injury and use of data analysis to predict survival." Journal of neurosurgery 46(6): 784-794.

The authors describe cerebrovascular and cerebral metabolic changes in monkeys, subjected to cerebral missile injury. After injury with BB pellet at 90 m/sec, there is a rapid rise in intracranial pressure (ICP), which reaches a peak 2 to 5 minutes posttrauma, and then falls to about 20 to 30 mm Hg. This, with a fall in mean blood pressure (MBP), results in a 50% reduction in cerebral perfusion pressure (CPP), Cerebral blood flow (CBF) is also reduced, although acutely there is no close relationship with (CPP). Cerebrovascular resistance falls initially and then at 30 minutes rises to very high values. Cerebral metabolic rates (CMR's) for oxygen fall after injury and remain low for the rest of the animal's life; CMR's for lactate rise immediately after injury and persists for 5 hours, then fall. After injury with a faster missile (180 m/sec), the ICP rises higher and faster, and the peak is shorter. The CCP is reduced in this injury to approximately 30 mm Hg, and only one animal survived more than 1 hour. With the conventional forms of data analysis, the length of survival after injury correlates well with MBP, ICP, and CBF, but separately they were completely unsatisfactory for prediction of an individuals prognosis. With the technique of multiple linear regression analysis, the survival of individual animals could be predicted with great accuracy. This is possible also when two postinjury parameters,CBF and MBP, are used.

1172. Crone, K. R., et al. (1986). "Superior sagittal sinus air after penetrating craniocerebral trauma." Surgical neurology 25(3): 276-278.

Intracranial air secondary to craniocerebral trauma is not uncommon. Computed tomography scanning may show the air within specific intracranial compartments. We report a case of air within the superior sagittal sinus visualized with computed tomography and documented at operation.

1174. Crutcher, C. L., 2nd, et al. (2016). "Racial Disparities in Cranial Gunshot Wounds: Intent and Survival." Journal of racial and ethnic health disparities 3(4): 687-691.

BACKGROUND: Gunshot wounds (GSW) to the head are associated with the highest mortality of all gun-related injuries, with assault reported as the leading cause of penetrating GSW. Several studies have explored factors and trends related to assault and self-inflicted GSW separately. The aim of this study was to investigate epidemiological characteristics and racial differences collectively in patients with GSW to the head by examining associations to injury intent and survival., METHOD: A retrospective study was performed by accessing the hospital trauma registry at our regional Level 1 Trauma Center. A query of neurosurgery consults with penetrating trauma was completed from January 2008 to October 2013. Patients with penetrating intracranial GSW were included in the study. A chi-square test was used to evaluate association between patients' characteristics and intent of injury. Logistic regression analyses predicting intent of injury and survival were also conducted., RESULTS: Of 111 patients, the majority were male (87.4 %). Most were African American (57.7 %) and Caucasian (35.1 %). Compared to African Americans, Caucasian patients were more likely to inflict self-harm (odds ratio (OR) 16.369 (95 % confidence interval (CI) 5.633-47.571), $p < 0.0001$), while African Americans (OR 26.413 (95 % CI 8.957-77.890), $p < 0.0001$) were more likely to be victims of assault. Race and other demographic variables did not predict survival nor did intent of injury ($p = 0.368$)., CONCLUSION: This study reports that there are racial disparities between assault GSW and self-inflicted GSW. However, neither race nor intent is a predictor of survival outcome. Targeted efforts are needed to reduce occurrence of cranial GSW events in order to decrease associated morbidity and mortality.

1175. Cruvinel Isaac, D. L., et al. (2003). "Prognostic factors in open globe injuries." Ophthalmologica. Journal international d'ophtalmologie. International journal of ophthalmology. Zeitschrift fur Augenheilkunde 217(6): 431-435.

PURPOSES: To evaluate the main factors related to visual outcome after open globe injuries (excluding intraocular foreign bodies)., METHODS: Retrospective study analyzing consecutive ocular lacerations, primarily repaired in this institution, between January 1993 and January 2000. Of the 364 cases, 283 (77.75%) lacerations were statistically analyzed, correlating the preoperative variables with the postoperative visual acuity (VA). Excluded from this study were all patients with less than 6 months of follow-up, previous ocular surgery, unreliable information on VA, intraocular foreign bodies and endophthalmitis. When a bilateral injury was detected, only 1 eye was randomly chosen., RESULTS: It was observed, after statistical analysis (multivariate analysis), that the most important factors related to postoperative poor VA (less than 20/100) were: the length of the laceration, the elapsed time between the injury and the surgery and the presence or absence of vitreous loss, cataract (lens damage), hyphema, laceration posterior to rectus muscle insertion and retinal detachment., CONCLUSION: With this study, it was possible to point out the most important factors related to visual prognosis in open globe injuries. The results found are similar to results previously reported. Copyright 2003 S. Karger AG, Basel

1176. Cruz Filho, N. A., et al. (2013). "Facial nerve grafting and end-to-end anastomosis in the middle ear: tympanic cavity and mastoid." Brazilian journal of otorhinolaryngology 79(4): 441-445.

UNLABELLED: Sectioned facial nerves can be repaired with grafting or end-to-end anastomosis., OBJECTIVE: To discuss these repair procedures and what can be expected of them., METHOD: Seven patients with sectioned facial nerves were included in the study. Four underwent grafting and three were offered end-to-end anastomosis. Facial nerve palsy was iatrogenic in five patients and was caused by bullet wounds in two. Assessment of motor function recovery was based on Janssen's scale., RESULTS: Mean motor recovery was rated at 72.5% for subjects offered grafting and 73.3% for patients submitted to anastomosis., CONCLUSION: 1. Grafting and anastomosis are proper solutions to repair sectioned facial nerves; complete recovery is never attained; synkinesis may occur. 2. In principle anastomosis is the procedure of choice, but when there is minimal traction in the facial nerve stump grafting is preferred. 3. Both procedures yielded mean motor recovery rates above 70% (72.5% for grafting and 73.3% for anastomosis).

1177. Cruz, J., et al. (1996). "Cerebral extraction of oxygen, lactate production, and perfusion pressure in gunshot wound to the head: case report." The Journal of trauma 40(3): 445-448.

A case of gunshot wound to the head is presented, in which the patient made a satisfactory recovery after a prolonged period of elevated intracranial pressure and increased cerebral extraction of oxygen. Even though cerebral extraction of oxygen was increased in the most acute phase, the arteriojugular lactate difference was never abnormally decreased (ischemic). This finding indicated that, in this patient, increased cerebral extraction of oxygen was not sufficient to result in global cerebral ischemia (increased cerebral lactate production). To our knowledge, this is the first report on frequent serial assessment of cerebral extraction of oxygen and lactate production in severe penetrating head injury.

1178. Cucci, M., et al. (2022). "Evaluation of blood pressure variability in moderate to severe traumatic brain injuries." Critical care medicine 50(1 SUPPL): 772.

INTRODUCTION/HYPOTHESIS: Traumatic brain injuries (TBI) result in significant morbidity and mortality annually. Clinical practice guidelines recommend prevention of secondary injury by avoidance of hypotension; however, it is unknown if blood pressure variability (BPV) would have effects on clinical outcomes. The aim of this study is to evaluate whether increased BPV is associated with unfavorable Glasgow Outcome Scale (GOS) scores in patients with moderate to severe TBIs. METHODS: This study is a retrospective, cohort study of adult trauma ICU patients admitted to a level 1 trauma center with moderate to severe TBIs (head Abbreviated Injury Scale (AIS) >1, Glasgow Coma Scale (GCS) 3-12) from 1/1/2018 to 5/31/2020. Patients were excluded for anoxic and penetrating brain injuries and severe alcohol withdrawal. Group assignment was favorable (GOS 4-5) vs. unfavorable (GOS 1-3) GOS scores at discharge. The GOS was adjudicated by least two independent, blinded reviewers. The SBP was obtained from all BP readings in the initial 72 hours obtained on at least hourly. The primary outcome measure was the standard deviation (SD) of systolic blood pressure (SBP) and the coefficient of variance (CV) of SBP was also measured. The SD-SBP was computed by variance from the mean and CV-SBP by the SD divided by the mean. A generalized linear model was performed to test the association with the SD-SBP and the GOS. RESULTS: Of the 608 patients eligible for inclusion, 89 patients were included with 50 (56%) and 39 (44%) in the unfavorable and favorable groups, respectively. The study population had a mean age of 59 (SD 21), 65% male, median head AIS of 4 [IQR 3-5] and GCS of 6 [IQR 3-10], primarily subdural (n=54, 61%) and subarachnoid (n=48, 54%) hemorrhages, and 42 (47%) required surgical intervention. There was no significant difference between the mean SBP readings (125 vs. 123 mmHg, p=0.377), SD-SBP (16.8 vs. 18.2, p=0.236), or CV-SBP (0.13 vs. 0.15, p=0.104) between the favorable and unfavorable groups. Based on a generalized linear model, there was no association of SDSBP (estimate -0.03, p=0.213) or CV-SBP (estimate -0.04, p=0.173) with the GOS. CONCLUSIONS: Blood pressure variability measured by SD-SBP or CV-SBP may not be associated with an unfavorable outcome in patients with moderate to severe TBI.

1179. Cudnik, M. T., et al. (2012). "Prehospital factors associated with mortality in injured air medical patients." Prehospital emergency care : official journal of the National Association of EMS Physicians and the National Association of State EMS Directors 16(1): 121-127.

BACKGROUND: Air medical transport provides rapid transport to definitive care. Overtriage and the expense and risk of transport may offset survival benefits., OBJECTIVE: We assessed the ability of prehospital factors to predict resource need for helicopter-transported patients., METHODS: We performed a prospective, observational cohort analysis of injured scene patients taken to one of two level I trauma centers from October 2009 to September 2010. Variables analyzed included patient demographics, diagnoses, and clinical outcomes (in-hospital mortality, emergent surgery within 24 hours, blood transfusion within 24 hours, and intensive care unit [ICU] admission >=24 hours, as well as

a combined outcome of all clinical outcomes). Prehospital variables were prospectively obtained from air medical providers at the time of transport and included past medical history, mechanism of injury, and clinical factors. We compared those variables with and without the outcomes of interest via chi(2) analysis and the Kruskal-Wallis test, where appropriate. Multivariate logistic regression identified factors associated with outcomes of interest with the intent of developing a clinical prediction tool., RESULTS: Five hundred fifty-seven patients were transported during the study period. The majority of the patients were male (67%) and white (95%) and had an injury that occurred in a rural location (58%). Most injuries were blunt (97%), and patients had a median Injury Severity Score (ISS) of 9. The overall mortality was 4%; 48% of the patients had one of the four outcomes. The most common reasons for requesting air transport were motor vehicle collision (MVC) with high-risk mechanism (18%), MVC at a speed greater than 20 mph (18%), Glasgow Coma Scale score (GCS) less than 14 (15%), and loss of consciousness (LOC) greater than 5 minutes (15%). Factors associated with mortality were age greater than 44 years, GCS less than 14, systolic blood pressure (SBP) less than 90 mmHg, and flail chest. This model had 100% sensitivity and 50% specificity and missed no deaths. The combined endpoint of all four outcomes (death, receipt of blood, surgery, ICU admission) included intubation by emergency medical services, two or more fractures of the humerus/femur, presence of a neurovascular injury, a crush injury to the head, failure to localize to pain on examination, GCS less than 14, or the presence of a penetrating head injury. This model had a sensitivity of 57% (53%-61%) and a specificity of 78% (75%-87%)., CONCLUSIONS: Very few prehospital criteria were associated with clinically important outcomes in helicopter-transported patients. Evidence-based guidelines for the most appropriate utilization of air medical transport need to be further evaluated and developed for injured patients.

1180. Cui, Y., et al. (2018). "Removal of an intraorbital metallic foreign body following double-penetrating ocular injury: A case report." Medicine 97(51): e13790.

RATIONALE: Open eye injury is one of the commonest ophthalmic emergencies, and when accompanied by intraorbital foreign bodies, the condition carries a poor prognosis., PATIENT CONCERNS: A 28-year-old man presented to the emergency department of our hospital complaining of sudden painful loss of vision in the left eye after he hammered an iron plate., DIAGNOSIS: The ocular examination revealed a 4-mm full thickness scleral laceration with prolapsed uveal tissue, a traumatic cataract. Computed tomography (CT) demonstrated an orbital foreign body in the retrobulbar area., INTERVENTIONS: The patient underwent emergency scleral suturing, severance of medial rectus muscle, and removal of the orbital foreign body. Twelve days after the emergency operation, pars plana lensectomy and pars plana vitrectomy were performed., OUTCOMES: After 3 months of follow-up, there was no immune response. Visual acuity in the left eye was the perception of hand motion. The retina remained mostly attached with normal intraocular pressure, and good cosmetic appearance. The globe anatomy was maintained, but the vision could not be restored due to the grave nature of the trauma., LESSONS: Transconjunctival approach extraocular muscle severance may thus be a suitable approach to the removal of intraorbital metallic foreign body.

1181. Cullen, E. F. and T. M. Luckasevic (2010). "Suicide with a homemade shotgun: case report and review of literature." The American journal of forensic medicine and pathology 31(3): 255-257.

This is a 57-year-old white man with a medical history of depression and recent suicidal ideation that necessitated police response with confiscation of his shotgun. Approximately 3 weeks later he was found by his landlord lifeless on the floor surrounded by a pool of blood.Scene investigation revealed a homemade shotgun and a hammer lying near the decedent. Autopsy revealed a contact shotgun wound to the right side of the decedent's head. The shotgun blast caused injury to the skull with evisceration of the brain. Soot and shotgun filler were present surrounding and within the entrance wound. In this case report, we show that the preventive measures of taking away one's firearms and admission into a psychiatric hospital is in some cases not enough to prevent suicide. The desire to end one's existence may lead to a well thought out and ingenuous means to commit the act of suicide.

1184. Cunliffe, C. H. and J. S. Denton (2008). "An atypical gunshot wound from a home-made zip gun--the value of a thorough scene investigation." Journal of forensic sciences 53(1): 216-218.

Zip guns and the atypical gunshot wounds they produce are rare in forensic pathology. Because of this, investigators and forensic pathologists may be unfamiliar with their construction, appearance, and the wounds associated with them. A 43-year-old mechanic, with a history of depression was found dead in a washroom stall at work with an atypical gunshot wound of the head. Upon initial investigation, no weapon was found at the scene. Due to the nature of the scene, and the unusual characteristics of the wound, the manner of death was at first thought to be a homicide. Subsequently, a simple zip gun, which had been overlooked during the scene investigation, was discovered by a co-worker while he was cleaning the stall. Examination of the wound revealed evidence of contact range firing. A markedly deformed bullet was recovered from the head, consistent with the use of the home-made gun. These findings, along with further police investigation and review of the past medical history, indicated that the manner of death was a suicide.

1185. Cunningham, T. J., et al. (2004). "Systemic treatment of cerebral cortex lesions in rats with a new secreted phospholipase A2 inhibitor." Journal of neurotrauma 21(11): 1683-1691.

An internal fragment of the human neuroprotective polypeptide DSEP (Diffusible Survival Evasion Peptide) was delivered at 0.4 mg/kg (subcutaneously) 20-30 min after stab wound lesions in the parietal cortex of anesthetized rats. The peptide, CHEASAAQC or CHEC-9, inhibited the inflammatory response to the lesion and the degeneration of neurons adjacent to the wound. Four days after surgery, peptide-treated animals ($n = 6$) had 75% fewer reactive ameboid microglia/brain macrophages in the cortical parenchyma surrounding the lesion compared to vehicle-injected control rats ($n = 6$, $p = 0.004$). The cortical laminae in area 2 adjacent to the lesion were completely obscured in controls because of the increase in inflammatory cells and frank degeneration of neurons, while there was preservation of the neurons and cytoarchitecture after peptide treatment. In parallel experiments, CHEC-9 was found to inhibit the enzymatic activity of secreted phospholipase A2 (sPLA2), including activity present in the serum of peptide-injected rats. Kinetic analysis revealed the peptide increased the average Km for serum by 318% when tested 45 min after treatment (peptide-treated, $n = 6$; control-treated, $n = 6$; $p = 0.0087$), suggesting the principal effect of the peptide was to lower the affinity of serum sPLA2 for substrate. The sPLA2 inhibition by this particular peptide sequence appeared to be highly specific since inversion of a single pair of amino acids eliminated the inhibitory effect. Phorbol-12-myristate-13-acetate stimulated platelet aggregation, a PLA2-regulated activity, was also inhibited by the peptide. The discovery of CHEC-9 makes it possible to study in vivo the long appreciated contribution made by PLA2-directed inflammation to both acute and chronic neurodegeneration and may be helpful in designing therapies to limit neuron death in these conditions.

1186. Cunningham, T. L., et al. (2014). "Correlations between blood-brain barrier disruption and neuroinflammation in an experimental model of penetrating ballistic-like brain injury." Journal of neurotrauma 31(5): 505-514.

Abstract Blood-brain barrier (BBB) disruption is a pathological hallmark of severe traumatic brain injury (TBI) and is associated with neuroinflammatory events contributing to brain edema and cell

death. The goal of this study was to elucidate the profile of BBB disruption after penetrating ballistic-like brain injury (PBBI) in conjunction with changes in neuroinflammatory markers. Brain uptake of biotin-dextran amine (BDA; 3 kDa) and horseradish peroxidase (HRP; 44 kDa) was evaluated in rats at 4 h, 24 h, 48 h, 72 h, and 7 days post-PBBI and compared with the histopathologic and molecular profiles for inflammatory markers. BDA and HRP both displayed a uniphasic profile of extravasation, greatest at 24 h post-injury and which remained evident out to 48 h for HRP and 7 days for BDA. This profile was most closely associated with markers for adhesion (mRNA for intercellular adhesion molecule-1) and infiltration of peripheral granulocytes (mRNA for matrix metalloproteinase-9 [MMP-9] and myeloperoxidase staining). Improvement of BBB dysfunction coincided with increased expression of markers implicated in tissue remodeling and repair. The results of this study reveal a uniphasic and gradient opening of the BBB after PBBI and suggest MMP-9 and resident inflammatory cell activation as candidates for future neurotherapeutic intervention after PBBI.

1187. Curado, R. L., et al. (2020). "Demographic Profile of the Patient Operated with Hepatic-Splenic Trauma in a Tertiary University Hospital (1990-2009)." Journal of the American College of Surgeons 231(4): e232.

Introduction: Analyze the profile, risk factors and prognosis of patients operated with hepatosplenic trauma in a Tertiary University Hospital. Methods: Retrospective study, patients operated with hepatic-splenic trauma. Variables analysed: gender, age, systolic blood pressure, diastolic blood pressure, glasgow coma scale, heart rate, respiratory rate, place of first visit, hemodynamic stability, trauma mechanism, complementary procedures in the primary assessment. RTS, ISS, TRISS, treatment instituted, consumption of blood products, associated injuries and length of hospital stay. Results: 70 patients with hepatic-splenic injury, mechanism was penetrating in 48.58% (34 cases), blunt trauma in 51.42% (36 cases). Most were male (penetrating: 91.17% and blunt 86.11%). The variables that showed a statistical difference between the penetrating and blunt trauma were: mean age: 25.05 ± 6.85 years / 30.42 ± 10.47 years (p = 0.0015); Glasgow Coma Scale: 14.82 ± 0.63 / 9.48 ± 4.97 (p = 0.001); RTS: 7.42 ± 0.82 / 5.46 ± 2.55 (p = 0.001); TRISS 0.92 ± 0.16 / 0.69 ± 0.38 (p = 0.003); time elapsed between the initial care and the start of surgery: 45.12 ± 34.42 minutes / 135.35 ± 141.12 minutes (p = 0.001); exploratory laparotomy: 82.35% / 82.92% (p = 0.023). Conclusion: The profile of patients operated for hepatic-splenic trauma is: young man, with initial external care. Predominance of gunshot injury in penetrating trauma and car accident in blunt trauma; TBI was more present in blunt trauma, which defined lower RTS and TRISS in this group; most hepatosplenic lesions were of lesser severity.

1188. Curry, J. T., 3rd and R. D. Zallen (1974). "The use of malleable metal mesh in open mandibular reductions. Report of nine cases." Oral surgery, oral medicine, and oral pathology 38(3): 335-343.

1189. Curtin, F., et al. (2016). "High dose clinical pharmacology study of GNbAC1, a humanized monoclonal antibody for multiple sclerosis." Neurology 86(16).

Objective: to assess safety and pharmacology of GNbAC1 a humanized monoclonal antibody Background: MSRV-Env is a protein of endogenous retroviral origin. This protein is expressed in active brain lesions of multiple sclerosis (MS) patients. Due to its pro-inflammatory and myelinotoxic effects, MSRV-Env appears as a pertinent target in MS. GNbAC1 is an IgG4 humanized monoclonal antibody (mAB) which neutralizes MSRV-Env and prevents cytokine release and the nitrosative stress process at the OPC level. Design: This randomized placebo-controlled dose-escalation study evaluated the safety and pharmacokinetics in the plasma and cerebro-spinal fluid (CSF) of GNbAC1 in 21 healthy volunteers at doses of 6, 18, 36 mg/kg. Lumbar punctures were performed at Days 2, 15 and 29 post-infusion. Results: All subjects completed the study. GNbAC1 was well tolerated. All adverse events were mild or moderate in severity. No subject was withdrawn as a result of adverse events. There were no notable dose or treatment related trends in the number or type of adverse events. Pharmacokinetic data show a

dose-linear pharmacokinetics in the plasma with half-life ranging from 21.5 to 25.3 days. The concentration of GNbAC1 in CSF was assessed after intravenous infusion at Day 2, 15, and 29. A CSF/plasma ratio of 0.13[percnt] was observed at Day 2 increasing to 0.36[percnt] at Day 15 and 0.28[percnt] at Day 29. The pharmacokinetic profile of GNbAC1 in the CSF shows a progressive increase in this compartment up to an equilibrium. Conclusion: These CSF pharmacokinetic data show that the brain penetration of GNbAC1 is in line with data from other mABs and sufficient to neutralize the MSRV-Env target expressed in brain lesions. These favourable results pave the way to launch a Phase IIb trial testing GNbAC1 in MS patients.

1190. Cury, R. G., et al. (2017). "Holmes Tremor Secondary to a Stabbing Lesion in the Midbrain." Tremor and other hyperkinetic movements (New York, N.Y.) 7: 523.

Background: The development of Holmes tremor (HT) after a direct lesion of the midbrain has rarely been reported in the literature, although several etiologies have been linked with HT, such as stroke, brainstem tumors, multiple sclerosis, head trauma, or infections., Phenomenology Shown: A 31-year-old male, having been stabbed in the right eye, presented with a rest and action tremor in the left upper limb associated with left hemiparesis with corresponding post-contrast volumetric magnetic resonance imaging T1 with sagittal oblique reformation showing the knife trajectory reaching the right midbrain., Educational Value: Despite the rarity of the etiology of HT in the present case, clinicians working with persons with brain injuries should be aware of this type of situation.

1193. Cvetinovic, M., et al. (1997). "Implants in management of gunshot injuries of teeth, facial bones and jaws." Vojnosanitetski pregled 54(4 Suppl): 37-39.

The use of implants in management of gunshot injuries of teeth, face and jaws presents novelty that is manifested in primary surgical treatment, reduction and fixation of bone fragments and teeth, replacement of lost parts of bone tissues as well as preparation for definitive prosthetic management. At the Clinic for Maxillofacial Surgery of the MMA 173 implants of different types and purposes have been placed in the period 1991-1997, in rehabilitation of the patients injured during the civil war. Although this number of placed implants is significant, the conclusive estimate about benefit of using implants may be obtained only after a longer period of time. Early results are satisfactory.

1194. Cvetkovic, D., et al. (2018). ""The pen is mightier than the sword" - suicidal trans-orbital intracranial penetrating injury from a pencil." Forensic science, medicine, and pathology 14(2): 221-224.

A 40-year-old drug addict, who was being treated with methadone and occupational therapy, committed suicide by striking a wooden pencil into his right eye socket. While still conscious, he hit his head hard against a table, jamming the pencil even deeper into his head. The autopsy showed that the pencil missed the globe and lodged in the inner part of the right eye socket. It pierced the orbital part of the right ethmoid bone, the right ethmoid cells, and the right superior nasal concha, then passed through the body of the sphenoid bone and the clivus of the occipital bone before stopping in the brain tissue. The basilar artery was transected at the pontomedullary junction, where the tip of the pencil had lodged. Also, at the pontomedullary junction, an approximately 3 mm deep laceration of the brainstem was evident together with flecks of green paint. Histological examination revealed that laceration at the

pontomedullary junction was even deeper than the macroscopic appearance had suggested, with several small lateral cracks, focal deep hemorrhage, and disruption of both gray and white matter of the brainstem. Fragments of cellulose originating from the wooden pencil could also be clearly distinguished. Toxicological analysis was performed using liquid chromatography with mass spectrometry, and it showed traces of methadone in the blood and humor vitreous samples. The cause of death was damage to the vital structures in the brainstem, resulting from a penetrating injury to the head by a pencil. Herein, we present a self-inflicted trans-orbital penetrating injury by a non-missile, low-velocity object - a pencil, with a rather unusual, immediately incapacitating outcome.

1195. Cychowska, M. and E. Bloch-Boguslawska (2013). "Cases of non-fatal chop wounds to the head." Przypadki obrazen rabanych glowy bez skutku smiertelnego. 63(4): 283-287.

Chop wounds, due to the fact that they are usually located on the head and are inflicted by a weapon or an object with a large mass, usually lead to death from an extensive damage to the skull and brain structures. Non-lethal chop wounds to the head are found very rarely in forensic practice. The following paper presents three cases, in which the occurrence of wounds has been attributed to the use of an axe. In the first case, the sustained injuries actually resulted in a life-threatening condition. The injuries in the second case bore attributes of exposure to direct danger to life and health within the meaning of the relevant article of the Criminal Code. The third case can be considered interesting, not only because of the nature of the suffered post-traumatic lesions, but also in view of the circumstances of the death of the victim occurring later on in life.

1198. D'Addario, J., et al. (2022). The Role of Neurointervention in Traumatic Vascular Injury and Vascular Surgery: 251-260.

There is an increasing recognition of the devastating consequences of delayed recognition of traumatic injuries to vasculature of the head and neck. This has prompted the development of more aggressive screening criteria. When intervention is needed but open surgical treatment is not viable, the neurointerventional specialist may be able to address many of these difficult lesions. Similarly, there is great opportunity for collaboration between vascular surgeons and neurointerventionalist in less acute patient care such as in the case of incidentally discovered intracranial aneurysms and intracranial stenosis. The neurointerventionalist also can take advantage of the emerging field of transcarotid artery revascularization for patients needing carotid revascularization who are at high risk for transradial or transfemoral stenting.

1199. da Costa, L. and M. Chapman (2022). Measurement of Cerebrovascular Reactivity Using Transcranial Doppler. 175: 59-73.

The Doppler effect (or Doppler shift), which is the basis for the transcranial Doppler (TCD) technique, was described by Christian Andreas Doppler, an Austrian physicist, at a meeting of the Natural Sciences Section of the Royal Bohemian Society in Prague on 25 May 1842. The principle was presented in the paper Über das farbige Licht der Doppelsterne (Eden, Ultrasound Med Biol 16:831–832, 1990) (Concerning the colored light of the double stars) and initially applied to astronomy. In 1965, M. Miyazaki and K. Kato (Jpn Circ J 29:375–382, 1965) described the use of ultrasonic Doppler

technique in the evaluation of blood flow and hemodynamics. However, ultrasound technology at the time was not able to penetrate the skull, and therefore cerebral blood flow (CBF) could not be assessed directly. With the development of the low frequency pulsed Doppler technique (2 MHz), able to penetrate the calvarium in most skulls, Aaslid et al. (J Neurosurg 57:769–774, 1982) were able to use TCD to measure blood flow velocity in the intracranial arteries for the first time. Since then, TCD has been used in medical practice as a technique to measure CBF and later cerebrovascular reactivity (CVR) in many conditions, including ischemic stroke, TBI, subarachnoid hemorrhage and vasospasm, and brain death, both in clinical practice and as a research tool in the search of better understanding physiologic responses of the intracranial circulation to healthy and pathologic stimuli. The objective of this chapter is to provide a brief summary of the use of TCD in the evaluation of cerebrovascular reactivity, with a brief overview of its use in TBI and aneurysmal subarachnoid hemorrhage.

1200. da Costa, L. B., et al. (2006). "Shotgun pellet embolization to the posterior cerebral circulation." AJNR. American journal of neuroradiology 27(2): 261-263.

The embolization of missiles to the intracranial circulation is a rare event. We describe here a case of a man shot by a shotgun, presenting with a posterior fossa stroke and occlusion of the superior cerebellar artery by a metallic pellet. To our knowledge, this is the third case of posterior fossa circulation pellet emboli.

1201. da Silva, A. M., et al. (1992). "Posttraumatic epilepsy in civilians: clinical and electroencephalographic studies." Acta neurochirurgica. Supplementum 55: 56-63.

Posttraumatic epilepsy (PTE) is a known consequence of head trauma. The factors involved in posttraumatic seizures generation and the relationship between acute seizures and posttraumatic epilepsy are not without controversy. This also applies to the evolution of the electroencephalographic characteristics. The study here reported was performed analysing data from patients with posttraumatic epilepsy (N = 205) and data from patients followed-up since trauma and considered as a high risk population for the development of PTE (patients with acute seizures and/or patients with focal lesions--contusion, haematomas or penetrating head injury) (N = 152). Seizure type was associated with age and trauma severity (children, elderly and worst trauma cases present with a higher proportion of partial seizures). Neurological deficit and lesion location were associated with the seizure occurrence. The increased incidence of seizures was found when the most diffused brain dysfunction was combined with neurological deficits. The analysis of sequential EEGs performed at first, at 6th and 12 months post trauma revealed a non-stationary pattern throughout these time periods with EEG focal abnormalities remaining frequent for more than two years after the trauma. Children and old people have a higher proportion of EEG abnormalities with more frequent abnormal generalized activity in children and more frequent abnormal focal EEG activity in the elderly.

1203. Dada, M. A., et al. (1993). "Shotgun pellet embolism to the brain." The American journal of forensic medicine and pathology 14(1): 58-60.

This report describes the autopsy findings in a young man who died after having been shot with a shotgun from about 30 m. Although not suspected clinically, a right middle cerebral artery territory infarct was found; its cause was shown to be a shotgun pellet embolus that had lodged just proximal to the trifurcation of the right middle cerebral artery. The case underscores the importance of performing a thorough postmortem examination, including a careful study of cerebral vasculature, in instances of brain infarction.

1204. Daghfous, A., et al. (2015). "Contribution of imaging in the initial management of ballistic trauma." Diagnostic and interventional imaging 96(1): 45-55.

INTRODUCTION: The purpose of this study is to specify the role of imaging in the initial management of ballistic traumas., METHODS: This is a retrospective study that colligated 83 victims of a gunshot wound during demonstrations, treated in our trauma centre between 12 January and 3 February 2011. All of the patients were haemodynamically stable and examined by conventional radiography and/or ultrasound and/or 16-slice CT-scan (CT)., RESULTS: The mean age of the victims was 26years with a sex ratio of 0.02. All wounds were unique. Injury to the limbs was most common in 75.5% of the cases (n=64) followed by that of the torso in 19.5% of the cases (n=16). Wounds in the spine (n=2), brain (n=2) and facial skeleton (n=1) were observed. Conventional x-rays objectified 32 cases of open fractures 95% of which were in the legs. Twenty-one of the victims of gunshot wounds had a CT-scan that objectified the path of the bullet and an assessment of the wound was made in all cases. The confrontation of the data from the CT-scan and that noted during surgery and during the monitoring demonstrated that the CT-scan is very efficient in the diagnosis of pleural effusion, vascular wounds, thoracic parenchymatous wounds and wounds of the solid organs and brain lesions and the facial skeleton. However, the sensitivity is low for the diagnosis of hollow organs., CONCLUSION: The CT-scan is very useful in the initial care of stable patients with gunshot wounds as regards the haemodynamics and helps objectify the path of the bullet and obtain a precise assessment of the damage. Conventional x-rays are unavoidable for wounds to the legs and spine.

1206. Dagi, T. F. and J. Fandino (2018). "Victor Horsley and surgical management of firearm injuries of the head." Journal of neurosurgery 128(4): 60-61.

Introduction: At the time of the Boer War, the major Biritsh conflict preceeding World War I, mortality from gunshot wounds of the head approximated 100% and these wounds were often purposely neglected. Sir Victor Horsley began studying these wounds at the end of the 19th century and concluded, by 1915, in advance of Cushing, that a methodical approach to penetrating injuries could save lives. This presentation reviews his work, its roots and its outcomes Methods: The military and civilian surgical literature from the end of the 19th century when new weapons and cartridges were introduced through the end of WWI was reviewed with special attention to Horsley's clinical and research investigation in the context of the culture of military surgery of the period. Results: Horsley's work was as important at Harvey Cushing's, though the early emphasis on animal models of head injury did not have the same influence as Cushing's clinical reports. Horsley succeed, however, in changing the attitude of British military surgical command, and thus contributed both neurosurgically and politically to the benefit of wounded soldiers. Conclusion: Horsley deserves to be recognized better for his contributions to the study, pathophysiology and surgery of intracranial penetrating injury, particularly prior to Cushing's celebrated involvement.

1207. D'Agostino, R., et al. (2021). "Management of Penetrating Traumatic Brain Injury: Operative versus Non-Operative Intervention." The Journal of surgical research 257: 101-106.

BACKGROUND: Penetrating traumatic brain injury (pTBI) is the most lethal form of TBI, with mortality rates as high as 90%. This high mortality rate leads many providers to feel that the treatment of pTBI is futile. Contrary to this point of view, several studies have shown that victims of pTBI who present with a Glasgow Coma Scale (GCS) >=6 have a reasonable chance of a meaningful outcome.

This study sought to investigate outcomes of pTBI patients based on GCS score who underwent neurosurgical intervention (craniotomy or craniectomy) and compare them with patients who did not undergo surgical intervention., MATERIALS AND METHODS: The study represents a secondary analysis of the data that were collected from 2006 to 2016 from 17 institutions as part of a multi-center study, investigating clinical outcomes for adult patients sustaining pTBI and surviving >72 h. Patients were divided into those with GCS 3-5 and those with GCS >=6. Within these groups, patients were stratified by whether they received surgical intervention, compared with standard non-surgical care. Patient level data (age and gender), clinical data (Injury Severity Score and Abbreviated Injury Score), GCS on admission, post-op infection rates, and outcomes data (mortality, length of stay [LOS], intensive care unit LOS) were collected. Both groups were compared using independent sample t-test or chi-squared test., RESULTS: Seven hundred twenty patients with pTBI were identified over 11 y, out of which 336 (46.7%) underwent surgery. The mean Injury Severity Score and Abbreviated Injury Score on admission were higher in the surgical intervention group than their non-surgical counterpart in patients with a GCS >=6 ($P < 0.0001$). Patients with GCS of 3-5 with surgical intervention demonstrated a higher survival rate than non-surgical patients ($P < 0.0001$). In the GCS >=6 group, surgical intervention did not impact near-term mortality. Intensive care unit LOS was significantly longer in the surgical intervention group in patients with GCS >= 6 ($P < 0.0001$) and GCS of 3-5 ($P < 0.0001$), as was total hospital LOS ($P < 0.0001$). Patients with a GCS 3-5 and >=6 who underwent surgical intervention were more likely to develop a central nervous system infection ($P = 0.016$; $P = 0.017$)., CONCLUSIONS: Surgical intervention in pTBI patients with GCS 3-5 results in improved mortality but comes at a cost of increased resource utilization in the form of longer LOS and higher infection rate. On the other hand, in patients with GCS >=6, surgery does not provide significant benefits in patient survival. Future prospective studies providing insight as to the impact of surgery on the resource utilization and quality of survival would be beneficial in determining the need for surgical intervention in this population.

1208. Dahl, H. M., et al. (2021). "Epidemiology of traumatic brain injury in children 15 years and younger in South-Eastern Norway in 2015-16. Implications for prevention and follow-up needs." European journal of paediatric neurology : EJPN : official journal of the European Paediatric Neurology Society 31: 70-77.

OBJECTIVE: This retrospective study aimed to describe the volume, severity, and injury mechanism of all hospital-admitted pediatric traumatic brain injury (pTBI) at Oslo University Hospital (OUH), emphasizing consequences for prevention and factors indicating a need for follow-up programs., METHOD: Data were extracted from the OUH Trauma registry on 176 children, 0-15 years old, admitted to OUH in 2015 and 2016 with a pTBI diagnosis. The dataset contains demographic data, injury mechanism, type, and severity (Glasgow coma scale, GCS; abbreviated injury scale, AIS; injury severity score, ISS), ICD-10 diagnosis codes, level of treatment, and destination of discharge., RESULTS: 79.5% had mild, 9% moderate, and 11.4% severe TBI. The incidence of hospital-treated pTBI in Oslo was 29 per 100,000 per year. The boy: girl ratio was 1.9:1, but in the young teenage group (14-15 years), the ratio was 1:1. Intracranial injury (ICI) identified on CT/MRI was associated with extended hospital stays, with a median of 6 days compared to 1 day for patients without ICI. 27% of the patients assessed as mild TBI at admission had ICI. Children below eight years of age had a higher incidence of moderate and severe ICI from trauma (53% v.s. 28% in children >= eight years)., CONCLUSION: The injury characteristics of hospital-treated pTBI are in line with other European countries, but we find the boy-girl ratio different as young teenage girls seem to be catching up with the boys. ICI and length of stay should be considered when deciding which patients need follow-up and rehabilitation.

1209. Dahlin, B. C. and B. Waldau (2016). "Surgical and Nonsurgical Treatment of Vascular Skull Base Trauma." Journal of Neurological Surgery, Part B: Skull Base 77(5): 396-403.

Vascular trauma is associated with blunt skull base fractures and penetrating injuries. We review the contemporary management of cranial vascular trauma, including blunt and penetrating cerebrovascular injury as well as refractory epistaxis from facial trauma.

1210. Dai, D., et al. (2018). "On a knife-edge: clinical uncertainty with an extensive knife blade in situ in the craniofacial region." BMJ case reports 2018.

A 25-year-old man presented to the trauma department following a penetrating stab wound to his left infraorbital margin with retained knife blade causing superoposterior displacement of the globe. Plain skull X-ray revealed an extensive retained blade with subsequent CT imaging revealing the tip of the blade had reached the right styloid process with no neurovascular compromise. Initial concern was primarily for the left eye leading to ophthalmology being the first specialty requested to review the patient. However, once the extent of the injury was established, ophthalmology requested further review from maxillofacial, ENT and neurosurgery. This resulted in an 84 hours wait between the initial injury and the removal of the knife blade. Incredibly, the patient had no initial sequelae from such an extensive injury and had an unremarkable recovery with no further complications aside from a laceration to the left inferior rectus muscle that was conservatively managed.

1211. Dailey, M., et al. (2017). "Enabling Donation after Cardiac Death in the Emergency Department: Overcoming Clinical, Legal, and Ethical Concerns." The Journal of emergency medicine 52(4): 588-592.

BACKGROUND: In light of the growing gap between candidates for organ donation and the actual number of organs available, we present a unique case of organ donation after cardiac death. We hope to open a discussion regarding organ procurement from eligible donors in the prehospital and emergency department setting., CASE: This case study, involving an otherwise healthy man who, after suffering an untimely death, was able to successfully donate his organs, highlights the need to develop an infrastructure to make this type of donation a viable and streamlined option for the future., DISCUSSION: Given the departure from traditional practice in United States transplantation medicine, we bring forth legal and ethical considerations regarding organ donation in the emergency department. We hope that this case discussion inspires action and development in the realm of transplant medicine, with the aim of honoring the wishes of donors and the families of those who wish to donate in a respectful way, while using our medical skills and technologies to afford candidates who are waiting for organs a second chance., CONCLUSIONS: We believe that this case shows that donation after cardiac death from the emergency department, while resource-intensive is feasible. We recognize that in order for this to become a more attainable goal, additional resources and systems development is required.

1212. Dal Monte, O., et al. (2013). "A voxel-based lesion study on facial emotion recognition after penetrating brain injury." Social cognitive and affective neuroscience 8(6): 632-639.

The ability to read emotions in the face of another person is an important social skill that can be impaired in subjects with traumatic brain injury (TBI). To determine the brain regions that modulate facial emotion recognition, we conducted a whole-brain analysis using a well-validated facial emotion recognition task and voxel-based lesion symptom mapping (VLSM) in a large sample of patients with focal penetrating TBIs (pTBIs). Our results revealed that individuals with pTBI performed significantly worse than normal controls in recognizing unpleasant emotions. VLSM mapping results showed that impairment in facial emotion recognition was due to damage in a bilateral fronto-temporo-limbic network, including medial prefrontal cortex (PFC), anterior cingulate cortex, left insula and temporal

areas. Beside those common areas, damage to the bilateral and anterior regions of PFC led to impairment in recognizing unpleasant emotions, whereas bilateral posterior PFC and left temporal areas led to impairment in recognizing pleasant emotions. Our findings add empirical evidence that the ability to read pleasant and unpleasant emotions in other people's faces is a complex process involving not only a common network that includes bilateral fronto-temporo-limbic lobes, but also other regions depending on emotional valence.

1213. Dal Monte, O., et al. (2014). "The left inferior frontal gyrus is crucial for reading the mind in the eyes: brain lesion evidence." Cortex; a journal devoted to the study of the nervous system and behavior 58: 9-17.

Deficit in the ability to understand and predict the mental states of others is one of the central features of traumatic brain injury (TBI), leading to problems in social-daily life such as social withdrawal and the inability to maintain work or family relationships. Although several functional neuroimaging studies have identified a widely distributed brain network involved in the Reading the Mind in the Eyes Test (RMET), the necessary brain regions engaged in this capacity are still heavily debated. In this study, we combined the RMET with a whole-brain voxel-based lesion symptom mapping (VLSM) approach to identify brain regions necessary for adequate RMET performance in a large sample of patients with penetrating TBI (pTBI). Our results revealed that pTBI patients performed worse on the RMET compared to non-head injured controls, and impaired RMET performance was associated with lesions in the left inferior frontal gyrus (IFG). Our findings suggest that the left IFG is a key region in reading the mind in the eyes, probably involved in a more general impairment of a semantic working memory system that facilitates reasoning about what others are feeling and thinking as expressed by the eyes.

1214. Dalgic, A., et al. (2010). "Brain injury due to air gun shot: report of three adult cases." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES 16(5): 473-476.

Air guns (AGs) are arms that use air or another compressed gas to propel a projectile. Generally, brain injury may occur in children due to their incomplete skull development; however, the less-resistant and thin region of the skull in adults may also be penetrated by an AG shot. In this paper, we present three adult cases treated in our clinic for brain injury caused by an AG. The first case had brain and skull damage related to the high pressure of the compressed gas, and the others additionally had foreign bodies in their brain. All of the patients were operated. Two were discharged without neurological deficit; the third case had a permanent slight hemiparesis. Average follow-up was 11 months and no abscess formation was observed in this period. AGs are known as low-velocity arms; however, they have the potential to cause brain injury, and brain penetration may occur especially in the relatively less resistant and thin sites of the skull such as the orbit and temporal and occipital bones. As cerebrospinal fluid leakage is one of the expected conditions, urgent surgery is usually required.

1215. D'Alise, M. D., et al. (1996). "External carotid-to-middle cerebral bypass in the treatment of complex internal carotid injury." The Journal of trauma 40(3): 452-455.

Patients with penetrating carotid injuries above C2 present special challenges to the cerebrovascular surgeon. A subgroup of patients may lack the vascular collaterals necessary to tolerate carotid sacrifice or prolonged ischemia during direct carotid repair. We present a technique of extracranial-intracranial (EC-IC) saphenous vein bypass in two patients with high cervical and skull base carotid injuries and poor vascular collaterals. This technique allows preservation of internal carotid flow during the proximal anastomosis. Interruption of cerebral blood flow is limited to the duration required for a distal intracranial anastomosis and is confined to the territory supplied by a single middle cerebral branch. The procedure eliminates systemic anticoagulation, includes trapping of the injured

segment of the internal carotid artery, and restores a volume of flow similar to that of the internal carotid artery. It is a valuable adjunct in this specific population of patients with high carotid injuries who cannot tolerate even brief periods of temporary occlusion or in whom clinical urgency precludes an endovascular trial occlusion.

1216. Dallas, J., et al. (2019). "Should ondansetron use be a reason to admit children with isolated, nondisplaced, linear skull fractures?" Journal of neurosurgery. Pediatrics: 1-7.

OBJECTIVE: Isolated, nondisplaced skull fractures (ISFs) are a common result of pediatric head trauma. They rarely require surgical intervention; however, many patients with these injuries are still admitted to the hospital for observation. This retrospective study investigates predictors of vomiting and ondansetron use following pediatric ISFs and the role that these factors play in the need for admission and emergency department (ED) revisits., METHODS: The authors identified pediatric patients (< 18 years old) with a linear ISF who had presented to the ED of a single tertiary care center between 2008 and 2018. Patients with intracranial hemorrhage, significant fracture displacement, or other traumatic injuries were excluded. Outcomes included vomiting, ondansetron use, admission, and revisit following ED discharge. Both univariable and multivariable analyses were used to determine significant predictors of each outcome ($p < 0.05$)., RESULTS: Overall, 518 patients were included in this study. The median patient age was 9.98 months, and a majority of the patients (59%) were male. The most common fracture locations were parietal (n = 293 [57%]) and occipital (n = 144 [28%]). Among the entire patient cohort, 124 patients (24%) had documented vomiting, and 64 of these patients (52%) received ondansetron. In a multivariable analysis, one of the most significant predictors of vomiting was occipital fracture location (OR 4.05, $p < 0.001$). In turn, and as expected, both vomiting (OR 14.42, $p < 0.001$) and occipital fracture location (OR 2.66, $p = 0.017$) were associated with increased rates of ondansetron use. A total of 229 patients (44%) were admitted to the hospital, with vomiting as the most common indication for admission (n = 59 [26%]). Moreover, 4.1% of the patients had ED revisits following initial discharge, and the most common reason was vomiting (11/21 [52%]). However, in the multivariable analysis, ondansetron use at initial presentation (and not vomiting) was the sole predictor of revisit following initial ED discharge (OR 5.05, $p = 0.009$)., CONCLUSIONS: In this study, older patients and those with occipital fractures were more likely to present with vomiting and to be treated with ondansetron. Additionally, ondansetron use at initial presentation was found to be a significant predictor of revisits following ED discharge. Ondansetron could be masking recurrent vomiting in ED patients, and this should be considered when deciding which patients to observe further or discharge.

1217. Dalve, K., et al. (2021). "Neighborhood disadvantage and firearm injury: does shooting location matter?" Injury Epidemiology 8(1).

Background: Firearm violence is a public health problem that disparately impacts areas of economic and social deprivation. Despite a growing literature on neighborhood characteristics and injury, few studies have examined the association between neighborhood disadvantage and fatal and nonfatal firearm assault using data on injury location. We conducted an ecological Bayesian spatial analysis examining neighborhood disadvantage as a social determinant of firearm injury in Seattle, Washington. Methods: Neighborhood disadvantage was measured using the National Neighborhood Data Archive disadvantage index. The index includes proportion of female-headed households with children, proportion of households with public assistance income, proportion of people with income below poverty in the past 12 months, and proportion of the civilian labor force aged 16 and older that are unemployed at the census tract level. Firearm injury counts included individuals with a documented assault-related gunshot wound identified from medical records and supplemented with the Gun Violence Archive between March 20, 2016 and December 31, 2018. Available addresses were geocoded to identify their point locations and then aggregated to the census tract level. Besag-York-Mollie (BYM2) Bayesian Poisson models were fit to the data to estimate the association between the index of neighborhood disadvantage and firearm injury count with a population offset within each census tract.

Results: Neighborhood disadvantage was significantly associated with the count of firearm injury in both non-spatial and spatial models. For two census tracts that differed by 1 decile of neighborhood disadvantage, the number of firearm injuries was higher by 21.0% (95% credible interval: 10.5, 32.8%) in the group with higher neighborhood disadvantage. After accounting for spatial structure, there was still considerable residual spatial dependence with 53.3% (95% credible interval: 17.0, 87.3%) of the model variance being spatial. Additionally, we observed census tracts with higher disadvantage and lower count of firearm injury in communities with proximity to employment opportunities and targeted redevelopment, suggesting other contextual protective factors. Conclusions: Even after adjusting for socioeconomic factors, firearm injury research should investigate spatial clustering as independence cannot be able to be assumed. Future research should continue to examine potential contextual and environmental neighborhood determinants that could impact firearm injuries in urban communities.

1218. Damestani, Y., et al. (2012). "Windows to the brain: Novel concept for providing non-invasive, chronic access to neural tissues for laser-based traumatic brain injury diagnostics and therapeutics." Lasers in surgery and medicine 44: 39-40.

Background: Based on the World Health Organization projection, road traffic accidents will be the third cause of the global burden of disease and disablement by 2020 and the major cause of traumatic brain injury (TBI). Our goal is to develop a novel transparent polycrystalline Yttria-Stablized-Zirconia (YSZ) cranial implant ("window") that enables life-long, non-invasive delivery and/or collection of laser light into and from shallow and deep brain tissue on demand. Our innovative cranial implant thus allows for real-time and highly precise visualization and treatment of MTBI without the need of future highly-invasive craniotomies or trepanation procedures. Study: The fractured skull will be replaced with YSZ implant to allow the delivery and/or collection of laser light precisely to multiple affected areas within the brain which must be detected and treated chronically. The window will be permanently covered with native scalp that can be rendered temporarily transparent on demand in a minimally-invasive manner using percutaneous drug delivery of optical clearing agents (OCAs) with microneedles. Results: An YSZ implant has been successfully fabricated with current-activated powder-assisted densification processing method. Waveguides have been written across millimeter-thick YSZ using femtosecond laser irradiation with ultralow energies. The optimal YSZ surface roughness for integration of the scalp and skull to the implant was determined by culturing mouse fibroblast and osteoblast cells on the implant. Optical coherence tomography images of YSZ implanted on mouse's skull suggest that the transparent YSZ implant improves axial and lateral resolution and penetration depth into the brain. Porcine skin samples treated with OCA using microneedles demonstrate significant optical clearing. Conclusion: The results from the present study suggest that novel YSZ implants in conjunction with OCA can be used in delivering and/or collecting laser light to the brain for treatment and monitoring of TBI.

1219. Damm, A., et al. (2015). "Transorbital impalement by a wooden stick in a 3-year-old child." BMJ case reports 2015.

We present a case of a 3-year-old girl with a transorbital impalement injury due to a wooden stick penetrating the lower inferior palpebra and progressing through the orbita, after the child jumped from a table and hit a wooden basket containing pieces of exposed stick. CT revealed the stick progressing transorbitally through the medial wall and terminating just below the sella turcica. The stick was successfully removed by neurosurgical and ophthalmological specialists. The eye was subsequently inspected, and showed no pathological findings. The girl was treated with topical chloramphenicol and discharged 2 days later. Follow-up examination 2 months after the trauma demonstrated normal visual acuity and ocular motility, with no diplopia, tearing or pain. Copyright 2015 BMJ Publishing Group Ltd.

1220. Dammeier, S., et al. (2016). "Mass-Spectrometry-Based Proteomics Reveals Organ-Specific Expression Patterns To Be Used as Forensic Evidence." Journal of proteome research 15(1): 182-192.

Standard forensic procedures to examine bullets after an exchange of fire include a mechanical or ballistic reconstruction of the event. While this is routine to identify which projectile hit a subject by DNA analysis of biological material on the surface of the projectile, it is rather difficult to determine which projectile caused the lethal injury--often the crucial point with regard to legal proceedings. With respect to fundamental law it is the duty of the public authority to make every endeavor to solve every homicide case. To improve forensic examinations, we present a forensic proteomic method to investigate biological material from a projectile's surface and determine the tissues traversed by it. To obtain a range of relevant samples, different major bovine organs were penetrated with projectiles experimentally. After tryptic "on-surface" digestion, mass-spectrometry-based proteome analysis, and statistical data analysis, we were able to achieve a cross-validated organ classification accuracy of >99%. Different types of anticipated external variables exhibited no prominent influence on the findings. In addition, shooting experiments were performed to validate the results. Finally, we show that these concepts could be applied to a real case of murder to substantially improve the forensic reconstruction.

1221. Dams-O'Connor, K. (2013). "Prior TBI history affects 6-month outcomes in individuals presenting to level i trauma centers with mild TBI: A track-tbi study." Journal of neurotrauma 30(15): A27.

Introduction The notion that multiple TBIs can have a cumulative detrimental impact is widely accepted, but most research support comes from athlete studies and relevance to community samples is not known. Given the prevalence of mild TBI (mTBI), it is important to understand the factors that contribute to poorer outcomes. Methods We investigated the prevalence of prior TBI (pTBI) in a community sample of individuals who received emergency department (ED) care for mTBI, and compared patients with and without pTBI on indices of pre-index injury psychosocial functioning, health, substance use, and 6-month outcomes. Subjects were recruited from three Level I trauma centers as part of the multicenter prospective Transforming Research and Clinical Knowledge in TBI (TRACK-TBI) study. Patients were eligible if they: 1) presented to the ED within 24 hours after sustaining mTBI of sufficient severity to require CT scan per evidence-based guidelines; 2) were ≥ 18 years old. Extensive data were collected at baseline to characterize the index injury (including medical record abstraction and CT scan) and pre-index injury functioning. Participants were screened for lifetime history of TBI. Index injury outcomes were assessed 6 months post-injury and included measures of postconcussion symptoms, psychosocial functioning, and cognitive functioning. Results Of 586 TRACK-TBI participants, 136 (23%) reported at least one pTBI with loss of consciousness (LOC). There were no demographic differences between individuals with and without pTBI. Individuals with pTBI had lower rates of employment and were less likely to be married than those with no pTBI ($p < .01$). Those with pTBI had worse medical and psychiatric health, as indicated by number of chronic medical conditions ($p = .001$) and higher rates of anxiety disorder, depression, sleep disorder, and bipolar disorder ($p < .05$). Individuals with pTBI were twice as likely to use tobacco, alcohol, and illicit drugs ($p = .000$). Surprisingly, individuals with a pTBI had less severe index injuries, as indicated by duration of LOC ($p = .001$), duration of post-traumatic amnesia (PTA; $p = .000$), length of hospital stay ($p = .000$), and rates of positive CT scans ($p = .000$). The groups did not differ in blood alcohol content at ED admission. Six months after index injury, individuals with a pTBI were less likely to have returned to work ($p = .023$) and reported greater family strain ($p = .000$). Individuals with pTBI reported more post-concussion symptoms and psychiatric problems, and had slower processing speed than those with no pTBI controlling for age, education and injury severity ($p < .01$). Effect sizes for most comparisons were moderate. Conclusions The current study found associations between pTBI and pre-index injury health and psychosocial problems, and overall worse outcomes among those with pTBI at 6 months post-index injury. While these findings are consistent with the athlete literature, it is notable that pTBI sustained years before the index injury had a marked impact on recovery from mTBI. Contrary to expectations, those with pTBI had less severe index injuries. Higher levels of pre-index emotional and health problems lead to these patients being viewed as complicated and contributed to the perceived

need for CT scans despite the index TBI itself being less severe. Most individuals recover completely within days or weeks after mTBI, and the enduring symptoms experienced by 15-20% of individuals are not well explained or understood. The findings of this study suggest that prior history of TBI may be an often overlooked predictor of poor outcomes after mTBI or concussion.

1222. Dandu, K. V., et al. (2017). "A 10-Year Analysis of Head and Neck Injuries Involving Nonpowder Firearms." Otolaryngology--head and neck surgery : official journal of American Academy of Otolaryngology-Head and Neck Surgery 156(5): 853-856.

Objectives Firearms have an enduring and visible presence within American culture. However, the public health impact of nonpowder firearms and other "toy" guns has not been fully studied. These guns-including BB guns (ie, ball bearing), paintball guns, and pellet guns-are typically marketed to a younger audience. The objective of this study is to analyze head and neck injuries related to nonpowder firearms. Study Design Cross-sectional analysis of a national database. Setting Academic medical center. Subjects and Methods The National Electronic Injury Surveillance System was queried for head and neck injuries involving nonpowder guns, including air, BB, and pellet guns, and associated ammunition. Analysis of age, sex, incidence, injury location, and diagnosis was performed. Results From 2005 to 2014, there were 1695 cases recorded, or 55,060 estimated emergency room visits, due to injuries related to nonpowder guns and fired ammunition. The majority of patients were male (80.9%). These injuries were most common in children 6 to 12 years of age (37.9%), followed by those 13 to 18 years old (27.1%) and adults (>=19 years old; 17.8%), while preschool children (0-5 years) represented 17.2%. The most common injury diagnosis was penetrating foreign body (34.9%), followed by lacerations (24.3%) and contusions/abrasions (13.7%). Conclusion Nonpowder and other nonlethal firearm-related injuries to the head and neck region are a frequent source of emergency room visits nationally. Safety measures and public education on a mainstream level are required.

1223. Danesh-Meyer, H. V., et al. (2001). "Gaze-evoked amaurosis produced by intraorbital buckshot pellet." Ophthalmology 108(1): 201-206.

OBJECTIVE: To report the first case of gaze-evoked amaurosis secondary to an intraocular foreign body and to highlight the characteristic clinical findings of patients with this symptom., DESIGN: Case report and review of the literature., METHODS: Case review, clinical history, electrophysiologic testing, and follow-up., MAIN OUTCOME MEASURES: Visual acuity, automated perimetry, and visual fields., RESULTS: A case of gaze-evoked amaurosis as a result of an intraorbital foreign body is described, and 19 additional cases of gaze-evoked amaurosis are reviewed from the English language literature. These cases share certain characteristics including good vision in primary position with deterioration of vision in eccentric gaze; concurrent objective pupillary abnormalities in eccentric gaze; stereotypic onset and recovery of vision; and funduscopic abnormalities consisting of disc edema and chorioretinal folds., CONCLUSIONS: Gaze-evoked amaurosis is a reliable sign of intraconal mass lesion. We report the first case of gaze-evoked amaurosis secondary to an intraorbital foreign body.

1224. D'Angelica, M., et al. (1995). "Hypopituitarism secondary to transfacial gunshot wound." The Journal of trauma 39(4): 768-771.

Hypopituitarism secondary to penetrating head trauma is extremely rare, and its diagnosis may be delayed for several years. We present a patient who developed hypopituitarism secondary to a transfacial gunshot wound and who experienced damage to the hypophysis secondary to transmission of energy and bullet fragments. The importance of a computerized tomographic scan of the head in facial gunshot wound is discussed.

1225. Daniels, J. S., et al. (2021). "Management of Maxillofacial Gunshot Injuries With Emphasis on Damage Control Surgery During the Yemen Civil War. Review of 173 Victims From a Level 1 Trauma Hospital in Najran, Kingdom of Saudi Arabia." Craniomaxillofacial Trauma and Reconstruction.

Study Design: Studies on the concept of Damage Control Surgery (DCS) in the management of firearm injuries to the oral and maxillofacial region are still scarce, hence the basis for the current study. Objectives: The objectives of the current study is to share our experience in the management of maxillofacial gunshot injuries with emphasis on DCS and early definitive surgery. Methods: This was a retrospective study of combatant Yemeni patients with maxillofacial injuries who were transferred across the border from Yemen to Najran, Kingdom of Saudi Arabia. Demographics and etiology of injuries were stored. Paths of entry and exit of the projectiles were also noted. Also recorded were types of gunshot injury and treatment protocols adopted. Data was stored and analyzed using IBM SPSS Statistics for Windows Version 25 (Armonk, NY: IBM Corp). Results: A total of 408 victims, all males, were seen during the study period with 173 (42.4%) males sustaining gunshot injuries to the maxillofacial region. Their ages ranged from 21 to 56 years with mean ± SD (27.5 ± 7.6) years. One hundred and twenty-one (70.0%) victims had extraoral bullet entry, while 53 (30.0%) victims had intraoral entry route. Ocular injuries, consisting of 25 (14.5%) cases of ruptured globe and 6 (3.5%) cases of corneal injuries, were the most commonly associated injuries. A total of 78 (45.1%) hemodynamically unstable victims had DCS as the adopted treatment protocol while early definitive surgery was carried out in 47(27.2%) hemodynamically stable victims. ORIF was the treatment modality used for the fractures in 132 (76.3%) of the victims. Conclusions: We observed that 42.4% of the war victims sustained gunshot injuries. DCS with ORIF was the main treatment protocol adopted in the management of the hemodynamically unstable patients.

1226. Danilovskii, M. A., et al. (1987). "[Role of endogenous neurohumoral factors in mechanisms of the pathogenesis and compensation of unilateral movement disorders after serial removal of the motor neocortex]." Rol' endogennykh neirogumoral'nykh faktorov v mekhanizmakh patogeneza i kompensatsii odnostoronnikh dvigatel'nykh rasstroistv posle seriinykh udalenii motornogo neokorteksa. 73(5): 602-606.

The role of neurohumoral factors in the mechanisms of restoring the lost motor functions after two successive unilateral removals of the neocortex motor region, was studied. The dynamics of the restoring correlated with the posture asymmetry factor (PAF) activity in the CSF. PAF activity was reduced during the restoring by an inactivation factor (FI). Periods of restoration after the 2nd extirpation and inactivation of PAF were shorter than after the 1st one. The existence of the FI before the 2nd extirpation may account for this phenomenon.

1227. Daradkeh, G., et al. (2014). "Nutritional status, assessment, requirements and adequacy of traumatic brain injury patients." Pakistan journal of biological sciences : PJBS 17(10): 1089-1097.

Traumatic Brain Injury (TBI) has been considered as a serious public health problem. Each year, traumatic brain injuries are contributing to a substantial number of cases of permanent disability and deaths and it can be classified according to the severity into penetrating and closed head injury. Symptoms, beside to be unconscious can be defined as vomiting, nausea, headache, dizziness, lack of motor coordination, difficulty in balancing, blurred vision and lightheadedness, bad taste in the mouth, ringing in the ears, fatigue and lethargy as well as changes in sleep patterns. The brain is known to be the functional regulator for all the metabolic activities inside the body and TBI patients mostly have a complex metabolic alterations including aberrant cellular metabolism, abnormal metabolic processes, changes in hormones functions and inflammatory cascade. The TBI patient's status needed to be assessed medically and nutritionally since the medical status of the patients can affect the nutrition part. Data from the four assessment tools are needed to be correctly used and interpreted in order to make a proper nutritional diagnosis, clinical assessment, biochemistry as well as anthropometric measurements. Regardless the methods used for assessing TBI patients, having adequate intake and medical care can

lead to a reduction in hospital costs, numbers of day hospitalized, numbers of hours of mechanical ventilation and in the overall infection rates.

1228. Darok, M. and R. Gatternig (2005). "Suspected suicide and suicide attempt with mysterious concomitant circumstances." Forensic science international 147 Suppl: S17-19.

Two cases of suicide and attempted suicide, respectively, are presented. A 15-year old boy suffering from diabetes died of hyperglycemia after continuous drinking of large amounts of sugared tea. He concealed his disease from the teachers as well as from the doctor. A 52-year old woman was found with multiple blunt force injuries and stab wounds. The suspicion of homicide attempt could be clarified, as all of the injuries were self-inflicted.

1229. Darsaut, T. E., et al. (2007). "Endovascular management of an embedded intracranial knife." The Canadian journal of neurological sciences. Le journal canadien des sciences neurologiques 34(4): 460-463.

BACKGROUND: Endovascular therapy (ET) is infrequently used in the setting of acute penetrating intracranial trauma., METHODS: We report a case where ET was used immediately prior to and following removal of an embedded intracranial knife, which was found to be disrupting the anterior cerebral artery., RESULTS: The proximal vessel was coiled and angiographically occluded and then the knife was removed with the microcatheter in place. Immediate angiography allowed us to see and quickly treat the contrast extravasation with further coiling. Despite full medical management, the patient died of elevated intracranial pressure., CONCLUSION: In this severely injured patient, endovascular therapy represented the most suitable means to attempt safe removal of the knife.

1230. Darwazeh, R., et al. (2018). "Traumatic Brain Injury Caused by Missile Wounds in the North of Palestine: A Single Institution's Experience with 520 Consecutive Civilian Patients." World neurosurgery 116: e329-e339.

BACKGROUND: Literature about traumatic brain injury caused by missile wounds is scanty. We shed some light on this field., METHODS: This retrospective study was carried out, between September 2000 and September 2010, on 520 civilian patients who sustained traumatic brain injury from missiles in the north of Palestine. Thorough detailed analyses were made of patients' admission Glasgow Coma Scale (GCS) scores, pupillary reactivity to light, site and mode of injuries, type of injurious agents, missile trajectory, method of treatment, radiologic manifestations, complications, and outcome. The GCS score was used to assess the level of consciousness, whereas the Glasgow Outcome Scale score was used to evaluate the outcome., RESULTS: Patients' age ranged from 6 months to 75 years. Only 50 (9.6%) patients were female. Patients injured by metallic bullets, rubber bullets, and shrapnel from bomb explosions numbered 351, 139, and 30, respectively. Of 384 patients who were treated conservatively, no mortality was detected, whereas of 136 surgically treated patients, 66 (48.5%) died of their injuries. Although our management of patients was not optimal because of many factors, the overall mortality was 12.7% (n = 66)., CONCLUSIONS: The promptness of transport to hospital was a decisive factor with a major bearing on decreasing mortality. Brain computed tomography was invaluable in the diagnosis and follow-up of our patients. In addition, age, pupillary reactivity, admission GCS score, missile trajectory, ventricular involvement, and site and mode of injury were important prognostic factors.

1231. Darwazeh, R., et al. (2022). "Spontaneous migration of retained intracranial missiles: experience with 16 cases." Neurosurgical review 45(3): 2417-2430.

Spontaneous migration of retained intracranial missiles is uncommon but a potentially serious phenomenon. Our objective is to increase awareness of the risk of spontaneous migration of retained

intracranial missiles by reporting our case series of 16 patients. We performed a retrospective single-center study on patients treated for intracranial missile injuries between 2000 and 2010 in Palestine with a particular focus on the migration of retained intracranial missiles. Detailed analyses were made of patients' age, sex, type of injurious agents (metallic bullets/rubber bullets/metallic shrapnel from bomb explosion), initial missile position, site to where the missile migrated, radiological and neurological manifestations, complications, treatment modalities (surgery vs. conservative) and functional outcome by Glasgow outcome scale-extended (GOSE) classification at last follow-up. In a cohort of 190 patients with retained intracranial missiles, we identified 16 (8.4%) patients with spontaneous migration. Patients' age ranged from 10 to 30 years (mean: 18.9 +/- 6.4 years). There were only 2 female patients. The missiles that migrated intracranially were metallic bullets (n = 10), rubber bullets (n = 3), and metallic shrapnel from a bomb explosion (n = 3). Among the 16 patients, 10 patients experienced symptoms due to missile migration and were treated surgically, while six patients did not develop new symptoms after missile migration and were managed conservatively. In our case series, 16/190 (8.4%) patients with retained intracranial missiles developed spontaneous migration. Neurosurgeons performing delayed surgery on patients with retained intracranial missiles should be aware of the risk of spontaneous migration and verify the location of the missile after positioning the patient for surgery.

1232. Das, D., et al. (2020). "Large organic orbitocranial foreign body." BMJ case reports 13(8).

1233. Das, J. M., et al. (2015). "Penetrating brain injury with a bike key: a case report." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES 21(6): 524-526.

Penetrating brain injury (PBI) may be caused by low-velocity or high-velocity objects. Several objects are known to cause such injury ranging from knives to rooster pecks. However, an assault with the key of a bike causing PBI has not been reported in the literature. The objective of this study was to report the case of a 21-year-old male patient, who presented after an assault with a bike key. The key was impacted in the left parietal region. Left parietal craniotomy was done and the key was removed. There was an underlying parenchymal contusion, which was excised. On post-operative day two, the patient developed motor aphasia, which subsided in subsequent days with antiedema measures. At the first month follow-up, the patient was having normal speech and consciousness. Prompt treatment of penetrating brain injury is important and angiography is not always necessary for PBI.

1234. Das, L., et al. (2000). "Spontaneous migration of an intracranial bullet across the midline." Asian Oceanian Journal of Radiology 5(1): 38-41.

Penetrating injuries of the brain may occur due to metallic foreign bodies such as bullets. Spontaneous migration of these bullets within the intracranial compartment or even to the spine is a well known phenomenon. Most of the movements described in various reports are within one hemisphere of the brain. To the best of the knowledge of the authors, no case of migration of a bullet across the midline to the opposite cerebral hemisphere of the brain has been reported in the English literature earlier. We present an extremely rare case of a spontaneous migration of a copper jacketed, intracranial bullet across the midline to the opposite cerebral hemisphere. The potential of intracranial bullets to migrate within the cranio spinal axis from a surgically accessible location to an inaccessible location and vice versa, makes serial imaging studies mandatory in all such patients.

1235. Dasgupta, S., et al. (2015). "Orbital foreign body- Study of a case series." Nepalese journal of ophthalmology : a biannual peer-reviewed academic journal of the Nepal Ophthalmic Society : NEPJOPH 7(1): 60-64.

BACKGROUND: Orbital foreign bodies (OFBs) may remain in the orbital cavity for considerable time and manifest with secondary complications., OBJECTIVE: To report five consecutive cases of orbital trauma with OFBs, who presented at our institute from Jan 2010 to Dec 2013., CASES: The first case of our series with a non-specific history of injury had a chronic granulomatous discharging sinus in the left upper eyelid and an intact globe. The second case, with an injury to the left lower eyelid following an assault, presented late and the manifestations were similar to that of the first case. The third case, of a road traffic accident, had sustained multiple facial and periocular injuries. The nature of all of three OFBs was uncertain by CT- scan, till surgical exploration. The fourth case had sustained injury to his left eye by a flying metal object. X-ray was sufficient to detect the OFB, but as scleral penetration was associated, management was complex. The fifth case had a nonspecific history of injury and the manifestation was similar to that of the first case. The surgical exploration revealed multiple OFB (wood)., CONCLUSION: The OFBs pose difficult diagnostic and therapeutic challenges. Management of such cases, at times, calls for innovation in decision making and formulation of strategies.

1236. Daszkiewicz, P., et al. (2016). "Airgun shot wound to the orbit with retention of pellet. Case report and review of the literature." Neurologia i neurochirurgia polska 50(5): 379-382.

Shot wounds become a growing clinical concern in the civilian setting, due to increasing popularity of air guns among minors. We present a pediatric case of a shot wound to the orbit with sparing of the eyeball and retention of airgun pellet in the retrobulbar space. The pellet was removed 3 months after injury via lateral orbitotomy. Pathophysiology and ballistics of shot wounds are briefly reviewed and current views on the management strategy of shot wounds with retained projectile are discussed.

1237. Datta, A., et al. (2020). "Traumatic brain injury induced amyloid plaque scintigraphy." European Journal of Nuclear Medicine and Molecular Imaging 47(SUPPL 1): S338.

Aim/Introduction: Epidemiological evidence implicates formation of diffused amyloid plaques after incident of Traumatic Brain Injury as a risk factor for developing associated neurodegenerative disorders. Early detection of these plaques consequently remains vital for better regulation of these diseases. Considering this, we developed a cost-effective, homodimeric chalcone scaffold-based SPECT radiotracer which specifically binds detrimental Aβ1-42 plaques. The bifunctional chelating agent, pentapa-en-NH2 was explored for the development of SPECT agent. We hypothesise the developed bivalent homodimeric molecule to display enhanced binding affinity and blood brain barrier penetration. Materials and Methods: The bifunctional chelator was synthesised through a series of steps in high purity and further conjugated to the chalcone derivative using bivalent approach. The molecule was conjugated to 99mTc and further used for pre-clinical studies. A repetitive mild TBI mouse model was developed and uptake of tracer was studied. Results: The molecular docking studies reported multiple binding of tracer at the recognition sites of Aβ fibrils with a significantly high binding score (-12.64) as compared to known Aβ ligands. Bischalcone derivative, 6,6'-(((2-(bis(2-(4-((E)-3-(4 (dimethylamino)phenyl)acryloyl) phenoxy)ethyl)amino)ethyl)azanediyl)bis(methylene)) dipicolinic acid, (Ch)2pa was synthesized in 95% yield with high purity. Radiolabelling was carried out with 99mTc under mild conditions with 95.4% efficiency and 103-124 MBq μmol-1 specific activity. In vitro binding assay with Aβ1-42 aggregates displayed high binding affinity of (Ch)2pa. The fluorescent data displayed absorption/emission at 410/540 nm and exhibited blue shift with 10-fold increase in emission intensity on binding with Aβ aggregates. Blood kinetics performed on normal rabbit displayed fast clearance (t1/2(F) = 32 ± 0.04 min; t1/2(S) = 3h 55min ± 0.03 min). A repetitive mild TBI mice model was established and ex vivo staining of TBI mice model brain sections with (Ch)2pa showed specific binding of complex to amyloid plaques. In vivo scintigraphy displayed two-fold increase of radioligand concentration in TBI model as compared to sham mice owing to higher amyloid burden in TBI model.

Ex vivo biodistribution analysis demonstrated high blood brain barrier penetration in TBI model mice with brain uptake of 5.24 ± 0.31% ID g-1 at 2 min p.i. and 3-fold higher than brain uptake in sham mice. Conclusion: These preliminary studies reveal the enhanced amyloid binding affinity by bivalent approach and offers a new perspective in 99mTc probes for β-amyloid imaging. The study also highlights the increased amyloid burden in traumatic brain injury cases and provides a novel approach for prognosis and ultimately better regulation of TBI induced dementia.

1238. Datta, H., et al. (2001). "An unusual case of a retained metallic arrowhead in the orbit and sphenoidal sinus." Indian journal of ophthalmology 49(3): 197-198.

A case of retained metallic arrowhead in orbit and sphenoidal sinus through an unusual route is reported. The eyeball was removed because of a possible risk of sympathetic ophthalmia.

1239. Dauch, W. A., et al. (1996). "[Post-traumatic seizure prevention--results of a survey of 127 neurosurgery clinics]." Posttraumatische Anfallsprophylaxe--Die Ergebnisse einer Umfrage unter 127 neurochirurgischen Kliniken. 57(4): 190-195.

Starting in November, 1993, until January, 1994, we performed a survey among 127 Neurosurgical Departments in Austria, Germany, and Switzerland concerning the practice of antiepileptic prophylaxis in head injured patients. Seventy seven percent of the 12-item multiple choice questionnaires were completed and returned. They indicate a variety of attitudes towards prophylaxis for seizures: in 12% of the responding institutions, antiepileptic prophylaxis is given to every brain trauma patient, in 36%, no prophylaxis is carried out. and in 52% some patients receive prophylaxis while others do not. Penetrating injuries, intracranial haemorrhages and electroencephalographic abnormalities were the most frequent reasons why prophylaxis was initiated. Phenytoin is by far the most popular drug, given usually for at least three months, and in most cases monitored by routine serum level observations. Nevertheless, about three out of four neurosurgeons conceded that a general renunciation of antiepileptic prophylaxis after brain trauma might be justified. There is no uniform way in which patients are informed about a possible risk of seizures, as it may be relevant, for instance, in respect of driving abilities.

1240. Daudfar, S., et al. (2018). "Hemiplegic Syndrome After Chopstick Penetration Injury in the Lateral Soft Palate of a Young Child." The Journal of the American Osteopathic Association 118(8): 555-559.

Soft palate penetrating injuries have been reported among children, particularly in children falling with objects in their mouth. The authors present a case of a healthy 14-month-old child who fell onto a blunt-ended chopstick, the subsequent cerebrovascular accident, and the role of the osteopathic tenets thereafter. The child had an acute infarction to the region of his right middle cerebral artery secondary to right internal carotid artery occlusion. Physicians should consider the neurologic sequelae of lateral soft palate injuries and damage to the surrounding anatomical structures. A thorough, whole-patient approach to physical examination is critical.

1241. Dave, J., et al. (2011). "Serum GFAP: A potential biomarker of mild traumatic brain injury produced by repeated exposure to low level blast overpressure." Journal of neurotrauma 28(6): A118-A119.

From the shear number of reported cases that have emerged since 2002, mild traumatic brain injury (mTBI) resulting from exposure to improvised explosive devices (IEDs) represents a major medical issue for deployed military personnel. This has created an urgent need to identify potential serum/blood biomarkers of brain injury resulting from exposure to blast overpressure (BOP), one component of IEDs, which may play a role in the long-term manifestation of cognitive and other

impairments. We have previously reported cognitive impairment after a single exposure to 75 and 120 kPa BOP and a long lasting cognitive deficit in rats given 12 exposures to 40 kPa. Since 1) our WRAIR TBI/biomarker group has demonstrated serum biomarker changes in a rodent model of penetrating brain injury that 2) have also been reported to be sensitive indicators of mTBI diagnosed in human patients, the objective of the present study was to determine if repeated, once daily exposures to 75 KPa for 3 days or 40 kPa for 3 days produced any changes in targeted serum biomarkers of brain injury. Anesthetized adult male rats exposed to BOP were assessed for serum levels of GFAP, Nestin, UCH-L1 and SBDP-145 (spectrin breakdown product) by Western blot analysis. Although the results of Nestin, UCH-L1 and SBDP-145 measurements in plasma were inconclusive, a significant increase in serum GFAP was observed that was also dependent on the severity of BOP. Further studies are under progress to determine alterations in these biomarkers in brain tissue using immunocytochemical analysis. These preliminary studies suggest that serum GFAP level may be a potential candidate biomarker of lowlevel blast overpressure-mediated mTBI.

1242. Dave, J. R., et al. (2011). "Acute neuroprotective effects of glial growth factor 2 on protein changes following penetrating ballistic-like brain injury." Journal of neurotrauma 28(6): A120-A121.

Traumatic brain injury (TBI) is a significant cause of morbidity and mortality for the civilian and military populations. To date there are no approved drug treatments for TBI. Glial growth factor 2 (GGF2; ACORDA Therapeutics) is a member of the endogenous protein family known as neuregulins. Neuregulins are required for normal development of the heart and brain and have recently demonstrated neuroprotective and neurorestorative effects in stroke injury models. Therefore, GGF2 was examined for possible acute neuroprotective effects in our model of penetrating ballistic-like brain injury (PBBI). Animals (n=6/group) were dosed via i.v. infusion at 30 min postinjury with GGF2 (100 or 500 μg/kg) or vehicle control. Changes in a-2 spectrin breakdown product-145 (SBDP-145), and ubiquitin carboxyl-terminal hydrolase L1 (UCH-L1) were examined in brain and plasma at 24 hr post injury using western blot analysis. PBBI injury caused a significant increase in both of these proteins in brain tissue and in plasma ($p<0.05$). GGF2 (both doses) significantly reduced PBBI-induced increases in UCH-L1 levels in brain tissue and (high dose only) significantly reduced SBDP-145 levels in plasma ($p<0.05$). In a separate experiment, GGF2 (both doses) significantly attenuated the PBBI-mediated up-regulation of caspase-3 activity in brain tissue. Overall, the current results indicate that a single, postinjury infusion of GGF2 provides significant protection against acute (≤24 hr) PBBI-induced protein changes. Since recent studies have suggested that GGF2 may have a stronger restorative function than a protection function, optimal dosing regiments of GGF2 should be examined during the sub-acute or chronic periods in the PBBI model.

1243. Davidson, J., et al. (2015). "Post-Traumatic Brain Injury: Genetic Susceptibility to Outcome." The Neuroscientist : a review journal bringing neurobiology, neurology and psychiatry 21(4): 424-441.

It is estimated that 2% of the population from industrialized countries live with lifelong disabilities resulting from traumatic brain injury (TBI) and roughly one in four adults are unable to return to work 1 year after injury because of physical or mental disabilities. TBI is a significant public health issue that causes substantial physical and economical repercussions for the individual and society. Electronic databases (PubMed, Web of Science, Google Scholar) were searched with the keywords traumatic brain injury, TBI, genes and TBI, TBI outcome, head injury. Human studies on non-penetrating traumatic brain injuries reported in English were included. To provide health care workers with the basic information for clinical management we summarize and compare the data on post-TBI outcome with regard to the impact of genetic variation: apolipoprotein E (APOE), brain-derived neurotrophic factor (BDNF), calcium channel, voltage dependent P/Q type, catechol-O-methyltransferase (COMT), dopamine receptor D2 and ankyrin repeat and kinase domain containing 1 (DRD2 and ANKK1), interleukin-1 (IL-1), interleukin-6 (IL-6), kidney and brain expressed protein (KIBRA), neurofilament, heavy polypeptide (NEFH), endothelial nitric oxide synthase 3 (NOS3), poly

(ADP-ribose) polymerase-1 (PARP-1), protein phosphatase 3, catalytic subunit, gamma isozyme (PPP3CC), the serotonin transporter (5-HTT) gene solute carrier family 6 member (SLC6A4) and tumor protein 53 (TP53). It is evident that contradicting results are attributable to the heterogeneity of studies, thus further researches are warranted to effectively assess a relation between genetic traits and clinical outcome following traumatic injuries. Copyright © The Author(s) 2014.

1244. Davidsson, J. and M. Risling (2015). "Characterization of pressure distribution in penetrating traumatic brain injuries." Frontiers in neurology 6(MAR).

Severe impacts to the head commonly lead to localized brain damage. Such impacts may also give rise to temporary pressure changes that produce secondary injuries in brain volumes distal to the impact site. Monitoring pressure changes in a clinical setting is difficult detailed studies into the effect of pressure changes in the brain call for the development and use of animal models. The aim of this study is to characterize the pressure distribution in an animal model of penetrating traumatic brain injuries (pTBI). This data may be used to validate mathematical models of the animal model and to facilitate correlation studies between pressure changes and pathology. Pressure changes were measured in rat brains while subjected to pTBI for a variety of different probe velocities and shapes; pointy, blunt, and flat. Experiments on ballistic gel samples were carried out to study the formation of any temporary cavities. In addition, pressure recordings from the gel experiments were compared to values recorded in the animal experiments. The pTBI generated short lasting pressure changes in the brain tissue; the pressure in the contralateral ventricle (CLV) increased to 8 bar followed by a drop to 0.4 bar when applying flat probes. The pressure changes in the periphery of the probe, in the Cisterna Magna, and the spinal canal, were significantly less than those recorded in the CLV or the vicinity of the skull base. High-speed videos of the gel samples revealed the formation of spherically shaped cavities when flat and spherical probes were applied. Pressure changes in the gel were similar to those recorded in the animals, although amplitudes were lower in the gel samples. We concluded cavity expansion rate rather than cavity size correlated with pressure changes in the gel or brain secondary to probe impact. The new data can serve as validation data for finite element models of the trauma model and the animal and to correlate physical measurements with secondary injuries.

1245. Davidsson, J. and M. Risling (2019). A Model for Research on Penetrating Traumatic Brain Injuries. 149: 47-59.

The animal model presented here produces high-speed penetrating traumatic brain injuries (pen-TBI) to simulate a form of neurotrauma that is severe and is the prevailing TBI in warzones and in areas with high incidence of violence. Commonly, these neurotraumas involve laceration of brain tissue, accompanying hemorrhage, edema, and inflammation. This also occurs in the pen-TBI model designed for rats that is presented here. During trauma, a probe, constructed in one single unit in aluminum and guided by a probe holder, is propelled by a lead bullet and penetrates at high speed into the brain parenchyma of the anesthetized animal. The animal’s head is held in position in a purposely built stereotactic frame. This frame can be adjusted in position relative the tip of the probe so that the tip of the probe is positioned on the exposed dura, using three orthogonally arranged horizontal slides. This procedure will facilitate high similarity in probe penetration location. By adjusting the air pressure in the air-driven accelerator used to accelerate the lead bullet, a large range of probe velocities can be achieved; 110 m/s probe velocity is commonly used. Several probe tip shapes are available for use in the pen-TBI model; pointy, blunt, and flat. The distance the probe penetrates the brain can be controlled. A typical distance is 5.5 mm, and this distance has been found to be almost independent of probe velocity and probe tip shape. After the probe has penetrated the animal, the pen-TBI device facilitates removal of the probe without causing additional brain damage. To do so, the animal is removed using the horizontal slider on the device that moves the animal’s head away from the probe in the direction of probe travel. The pen-TBI device is easy to operate and requires limited pre-trauma and post-trauma surgery. The device induces a small cavity, primary injury in a greater volume of the brain than the cavity and

secondary injuries in an even greater volume that is several times that of the primary injury volume. The model appears to produce identical injuries in terms of appearance and dimensions in-between animals of same sex and body mass. The device also produces substantial but short-lived intracranial brain pressure changes, some 8-bar overpressure in the contralateral ventricle has been recorded, with high repeatability.

1246. Davie, S. and D. Funk (2018). "The incidence and magnitude of cerebral desaturation in traumatic brain injury." Canadian Journal of Anesthesia 65(1): S33.

Introduction Traumatic brain injury (TBI) is a leading cause of death and disability worldwide1. The current management of TBI focuses on preventing secondary neurological injury. However, further neurological injury can continue undetected, despite the appearance of normal physiologic parameters in the ICU. Cerebral oximetry utilizes near-infrared spectroscopy to measure regional cerebral oxygen saturation (rSO2) in a non-invasive, continuous manner2. Studies have shown that episodes of cerebral ischemia can be revealed with the use of cerebral oximetry monitoring3,4. It is possible that secondary neurological injury not detected by our standard ICU monitors could be detected by cerebral oximetry. The objective of our study was to determine the incidence and severity of regional cerebral oxygen desaturation in patients with TBI. Methods This study was approved by the institutional Research Ethics Board. We conducted a single-centre prospective observational study to determine the incidence and magnitude of cerebral desaturation in patients with TBI. Adult patients admitted to the Surgical Intensive Care Unit (SICU) with a diagnosis of severe non-penetrating TBI, who were being mechanically ventilated and undergoing intracranial pressure (ICP) monitoring, were assessed for study enrollment. Cerebral oximetry data was collected continuously for up to 72 hours. Mean arterial pressure, ICP and cerebral perfusion pressure were collected at 5-minute intervals during the study period. The primary outcome was the incidence and magnitude of cerebral oxygen desaturation, defined as a rSO2 value of less than 65%. Secondary outcomes include the associated changes in other monitoring parameters. Results Data from 18 patients were analyzed for cerebral desaturation. Twelve of the 18 patients (67%) experienced a cerebral desaturation. The median nadir rSO2 was 57% [interquartile range 51-62%]. In the group of patients who desaturated, the time spent below the 65% threshold was 265 [57-1277] minutes, or 8.1% [2.6-26.0] of the recording time. In all patients, the area under threshold (AUT) of 65% for cerebral saturation was moderately correlated with the area above an ICP threshold of 20 mm Hg (Pearson r = 0.72). A linear regression analysis of AUT for rSO2 of 65% and area above an ICP threshold of 20 mmHg showed an R2= 0.52. Although patients who had a decreased rSO2 spent more time with a MAP and CPP less than 65 mm Hg, these results were not statistically significant. Discussion Our study demonstrated that cerebral desaturations occurred frequently in patients with TBI, and when they occurred, it was for a long period of time. These desaturations were moderately correlated with ICP increases.

1247. Davies, G., et al. (2003). "Prehospital thoracotomy (multiple letters)." Emergency Medicine Journal 20(4): 394-395.

1248. Davies, M. A., et al. (2014). "Pharmacokinetic and pharmacodynamic analysis of preoperative therapy with dabrafenib alone and in combination with trametinib in patients with BRAF mutation-positive melanoma with metastases to the brain (BRV116521)." Journal of Clinical Oncology 32(15).

Background: Dabrafenib (D) has clinical activity in patients (pts) with BRAF V600E/K mutation-positive melanoma brain metastases (MBM). The combination of D and trametinib (T) has increased activity in pts with BRAFV600E/K mutation-positive melanoma with extracranial metastases (ECM). It is not known whether the activity of D in MBM pts is due to blood-brain barrier penetration of the D parent compound or 1 (or more) of its active metabolites. In addition, the relationships between drug levels (parent compound and metabolites) achieved in MBM, and (1) peripheral exposure and (2)

target inhibition in plasma and ECM are unknown. Methods: This international, open-label study will enroll up to 30 evaluable pts with stage IV BRAFV600E/K metastatic melanoma with untreated, resectable MBM (1-4 cm) and accessible ECM. Pts will be treated with D 150 mg twice daily (BID) for 7-14 days (cohort A, n=15) or D 150 mg BID + T 2 mg once daily for 7-14 days (cohort B, n=15), followed by resection of intracranial lesion(s) and biopsy or resection of accessible ECM(s). Blood (mandatory) and cerebrospinal fluid (CSF; optional) will also be collected on the day of surgery. If clinically indicated, pts in both cohorts will be treated with D + T starting 72 hours postsurgery until disease progression. MBM and ECM tumor tissue will be studied for levels of D (parent and metabolites) and T; expression and activation of pharmacodynamic markers and oncogenic signaling networks (protein, mRNA); DNA mutations and methylation; and immune cell infiltrates. Plasma and CSF will be studied for pharmacokinetics (PK). Blood will also be studied for circulating immune cells and cytokines. The primary objective is to assess PK in MBM, ECM and peripheral blood. Safety and efficacy will also be evaluated. The trial is currently open for accrual in the United States and Australia.

1249. Davis, A., et al. (2009). "A comparison of two cognitive test paradigms in a military-relevant traumatic brain injury model." Journal of neurotrauma 26(8): A18.

The penetrating ballistic-like brain injury (PBBI) is a military-relevant model of traumatic brain injury (TBI) that mimics the pathopysiological changes that occur in ballistic entry wounds to the head. Although cognitive tests have often been used to ascertain TBI severity and provide useful information for drug development aimed at improving patients' learning and memory, not all tests may be appropriate for different types of TBI models. In this study, we compared the performance of PBBI animals in the novel object recognition (NOR) and Morris Water Maze (MWM) tasks. The NOR task exploits the rat's natural tendency to explore novel objects over familiar objects, while the MWM task is a spatial learning and memory test. Rats were exposed to unilateral frontal PBBI or sham surgeries. One week later cognitive abilities were assessed in both the NOR and MWM tasks. For the NOR task, the rats were allowed to explore two identical objects for 5min (familiarization phase) after a 1-h retention period; one familiar object and one novel object were then presented for another 5 min exploration period (test phase). The results suggest that sham animals exhibited a novelty preference during the test phase, resulting in a higher (better) discrimination index (DI) of 0.34 ±0.089, when compared to the PBBI group which had a DI of -0.04 ±0.18, indicating they explored the familiar and novel objects equally. However, statistical analysis revealed no significant difference between the two groups, which is likely due to the large within-group variability seen in PBBI animals. Furthermore, PBBI animals were not as motivated to explore the objects as sham animals, as seen by >3x less in the total exploration time of the objects during the familiarization phase (sham = 47.4 ± 6.32 s; PBBI = 13.8 ± 2.45 s). In the same rats, the results of MWM tests (20 trials/day; 90-s trial duration; 15-min inter-trial interval) showed that PBBI produced significant cognitive impairment that was sustained over the entire course of testing. Overall mean latency (PBBI = 66.2 ± 8.5 sham = 19.6±2.3s, $p<0.05$) and swimming distance (PBBI = 1458 ± 163 sham = 495± 64 cm, $p < 0.05$) taken to locate the hidden platform was significantly longer in injured animals than in controls. Collectively, in view of the measured effect of PBBI to significantly dampen exploration, these data suggest that the MWM test, which requires a motivational component of behaviour (i.e. escape), may be more appropriate to study cognitive deficits in the PBBI model than the NOR test, which relies heavily on the animal's spontaneous exploration to navigate its surroundings.

1250. Davis, A. R., et al. (2010). "A comparison of two cognitive test paradigms in a penetrating brain injury model." Journal of neuroscience methods 189(1): 84-87.

A rat model of penetrating ballistic-like brain injury (PBBI) was recently established to study military-relevant severe traumatic brain injury (TBI). The purpose of this study was to conduct a side-by-side evaluation of two well-established cognitive testing paradigms: the novel object recognition (NOR) task and the Morris water maze (MWM) task. Accordingly, male Sprague-Dawley rats were

subjected to PBBI and their cognitive abilities were assessed at 7 and 21 days post-PBBI. Although PBBI animals had more difficulty completing both tasks compared to sham animals, their performance on the NOR task was confounded by a high degree of within-group variability that was likely due to attention deficits produced by the injury. In contrast, PBBI produced consistent, significant spatial learning deficits in the MWM task. Overall, these results suggest that the MWM task provides a more appropriate cognitive test for the PBBI model that would be useful for testing promising neuroprotective therapeutics.

1252. Davis, G. A., et al. (2000). "Delayed presentation of transorbital intracranial pen." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia 7(6): 545-548.

A 13 year old Fijian boy sustained a stab wound to the left orbit 3 years ago. It was not appreciated by the treating physicians in Fiji that the plastic pen had crossed from the left orbit, through the nose, right orbit and right optic nerve, into the right middle cranial fossa and lodged in the right temporal lobe and that the pen remained in situ for the past 3 years. The boy presented to Australia with a discharge from the entry wound in his left lower eyelid. The retained foreign body was not detected on computed tomography imaging, but was detected on subsequent magnetic resonance image. A combined neurosurgery/plastic surgery craniofacial approach was undertaken with successful complete removal of the retained pen, and preservation of vision in his only seeing eye.

1253. Davis, K. L., et al. (2007). "The direct economic burden of blunt and penetrating trauma in a managed care population." The Journal of trauma 62(3): 622-630.

BACKGROUND: Although the prevalence of trauma in the United States is high, data on the economic burden of this public health problem to third-party payors is limited., METHODS: Retrospective claims from a large health plan were analyzed for 12,615 adults (age >or=18 years) hospitalized for blunt or penetrating trauma between January 1, 2003 and February 1, 2005. Per patient charges were estimated for resources utilized during a 6-month period before and after initial injury. Continuous health plan enrollment during these periods was required. Three cohorts were examined: isolated traumatic brain injury (TBI); other trauma with TBI (trauma w/TBI); and other trauma without TBI (trauma w/o TBI). Patients were also stratified by Injury Severity Score (ISS) and trauma designation of the admitting hospital., RESULTS: Initial hospitalization charges ranged from $32,627 for isolated TBI to $103,667 for trauma w/TBI. Charges for initial hospitalization were highest ($199,443) among patients with the most severe injuries. Overall, initial hospitalization charges were highest among those admitted to Level I trauma centers ($68,626); for trauma w/TBI, however, initial hospitalization charges were highest among those admitted to nontrauma centers ($130,997). Charges incurred during postdischarge medical encounters ranged from $16,361 for isolated TBI to $23,761 for trauma w/TBI. Increased charges for postdischarge encounters compared with the 6-month preinjury period ranged from $6,756 for isolated TBI to $19,771 for trauma w/TBI., CONCLUSIONS: The economic burden of blunt and penetrating trauma to third-party payors is high. Efforts to reduce the incidence of trauma may result in substantial economic savings to managed care systems.

1255. Davis, N. L., et al. (2004). "Souvenir knife: a retained transcranial knife blade." The American journal of forensic medicine and pathology 25(3): 259-261.

Upon necroscopic examination of a homeless male found comatose in the street and pronounced dead at a medical center 12 hours later, a sharp tip of a knife lodged in the right parietal region of his skull was incidentally discovered. The blade transected the diploe and penetrated the cerebral cortex. Subsequent police investigation revealed that this was the remnant of a stabbing attempt on his life several months prior to his death. The cause of death was determined to be unrelated to the metallic blade fragment, thus making it a truly incidental and rare finding of a "souvenir knife." Nevertheless, since the injury sustained in the stabbing was potentially life threatening, the investigation into that assault was reopened.A case report is presented, along with a brief review of the literature on "souvenir objects."

1256. Davis, R. E. and F. F. Telischi (1995). "Traumatic facial nerve injuries: review of diagnosis and treatment." The Journal of cranio-maxillofacial trauma 1(3): 30-41.

Both blunt and penetrating craniofacial trauma may lead to severe facial nerve injury and sequelae of facial paralysis. Initial evaluation involves quantitation of motor deficits using a clinical grading system, such as the House-Brackmann scale. High resolution computed tomography is used for localization of nerve injury in suspected cases of temporal bone trauma. In the absence of gross radiographic abnormalities, electrophysiologic testing helps predict the likelihood of spontaneous recovery. In patients with deteriorating facial nerve injuries by electroneuronography, surgical exploration is the preferred management. Primary end-to-end neurorrhaphy is the preferred management for transection injuries, while facial nerve decompression may benefit other forms of high-grade nerve trauma. Secondary facial reanimation procedures, such as cranial nerve crossovers, dynamic muscle slings or various static procedures, are useful adjuncts when initial facial nerve repair is unsuccessful or impossible. A review of facial nerve trauma management and case illustrations are presented.

1257. Davison, S. P., et al. (2008). "Vascularized calvarial bone flaps and midface reconstruction." Plastic and reconstructive surgery 122(1): 10e-18e.

LEARNING OBJECTIVES: After studying this article, the participant should be able to: 1. Identify the fascial layers of the temporalis region. 2. Understand the three-dimensional nature of the orbit and upper maxillectomy defects. 3. Understand the surgical harvest of temporalis flaps and temporoparietal flaps with vascularized bone. 4. Appreciate preoperative risk factors and postoperative complications., BACKGROUND: Although vascularized calvarial bone grafts were originally explored for use in reconstruction of midface hypoplasia defects, they offer significant value in application to oncologic reconstruction of the midface., METHODS: A review of eight cases of midface reconstruction using vascularized calvarial grafts was performed to illustrate the versatility and dependability of these flaps., RESULTS: Adequate bony and soft-tissue contours were achieved with no clinical evidence of bone graft resorption. No immediate postoperative complications including infection and hematoma or seroma formation were noted. One patient experienced a delayed sinusitis from a blocked duct., CONCLUSIONS: The use of vascularized calvarial grafts supported by temporoparietal fascia, combined deep temporal fascia, and temporalis muscle provides excellent soft-tissue coverage and adequate bone stock for reconstruction of complex defects. Maintaining vascularization of the bone graft not only resists infection but also opposes resorption associated with nonvascularized grafts, particularly those in compromised wounds.

1258. Dawood, A. W. A. (2011). "Medicolegal aspects of 3 cases of bizarre self-mutilation." The American journal of forensic medicine and pathology 32(1): 35-38.

Three cases of bizarre self-mutilation are reported because of the unusual methods used and the unexpected good sequel in one of them.

1259. Dawoud, F. M., et al. (2021). "Traumatic Cerebrovascular Injuries Associated with Gunshot Wounds to the Head: A Single-Institution Ten-Year Experience." World neurosurgery 146: e1031-e1044.

BACKGROUND: Cerebrovascular injury (CVI) is a potentially devastating complication of gunshot wounds to the head (GSWH), with yet unclear incidence and prognostic implications. Few studies have also attempted to define CVI risk factors and their role in patient outcomes. We aimed to describe 10 years of CVI from GSWH and characterize these injury patterns., METHODS: Single-institution data from 2009 to 2019 were queried to identify patients presenting with dural-penetrating GSWH. Patient records were reviewed for GSWH characteristics, CVI patterns, management, and follow-up., RESULTS: Overall, 63 of 297 patients with GSWH underwent computed tomography angiography (CTA) with 44.4% showing CVI. The middle cerebral artery (22.2%), dural venous sinuses (15.9%), and internal carotid artery (14.3%) were most frequently injured. Arterial occlusion was the most prominent injury type (22.2%) followed by sinus thrombosis (15.9%). One fifth of patients underwent delayed repeat CTA, with 20.1% showing new/previously unrecognized CVI. Bihemispheric bullet tracts were associated with CVI occurrence (P = 0.001) and mortality (P = 0.034). Dissection injuries (P = 0.013), injuries to the vertebrobasilar system (P = 0.036), or the presence of >=2 concurrent CVIs (P = 0.024) were associated with increased risk of mortality. Of patients with CVI on initial CTA, 30% died within the first 24 hours., CONCLUSIONS: CVI was found in 44.4% of patients who underwent CTA. Dissection and vertebrobasilar injuries are associated with the highest mortality. CTA should be considered in any potentially survivable GSWH. Longitudinal study with consistent CTA use is necessary to determine the true prevalence of CVI and optimize the use of imaging modalities.

1260. Dawson, M. R., et al. (2000). "NG2-expressing cells in the central nervous system: are they oligodendroglial progenitors?" Journal of neuroscience research 61(5): 471-479.

Antibodies against the chondroitin sulphate proteoglycan, NG2, are increasingly being used to identify the widespread population of oligodendrocyte progenitor cells in the adult mammalian CNS. However, the specificity of this marker and the role of NG2-expressing cells in CNS function are still open to question. In this review we consider the evidence that NG2(+) cells in the CNS are part of the oligodendrocyte lineage and whether they can give rise to new oligodendrocytes following demyelination. In both the developing and mature rodent CNS, NG2(+) cells express the established oligodendrocyte lineage marker PDGF-alphaR and from P7, the late progenitor antigen O4, which persists in immature oligodendrocytes. They do not express markers of other CNS populations, such as OX42 or GFAP, at any developmental age. NG2(+) cells represent the major cycling cell population in the normal adult rat CNS, suggesting they have stem cell-like properties. NG2 immunoreactivity is upregulated as a result of physical, viral, excitotoxic and inflammatory insults to the CNS. Following demyelination NG2(+) cell number increases in the immediate vicinity of the lesion and rapid remyelination ensues. NG2 expression has also been investigated in human tissue. Multi-process bearing cells, which morphologically resemble those identified with antibodies against O4, persist in chronically demyelinated multiple sclerosis lesions.

1261. Day, L. (2001). "How nurses shift from care of a brain-injured patient to maintenance of a brain-dead organ donor." American journal of critical care : an official publication, American Association of Critical-Care Nurses 10(5): 306-312.

BACKGROUND: The responsibility of obtaining organs for transplantation rests partly on critical care nurses. How nurses balance care of critically ill, brain-injured patients with the professional responsibility to procure organs is a question of ethical and clinical importance., OBJECTIVES: To describe the experiences of critical care nurses in making the shift from caring for a brain-injured patient

identified as a potential organ donor to maintaining a brain-dead body., METHODS: An interpretive, phenomenological design was used. In 2 trauma centers, 9 critical care nurses were interviewed, and 2 of the 9 nurses were observed., RESULTS: Identification of potential organ donors is made under conditions of prognostic ambiguity. The transition from brain injury to brain death is a period of instability in which the critical care team must decide quickly whether to resuscitate a patient in order to procure organs. After a patient is brain dead, critical care nurses' relationship with and responsibility toward the patient change., CONCLUSIONS: The process of identifying potential organ donors and holding open the tentative possibility of organ procurement illustrates the practical difficulties of early referral of potential donors to organ procurement organizations. Early referral to an organ procurement organization implies a commitment to organ procurement that some nurses may hesitate to make because such a commitment changes their relationship with a brain-injured patient.

1262. Day, T. A., et al. (1998). "Management of frontal sinus fractures with posterior table involvement: a retrospective study." The Journal of cranio-maxillofacial trauma 4(3): 6-9.

Management of frontal sinus fracture has been a matter of debate. Combined fractures of the anterior and posterior walls have been managed by various techniques, including observation, open reduction and internal fixation, ablation, obliteration, and, most recently, cranialization. The earlier techniques have met with frequent complications, including sinusitis, mucopyocele, cerebrospinal fluid leak, meningitis, and brain abscess, along with various chronic pain symptoms. Cranialization of the frontal sinus was first introduced for injuries of both walls with intracranial penetration. From 1990 to 1996, frontal sinus fractures of 11 patients (10 men and 1 woman) were treated using the cranialization procedure. Based on patient history, clinical findings, radiographic diagnoses, operative techniques, and follow-ups of these patients the authors conclude that cranialization of the frontal sinus is a safe and effective method of treating posterior table frontal sinus fractures.

1263. Daya, M. (2008). "Peroneal artery perforator chimeric flap: changing the perspective in free fibula flap use in complex oromandibular reconstruction." Journal of reconstructive microsurgery 24(6): 413-418.

The fibula osteoseptocutaneous flap has undergone multiple refinements since its first description in oromandibular reconstruction. There is now a better understanding of the blood supply to the skin of the lateral aspect of the leg. Multiple free skin paddles can be harvested freestyle from the lateral aspect of the leg. The size of the flaps that can be harvested has not been clearly defined. A case report of a complex oromandibular reconstruction following a shotgun injury to the face demonstrates a way of maximizing the skin harvest. An osteoseptocutaneous fibula flap was used for the replacement of the mandible and the internal lining of the oral cavity. A larger lateral leg flap based on a musculocutaneous perforator of the peroneal artery was used for the external and full-thickness lower-lip defect. The latter flap by definition is a peroneal artery perforator flap, which to the best of my knowledge is terminology that has not been used in the English literature. The main purpose of this article is to review the blood supply of the lateral leg and how this can be utilized to reach the goals of a complex oromandibular and total lower-lip reconstruction.

1264. de Almeida Prado, P. S., et al. (2019). "Surviving a transfixing gunshot wound to the head 70 years ago." Forensic science, medicine, and pathology 15(1): 159-163.

Surviving a gunshot wound to the head is a rare event, particularly in the past when medical treatment was much less advanced than it is today. Moreover, the finding of such a case as an identified specimen within a museum collection is even more uncommon. This led us to report on this unique case in this paper as it poses a challenge to forensic anthropology and provides a unique educational oppourtunity. The skull from the Collection at the Cranium Museum in the Department of Morphology and Genetic at the Federal University of Sao Paulo (UNIFESP) dates back to 1946. For trauma

registration the bone location, severity, trauma aetiology, trauma classification, description, callus formation, periosteal reaction, degree and success of repair, and an estimate of the time elapsed since the trauma, were all assessed. To explore the case radiologically a CT scan of the skull was performed. Considering the survival of the patient and the morphology of the wound it is likely that the injury was caused by a small calibre, low-velocity gunshot. The bullet path shows an almost vertical direction on the right side of the individual's splanchno and neurocranium. The path of the projectile is consistent with a suicide attempt, although the possibility of a homicide simulating a suicide cannot be discarded. This case highlights how informative such cases can be to the practice of forensic anthropology.

1265. de Andrade, A. F., et al. (2006). "Penetrating screwdriver injury to the brainstem. Case illustration." Journal of neurosurgery 104(5): 853.

1266. De Benedictis, A., et al. (2020). "Asymptomatic intrapetrous carotid artery stenosis after a gunshot to the head." Neurology 95(23): 1057-1058.

1267. De Burgh, H. T., et al. (2012). "Incidence of significant head injury among UK armed forces personnel." Brain injury 26(4-5): 668.

Objectives: Head injuries cause significant morbidity and are a leading cause of death and disability within the general population. Although prevalence estimates of Mild Traumatic Brain Injury (mTBI) in the UK military have been published, and shown to occur at considerably lower rates than the US, little is known about more serious head injuries occurring in theatres of operations today. Military personnel are at risk of both blunt and penetrating head trauma in the combat environment as shown by US data, which shows 30,893 moderate TBI cases, 1,891 severe TBI cases and 3,175 penetrating injuries between 2000 and 2010. Aim: To describe the incidence of head injury in UK military personnel who have served in Afghanistan and Iraq from 2003 to 2011. Method: The Joint Theatres Trauma Registry (JTTR), a Ministry of Defence resource since 2003, records data for all personnel injured in operational theatres which have triggered a trauma team response. The JTTR was interrogated to identify all personnel who had sustained a head injury, either as their main injury or an additional injury. Correlations between Injury Severity Score (ISS), Glasgow Coma Score (GCS), mechanism of injury and survival outcomes were examined. Results: Injury pattern: A total of 482 military patients with head injuries were recorded between 2003 and 2011. The majority of these (397, 82%) were British Army personnel and 84% were hostile intent injuries (405). 93% of head injuries sustained in Afghanistan were of hostile intent versus 62% of head injuries in Iraq. The highest number of head injuries was seen in 2009 (117) followed by 2007 (82) and 2010 (76).Mechanism of injury: Improvised Explosive Device related injuries were the single most common cause of injury (228 in total). Survival: The overall survival rate for all personnel with head injury was 39%. For 376 personnel, head injury was their most significant injury and 59% of these were fatalities. Factors associated with a lower survival rate include: having multiple injuries to the head (90% of those with a maximum ISS head score of 6 were fatalities); a GCS of less than 9; and having a higher number of total injuries. Overall, 23 personnel were coded on ISS as unexpected survivors (score 60-75). Conclusions: Analysis of this data highlights a small but significant number of head injuries in the UK military population sustained during active duty. Significant numbers of severely injured personnel survive potentially fatal injuries. Further examination of longer-term outcomes of these survivors is needed.

1269. De Carvalho Oliveira, L. C., et al. (2015). "Patient management with penetrating injury by white weapon in the face. three cases report." International Archives of Otorhinolaryngology 19: S47.

Introduction: Injuries by white weapons on the face are scarcely reported in the national literature. The highest incidence occurs in male individuals between 15 and 35 years old, with prevalence for left facial. In the initial treatment, the recognition of lesions and implementing measures are made to maintain life. Imaging studies are essential for the assessment of damages and surgical planning. Must assess the extent and depth of the injuries, injuries to important structures, need for immediate reconstruction after removal of the object and the time elapsed since the trauma. Treatment involves removal of the object and repair of injuries, trying to preserve the craniofacial function and esthetics. Objective: To present the rapid and multidisciplinary management of three cases of injury by white weapon (knife) in right hemiface, not removed in the pre-hospital, in male patients, averaging 26 years old who were admitted to the Emergency Room of the Base Hospital of Federal District. Resumed report: Patients presented with the housed object that affected: the right orbit to hypopharynx; right orbit to right cervical region, with penetration into jugular vein; and right nasal dorsum to spinal canal. With the stabilized phase, the Otolaryngology teams, Head and Neck Surgery and Ophthalmology started treatment together. Conclusion: This type of trauma can result in multiple injuries of vital structures. The rapid multidisciplinary intervention, coupled with the surgical technique minimizes the risk of complications and sequelae.

1270. de Crescenzo, C., et al. (2017). "Prehospital hypertonic fluid resuscitation for trauma patients: A systematic review and meta-analysis." The journal of trauma and acute care surgery 82(5): 956-962.

BACKGROUND: Prehospital assessment of a patient's circulation status and appropriate resuscitation with intravenous fluids plays a critical role in patients with obvious hemorrhage or systolic blood pressure below 90 mm Hg., OBJECTIVES: We assessed the efficacy and safety of prehospital administration of crystalloids or colloids to improve the survival rate of trauma patients with acceptable safety profile., DATA SOURCES: We searched SCOPUS, Embase, TRIP database, Cochrane Central Register of Controlled Trials, Ovid MEDLINE, and PubMed as per search protocol from January 1, 1900 to February 12, 2015., STUDY ELIGIBILITY CRITERIA: All randomized controlled trials were considered., PARTICIPANTS AND INTERVENTIONS: All patients had penetrating or blunt trauma, excluding traumatic brain or thermal injuries. At least one of the comparators should be a crystalloid or colloid., STUDY APPRAISAL AND SYNTHESIS METHODS: Detailed search strategy was developed and utilized. Duplicates were removed from the search results. We, the co-first authors (C.d.C. and F.G.), independently reviewed the article titles and abstracts to assess eligibility. Eligible articles were downloaded for full text review to determine inclusion in the review and analysis. We (C.d.C. and F.G.) performed a methodological quality assessment of each included article. The primary outcome was mortality. The secondary outcomes included adverse events, infections, multiple organ dysfunction score, and length of stay at the hospital. Heterogeneity was measured by I value. An I value greater than 50% was considered to be substantial heterogeneity. Fixed effect analysis and random effect analysis were performed when needed., RESULTS: A total of nine trials (3,490 patients) were included in the systematic review, and six trials were included in meta-analyses. There were no significant differences between hypertonic saline with dextran and lactated Ringer's solution in 1 day using two studies (2.91; 95% CI, 0.58-14.54; p = 0.19) and 28- to 30-day survival rates using another two studies (1.47; 95% CI, 0.30-7.18; p = 0.63). Adding dextran to hypertonic saline did not increase the survival rate (0.94; 95% CI, 0.65-1.34; p = 0.71). Overall, complications were comparable between all groups., LIMITATIONS: The quality of some of the included studies is not optimal., CONCLUSIONS AND IMPLICATIONS OF KEY FINDINGS: There is no beneficial effect of hypertonic saline with or without dextran in general traumatic patients. Further trials to evaluate its benefit in patients with penetrating trauma requiring surgery are warranted., LEVEL OF EVIDENCE: Systematic review and meta-analysis, level I.

1271. De Decker, R., et al. (2019). "Uneventful survival of a rural child after penetrating cardiac injury by a thorn: a case report." European heart journal. Case reports 3(3): ytz106.

BACKGROUND: Paediatric penetrating cardiac injury is extremely rare, precluding published management guidelines, therefore warranting a case-by-case approach with learning points gleaned from each case., CASE SUMMARY: A 7-year-old boy presented to a rural hospital with a stab wound to the chest by a Withaak (Vachellia tortilis) thorn. The patient was haemodynamically stable on presentation, but a 2 cm subcutaneous, pulsatile mass was present at the cardiac apex. Echocardiography revealed a foreign body penetrating from the apex into the heart, with evidence for a fistula between a cardiac chamber and the pulsatile mass. Angiography confirmed the existence of the fistula between the right ventricle (RV) and the pulsatile mass. A controlled extraction under general anaesthaesia via median sternotomy was performed in-theatre, with blood products and cardiac bypass on standby. The patient recovered without complications and was discharged after 4 days., DISCUSSION: Our case illustrates the limitations of echocardiography in identifying the precise anatomical definition of penetrating cardiac injuries. Angiography is therefore indicated in such cases. The injury to the RV and the haemostatic effects of the in situ thorn were favourable prognostic factors. We believe that the mortality risk reduction of extraction under full control warrants the minor morbidity of a median sternotomy.

1272. De Dominicis, K., et al. (2016). "Longitudinal changes in BAX and BCL-2 in key regions of interest following penetrating traumatic brain injury in rats." Journal of neurotrauma 33: A17.

Acute alterations of the pro- and anti- apoptotic factors BAX and Bcl-2 have been well established following severe penetrating traumatic brain injury (TBI). However, changes into the subacute period have not been well described. Here, we examine longitudinal alterations of these two apoptotic factors up to one month following penetrating ballistic-like brain injury (PBBI) in specific regions of interest. Unilateral frontal PBBI was induced by inserting a probe through the right frontal cortex (FCx) and striatum (St) followed by rapid balloon inflation to create a temporary cavity. Additional animals were exposed to probe insertion without balloon inflation or sham surgery (craniotomy only). Acute motor deficits were assessed 24 hr following injury. At 24 hr, 3d, 7d, or 1m post-injury, the ipsilateral FCx, St, hippocampus (HC), and residual midbrain (RMb) were dissected for analysis of BAX and Bcl-2 expression levels by western blot. Percent change from sham was determined for PBBI and probe only animals at each time point. PBBI resulted in significant elevations of BAX at 24 hr (FCx, St, and RMb) and at 3d and 7d (FCx and St), while probe resulted in more limited elevations in BAX at 24 hr (FCx), 3d (FCx and St), and 7d (FCx). Reduced expression of Bcl-2 was observed at 7d (FCx) in both the PBBI and probe groups. Significant correlations were detected between the expression of apoptotic factors and acute motor deficits at one week post-injury. These results indicate that expression of pro- and anti- apoptotic factors remains altered one week following severe penetrating TBI. For the most part, the observed alterations in BAX and Bcl2 expression appear to be limited to areas surrounding the injury trajectory. This work establishes a timeline against which these pathological markers can be used to evaluate the efficacy of anti-apoptotic pharmacotherapies and emphasizes the need to design drug therapy treatment regimens that extend beyond the acute post-injury phase.

1273. De Dominicis, K., et al. (2016). "Regional acute and subacute alterations in GFAP, spectrin, and breakdown products following penetrating ballistic-like TBI in rats." Journal of neurotrauma 33: A16-A17.

Acute alterations of glial fibrillary acidic protein (GFAP), GFAP breakdown products (GFAP-BDPs), spectrin, and spectrin breakdown products (SBDPs) have been well studied following TBI but their longitudinal trajectory has not been well described. Here, we assess these pathology markers out to 1 month post injury following a penetrating ballistic-like brain injury (PBBI). Unilateral frontal PBBI

was induced by inserting a probe through the right frontal cortex (FCx) and striatum (St) followed by a rapid balloon inflation to create a temporary cavity. Additional animals were exposed to probe insertion without balloon inflation or sham surgery (craniotomy only). At 3d, 7d, or 1m following injury, the ipsilateral FCx, St, hippocampus (HC), and residual midbrain (RMb) were dissected for analysis by western blot. Percent change from sham was determined at each time point. PBBI produced acute increases in GFAP at 3d (FCx, St, and HC) and 7d (FCx, St, HC and RMb) that remained evident at 1m post-injury in FCx, St and RMb. Concomitantly, GFAP-BDPs were increased in all regions at 3d and 7d and remained elevated at 1m in FCx, St, and RMb. Probe insertion also resulted in significant regional specific increases in GFAP and GFAP-BDPs that were mostly resolved by 1m post-injury. At 3d post-PBBI, spectrin decreased in the FCx whereas SBDPs increased in FCx, St, and RMb. At 7d, spectrin decreased in HC while SBDPs increased in FCx, St, and RMb. At 1m, spectrin decreased and SBDPs increased in St. Probe insertion resulted in increased SBDPs at 3d in FCx and decreased spectrin at 1m. Correlation analyses between these pathology metrics and acute neuroscore were performed and significant correlations were obtained, even one month following injury. These data demonstrate that TBI pathology remains evident into the subacute period and is not limited to the area of the injury tract. This highlights the need to consider long-term interventions when assessing TBI therapeutics.

1274. De Donno, A., et al. (2009). "Manners of killing and rituals in Apulian mafia murders." Journal of forensic sciences 54(4): 895-899.

The Apulian (South of Italy) territory saw the birth of a criminal organization called Sacra Corona Unita (SCU, United Holy Crown) which transformed the rules of traditional mafia organizations. This work examined 83 victims of the SCU between 1980 and 2000. The bodies were mainly of SCU members and in some cases, of police and law enforcement officers and other citizens caught in the crossfire. Some of these were discovered; thanks to the collaboration of "repented" SCU members who became police informers. The condition of the bodies varied in relation to the date and manner of killing. In some cases anthropometric research methods were necessary. In 73% of the cases, lesions of the head were the only marks left on the body. In conclusion, the existence of some social aspects connected with the symbolisms and membership rites that characterized the origin, evolution, and decline of the SCU is stressed.

1275. De Fazio, M., et al. (2011). "Alterations in cerebral oxidative metabolism following traumatic brain injury." Neurocritical care 14(1): 91-96.

BACKGROUND: Traumatic brain injury (TBI) generates regional alterations in cerebral metabolism, leading to the potential evolution of persistent metabolic dysfunction. In the case of penetrating, firearm-related TBI, the pathophysiological mechanisms underlying these acute-phase metabolic derangements are not entirely understood-hindering the potential effectiveness of therapeutic intervention. The use of cerebral microdialysis to monitor biochemical alterations that occur, post-TBI, provides critical insight into the events that perpetuate neurological deterioration., METHODS: Cerebral microdialysis was used to monitor alterations in the brain tissue chemistry of a 22-year-old female patient who sustained a penetrating gunshot wound to the head. Extracellular glucose, lactate, pyruvate, and lactate pyruvate ratio (LPR) were monitored over the course of the first-week post-injury., RESULTS: Analysis of the microdialysate revealed sustained elevations in LPR with peaks in excess of those seen in patients who have sustained permanent ischemic injury. This interval of persistently elevated LPR was followed by a spontaneous reduction of values, to levels below the defined threshold for metabolic crisis, over a period of several days., CONCLUSIONS: Microdialysis studies may significantly improve the understanding of the metabolic alterations that occur in patients who sustain a variety of forms of neurotrauma. Ultimately, monitoring these variations in brain tissue chemistry will improve the insight into the neuropathological mechanisms underlying penetrating traumatic brain injury, and enhance the therapeutic approach of these patients.

1276. De Figueirêdo, B., et al. (2021). "Multiple sites bullet embolism as a cause of acute abdomen." Turkish Journal of Emergency Medicine 21(3): 125-128.

Bullet embolism (BE) is a rare and misdiagnosed phenomenon that can significantly affect the cardiovascular system. It occurs when a bullet enters and migrates through the body vessels in gunshot victims. We report in this article a case of a 25-year-old male patient, victim of penetrating trauma caused by a firearm projectile that presented two embolism destinations with acute ischemic repercussions: the right brachial artery and the branches of the superior mesenteric artery. We quickly performed surgical exploration to assess the level of ischemia and resect the foreign body. To the best of the authors' knowledge, this is the only case of acute vascular abdomen due to BE in the literature. There is no standard treatment for BE, and each case should be studied according to signs and symptoms while considering the risks of the destination vessel for the victim. Imaging is necessary for early diagnosis, and the medical team must be aware of multiple and extraordinary critical ischemia presentations when bullet trajectory suggests embolism.

1277. de Freminville, H., et al. (2010). "Less-lethal hybrid ammunition wounds: a forensic assessment introducing bullet-skin-bone entity." Journal of forensic sciences 55(5): 1367-1370.

Agencies all around the world now use less-lethal weapons with homogeneous missiles such as bean bag or rubber bullets. Contusions and sometimes significant morbidity have been reported. This study focuses on wounds caused by hybrid ammunition with the pathologists' flap-by-flap procedure. Twenty-four postmortem human subjects were used, and lesions caused on frontal, temporal, sternal, and left tibial regions by a 40-mm hybrid ammunition (33 g weight) were evaluated on various distance range. The 50% risk of fractures occurred at 79.2 m/sec on the forehead, 72.9 m/sec on the temporal, 72.5 m/sec on the sternum, and 76.7 m/sec on the tibia. Skin lesions were not predictors of bone fracture. There was no correlation between soft and bone tissue observed lesions and impact velocity (correlated to distance range). Lesions observed with hybrid ammunition were the result of bullet-skin-bone entity as the interaction of the projectile on skin and bone tissues.

1278. De Fries, H. O., et al. (1971). "Reconstruction of the mandible. Use of a homograft combined with autogenous bone and marrow." Archives of otolaryngology (Chicago, Ill. : 1960) 93(4): 426-432.

1279. De Girolami, U. (2014). "Introduction and classification of small vessel disease." Brain Pathology 24: 4.

Central nervous system (CNS) small vessel disease is an arbitrary subdivision that separates those groups of disorders that affect the nervous system from injury to vessels outside the parenchyma of the brain, i.e. large extra cranial vessels that supply the nervous system and intracranial vessels within the subarachnoid space, from those that penetrate the parenchyma of the brain, i.e. typically arterioles, venules and the components of the microcirculation. This operational definition serves to distinguish major pathophysiological mechanisms of stroke and corresponding clinical syndromes that differ greatly between the two groups. Three generalizations apply to most forms of CNS small vessel disease - these are disorders that affect multiple vessels throughout the neuraxis; a broad range of abnormalities accompanies the vascular injury, be it inflammatory, or predominantly non-inflammatory; the vascular lesions are associated either with focal hemorrhage or thrombosis, with corresponding parenchymal brain injury. In some, the principal clinical manifestations are those of focal neurological deficits referable to the anatomic region involved, whereas in others, syndromes of dementia (with or without associated degenerative disease), or encephalopathies, predominate. The armamentarium of new radiological imaging methods has enhanced awareness of these important causes of neurological morbidity. Some of these affect predominantly or exclusively the CNS, whereas others are systemic vascular disorders that involve the brain and spinal cord along with other organ systems. For purposes of

classification, and conceptually, these are disorders of the “microcirculation” and small blood vessels in general. The socalled “small arteries” or arterioles include perforators with diameters from 40 to 400 μ m. Some emerge from the leptomeningeal arteries, enter the brain parenchyma from the surface of the brain, and extend within to a variable depth, some reaching the deep white matter as medullary branches. Other perforators enter the brain at the base (supplying the basal ganglia and thalamus), and yet others irrigate the brainstem arising from long and short circumferential branches. For the most part, these are end-arteries with limited collateral anastomoses until the capillary network is reached.

1280. de Groot, Y. J., et al. (2011). "Remarkable changes in the choice of timing to discuss organ donation with the relatives of a patient: a study in 228 organ donations in 20 years." Critical care (London, England) 15(5): R235.

INTRODUCTION: We studied whether the choice of timing of discussing organ donation for the first time with the relatives of a patient with catastrophic brain injury in The Netherlands has changed over time and explored its possible consequences. Second, we investigated how thorough the process of brain death determination was over time by studying the number of medical specialists involved. And we studied the possible influence of the Donor Register on the consent rate., METHODS: We performed a retrospective chart review of all effectuated brain dead organ donors between 1987 and 2009 in one Dutch university hospital with a large neurosurgical serving area., RESULTS: A total of 271 medical charts were collected, of which 228 brain dead patients were included. In the first period, organ donation was discussed for the first time after brain death determination (87%). In 13% of the cases, the issue of organ donation was raised before the first EEG. After 1998, we observed a shift in this practice. Discussing organ donation for the first time after brain death determination occurred in only 18% of the cases. In 58% of the cases, the issue of organ donation was discussed before the first EEG but after confirming the absence of all brain stem reflexes, and in 24% of the cases, the issue of organ donation was discussed after the prognosis was deemed catastrophic but before a neurologist or neurosurgeon assessed and determined the absence of all brain stem reflexes as required by the Dutch brain death determination protocol., CONCLUSIONS: The phases in the process of brain death determination and the time at which organ donation is first discussed with relatives have changed over time. Possible causes of this change are the introduction of the Donor Register, the reintroduction of donation after circulatory death and other logistical factors. It is unclear whether the observed shift contributed to the high refusal rate in The Netherlands and the increase in family refusal in our hospital in the second studied period. Taking published literature on this subject into account, it is possible that this may have a counterproductive effect.

1281. de Holanda, L. F., et al. (2016). "Neurosurgical Management of Nonmissile Penetrating Cranial Lesions." World neurosurgery 90: 420-429.

OBJECTIVE: The objective of this study is to present a case series of nonmissile penetrating (NMP) injuries and to establish a workflow for an uncommon mechanism of traumatic head injury through the analysis of each case, classification of the type of lesion, management, and outcome score at follow-up., METHODS: From January 1991 to December 2008, 36,000 patients presenting with traumatic brain injury (TBI) were admitted in the Department of Neurosurgery, Hospital Antonio Targino, Campina Grande-PB, Brazil. From these patients, 11 presenting with lesions caused by NMP objects were selected., RESULTS: Among the 11 patients, 9 were men and 2 were women. Their ages ranged from 7 to 74 years old (mean age +/- SD, 29.1 +/- 22.99 years). All patients underwent neuroradiologic evaluation. The entry point was classified as natural (orbit) or artificial (skull transfixation), and we also divided the patients presenting with secondary parenchymal or vascular damage from those presenting with only lesions caused by the primary penetration into the cranium and meninges. All patients were neurosurgically treated with removal of the foreign body through craniotomy, except the patient whose object (pen) was removed without craniotomy with local anesthesia. Glasgow Coma Scale (GCS) score on admission was a statistically significant factor on

prognosis, and any patient who presented with a GCS score of 15 evolved satisfactorily, and there were no deaths in this group of patients (P = 0.04)., CONCLUSIONS: TBIs caused by NMP objects are unusual and caused by aggression, self-inflicted harm (in the case of psychiatric patients), and accident. The foreign body may enter into the skull through a natural hole (orbit, nose, mouth, or ear) or crosses the skull, causing a fracture and creating an artificial hole. Preoperative neuroradiologic assessment is paramount for the correct neurosurgical approach. The main prognostic factor for these patients is the GCS score at admission.

1282. De Jesus Encarnacion-Ramirez, M., et al. (2022). "Surgical management of a penetrating drill bit injury to the skull base." Surgical neurology international 13.

Background: Low-energy penetrating brain injuries are rarely encountered in neurosurgical practice. Immediate surgical management remains the primary treatment strategy to control potential bleeding and prevents infectious complications. Case Description: A 28-year-old man presented with an orbital injury with left-sided chemosis, amaurosis, and ophthalmoplegia following an assault. Cranial CT revealed an industrial drill bit causing a penetrating injury to the skull base. The tip of the object reached the petrous apex. CT angiography showed no signs of cerebrovascular damage. The drill bit was visualized through a frontotemporal craniotomy. It was then carefully removed under direct microscopic vision. Postoperative ceftriaxone was administered. The patient was discharged in good condition on postoperative day 6. His vision impairment remained.Conclusion: Timely access to neuroimaging diagnostics and microneurosurgical facilities allows for good outcomes in the surgical treatment of low-velocity penetrating brain injuries.

1283. de Jongh, K., et al. (2004). ""William Tell" injury: MDCT of an arrow through the head." AJR. American journal of roentgenology 182(6): 1551-1553.

1284. de Jongh, M. A. C., et al. (2013). "Response to "Benefit of Helicopter Emergency Medical Services on trauma patient mortality in the Netherlands?"." Injury 44(2): 275-276.

1285. de Jongh, M. A. C., et al. (2012). "The effect of Helicopter Emergency Medical Services on trauma patient mortality in the Netherlands." Injury 43(9): 1362-1367.

INTRODUCTION: Object of this study was to evaluate the effect of the Helicopter Emergency Medical Services (HEMS) on trauma patient mortality and the effect of prehospital time on the association between HEMS and mortality., MATERIALS AND METHODS: Trauma patients admitted to a level 1 trauma centre and treated on-scene by the HEMS and Emergency Medical Services (EMS) between 2003 and 2008 were included (n = 186). A control group treated by EMS only (n = 186) was created by matching on ISS, age and severe traumatic brain injury (TBI). Mortality was compared by calculating odds ratios (OR) and numbers needed to treat (NNT), with adjustment for prehospital coded Revised Trauma Score. The effect of prehospital time mortality was tested by a logistic regression. Analyses were made for patients with and without TBI., RESULTS: The OR of early trauma fatality for the HEMS/EMS versus EMS-only groups was 0.8 for patients both with TBI (95% CI 0.4-1.7; NNT: 22) and without TBI (95% CI 0.2-3.3; NNT: 273). The risk of in-hospital mortality was non-significantly higher for patients with TBI in the HEMS/EMS group (OR = 1.3; 95% CI 0.6-2.7; NNT: -15) compared to the EMS-only group and non-significantly lower for patients without TBI (OR = 0.9; 95% CI 0.3-2.5; NNT: 129). After adjustment for prehospital time, the risk of early trauma fatality for patients with TBI treated by the HEMS decreased (OR = 0.6; 95% CI 0.3-1.6). The risk of in-hospital mortality for these patients decreased from 1.3 to 0.8 (95% CI 0.4-2.0). The effect of the HEMS on patients without TBI did not change after adjustment for prehospital time., DISCUSSION: HEMS treatment is associated with a non-significantly higher risk of in-hospital mortality for patients with TBI and a non-significantly

lower risk for patients without TBI. This increased risk of mortality in TBI patients is attributable to the increased prehospital time. These results indicate that HEMS does not have a positive impact on survival.

1286. de la Grandmaison, G. L., et al. (2001). "Frequency of bone lesions: an inadequate criterion for gunshot wound diagnosis in skeletal remains." Journal of forensic sciences 46(3): 593-595.

A retrospective study was carried out on 130 fatalities due to gunshot wounds to determine whether the combined absence of bone damage and projectile in a skeleton is sufficient to eliminate a diagnosis of gunshot wound. Our findings showed that bone lesions were present in about 90% of the cases and were associated with intracorporeal projectile(s) in about 70% of the cases. The presence or absence of bone lesions seemed independent of the gun characteristics, the shot conditions, and the type of death. The cause of death was predominantly brain injury in cases with bone lesions whereas thoracic, abdominal, and peripheral vascular causes were more frequently encountered in cases without bone damage. We concluded that the combined absence of bone lesions and intracorporeal projectile (about 5% in our series) cannot exclude a diagnosis of death secondary to gunshot wounds.

1287. De Mukhopadhyay, K., et al. (2011). "Unraveling the molecular signature that drives breast cancer-induced brain metastasis in a mouse xenograft model." Cancer Research 71(8).

Brain metastases are most feared complication in breast cancer (BCa). Nearly 20% of patients with advanced BCa are eventually diagnosed with brain lesions, making breast tumors the main source of metastatic brain disease in women. Presently available treatment regimens are not capable of significantly treating the BCa-induced brain metastases due to their inability to penetrate the blood brain barrier. Rodent model systems have been reported for brain metastasis in BCa but the current models for brain metastasis have limitations. As such, there is a need of an efficient model system that can significantly contribute towards our understanding of different factors from both host and tumor leading to brain metastasis. Previously we isolated and characterized B6TC cells, derived from the stable spontaneous fusion of MDA-MB-231/GFP/Neo and ZR-75-1/GFP/puro in mouse bone marrow microenvironment. The low ER-expressing B6TC has propensity to metastasize to brain in addition to lung and bone, to express CD44 and ALDH, and to form mammospheres indicating its stem cell-like features. In this study using B6TC, we have developed an efficient and novel mouse model for studying BCa-induced brain metastasis. We performed RNA microarray to identify genes whose RNA levels are significantly altered in B6TC cells by greater than 2-fold at the false discovery rate of 0.001, when compared to the parental metastatic MDA-MB-231 or non-aggressive ZR-75-1 cells. Interestingly we identified genes like MMP1, HB-EGF, ST3GAL1, PTGS2, ITGA3, and CXCR4 implicated in metastasis regulation. Then we derived a Luc-GFP transfected B6TC line and enriched it by 4 successive in vivo passages to obtain a highly aggressive B6TC/Luc-GFP cell line with 100% brain metastatic frequency. A second round of RNA microarray was performed with highly brain metastatic B6TC/Luc-GFP and parental B6TC cells to derive a core signature of up- and down-regulated genes to select unique potential brain metastatic genes by comparing two sets of microarray data. Apart from potent brain metastatic genes detected earlier, we identified ZEB2, an EMT activator, a crucial promoter for metastasis, and a modulator of TGF beta signaling pathway, which shows up-regulation over successive in-vivo passages. Further analyses are underway to establish a refined signature of BCa-induced brain metastasis in our novel model system. Our study is significant in that they suggest potential brain metastasis genes for BCa. This will not only provide valuable insight into molecular mechanism of BCa-induced brain metastasis but also lay the foundation to identify novel prognostic and therapeutic markers of brain metastases, leading ultimately to the discovery of novel molecularly targeted drugs to prevent and eradicate BCa metastasis initiation, progression and recurrence.

1288. De Mukhopadhyay, K., et al. (2012). "Determining the molecular mechanism of the breast cancer-induced brain metastasis and a role of a novel pan-TGF-β inhibitor as a potential therapy for brain metastasis in a mouse xenograft model." Cancer Research 72(24).

Breast cancer (BCa) is the most common malignant disease in women in the U.S. Nearly 20% of patients with advanced BCa are eventually diagnosed with brain lesions, which is a devastating complication in patients with BCa over-expressing EGF receptor family members including Her2 positive and triple negative breast cancer. It is the most feared complication of BCa in part because are not capable of significantly treating the BCa-induced brain metastases due to the inability of the available treatment regimens to effectively penetrate the blood brain barrier (BBB) and also due to our limited knowledge on cellular and molecular mechanisms that drive the homing to and growth in the brain of BCa cells. Therefore, there is a need of efficient model system that can significantly contribute towards our understanding of different factors from both host and tumor leading to brain metastasis. We have recently isolated a novel BCa cell line B6TC that was generated through fusion between human BCa, MDA-MB-231 and ZR-75-1 cells in mouse bone marrow. This B6TC cell line showed higher propensity to metastasize to brain than its parental cells when inoculated through intracardiac injection in female athymic nude mice. In order to generate a highly brain metastatic breast cancer model for mechanistic research, we subjected the B6TC cells through four rounds of selection for cells that were capable of trans-endothelial cell invasion to obtain cells that could invade through BBB. This in vitro selected cell line was further subjected through three rounds of in vivo selection for cells that were capable of metastasizing to the brain and the cells after third round selection was named N3LR, which has the highest potential to cause brain metastasis. In searching for genes and pathways that may contribute to the increased brain metastasis of N3-LR cell with microarray analysis, we found that the transforming growth factor-beta (TGFβ) signaling pathway is upregulated in N3-LR cell in comparison with B6TC cell, in addition to the EGF and prostaglandin signaling pathways that have been reported to be associated with brain metastatic breast cancer cells. Functional comparison also showed that N3-LR cell was more migratory than B6TC cell and more responsive to TGFβ-induced phosphorylation of Smad3 as well as migration, suggesting that TGFβ signaling may contribute to the increased brain metastatic potential. We next investigated whether metastatic tumor growth in the brain microenvironment can be inhibited by systemic administration of a potent pan-TGFβ inhibitor, BGERII- a recombinant fusion protein containing the endoglin domain of betaglycan (BGE) and the extracellular domain of RII. The animals were inoculated intracardically with N3LR, the most potent subline of highly metastatic B6TC cells, and were then treated with vehicle or BGERII systemically via i.p. injection right after the inoculation. After three weeks, the BGERII treated group showed lower brain metastasis incidence and tumor burden as detected by whole mouse bioluminescence and GFP imaging. Further analyses to understand the underlying molecular and regulatory mechanism of brain metastasis and its intervention in our mouse model is underway for the discovery of novel molecularly targeted drugs to prevent and eradicate BCa metastasis initiation, progression and recurrence.

1289. De Mukhopadhyay, K., et al. (2012). "Delineating the molecular signature of the breast cancer-induced brain metastasis and the role of a novel pan-TGF-β inhibitor to block brain metastasis in a mouse xenograft model." Cancer Research 72(8).

Breast cancer (BCa) is the most common malignant disease in women in U.S. Nearly 20% of patients with advanced BCa is eventually diagnosed with brain lesions. The available treatment regimens are not capable of significantly treating the BCa-induced brain metastases due to their inability to penetrate the blood brain barrier. The exact molecular mechanism for metastases of BCa into brain is unknown. The current rodent model systems for BCa brain metastasis have limitations. Therefore, there is a need of efficient model system that can significantly contribute towards our understanding of different factors from both host and tumor leading to brain metastasis. Previously we reported estrogen-independent B6TC cell, derived from the stable spontaneous fusion of MDA-MB-231 and ZR-75-1 cells in mouse bone-marrow microenvironment, which has propensity to metastasize to brain when inoculated through intracardiac route, and express stem cell-like features. In this study using B6TC, we have

developed an efficient and novel mouse model for studying BCa-induced brain metastasis and investigated the role of a potent pan-TGF-β inhibitor, BGERII, for blocking brain metastasis. We have generated three cell lines from B6TC through three successive rounds of inoculation in mouse and isolation of brain metastatic cells. Each round of selection enhanced the brain metastatic propensity. An initial microarray analysis identified genes implicated in metastasis regulation- MMP1, HB-EGF, ST3GAL1, PTGS2, ITGA3, and CXCR4, showing significant up-regulation in B6TC compared to its parental MDA-MB-231 and ZR-75-1 cells. Analyses of second round of RNA microarray, performed with three sub-lines of B6TC with successively enhanced brain metastatic propensity over generations, identified some molecular pathways, including TGF beta signaling pathway that are associated with enhanced brain metastasis. We next investigated whether metastatic tumor growth in the brain microenvironment can be inhibited by systemic administration of a potent pan-TGF-β inhibitor, BGERII- a recombinant fusion protein containing the endoglin domain of betaglycan (BGE) and the extracellular domain of RII. The animals were inoculated intracardically with N3LR, the most potent sub-line of highly metastatic B6TC cells and were then treated with vehicle or BGERII systemically via i.p. injection right after the inoculation. After three weeks, the BGERII treated group showed lower brain metastasis incidence and tumor burden as detected by whole mouse bioluminescence and GFP imaging. Further analyses to understand the underlying molecular and regulatory mechanism of brain metastasis and its intervention in our mouse model is underway for the discovery of novel molecularly targeted drugs to prevent and eradicate BCa metastasis initiation, progression and recurrence.

The animals were inoculated intracardiacally with N3LR, the most potent sub-line of

highly metastatic B6TC cells, and were then treated with vehicle or BGERII systemically via i.p. injection right after the inoculation. After 3 weeks, the BGERII treated group showed lower brain metastasis incidence and tumor burden as detected by whole mouse bioluminescence and GFP imaging. Further analyses to understand the underlying molecular and regulatory mechanism of brain metastasis and its intervention in our mouse model is underway for the discovery of novel molecularly targeted drugs to prevent and eradicate BCa metastasis initiation, progression and recurrence.

1291. de Oliveira Barbosa, M. D., et al. (2012). "Treatment strategy in a child with a retained bullet in the cerebellomedullary cistern." Journal of neurosurgery. Pediatrics 10(3): 192-194.

A 6-year-old girl was admitted to our emergency room because of a gunshot wound in the posterior craniocervical junction. On admission, she was alert, but left hemiplegia and right hemiparesis were noted. Cranial CT scanning showed a retained bullet in the cerebellomedullary cistern without bone destruction. Moreover, fourth ventricle hemorrhage was observed. There were no signs of acute hydrocephalus. The patient underwent suboccipital craniectomy and C-1 laminectomy for bullet removal. Postoperatively, the patient experienced significant neurological improvement. To the best of the authors' knowledge, this is the first documented case of a patient with a retained bullet in the cerebellomedullary cistern. The management strategies in such a unique case are discussed.

1292. de Oliveira-Souza, R., et al. (2001). "Executive amnesia in a patient with pre-frontal damage due to a gunshot wound." Neurocase 7(5): 383-389.

This paper reports the case of a young patient with extensive pre-frontal damage in whom we tested the hypothesis that intensive training improves executive performance as assessed by the Wisconsin Card Sorting Test (WCST). As long as her declarative memory, complex perceptual abilities and global cognitive status were spared, we surmised that any deficit in executive learning would have occurred in relative isolation. We showed that her abnormal performance on the WCST, both on the standard as well as on the post-instruction condition, was due to an impairment of shifting attention across perceptual dimensions (extra-dimensional). In contrast, her ability to shift attention within perceptual categories (intra-dimensional) was spared, as were her declarative memory, object and visuospatial perception, oral language comprehension and praxis (ideomotor, tool use and constructional). This case supports the hypothesis that executive amnesia is a type of amnesic disorder distinct from the classic amnesic syndrome due to mamillo-temporomedial damage. As such, it is probably closely related to procedural learning and may depend on the same fronto-subcortical loops that mediate the actual execution of behaviour.

1293. De Ponte, F. S., et al. (1995). "[Bicoronal approach in the management of frontal sinus fractures]." L'approccio bicoronale nel trattamento delle fratture del seno frontale. 44(11): 507-514.

The frontal sinus is located at the level of the junction between the naso-ethmoido-orbital region, the cranial vault and the skull base and plays a particularly important role in the biomechanics of the centro-facial region. It represents a locus minoris resistentiae placed between the fronto-orbital frame, whose resistance to trauma is good, and the thin posterior fronto-ethmoidal structures. Fractures of the frontal sinus more frequently involve the anterior wall of the frontal sinus and, occasionally, also the posterior wall and the base of the sinus. Where the fracture involves the anterior sinsu wall alone, surgical reduction is indicated to correct cosmetic defects arising from an altered bone profile, either via bicoronal access or by direct attack when there are skin lesions too. If the fracture extends to the posterior wall of the sinus without causing bone displacement or dural lesion, most authors agree that only the fractures of the anterior wall should be treated to avoid obliterating the sinus cavity. When the fracture of the posterior wall is comminuted with displacement of bone fragments, there are usually dural lesions too; in this event, once dural plasty has been performed, it is necessary to cranialize the frontal sinus by demolishing its posterior wall. Fractures of the skull base, associated with a high

frequency of lesion or obstruction of the sinusal ostio and severe infective complication, require cranialization of the sinus that is also separated from the cranial cavity using a median-pedicled pericranial flap. To control the point of fracture, a rigid fixation system can be employed (microplates) or osteosynthesis with metal wires that restore the eurhythm of the frontal-orbital region and simultaneously guarantee good stability of the repositioned fragments.

1294. de Santana Santos, T., et al. (2011). "Fracture of the coronoid process, sphenoid bone, zygoma, and zygomatic arch after a firearm injury." The Journal of craniofacial surgery 22(6): e34-37.

A rare case of fracture of the coronoid process, sphenoid bone, zygoma, and zygomatic arch caused by a firearm is described. A 25-year-old man was hit in the face with a bullet, resulting in restricted mouth opening, difficulty chewing, and pain when opening the mouth. The clinical examination revealed a perforating wound in the right parotid region. A computed tomographic scan revealed a comminuted fracture of the left coronoid process with the bullet stopping in the intact left coronoid process. Treatment was bilateral coronoidectomy associated with speech therapy and was successful. Details of the clinical signs, computed tomography, treatment, and follow-up are presented.

1295. De Santis, G., et al. (1992). "[Hemimandibular reconstruction via an autologous transplant of vascularized fibula. A report of a clinical case]." Ricostruzione di un emicorpo mandibolare mediante trapianto autologo di perone vascolarizzato. Presentazione di un caso clinico. 41(1-2): 41-49.

The authors illustrate the advantage of vascularised as opposed to conventional edges in the reconstruction of the jaw, focusing in particular on the use of a fibular autologous transplant. After a rapid description of the surgical technique used to remove the graft, they report a case of mandibular reconstruction in a young patient who had been involved in a shooting accident which had led to the loss of the left of this jaw.

1296. de Silva, D. J. and G. E. Rose (2011). "Orbital blowout fractures and race." Ophthalmology 118(8): 1677-1680.

PURPOSE: To examine the type of orbital blowout fracture and its variation with race., DESIGN: Retrospective review of computed tomography (CT) scans and demography in an unselected cohort of patients with orbital blowout fractures., PARTICIPANTS: Patients with a high-resolution CT scan of adequate quality for analysis who presented with an orbital blowout fracture to the Orbital Clinic at Moorfields Eye Hospital. Patients with fractures involving the orbital rim or the cranium, or with penetrating injuries of the globe or orbit, were omitted from the study., METHODS: Demographic and ethnic information was collected for each patient, and the orbital scans were reviewed by a single observer. On the basis of coronal and axial imaging, a fracture was classified as affecting up to 4 areas: the floor lateral to the infraorbital canal (area 1, "A1"), the floor medial to the canal ("A2"), the maxillo-ethmoidal strut ("inferomedial" strut, "A3"), and the medial wall blowout fracture ("A4"); with fractures involving the inferomedial strut, it was noted whether there was displacement or rotation of the strut. Ethnic origin was classified as Caucasian, Afro-Caribbean, or Asian (Oriental or Indian)., MAIN OUTCOME MEASURES: The proportion of different walls involved in orbital blowout fractures within 3 ethnic groups., RESULTS: A total of 152 patients (125 men, 82%) had imaging adequate for analysis; 103 (68%) were Caucasian, 19 (12%) were Afro-Caribbean, and 30 (20%) were Asian. Caucasians most commonly had floor fractures (A1 or A2 in 56 orbits, 54%) compared with 10 of 103 purely medial fractures (A4, 10%); in contrast, medial fractures were the most common type in Afro-Caribbean patients (7/19 cases, 37%), and purely floor fractures occurred in only 2 cases (10%) ($P<0.005$). Asian patients had results similar to those for Caucasian patients, with isolated floor fractures being the most common (14/30 cases, 47%)., CONCLUSIONS: Most blowout fractures involve the orbital floor in Caucasian and Asians, whereas in Afro-Caribbeans the most common site for fracture is the medial wall., FINANCIAL DISCLOSURE(S): The author(s) have no proprietary or commercial interest in any

materials discussed in this article.

1297. De Silva, G. S., et al. (2014). "Lack of identifiable biologic behavior in a series of porcine mesh explants." Surgery 156(1): 183-189.

INTRODUCTION: Biologic matrices used in abdominal wall reconstruction are purported to undergo remodeling into connective tissue resembling native collagen. Key steps in that process include inflammatory response at the mesh/tissue interface, cellular penetration, and neovascularization of the matrix, followed by fibroblast proliferation and collagen deposition. We aimed to examine the concept of biologic mesh remodeling/regeneration in a series of explanted porcine biologic meshes., MATERIALS AND METHODS: A cohort of patients who underwent removal of porcine biologic mesh was identified in a prospective database. Mesh/tissue samples were analyzed using standard hematoxylin/eosin and Masson's trichrome staining. Main outcome measures included: inflammatory response at the mesh/tissue interface, foreign body reaction (FBR), cellular penetration, neovascularization, and new collagen deposition. All evaluations were performed by a blinded senior pathologist using established grading scales., RESULTS: A total of 14 cases with implant time ranging from 4 to 33 months were identified and analyzed. All meshes were placed as intraperitoneal underlay. There were 7 non-cross-linked and 7 cross-linked grafts. Cross-linked grafts were associated with mild FBR and moderate fibrous capsule formation. Similarly, non-cross-linked grafts had mild-to-moderate FBR and encapsulation. Furthermore, non-cross-linked grafts were associated with no neovascularization and minimal peripheral mesh neocellularization. Cross-linked grafts demonstrated neither neovascularization nor neocellularization. Although no grafts were associated with any quantifiable new collagen deposition within the porcine biologic matrix, minimal biodegradation/remodeling was observed at the periphery of the non-cross-linked grafts only., CONCLUSION: The biologic behavior of porcine meshes is predicated on their ability to undergo mesh remodeling with resorption and new collagen deposition. In the largest series of human biologic explants, we detected no evidence of xenograft remodeling, especially in the cross-linked group. Although underlay mesh placement and other patient factors may have contributed to our findings, the concept of porcine biologic mesh regeneration does not seem to be prevalent in the clinical setting.

1298. de Souza, A. (2020). "New-onset tic disorder following circumscribed brain injury." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia 75: 234-239.

Adult-onset tics represent either a secondary tic disorder ("tourettism") or a late presentation of childhood tics, which may have been previously unrecognised. Head trauma has been recognised as an infrequent cause of adult-onset tic disorder, which exhibits variable temporal relationship to the inciting injury and response to therapy. We present a patient who presented with late-onset tics seven years after a circumscribed brain injury, responding well to antidopaminergic treatment. A review of all the previously reported cases of post-traumatic tic disorder is provided. Our patient is unusual in that the injury presumed to be responsible for the development of tics was of a very focal nature, akin to previously described tic disorder following vascular insults. We discuss the rare occurrence of tourettism after such focal brain lesions and analyse the insights this provides into the anatomical substrates underlying tic disorders.

1299. De Souza, R. B., et al. (2013). "Pourfour du Petit syndrome caused by traumatic pseudo-aneurysm of the internal carotid artery." Journal of Pediatric Neurology 11(3): 189-191.

Pourfour du Petit syndrome, or reverse Horner syndrome, is described as an overactive sympathetic nervous system, being characterized by mydriasis, eyelid retraction, and hyperhidrosis. We described a case of Pourfour du Petit syndrome after cervical injury by gunshot, with a little review

about this rare syndrome. Angiography revealed dissection and formation of pseudo aneurysm of the left carotid artery. We believe that this lesion caused hyper-stimulation of the left cervical sympathetic chain, resulting in reverse Horner syndrome or Pourfour du Petit syndrome. There was reversal of symptoms spontaneously after 3 wk. © 2013 IOS Press and the authors.

1300. de Souza, R. B., et al. (2013). "Traumatic brain injury by a firearm projectile: a 16 years experience of the neurosurgery service of Santa Casa de Sao Paulo." Revista do Colegio Brasileiro de Cirurgioes 40(4): 300-304.

OBJECTIVE: To evaluate the epidemiology and prognostic factors associated with traumatic brain injury by a firearm projectile (FAP)., METHODS: We reviewed the medical records of 181 patients in the Department of Neurosurgery of Santa Casa de Sao Paulo (Sao Paulo Holy House) diagnosed with traumatic brain injury (TBI) resulting from FAP from January 1991 to December 2005. Were evaluated: age, sex, Glasgow Coma Scale (GCS) on admission, brain region affected by the FAP, type of injury (penetrating or tangential), type of treatment and outcome, based on GCS. The relationship between therapeutic strategy and outcome was analyzed using the Chi-square test with Yates correction. The Fisher test was used to verify the same correlation individually for each group stratified by GCS on admission., RESULTS: Of the 181 patients, 85% were male (n = 154) and 15% female (n = 27). Mean age was 31.04 years (+/- 10.98). The mostly affected brain region was the frontal lobe (27.6%), followed by temporal (24.86%) and occipital (16.57%) ones. Of the TBIs evaluated, 16% were tangential and 84%, penetrating., CONCLUSION: Patients undergoing surgical treatment had better outcome than those submitted to conservative treatment, and patients who were more severe at admission (GCS 3-8) have better results with the neurosurgical procedure.

1301. De Tommasi, A., et al. (2006). "Emergency surgery in a severe penetrating skull base injury by a screwdriver: case report and literature review." World journal of emergency surgery : WJES 1: 36.

BACKGROUND: Very few cases of severe penetrating injuries to the skull base with a seemingly innocuous object have been described in the literature. Of the cases reported, only ten involve a penetrating screwdriver. However, the choice of therapeutic management, whether it be emergency surgical or non-surgical removal of the penetrating object as well as the selected surgical approach remain quite controversial., CASE PRESENTATION: The authors describe the case of a severe penetrating skull base injury caused by a screwdriver, following an accidental fall from a ladder. The patient was admitted in Glasgow Coma Scale (GCS) 11 with a cerebrospinal fluid (CSF) leak in the right maxillary area. The tri-dimensional computerized tomography (3-D CT) scan revealed an oblique trajectory of the screwdriver shank through the skull base. The authors opted for an emergency surgical extraction of the object. A contra-lateral pterional approach was successfully performed and a two-year follow-up showed no neurological deficits., CONCLUSION: The reported case supports the choice of emergency surgical removal of the object in penetrating skull base injuries involving the anterior skull base with neurovascular lesions. Surgical aspects of the pterional approach, and in particular the left pterional approach as well as other cranio-facial approaches in severe penetrating skull base injuries are discussed.

1302. de Tribolet, W., et al. (1979). "Brain abscess after transnasal intracranial penetration of a paint-brush." Surgical neurology 11(3): 187-189.

The case of a brain abscess caused by intracranial, transnasal penetration of a paint-brush is presented. The danger that such foreign bodies may remain unnoticed, especially in children, is stressed. Cure was achieved by total resection of the abscess capsule.

1303. de Villiers, J. C. and A. R. Grant (1985). "Stab wounds at the craniocervical junction." Neurosurgery 17(6): 930-936.

Between 1976 and 1984, 11 patients with stab wounds at the craniocervical junction were seen in the Department of Neurosurgery at Groote Schuur Hospital. The injury usually occurred in males, and the left side was predominantly involved. Because of the anatomical features of this region, the penetrating instrument is deflected by the occipital squama into the atlantooccipital or atlantoaxial interspace, and an almost predictable syndrome occurs. The dura mater is penetrated, so that cerebrospinal fluid leakage and meningitis are common complications (meningitis occurred in 5 patients). A meningocele may develop at this site and did occur in 4 patients, but only 2 required surgical repair. Because of the exposed position of the vertebral artery at this level, this vessel was injured in 4 patients; an arteriovenous fistula developed in 2, vertebral artery occlusion occurred in 1, and a false aneurysm developed in another patient. The neurological deficit varied in magnitude, was often transient, affected the upper limbs more than the lower, was asymmetrical (suggestive of lateralized injury), and at times showed a remarkable tendency to recover. Awareness of the existence of this syndrome may help in forestalling complications. The only warning sign may be an insignificant wound in the suboccipital or retromastoid region.

1304. De Witte, O., et al. (1995). "[Association of traumatic cortical aneurysm of the middle cerebral artery and spontaneous aneurysm of the trifurcation of the same cerebral artery]." Association d'un anevrisme traumatique sylvien cortical et d'un anevrisme spontane de la trifurcation sylvienne sous-jacente. 41(6): 432-435.

Traumatic aneurysms constitute a very small percentage of all intracranial aneurysms. A high mortality results of a catastrophic rupture and they run an unpredictable course. Traumatic aneurysms usually involve the large basal arteries or the middle meningeal arteries. We report a case of an association of a traumatic aneurysm with a congenital aneurysm located on the same middle cerebral artery. At our knowledge, it is the first described case of the literature.

1305. Deakin, C. and G. Davies (1994). "Defining trauma patient subpopulations for field stabilization." European journal of emergency medicine : official journal of the European Society for Emergency Medicine 1(1): 31-33.

Despite several large studies, the scoop and run versus field stabilization debate in prehospital trauma care continues. It is unlikely that all trauma patients are best treated by either field stabilization or scoop and run and the most effective form of prehospital care may be dependent upon the type of injuries sustained. Studies suggest that penetrating trauma involving major vascular injury may be best treated by scoop and run since advanced life support (ALS) measures serve only to delay time to definitive surgical treatment. Conversely, patients with head injuries may benefit from rapid ALS performed on scene in order to control airway and breathing problems, and reduce intracranial pressure prior to transport. Between these two groups of patients lie those with blunt trauma in whom scoop and run may be most appropriate if there is major vascular damage or those in whom field stabilization may offer the patient a greater chance of survival if blood loss is not a life-threatening problem.

1308. DeBono, R., et al. (1998). "The survival of human skin stored by refrigeration at 4 degrees C in McCoy's 5A medium: does oxygenation of the medium improve storage time?" Plastic and reconstructive surgery 102(1): 78-83.

To establish the viable storage time of human skin stored by refrigeration at 4 degrees C in McCoy's 5A medium and to establish whether oxygenating the medium improves the viable storage time, the following experiment was conducted. Eighty discs of human split-thickness skin graft, each 3 mm in diameter, were stored in 40 sterile sealable containers under four different conditions: in 0.9% saline, in McCoy's 5A medium, in oxygenated McCoy's 5A medium, and in carbon dioxide supplemented McCoy's 5A medium. Skin graft viability was assessed using tissue culture. Skin stored in saline was viable for only 1 week, whereas skin stored in McCoy's 5A medium and in oxygenated McCoy's 5A medium was viable for 4 weeks. Skin stored in carbon dioxide supplemented McCoy's 5A solution did not even survive the first week. These findings show that McCoy's 5A medium allows at least 4 weeks of viable human skin storage by refrigeration at 4 degrees C. Furthermore, oxygenating the medium does not seem to improve the viable storage time, and carbon dioxide supplementation is detrimental. The advantages of skin storage by refrigeration and the implications of the above findings are discussed. A clinical case in which split-thickness skin was stored for approximately 5 weeks and still resulted in good graft take is quoted as an example of our experience with the use of McCoy's 5A medium.

1309. Debus, E. S. and R. T. Grundmann (2020). "Acute carotid part 3: artery injury." Gefasschirurgie 25(5): 356-363.

Objective: In the present overview, the aim was to comment on the evidence-based treatment of penetrating and blunt carotid injuries. Method: Literature search in PubMed for the years 2010 to 2019 under the keywords “Carotid artery [Title] AND injury [Title/Abstract]”. Results: There are only a few guideline recommendations for the treatment of penetrating carotid injuries; injuries to zone II of the artery between the angle of the mandible and the bottom of the cricoid cartilage, which are rare in Europe, are mostly treated by open surgery. On the other hand, zone I or III injuries may benefit from endovascular management. For blunt injuries, conservative treatment with anticoagulation/platelet aggregation inhibitors is the first management strategy; in grade 3 injuries endovascular treatment seems to be useful—provided it is performed in centers where there is great expertise. In an overview of the value of the endovascular treatment of traumatic internal carotid artery pseudoaneurysms, road traffic accidents (51%) and assaults (gunshots, stabs, or blasts, 12%) were the most common causes of injury. Most of the patients were treated with a covered stent graft; coils, self-expanding stents, and detachable occlusion balloons were also used. The total success rate of pseudoaneurysm occlusion was 84%. The reported peri-procedural morbidity rate was calculated to be 6%, and the reported perioperative mortality rate was 1.2%. Treatment method of choice postoperatively was platelet aggregation inhibitors (either single or dual) for at least 3 months. Iatrogenic carotid injuries are rare; they are particularly observed after endoscopic endonasal surgery. Conclusion: Preferably, despite the increasing propagation of endovascular techniques, penetrating carotid injuries should continue to be treated by open surgery. In the case of blunt injuries, on the other hand, non-operative management is the first priority.

1310. DeChamplain, R. W. (1973). "Mandibular reconstruction." Journal of oral surgery (American Dental Association : 1965) 31(6): 448-462.

1311. DeCuypere, M., et al. (2016). "Pediatric intracranial gunshot wounds: the Memphis experience." Journal of neurosurgery. Pediatrics 17(5): 595-601.

OBJECTIVE Penetrating brain injury in civilians is much less common than blunt brain injury but is more severe overall. Gunshot wounds (GSWs) cause high morbidity and mortality related to penetrating brain injury; however, there are few reports on the management and outcome of intracranial

GSWs in children. The goals of this study were to identify clinical and radiological factors predictive for death in children and to externally validate a recently proposed pediatric prognostic scale. METHODS The authors conducted a retrospective review of penetrating, isolated GSWs sustained in children whose ages ranged from birth to 18 years and who were treated at 2 major metropolitan Level 1 trauma centers from 1996 through 2013. Several standard clinical, laboratory, and radiological factors were analyzed for their ability to predict death in these patients. The authors then applied the St. Louis Scale for Pediatric Gunshot Wounds to the Head, a scoring algorithm that was designed to provide rapid prognostic information for emergency management decisions. The scale's sensitivity, specificity, and positive and negative predictability were determined, with death as the primary outcome. RESULTS Seventy-one children (57 male, 14 female) had a mean age of 14 years (range 19 months to 18 years). Overall mortality among these children was 47.9%, with 81% of survivors attaining a favorable clinical outcome (Glasgow Outcome Scale score >= 4). A number of predictors of mortality were identified (all $p < 0.05$): 1) bilateral fixed pupils; 2) deep nuclear injury; 3) transventricular projectile trajectory; 4) bihemispheric injury; 5) injury to >= 3 lobes; 6) systolic blood pressure < 100 mm Hg; 7) anemia (hematocrit < 30%); 8) Glasgow Coma Scale score <= 5; and 9) a blood base deficit < -5 mEq/L. Patient age, when converted to a categorical variable (0-9 or 10-18 years), was not predictive. Based on data from the 71 patients in this study, the positive predictive value of the St. Louis scale in predicting death (score >= 5) was 78%. CONCLUSIONS This series of pediatric cranial GSWs underscores the importance of the initial clinical exam and CT studies along with adequate resuscitation to make the appropriate management decision(s). Based on our population, the St. Louis Scale seems to be more useful as a predictor of who will survive than who will succumb to their injury.

1312. DeDominicis, K., et al. (2017). "Longitudinal profile of GFAP, alpha-ii-spectrin, and their breakdown products in rat CSF after probe insertion or penetrating TBI." Journal of neurotrauma 34(13): A19-A20.

Biofluid based biomarkers hold great potential for tracking severe TBI progression. Increased CSF levels of glial fibrillary acidic protein (GFAP), alpha-II-spectrin, and their break-down products (BDPs) have been described acutely after TBI. However, their use as subacute-chronic biomarkers is unclear. This work conducted longitudinal analyses of GFAP, alpha-II-spectrin, and their BDPs following severe TBI. Penetrating ballistic-like brain injury (PBBI) was induced by inserting a probe through the right frontal pole followed by rapid balloon inflation to create a temporary cavity. Additional rats sustained a less severe probe insertion without balloon inflation (probe) or were exposed to craniotomy alone (sham). CSF was collected 24 h, 3 d, 7 d, 1m, or 3m after injury and concentrated with centrifugal spin-filters. GFAP, alpha-II-spectrin, and BDPs were assessed by Western blot and/or ELISA. Based on western blots, alpha-II-spectrin and its BDPs were not elevated following probe injury but PBBI led to widespread elevation compared to sham. Full length protein (280kDa) was significantly elevated at 24 h and 3 d following PBBI. SBDP145-150 were robustly increased at 24 h-1 m. SBDP-120 was detected at 3 d. ELISAs indicated that GFAP levels were not significantly upregulated at 24 h or 3 d. At 7 d-3 m, GFAP was not detected in the majority of samples. To confirm these results, western blots were performed to determine if full length GFAP or its BDPs could be ascertained. These data indicate that GFAP-BDPs were significantly increased at 24 h following PBBI. In accordance with ELISA quantitation, GFAP and its BDP were not detectable in most samples collected at 7 d-3 m. However, nearly half of PBBI rats at 1m and 10% of sham rats at 3m did display the characteristic banding of GFAPBDPs. These data indicate that elevation in injury-induced biomarkers remain detectable in CSF as late as 1m following PBBI. Alpha-IIspectrin and its SBDP145-150, as opposed to GFAP, may have greater utility as acute-chronic CSF biomarkers.

1313. DeDominicis, K. E., et al. (2018). "Cerebrospinal fluid biomarkers are associated with glial fibrillary acidic protein and αII-spectrin breakdown products in brain tissues following penetrating ballistic-like brain injury in rats." Frontiers in neurology 9(JUL).

Treatments to improve outcomes following severe traumatic brain injury (TBI) are limited but may benefit from understanding subacute-chronic brain protein profiles and identifying biomarkers suitable for use in this time. Acute alterations in the well-known TBI biomarkers glial fibrillary acidic protein (GFAP), αII-spectrin, and their breakdown products (BDPs) have been well established, but little is known about the subacute-chronic post-injury profiles of these biomarkers. Thus, the current study was designed to determine the extended profile of these TBI-specific biomarkers both in brain tissue and cerebral spinal fluid (CSF). Protein abundance was evaluated in brain tissue samples taken from regions of interest and in CSF at 24 h, 3 days, 7 days, 1 month, and 3 months following severe TBI in rats. Results showed increased full length GFAP (GFAP-FL) and GFAP-BDPs starting at 24 h that remained significantly elevated in most brain regions out to 3 months post-injury. However, in CSF, neither GFAP-FL nor GFAP-BDPs were elevated as a consequence of injury. Regional-specific reduction in αII-spectrin was evident in brain tissue samples from 24 h through 3 months. In contrast, SBDP-145/150 was robustly elevated in most brain regions and in CSF from 24 h through 7 days. Correlation analyses revealed numerous significant relationships between proteins in CSF and brain tissue or neurological deficits. This work indicates that TBI results in chronic changes in brain protein levels of well-known TBI biomarkers GFAP, αII-spectrin, and their BDPs and that SBDP-145/150 may have utility as an acute-chronic biomarker.

1314. Dehghani, S., et al. (2014). "Intracranial meningioma at the site of a previous cranial penetrating trauma due to shrapnel." The Journal of craniofacial surgery 25(2): e125-127.

Meningiomas are common and mostly benign intracranial tumors, which originate from arachnoid cells of the meninges, and account for approximately 25% of all primary intracranial tumors. Many external etiological factors have been described as etiology of meningioma in the literature, one of which is head trauma. However, trauma as a cause of meningioma remains a controversial subject. Here, a case of a patient with posttraumatic meningioma, who was wounded 25 years before, is presented. The assessment of the clinical characteristics of the patient and those reported in the literature seem to confirm that, in some cases, head trauma may be a factor contributing to the development of meningioma.

1315. Dekker, A. P., et al. (2014). "An unusual transorbital penetrating injury and principles of management." Craniomaxillofacial trauma & reconstruction 7(4): 310-312.

The objective of this study was to present an unusual low velocity transorbital penetrating injury. The study design was a clinical record (case report). A 38-year-old gentleman tripped and fell face first onto the wing of an ornamental brass eagle. This penetrated the inferomedial aspect of the right orbit, breaching the lamina papyracea to extend into the ethmoid sinuses and reaching the dura of the anterior cranial fossa. The foreign body was removed in theater under a joint ophthalmology and ENT procedure. The patient was left with reduced visual acuity in the right eye but no other long-term sequelae. Transorbital penetrating injury presents unusual challenges to investigation and management requiring a multidisciplinary approach to prevent significant morbidity and mortality. If managed well the prognosis is good.

1316. Del Castillo-Calcaneo, J. D., et al. (2016). "Traumatic brain injury with a machete penetrating the dura and brain: Case report from southeast Mexico." International journal of surgery case reports 23: 169-172.

INTRODUCTION: Traumatic Brain Injury (TBI) is a major cause of death and disability in our society, we present the first case report of non-missile penetrating (NMP) cranial trauma with a machete in Mexico, and our objective by presenting this case is to prove the usefulness of recently proposed algorithms in the treatment of NMP PRESENTATION OF CASE: We present the case of a 47 year old woman who received a machete hit to the right side of her head during an assault., she arrived fully

conscious to the emergency department (ED), computed tomography was performed and based on the findings of this study and in accordance to recently proposed algorithms for managing NMP cranial trauma a craniotomy was performed, at follow-up the patient presented wtih minor neurological disability in the form of left hemiparesis., DISCUSSION: Non-missile penetrating (NMP) lesions are defined as having an impact velocity of less than 100m/s, causing injury by laceration and maceration, An algorithm for treating NMP cranial trauma has been recently published in the Journal World Neurosurgery by De Holanda et al., in this case we followed the algorithm in order to provide best care available for our patient with good results., CONCLUSION: The use of current algorithms for managing NMP cranial trauma has proved to be very useful when applied on this particular case. GCS on admission is an important prognostic factor in NMP cranial trauma.

1317. del Cerro, M. and A. A. Monjan (1979). "Unequivocal demonstration of the hematogenous origin of brain macrophages in a stab wound by a double-label technique." Neuroscience 4(9): 1399-1404.

1318. Del Rosario Munoz Ramirez, M., et al. (2011). "Clinical brain death in a patient with severe brain injury without cerebral angio graphic criteria." Critical care medicine 39: 249.

Case Reports: Brain death is defined as the irreversible cessation of all functions of the entire brain including the brain stem, and is based in a clinical assessment. In several countries a confirmatory tests are required by law. A selective four vessels angiography is the standard of confirmatory tests and may show lack of contrast opacification of the internal carotid arteries beyond the carotid siphon, and filling of the vertebral arteries but no beyond, their intracranial penetration. Case: A 35-year old woman was transferred from an outside hospital 24 hours after suffering a head gunshot wound with brain parenchyma protruding through a left parietal skull defect. On admission GSC 3, in the next 48 hours she developed brain death. Apnea testing documented an increase of PaCO2 above 60 mm Hg. She was considered a medico-legal case and candidat for organ donation. The confirmatory test was made by cerebral angiography which reported patency of the bilateral carotid arteries displaying filling of the middle cerebral artery and through the anterior cerebral artery, passage of contrast media to the contralateral carotid system. Patency of the basilar artery was observed with passage of contrast media through the posterior communicanting artery to the contralateral carotid artery. However, no cerebral parenchymogram in capillary and venous phase was observed. The organ donation process could not carry out because of legal statements of the Mexican Health Law. Conclusions: Arterial blood flow does not exclude brain death, and cerebral blood flow occurs in those conditions where the intracranial pressure is less than intravascular pressure as in decompressive crani-ectomy or like in this case by skull defects. The absence of the cerebral deep venous dranaige or parenchymogram may be consistent with brain death and the medical staff should be aware of this findings to avoid losing time for brain death declaration in case of organ transplant.

1319. Del Signore, A., et al. (2011). "Trauma induced complete sinonasal separation and subsequent frontoethmoid mucocele formation." Laryngoscope 121(SUPPL. 5): S359.

Educational Objective: At the conclusion of this presentation, the participant should be able to recognize trauma as a potential cause of sinus mucoceles and discuss the options for management. Objectives: To highlight a unique presentation and subsequent management of a frontoethmoid mucocele caused by trauma. Study Design: Case report and literature review. Methods: The patient chart, including history, physical examination, radiologic imaging, operative report and pathologic results, was reviewed. A literature search was performed; appropriate Englishlanguage papers were identified and reviewed. Results: The patient is a 40-year-old woman who suffered a gunshot wound to the nasal region 15 years prior to presentation. At that time, she was managed surgically, including enucleation of one eye. She presently developed preseptal cellulitis of the remaining eye; a CT scan

demonstrated a large frontoethmoid mucocele with complete sinonasal separation caused by scarring. Using a combined endoscopic and open approach, a drainage pathway was successfully created to the nasal cavity and a stent placed, with subsequent resolution of the infection. Although trauma is a known etiology of mucoceles, a literature review failed to find any other reported cases caused by such distinct separation of the nasal cavity and sinuses. Conclusions: This case represents a unique illustration of the pathogenesis of mucocele formation in the setting of complete separation of the frontal and ethmoid sinuses from nasal cavity. It emphasizes the importance of thorough evaluation and management of craniofacial trauma involving the paranasal sinuses. Surgical obliteration or serial imaging to monitor for mucocele formation should be performed for cases resulting in such significant derangement of the normal drainage pathways.

1320. Del Verme, J., et al. (2020). "Classification of orbitocranial wooden foreign body penetration injuries: what to do when they violate the intracranial space? A systematic review." Journal of neurosurgical sciences 64(2): 190-199.

INTRODUCTION: Orbitocranial wooden foreign body (OWF) penetrations are rare but challenging occurrences that may violate the intracranial space resulting in brain damage and hemorrhagic, as well as infectious, complications. Moreover, there is a specific subset of cases of OWF penetrations that are particularly challenging to treat. Although there are well-defined management guidelines for pure intraorbital localization, there is not yet a defined treatment protocol for foreign bodies reaching the intracranial space. However, their removal performed either directly or through craniotomy, is often easily attainable given the condition that all necessary precautions are accounted for., EVIDENCE ACQUISITION: After having treated a 48-year-old man with a transorbital OWF penetration injury at our neurosurgical department, we systematically reviewed the last 15 years of literature to define and summarize the best management strategy. Multiple databases were searched for case reports and case series involving patients with intraorbital and transorbital OWF penetration injuries. For each study, we extracted data on age, sex, imaging modality, type of wood (processed vs. unprocessed), location of periorbital and intracranial entry site, treatment type ("pull and see" or "open and see"), antibiotic therapy, and complications., EVIDENCE SYNTHESIS: We classified transorbital OWFs into two categories: transorbital with only cavernous sinus involvement and transorbital with more extensive intracranial involvement. We described what we believed was the most appropriate management conduct in each case., CONCLUSIONS: Grounded on our experience and on the review of the literature, we suggest, based on the anatomical localization of the OWF, a classification system for OWFs which is coupled with a tailored treatment strategy for each case. These suggestions are made to provide surgeons with direction on the correct management of such rare but challenging occurrences.

1323. Delannoy, Y., et al. (2013). "Typical external skull beveling wound unlinked with a gunshot." Forensic science international 226(1-3): e4-8.

Lesions of the cranial vault resulting from firearms are traditionally described in forensic medical literature with many reports illustrating atypical bone lesions carried out to the skull by gunshot wounds. The authors present this report which illustrates an external beveled skull wound, associated with internal beveling damage, caused by a stabbing injury. A partially buried human skeleton was

found in a forest. The examining of the skull revealed a hole resembling the exit wound caused by a bullet and two other smaller stab wounds. No typical entering bullet wound and no other bone lesions were found. During the course of the investigation, one of the perpetrators admitted to hitting the victim, using a sickle, and to hiding the body. For this purpose, he dragged the corpse with the sickle still implanted in the skull, using it as a hook. Upon retrieving the sickle, a piece of cranial vault was removed, thus creating an external beveled wound. In order to identify the mechanism which brought about this kind of lesion, experimental work was carried out on a human skull. In this particular case, the tip of the sickle penetrated into the bone, creating a lesion that would typically be produced with a stabbing instrument when applied with vertical force. When the body was dragged, using the sickle as a hook, this was a hand-produced vertical force, which was applied in the opposite direction. It caused the tearing of a piece of bone and the creation of an outer bevel. This atypical lesion should be made known to medical examiners and pathologists in order to help investigating and understanding of the circumstances of injuries.

1324. Delannoy, Y., et al. (2016). "The mechanism of the keyhole lesion reassessed: An experimental approach." Journal of forensic and legal medicine 37: 1-7.

The initial description of the keyhole defect was detailed as a peculiar gunshot entrance wound in the cranial vault due to firearm discharge in a tangential path. This injury may be described in two parts: a rounded section with inner table beveling and a triangular section with outer table beveling. We report a case of a gunshot skull wound "keyhole" shaped, appeared to have been made perpendicularly to the bone. Performing an experimental study on cranial bones with shots made perpendicularly to the skull approved this hypothesis, and bone injuries were then architecturally characterised using high-resolution micro computed tomography. The singular link between the tangential gunshot path and the keyhole pattern has been refuted several times, and some authors have hypothesised that there is an important role for concentric fractures that occur far away from the initial impact point of the bullet. Micro computed tomography analysis of the bone showed these keyhole defect features with a particular high description. Then, the whole pattern has a spider-web effect, and these concentric fractures could explain the keyhole pattern even in a perpendicular gunshot path.

1325. Deliverska, E. G. (2014). "Mechanism of injury- A significant com-ponent in evaluation of maxillofacialtraumatic patients status." Journal of IMAB - Annual Proceeding (Scientific Papers) 20(1): 478-483.

Knowing the injury mechanisms is of extreme importance for correct diagnostic evaluation. Specific injury models can be related to exactly determine trauma mechanisms. Understanding the way of injury may be a key to solving the occult injuries. Thus, some life threatening injuries may be diagnosed without present clinical symptoms at the moment of examination. Purpose: The aim of our study is to analyse the risk factors for arising of associated maxillofacial trauma injuries (AMFI) Material and methods: A total of 352 traumatic patients were retrospectively and prospectively examined for the period 05. 2005 - 12. 2011, treated at the Department of Oral and maxillofacial surgery at the St. Anna University Hospital, Sofia, whereas AMFI were determined in 129 patients Results: Our study results indicate that most often, RTA are a reason for a combined trauma at the age group of 20-29, followed by the age group of 30-39, and less in the age group of 40-49. The most often reasons for combined traumas are RTA(road traffic accident) and IPV(interpersonal violence), each of which has a relative share, significantly higher than the other reasons (x2, r{cyrillic}<0.001). Our study results indicate that following a RTA, the most common combined trauma is CrT - 31 patients, followed by muscular skeletal system trauma - 11, equal number of eye injuries and polytrauma - 4 patients, spinal cord trauma - 1, and more than one concomitant injury - 1. When analyzing the mutual relation between aetiology and combined trauma, the most common reasons are included (RTA and thrash) as well as combined traumas (neurosurgical, MSS trauma and eye trauma). Conclusion: Data analysis in our study

indicates that trauma mechanism is the most important factor that imposes the need of CT examination, especially in intoxicated and disorientated patients, as well as in unconscious patients.

1326. Della Sala, S. (2011). "A daguerreotype of Phineas Gage?" Cortex; a journal devoted to the study of the nervous system and behavior 47(4): 415.

1327. Dell'Aquila, A., et al. (2003). "Actual trend in firearms injures of the cranio-maxillo-facial region." IJCI - International Journal of Clinical Investigation 11(2-4): 41-44.

Firearms induce severe morfhological and structural alteration on both soft and bony tissues of the cranio-maxillo-facial region, and it's therefore essential to restore their previous functionality. This lesions must be evaluated precisely through clinical and instrumental diagnostic examinations, preferably with a three-dimensional construction C.T. scan. The appropiate managment of ballistic facial injuries is conservative in low velocity injuries, while is aggressive in high-]energy avulsive trauma. In this cases is actually preferred a initial primary repair of existing tissues, serial conservative debridment and early definitive reconstruction.

1328. DeLong, G. R. (2002). "Mid-gestation right basal ganglia lesion: clinical observations in two children." Neurology 59(1): 54-58.

OBJECTIVE: To describe the neurobehavioral syndrome in two children with destruction of the right basal ganglia ostensibly from amniocentesis needle penetration at 17 weeks of gestation., BACKGROUND: Early-life unilateral lesions of the basal ganglia are rare and the resulting syndrome not described., METHODS: Both children had repeated clinical assessments, MRI and (18)F-fluorodeoxyglucose PET scans, and psychometric and achievement testing over 10 years., RESULTS: Right basal ganglia destruction was similar and virtually coextensive in both children; optic nerve and oculomotor dysfunction were disparate. One had a right temporal pole porencephalic cyst with anomalous overlying cortex. The clinical syndrome included left hemiparesis with distal spasticity and without hypotrophy; extraocular movement disorders; severe episodic disinhibition, impulsiveness, hitting reflexively, and extreme emotional lability. Outbursts of screaming and cursing resembled "sham rage." Both had mild intellectual retardation with competent language but poor nonverbal and visual-spatial abilities, visual memory, and daily living and socialization skills., CONCLUSIONS: The shared behavioral and cognitive syndrome is most reasonably attributed to the right basal ganglia lesions, which were complete and coextensive in both, whereas other lesions were partial, milder, and disparate. Early destruction of the right basal ganglia may preclude normal development of right hemisphere functions without evidence of plasticity and appears associated with intense disinhibition and impulsiveness of aggressive attack activities and with general lability and dyscontrol of emotion.

1329. DelRosso, L. M., et al. (2014). "Sleep-wake pattern following gunshot suprachiasmatic damage." Journal of clinical sleep medicine : JCSM : official publication of the American Academy of Sleep Medicine 10(4): 443-445.

BACKGROUND: The suprachiasmatic nucleus (SCN) plays a critical role in maintaining melatonin and sleep-wake cycles., METHODS/PATIENT: We report a case of 38-year-old woman who, after gunshot wound to the right temple, developed a sleep complaint of multiple nocturnal awakenings and several naps throughout the day., RESULTS: Computerized tomography and magnetic resonance imaging revealed bilateral optic nerve and optic chiasm damage. Diagnostic polysomnography and actigraphy revealed an irregular sleep wake rhythm., CONCLUSIONS: We speculate concurrent damage of the SCN and optic nerves bilaterally resulted in the posttraumatic irregular sleep-wake rhythm.

1330. Delrue, S., et al. (2016). "Surgical Management and Hearing Outcome of Traumatic Ossicular Injuries." The journal of international advanced otology 12(3): 231-236.

OBJECTIVE: The purpose of this study was to investigate etiological, clinical, and pathological characteristics of traumatic injuries of the middle ear ossicular chain and to evaluate hearing outcome after surgery., MATERIAL AND METHODS: Thirty consecutive patients (31 ears) with traumatic ossicular injuries operated on between 2004 and 2015 in two tertiary referral otologic centers were retrospectively analyzed. Traumatic events, clinical features, ossicular lesions, treatment procedures, and audiometric results were evaluated. Air conduction (AC), bone conduction (BC), and air-bone gap (ABG) were analyzed preoperatively and postoperatively. Amsterdam Hearing Evaluation Plots (AHEPs) were used to visualize the individual hearing results., RESULTS: The mean age at the moment of trauma was 27.9+/-17.1 years (range, 2-75 years) and the mean age at surgery was 33.2+/-16.3 years (range, 5-75 years). In 10 cases (32.3%), the injury occurred by a fall on the head and in 9 (29.0%) by a traffic accident. Isolated luxation of the incus was observed in 8 cases (25.8%). Dislocation of the stapes footplate was seen in 4 cases (12.9%). The postoperative ABG closure to within 10 and 20 dB was 30% and 76.7%, respectively., CONCLUSION: Ossicular chain injury by direct or indirect trauma can provoke hearing loss, tinnitus, and vertigo. As injuries are heterogeneous, they require a tailored surgical approach. In this study, the overall hearing outcome after surgical repair was favorable.

1331. Delteil, C., et al. (2018). "Tangential cranial ballistic impact: An illustration of the limitations of post-mortem CT scan?" Legal medicine (Tokyo, Japan) 32: 61-65.

Post-mortem imaging has become more frequently used in forensic procedures, notably in a ballistic context. Despite many advances in this field, the interpretation of computed tomography (CT) can be a very complex matter. Our case illustrates the difficulties of interpretation after quasi-tangential cranial ballistic impact and keyhole wounds. These wounds are difficult to visualize on CT and are among the factors complicating the precise determination of ballistics. These sources of error remind us that CT findings must be interpreted in close comparison with autopsy findings.

1333. Demetriades, A. K. and M. C. Papadopoulos (2007). "Penetrating head injury in planned and repetitive deliberate self-harm." Mayo Clinic proceedings 82(5): 536.

44-year-old man presented to his local emergency department wearing a baseball cap and complaining of headaches that had progressively worsened over the preceding 11 weeks. After we provided generous analgesia and performed simple investigations that failed to identify a diagnosis, the patient removed his cap to reveal an assortment of metallic objects embedded in his scalp. Plain radiographs showed 11 nails penetrating into his brain. A detailed history revealed a diagnosis of paranoid schizophrenia, and the patient confirmed that he had hammered a nail into his head each week for the past 11 weeks to rid him of evil. The nails were removed with the patient under general anesthesia, and he made an uncomplicated recovery with no neurological deficits.

1334. Demetriades, A. K., et al. (2008). "Fatal cerebral ischaemia by embolization of a gunshot fragment from an extracranial penetrating injury." British journal of neurosurgery 22(2): 298.

1335. Demetriades, D., et al. (1998). "Initial evaluation and management of gunshot wounds to the face." The Journal of trauma 45(1): 39-41.

BACKGROUND: The literature on early management of gunshot wounds (GSWs) to the face is scant, with only six series reported in the English-language literature in the last 12 years. In the current study, we present a large series from a busy trauma center in an effort to identify early diagnostic and therapeutic problems and recommend management guidelines., METHODS: Retrospective analysis was done for all GSWs of the face during a 4-year period. Data were obtained from the Trauma Registry and Trauma Patient Summary hard copies., RESULTS: During the study period, there were 4,139 admissions for GSWs, with 247 (6%) involving the face. An associated brain trauma was found in 42 patients (17.0%), and cervical spine fracture was found in 20 patients (8.1%) with GSWs to the face. In 43 patients (17.4%), there was a need for emergency airway control because of local hematoma or edema. Angiography was performed in 70 patients (28.3%) for evaluation of a large hematoma or continuous bleeding, and in 10 of these patients successful embolization of bleeders was achieved. No patient required operative control of bleeding from facial structures. Overall, only 96 patients (38.9%) underwent operation for soft-tissue repair or reduction of facial bone fractures. There were 36 deaths (14.5%) from severe brain injury or severe bleeding from associated chest or abdominal injuries. No death occurred in isolated GSWs to the face., CONCLUSION: Most civilian GSWs can safely be managed nonoperatively. Airway control is required in a significant number of patients and should be established very early. Bleeding from the face is best controlled angiographically. The brain and cervical spine should be aggressively assessed radiologically because of the high incidence of associated trauma.

1336. Demetriades, D., et al. (2006). "Early prediction of mortality in isolated head injury patients: a new predictive model." The Journal of trauma 61(4): 868-872.

BACKGROUND: To construct a predictive model of survival in isolated head injury patients, on the basis of easily available parameters that are independent risk factors for survival outcome., METHODS: Trauma registry-based study of head injury patients who had no other major extracranial injuries and were not hypotensive at admission. A predictive model of probability of death was constructed using discriminant analysis, on the basis of admission Glasgow Coma Scale (GCS) score, head Abbreviated Injury Score (AIS), age, and mechanism of injury., RESULTS: The study included 7,191 patients with head trauma. The overall correct classification rate of the proposed predictive model was 94.2% as compared with 89.0% of the admission GCS score ($p < 0.05$) and 92.8% of the head AIS ($p < 0.05$). The correct classification rate of the predictive model developed for the severe head trauma (GCS score 4-8) patients was 79.9%, as compared with 72.6% using the admission GCS score alone or 75.1% ($p < 0.05$). A one-page, easy to use table summarizing the predicted mortality on the basis of GCS score, head AIS, mechanism of injury, and age was developed., CONCLUSIONS: The proposed model has a significantly better predictive power, especially in severe head trauma, than the extensively used GCS and head AIS. A simple table on the probability of death of a particular patient based on admission GCS score, head AIS, mechanism of injury and age of patient can provide instant information.

1337. Demetriades, D., et al. (2004). "Mortality prediction of head Abbreviated Injury Score and Glasgow Coma Scale: analysis of 7,764 head injuries." Journal of the American College of Surgeons 199(2): 216-222.

BACKGROUND: We assessed the prognostic value and limitations of Glasgow Coma Scale (GCS) and head Abbreviated Injury Score (AIS) and correlated head AIS with GCS., STUDY DESIGN: We studied 7,764 patients with head injuries. Bivariate analysis was performed to examine the relationship of GCS, head AIS, age, gender, and mechanism of injury with mortality. Stepwise logistic regression analysis was used to identify the independent risk factors associated with mortality., RESULTS: The overall mortality in the group of head injury patients with no other major extracranial injuries and no hypotension on admission was 9.3%. Logistic regression analysis identified head AIS, GCS, age, and mechanism of injury as significant independent risk factors of death. The prognostic value of GCS and head AIS was significantly affected by the mechanism of injury and the age of the

patient. Patients with similar GCS or head AIS but different mechanisms of injury or ages had significantly different outcomes. The adjusted odds ratio of death in penetrating trauma was 5.2 (3.9, 7.0), p < 0.0001, and in the age group > or = 55 years the adjusted odds ratio was 3.4 (2.6, 4.6), p < 0.0001. There was no correlation between head AIS and GCS (correlation coefficient -0.31)., CONCLUSIONS: Mechanism of injury and age have a major effect in the predictive value of GCS and head AIS. There is no good correlation between GCS and head AIS.

1338. Demetriades, D., et al. (2004). "Outcome and prognostic factors in head injuries with an admission Glasgow Coma Scale score of 3." Archives of surgery (Chicago, Ill. : 1960) 139(10): 1066-1068.

HYPOTHESIS: To identify significant risk factors associated with mortality in patients with a Glasgow Coma Scale score of 3., DESIGN: Trauma registry study., SETTING: Level I urban trauma center., PATIENTS: A total of 760 patients with head injury with an admission Glasgow Coma Scale score of 3. Analysis was performed in all patients and in only patients who reached the hospital alive and had no major extracranial injuries (exclusion of patients with a chest or abdominal Abbreviated Injury Score [AIS] >3)., MAIN OUTCOME MEASURES: Stepwise logistic regression analysis was used to identify independent risk factors associated with mortality., RESULTS: Blunt trauma accounted for 477 (63%) and penetrating trauma for 283 (37%) of the 760 head injuries. Penetrating trauma was significantly more likely to be associated with a lack of vital signs on admission (15% vs 9%; P = .03). Overall mortality was 76% (94% for penetrating injuries and 65% for blunt injuries; P<.001). Overall, 79% of patients had a head AIS of 4 or greater. Mortality in the subgroup was 64% (320/497) and was significantly higher in penetrating vs blunt trauma (89% vs 52%; P<.001). Penetrating trauma, high head AIS, hypotension on admission, and age older than 55 years were independent significant risk factors associated with mortality. Only 10% of the 177 survivors had good functional outcome at hospital discharge. Eighty-six patients (17% of those with vital signs on admission) became organ donors., CONCLUSIONS: Patients with head injury with an admission Glasgow Coma Scale score of 3 have a poor prognosis. Mechanism of injury, head AIS, hypotension on admission, and age play a critical role in outcome. These patients are an important source of organ donation and should be evaluated and resuscitated aggressively.

1339. Demetriades, D., et al. (2004). "Trauma fatalities: time and location of hospital deaths." Journal of the American College of Surgeons 198(1): 20-26.

BACKGROUND: Analysis of the epidemiology, temporal distribution, and place of traumatic hospital deaths can be a useful tool in identifying areas for research, education, and allocation of resources., STUDY DESIGN: Trauma registry-based study of all traumatic hospital deaths at a Level I urban trauma center during the period 1993 to 2002. The time and hospital location where deaths occurred were analyzed according to mechanism of injury, age, Glasgow Coma Score, and body areas with severe injury (Abbreviated Injury Scale [AIS] >/= 4). Logistic regression analysis was used to identify risk factors associated with death at various times after admission., RESULTS: During the study period there were 2,648 hospital trauma deaths. The most common body area with critical injuries (AIS >/= 4) was the head (43%), followed by the chest (28%) and the abdomen (19%). Overall, 37% of victims had no vital signs present on admission. Chest AIS >/= 4, penetrating trauma, and age greater than 60 years were significant risk factors associated with no vital signs on admission. Patients with severe chest trauma (AIS >/= 4) reaching the hospital alive were significantly more likely to die within the first 60 minutes than were patients with severe abdominal or head injuries (17% versus 11% versus 7%). In patients reaching the hospital alive, the time and place of death varied according to mechanism of injury and injured body area. Deaths caused by severe head trauma peaked at 6 to 24 hours, and deaths caused by severe chest or abdominal trauma peaked at 1 to 6 hours after admission., CONCLUSIONS: The temporal distribution and location of trauma deaths are influenced by the

mechanism of injury, age, and the injured body area. These findings may help in focusing research, education, and resource allocation in a more targeted manner to reduce trauma deaths.

1340. Demir, O., et al. (2012). "Transcranial injury: Case report." Turkiye Klinikleri Journal of Medical Sciences 32(5): 1496-1500.

Penetrating cranial injury is a potentially life-threatening condition. Shell and shrapnel fragments are the most common cause of high velocity penetrating head injuries. The pathophysiological consequences of penetrating head injuries depend on the kinetic energy and trajectory of the object. If the velocity of the penetrating object is high enough, the object shape and sharpness is not very important for penetrance. We reported a case of transcranial injury caused by a broken wooden shovel handle. The Glasgow Coma Scale score of the patient was 4 in the emergency department. Wooden shovel handle had entered through the right maxillary region, penetrated the brain and come out of the skull through the right parietal bone. Surgery was planned according to the radiological studies. Expeditious removal of the foreign body was carried out by craniotomy. The patient died on postoperative day 3. A number of high velocity transcranial injuries have been reported in the literature, but to the best of our knowledge, there was no report on transcranial injury with a wooden shovel handle. © 2012 by Türkiye Klinikleri.

1341. Demirbilek, H. and M. N. Ozbek (2012). "Multiple pituitary hormone deficiency due to gunshot injury in a 6-year-old girl." Hormone Research in Paediatrics 78: 307-308.

Background: Gunshot injuries of cranial area has an extremely high mortality rate. Herein we present a girl who living with a bullet on the posterior sellar region and causes multiple pituitary hormone deficiency. Case: A 6-year-old girl was admitted to our clinic with the complaint of headache, polyuria and polydypsia. Her previous history revealed that she was healthy until 5 months ago. In that date, while she was playing in the garden she was injured from her head with a foreign object. Radiological examination revealed a bullet in her skull (Figure). Thus it was thought a gunshot injury. Since the bullet was adjacent to a vital region of brain, she considered inoperable. Thereafter, she was living with a bullet in her brain. Her complaints had started after that. At the time of admission her height was 113.5 cm (25th-50th p), weight was 21 kg (50th p). Other physical findings were normal. Her 24 hour urine output was 4.5 L. Water deprivation test showed failure to concentrate urine. After a test dose nasal desmopressin (5 mcg) urine output decreased and urine osmolarity increased. She was considered central diabetes insipitus and her complaints were resolved with a maintenance dose of desmopressin. Evaluation of other pituitary hormone revealed central hypothyroidism (free T4:0.5 ng/dl(0.7-1.26) and TSH:1.1 mIU/ml). Low dose ACTH test showed normal adrenal function. Very low growth rate (0.2 cm/6 months) during follow up suggested growth hormone(GH) deficiency. Growth hormone stimulation tests for the diagnosis of GH are going on. Now except for mentioned hormonal deficiencies and a slight headache she has not suffering from her bullet in here brain. Conclusion: Present case was found interesting in here outcome of gunshot injury which causes pituitary hormone deficiency. However, although she had a life threatening injury to be alive still may be a chance for she. (Figure presented) .

1342. Demirci, S., et al. (2014). "Evaluation of shotgun suicides in Konya, Turkey between 2000 and 2007." The American journal of forensic medicine and pathology 35(1): 45-49.

The number of the suicides is increasing all around the world. In this study, the cases autopsied between 2000 and 2007 in The Konya Branch of Forensic Medicine Council were retrospectively investigated. Fifty-seven shotgun suicides were determined. The cases were evaluated in terms of their demographic characters, site of entrance wound, the type of the cartridge used, shooting distance, the place of incident, the place of death, motive for suicide, and the presence of previous suicide attempts. The most preferred site of entrance wound was the head with 34 cases (59.7%). Of 34 cases in which the

entrance wound was on the head, there was indirect mandibular fracture in 16 cases (47.1%). In 11 cases (19.3%), there observed small ecchymosed abrasions on the finger surfaces, which are thought to have resulted from the trigger kicking back during triggering or the finger having been stuck between the trigger and the trigger guard. It is concluded that there is a need for a legal regulation that makes obtaining of shotguns more difficult and the people who have them are to be educated not to keep them in easily accessible places.

1343. Demirci, S., et al. (2008). "Deaths caused by mole guns: three case reports." International journal of legal medicine 122(4): 323-325.

Possession of firearms is limited because of the technological requirements in production and strict laws. However, anyone can manufacture a handmade firearm by following simple instructions and has no legal liability. A mole gun is an unusual weapon used to kill moles in agricultural areas. It propels pellets in a similar way as a shotgun. This study presents three cases of death caused by mole guns. Two of the cases were accidental, and the other case was suicidal. The first case involved a 51-year-old man who was checking the mole gun when it fired, injuring his left eye and the left region of his face. He died in the hospital after 3 days of medical treatment. The second case was a 78-year-old man, who had been intermittently treated for depression over the last 15 years. He died instantly after placing the mole gun vertically against his head and firing it. The third case was a 43-year-old man who had been trying to set up a mole gun device in his potato field when the weapon accidentally discharged. The victim was injured seriously and died in the hospital a short time later. In conclusion, because the mole gun may cause lethal wounds in humans when fired from a short distance, the researchers believe that its production and use should be in accordance with firearms laws.

1344. Demontis, R., et al. (2019). "Case report of sudden death after a gunshot wound to the C2 vertebral bone without direct spinal cord injury: Histopathological analysis of spinal-medullary junction." Forensic science international 301: e49-e54.

Gunshot wounds (GSW) are one of the most common causes of penetrating spinal injury, however few data are available regarding GSW causing an indirect fatal nervous tissue injury, such as that induced by the concussive force secondary to the bullet penetration. This report describes a rare case of a death following a GSW spine injury at the level of C2 vertebral body, without direct contact with the spinal cord, as seen with computed tomography scan performed soon after the death. At autopsy, vertebral canal and dura mater, as well as spinal cord and medulla oblongata, appeared devoid of pathologies and/or lesions, major viscera were unaltered. The cause of death was attributed to a cardiorespiratory arrest subsequent to the GSW injury of the C2 vertebral bone. Histopathological analysis of spinal cord and medulla oblongata was performed by means of conventional stainings, and glial fibrillary acidic protein (GFAP) and Neurofilaments 200kD (NF) immunohistochemistry. Histological alterations stood out against a tissue with no other evident sign of neuropathology, and could be observed from the caudalmost part of the medulla oblongata to the level of the inferior olivary nucleus. Main structural changes were found in the white matter, involving often the adjacent gray matter, where they appeared as multiple scattered areas of degeneration, lacking the usual staining affinity, and showing a disrupted fibrillary pattern as evidenced by myelin staining, and GFAP- and NF-immunolabelling. The shock wave secondary to the impact on the C2 vertebral bone is likely to have been the cause of a widespread neuronal-axonal histopathological damage at the spinal-medullary junction and caudal medulla oblongata that is compatible with a severe fatal respiratory dysfunction and dysregulation of the autonomic pathways subserving the control of blood pressure and cardiac activity.

1345. Dempsey, L. C., et al. (1977). "Stab wounds of the brain." The Western journal of medicine 126(1): 1-4.

Unlike the penetrating injuries to the brain caused by missiles, injuries by stabbing are largely restricted to the wound tract. Early recognition, debridement and judicious antibiotic therapy can limit or prevent complications in the management of stab wounds. Among the common sequelae of stab wounds of the brain are pneumocephalus, meningitis, intracerebral hemorrhage and direct blood vessel or nerve injury.

1346. Demuren, O. A. and D. S. Mehta (1997). "Spontaneous gun pellet migration in the brain." West African journal of medicine 16(2): 117-120.

Majority of airgun injuries in the Kingdom of Saudi Arabia are accidental and involve children and adolescents. Potentially lethal penetrating injuries to the head often result from airguns. Computed tomography (CT) is the imaging modality of choice to determine the location of the pellet, and any associated brain parenchymal damage or haematoma formation. CT is also useful in demonstrating the fracture at the entry site of the pellet and any bone fragment which may be propelled into the brain. Although there have been a few case reports of spontaneous migration of metallic foreign body within the brain in the world literature, this case highlight the speed with which it can occur, even in a patient on complete bed rest.

1347. Denbsky, G. and H. Fischer (1972). "[Postmortal blood adrenalin level]." Postmortaler Adrenalin-Gehalt im Blut. 114(45): 1993-1996.

1348. Deng, D., et al. (2015). "Conventional and contrast-enhanced ultrasound assessment of craniocerebral gunshot wounds." Genetics and molecular research : GMR 14(2): 3345-3354.

This study aimed to investigate the characteristic features of craniocerebral gunshot wounds by conventional ultrasound (CUS) and evaluate the efficacy of contrast-enhanced ultrasound (CEUS) in differentiation of tissue condition in wounds. Twenty crossbreed dogs (treatment: N = 15; control: N = 5) were used in the study. Pipe-shaped hyperechoes of varying size were found by CUS in most of the treated animals. The echoic areas were distinct from the neighboring brain tissue and did not change with time. CEUS revealed that the pipe-shaped echo was unenhanced in majority of the injured brains and the surrounding tissue was either heterogeneously enhanced or unenhanced. Pathological analysis confirmed that the contrast-filling-defect area indicated necrotic tissue and the heterogeneous minimally enhanced areas indicated degenerative tissue. CUS imaging enabled detection of hematomas and CEUS indicated that the filling defect was in the center of the hematoma, with enhancement gradually increasing towards the periphery. CUS could effectively detect a wound tract, hematoma, and the craniocerebral area injured by a gunshot, while CEUS could accurately reveal necrotic tissue in the injured area and differentiate the degenerative from normal tissue.

1349. Deng, H., et al. (2018). "Pediatric firearm-related traumatic brain injury in United States trauma centers." Journal of Head Trauma Rehabilitation 33(3): E84.

Objective Pediatric firearm-related deaths are a national public health concern in the United States and a leading cause of deaths in the American youth. In particular, outcomes following gunshot wounds to the head (GSWH) remain in need of systematic characterization. Here we analyze pediatric GSWH from a population-based sample to identify predictors of prolonged hospitalization, morbidity and mortality. Methods Pediatric GSWH patients were extracted from the National Sample Program of the National Trauma Data Bank, years 2003-2012. Predictors included injury intent, firearm choice, injury site, age, Charlson Comorbidity Index (CCI), sex, race, health insurance, geographic region, trauma center level, isolated TBI, emergency department (ED) hypotension, Glasgow Coma Scale (GCS), and Injury Severity Score (ISS). Multivariable regression was performed for outcome measures including hospital length of stay (HLOS), ICU LOS, complications, mortality, and discharge disposition.

Statistical significance was assessed at $\alpha < 0.001$ to correct for multiple comparisons. Results A weighted sample of 2,847 pediatric GSWH were included. Age was 14.8±3.3 years and 59.0% were severe TBI (GCS 3-8). Assault intent (63.0%), handgun weapon (45.6%), and residential area (40.6%) were of highest incidence. Mean HLOS was 11.6±14.4 days and ICU LOS was 9.3±10.3 days for survivors at discharge. Blood pressure (BP), GCS, and ISS were significant predictors across all outcome measures. Overall mortality was 45.1%; by intent, suicides associated with worse outcomes and the highest mortality (71.5%); by firearm type, shotgun mortality was the highest (56.5%). Versus handgun, hunting rifle resulted in greater odds of complications but lower odds of death; shotgun resulted in better odds of discharge to home for survivable injuries. When compared to injury at a residential area, injury on the street/highway resulted in greater odds of death and injury at a recreational/sport site resulted in longer ICU LOS. Outcomes varied with insurance, including the private/commercially insured having lower odds of mortality versus the other insurances. Compared to the Midwest, the South had higher odds of complications and lower odds of discharge to home, the Northeast had higher odds of mortality and lower odds of discharge to home, and the West experienced shorter ICU LOS and lower odds of complications. Age was associated with the likelihood of being discharged to home; CCI and race associated with odds of mortality. Compared to level I trauma center, level II trauma center had lower odds of discharge to home. Conclusions Hypotension, injury severity, injury intent, and firearm type are important prognostic variables in pediatric firearm-related TBI. Demographics, level of trauma center and geographic region also associated with outcomes. Improved understanding of pediatric GSWH is critical to promoting increased awareness of firearm injuries as a public health concern, and reducing its debilitating injury burden to patients, families, and healthcare systems.

1350. Deng, H., et al. (2019). "Adult Firearm-Related Traumatic Brain Injury in United States Trauma Centers." Journal of neurotrauma 36(2): 322-337.

Civilian firearm injury is an important public health concern in the United States. Gunshot wounds to the head (GSWH) remain in need of update and systematic characterization. We identify predictors of prolonged hospital length of stay (HLOS), intensive care unit length of stay (ICU LOS), medical complications, mortality, and discharge disposition from a population-based sample using the National Sample Program (NSP) of the National Trauma Data Bank (NTDB), years 2003-2012. Statistical significance was assessed at alpha < 0.001 to correct for multiple comparisons. In total, 8148 adult GSWH patients were included extrapolating to 32,439 national incidents. Age was 36.6 +/- 16.4 years and 64.4% were severe traumatic brain injury (TBI; Glasgow Coma Scale [GCS] score 3-8). Assault (49.2%), handgun (50.3%), and residential injury (43.2%) were of highest incidence. HLOS and ICU LOS were 7.7 +/- 14.2 and 5.7 +/- 13.4 days, respectively. Overall mortality was 54.6%; suicide/self-injury was associated with the highest mortality rate (71.6%). GCS, Injury Severity Score, and hypotension were significant predictors for outcomes overall. Medicare/Medicaid patients had longer HLOS compared to private/commercial insured (mean increase, 4.4 days; 95% confidence interval [2.6-6.3]). Compared to the Midwest, the South had longer HLOS (mean increase, 3.7 days; [2.0-5.4]) and higher odds of complications (odds ratio [OR], 1.7 [1.4-2.0]); the West had lower odds of complications (OR, 0.6; [0.5-0.7]). Versus handgun, shotgun (OR, 0.3; [0.2-0.4]) and hunting rifle (OR, 0.5; [0.4-0.8]) resulted in lower mortality. Patients with government/other insurance had higher odds of discharging home compared to private/commercially insured (OR, 1.7; [1.3-2.3]). In comparison to level I trauma centers, level II trauma centers had lower odds of discharge to home (OR, 0.7; [0.5-0.8]). Our results support hypotension, injury severity, injury intent, firearm type, and U.S. geographical location as important prognostic variables in firearm-related TBI. Improved understanding of civilian GSWH is critical to promoting increased awareness of firearm injuries as a public health concern and reducing its debilitating injury burden to patients, families, and healthcare systems.

1351. Deng, H., et al. (2019). "Pediatric firearm-related traumatic brain injury in United States trauma centers." Journal of neurosurgery. Pediatrics: 1-11.

OBJECTIVE: Pediatric firearm injury is a leading cause of death and disability in the youth of the United States. The epidemiology of and outcomes following gunshot wounds to the head (GSWHs) are in need of systematic characterization. Here, the authors analyzed pediatric GSWHs from a population-based sample to identify predictors of prolonged hospitalization, morbidity, and death., METHODS: All patients younger than 18 years of age and diagnosed with a GSWH in the National Sample Program (NSP) of the National Trauma Data Bank (NTDB) in 2003-2012 were eligible for inclusion in this study. Variables of interest included injury intent, firearm type, site of incident, age, sex, race, health insurance, geographic region, trauma center level, isolated traumatic brain injury (TBI), hypotension in the emergency department, Glasgow Coma Scale (GCS) score, and Injury Severity Score (ISS). Risk predictors for a prolonged hospital stay, morbidity, and mortality were identified. Odds ratios, mean increases or decreases (B), and 95% confidence intervals were reported. Statistical significance was assessed at alpha < 0.001 accounting for multiple comparisons., RESULTS: In a weighted sample of 2847 pediatric patients with GSWHs, the mean age was 14.8 +/- 3.3 years, 79.2% were male, and 59.0% had severe TBI (GCS score 3-8). The mechanism of assault (63.0%), the handgun as firearm (45.6%), and an injury incurred in a residential area (40.6%) were most common. The mean hospital length of stay was 11.6 +/- 14.4 days for the survivors, for whom suicide injuries involved longer hospitalizations (B = 5.9-day increase, 95% CI 3.3-8.6, p < 0.001) relative to those for accidental injuries. Mortality was 45.1% overall but was greater with injury due to suicidal intent (mortality 71.5%, p < 0.001) or caused by a shotgun (mortality 56.5%, p < 0.001). Lower GCS scores, higher ISSs, and emergency room hypotension predicted poorer outcomes. Patients with private insurance had lower mortality odds than those with Medicare/Medicaid (OR 2.4, 95% CI 1.7-3.4, p < 0.001) or government insurance (OR 3.6, 95% CI 2.2-5.8, p < 0.001). Management at level II centers, compared to level I, was associated with lower odds of returning home (OR 0.3, 95% CI 0.2-0.5, p < 0.001)., CONCLUSIONS: From 2003 to 2012, with regard to pediatric TBI hospitalizations due to GSWHs, their proportion remained stable, those caused by accidental injuries decreased, and those attributable to suicide increased. Overall mortality was 45%. Hypotension, cranial and overall injury severity, and suicidal intent were associated with poor prognoses. Patients treated at level II trauma centers had lower odds of being discharged home. Given the spectrum of risk factors that predispose children to GSWHs, emphasis on screening, parental education, and standardization of critical care management is needed to improve outcomes.

1352. Deng, H., et al. (2019). "Pediatric firearm-related traumatic brain injury in United States trauma centers." Clinical neurosurgery 66: 39.

INTRODUCTION: Firearm injury is a leading cause of death and disability in the American youth. Epidemiology and outcomes following gunshot wound to the head (GSWH) are in need of systematic characterization. Here, we analyzed pediatric GSWH to identify predictors of prolonged hospitalization, morbidity and mortality. METHODS: All patients < 18 yr with GSWH in the National Sample Program (NSP) of the National Trauma Data Bank (NTDB) from 2003 to 2012 were identified. Variables included injury intent, firearm choice, injury site, age, sex, race, health insurance, geographic region, trauma center level, isolated TBI, emergency department (ED) hypotension, Glasgow Coma Scale (GCS), and Injury Severity Score (ISS). Outcomes were hospital length of stay (HLOS), morbidity and mortality. Odds ratios (OR), mean increase/decrease (B), and 95% confidence intervals (CI) were reported. Statistical significance was assessed at a < 0.001 accounting for multiple comparisons. RESULTS: In a weighted sample of 2847 pediatric GSWHs, age was 14.8 ± 3.3 yr, 79.2% were male, and 59.0% had severe traumatic brain injury (TBI; Glasgow Coma Scale [GCS] score 3-8). Assault (63.0%), handgun as firearm (45.6%), and injury in residential areas (40.6%) were most common. HLOS was 11.6 ± 14.4 d for the survivors, for which suicide injuries had longer hospitalization (B = 5.9 day increase, 95% CI [3.3-8.6], P < .001) relative to accidents. The overall mortality was 45.1%, and was greater with suicide intent (mortality = 71.5%, P < .001) and shotgun as firearm (mortality = 56.5%,

P < .001). Lower GCS, higher ISS, and hypotension predicted poorer outcomes. Management at level II centers was associated with lower odds of returning home (OR = 0.3, [0.2-0.5], P < .001). CONCLUSION: From 2003 to 2012, the proportion of accidental injuries decreased while suicides increased. The overall mortality was 45%, with hypotension, cranial and overall injury severity, and suicide intent being associated with poor prognosis. Patients treated at level II trauma centers had lower odds of being discharged home. Improved risk screening, parental education and standardization of critical care management are needed.

1353. Deng-Bryant, Y., et al. (2011). "Neuroprotective effects of amnion-derived cellular cytokine suspension in an experimental model of penetrating ballistic-like brain injury." Journal of neurotrauma 28(6): A44.

Previous work has shown that amnion-derived multipotent progenitor (AMP) cells are neuroprotective in a rat model of penetrating ballistic- like brain injury (PBBI). To some extent, this neuroprotection may be mediated by the sustained secretion of AMP cell-derived neurotrophic factors which are abundant in the amnion-derived cellular cytokine suspension (ACCS) medium. To test this hypothesis, we investigated 1) the bioactive stability and neuroprotective capacity of ACCS on cultured embryonic cortical neurons treated with staurosporine (an apoptosis-inducer) and 2) the effects of chronic ACCS delivery (via Alzet osmotic pumps) on PBBI-induced motor and cognitive deficits. Results confirmed that ACCS is thermally stable for at least one week at 37°C and demonstrated that co-treatment with ACCS facilitated neurite outgrowth (i.e. neuroplasticity) in an in vitro model of apoptotic cell death. Chronic delivery of ACCS or control medium (1µl/hr or 5µl/hr) into the cerebral ventricles was initiated within 30min following PBBI. Rotarod motor function assessments and Morris water maze (MWM) spatial learning tests were performed at 1, 2, 3, or 4 weeks for each respective group. The high dose (5µl/hr) of ACCS improved rotarod performance (10, 15 and 20rpm) at 1 and 2 weeks post injury with a significant effect at 2 weeks ($p < 0.05$). However, this infusion rate resulted in some mortality possibly due to the buildup of cerebral spinal fluid. The low dose (1µl/hr) of ACCS (which exhibited no signs of toxicity) produced extended therapeutic effects evident out to 3 weeks post-injury on the rotarod test ($p< 0.05$) with the optimal effect observed again at 2 weeks post-injury. Chronic ACCS infusion (at either dose) failed to produce significant improvement on MWM performance at any time point tested. Collectively, our results support the hypothesis that the neuroprotective effects of AMP cells may be partially mediated through a sustained delivery of neurotrophic factors.

1354. Deng-Bryant, Y., et al. (2016). "Global metabolomics analysis in rats following penetrating ballistic-like brain injury." Journal of neurotrauma 33: A54.

There is increasing interest in metabolic management in the treatment of traumatic brain injury (TBI) patients. However, clinical studies have yielded mixed results, in part due to the complex pathological responses of the neurometabolic network. This study was designed to profile the metabolomes in rat brain tissue, cerebrospinal fluid (CSF), and serum following penetrating ballistic-like brain injury (PBBI). Rats received either a sham craniotomy or a PBBI. Ipsilateral frontal cortices, CSF, and serum were collected at 30 min, 6 h, 24 h, 72 h, and 7d post-injury (n = 6/group/time-point). High throughput mass spectrometry-based metabolomics was performed to determine the entire metabolome. Metabolomics profiling detected a total of 535, 448, and 629 biochemicals in the brain tissue, CSF, and serum respectively. Immediately following injury at 30 min, the percentage of biochemicals significantly altered compared to sham in the three biological compartments were 23.2% (brain), 4.7% (CSF), and 9.1% (serum) of total biochemicals ($p < 0.05$); this quickly elevated to 51.0-65.0% (brain), 8.5-21.0% (CSF), and 13.4-28.5% (serum) starting at 6 h and lasting out to 7d post-injury ($p < 0.05$). Importantly, biochemical pathway analysis showed a significant and complex metabolic response of the brain to severe TBI that includes osmotic stress, imbalance in multiple neurotransmitters, increase in glycolytic metabolism, depletion of creatine stores, and enhanced complex lipid hydrolysis.

Additionally, principal component analysis (PCA) revealed a distinct separation between sham and PBBI samples starting from 6 h post-injury in brain tissues and serum samples, indicating a PBBI metabolic profile that is different from the sham in these two compartments. Interestingly, this distinct PBBI metabolic profile was only observed at 6 h post-injury in the CSF, and was absent at other time points. Overall, the comprehensive metabolomics analysis of the traumatically injured brain tissue, and the comparison of its compositions in the CSF and peripheral circulation have defined a pathological metabolic profile that is different from a normal physiological state, which provides crucial information for the advancement of translating metabolomics to the clinical setting.

1355. Deng-Bryant, Y., et al. (2014). "Region-specific impairment of cerebral mitochondrial bioenergetics following penetrating ballistic-like brain injury in rats." Journal of neurotrauma 31(12): A94.

Mitochondria play a pivotal role in secondary brain damage mechanisms following traumatic brain injury (TBI), which have positioned themselves as leading target for therapeutic intervention. This study was designed to assess regional cerebral mitochondrial bioenergetics following penetrating ballistic-like brain injury (PBBI). Sprague-Dawley rats received either sham injury (craniotomy; n = 11) or unilateral frontal PBBI (10% injury severity; n = 15). Rats were euthanized at 2 hr post-injury, and brain regions of interest were dissected and processed for mitochondrial Ficoll isolation. The Seahorse Bioscience XFe24 Flux Analyzer was used to evaluate mitochondrial bioenergetics. Outcome metrics include mitochondrial oxygen consumptions during: ADP/pyruvate/malate-induced complex-I respiration (State III), oligomycin-induced minimal complex-I respiration (State IV), uncoupler (2,4-dinitrophenol)-stimulated maximal complex-I respiration (State V-I), and succinate/rotenone-induced complex-II respiration (State V-II). Regional differences intrinsic to cortex, striatum and hippocampus were compared in the uninjured brains (sham control). The results show that cortex exhibited significantly higher State III respiration compared to striatum and hippocampus ($p < 0.05$). Additionally, hippocampus showed lower State IV ($p < 0.05$) and State V-I respiration ($p = 0.07$) compared to cortex and striatum, indicative of a differential profile of basal mitochondrial function across normal (sham) brain regions. Subsequently, the region-specific response to PBBI was compared to sham controls. No between-group differences were detected in complex-I function measured by State III and State IV respiration across all regions tested. However, complex-I maximal respiration measured by State V-I respiration was significantly reduced in cortex (34%; $p < 0.05$ vs. sham) and striatum (51%; $p < 0.05$ vs. sham), but not hippocampus, demonstrating an acute (2 hr postinjury) onset of bioenergetic failure in cortex and striatum following PBBI. No differences were detected in State V-II respiration, which suggests complex-II function was not compromised at this time point post-PBBI. Overall, the results indicate that PBBI produced region-specific mitochondrial bioenergetic deficits that are unique to the penetrating, temporary cavity mechanism. Furthermore, the results demonstrate an acute onset of PBBI-induced mitochondrial dysfunction which underscores the importance of early therapeutic intervention targeting mitochondrial bioenergetics for neuroprotection.

1356. Deng-Bryant, Y., et al. (2014). "Penetrating ballistic-like brain injury promotes time-dependent cell proliferation in adult rat hippocampus." Journal of neurotrauma 31(12): A118.

Research has shown that the adult hippocampus retains the ability to produce neural precursor cells and replace lost cells in response to brain injuries. The current study examined the time course of penetrating ballistic-like brain injury (PBBI)-induced cell proliferation in adult rat hippocampus. Unilateral frontal PBBI (10% injury severity) or craniotomy (sham control) was performed on isoflurane anesthetized Sprague-Dawley rats. To evaluate cell proliferation at specific post-injury time points, BrdU (50 mg/kg x 3 i.p. injections delivered at 4 h-intervals) was initiated at 24 h prior to each experimental endpoint. At 24 h, 48 h, 72 h and 7 days post-injury rats were perfused and brains were processed for fluorescence immunostaining for BrdU, GFAP and Iba1. Minimal levels of BrdU-positive cells were detected in the brains of sham controls, and at 24 h and 7 days post-PBBI. However, a

dramatic increase of BrdU-labeled cells was detected at 48 h and 72 h post-PBBI in ipsilateral and contralateral hippocampal dentate gyri (DG). Further analysis was conducted to evaluate the spatial distribution of BrdU-positive cells in hippocampal DG at 48 h and 72 h post-PBBI. The results indicate that the majority of the BrdU-positive cells were located throughout molecular layer and hilus in the DG, accompanied by a few BrdU-positive cells scattered in the subgranular zone where neural stem cells reside. Molecular layer and hilus in the DG are regions where gliogenesis mainly occurs and therefore, the majority of the BrdU-labeled cells observed in the current study are potentially gliogenic. To confirm this, additional cellular markers for astrocyte (i.e. GFAP) and microglia (i.e. Iba1) were used to confirm the phenotype of these newly generated cells following PBBI. BrdU-positive cells were primarily co-labeled with Iba1, and to a lesser extent, with GFAP, suggesting that they are proliferating microglia and astrocytes. Overall, the robust upregulation of glial proliferation during acute phases after PBBI may reflect an increasingly unfavorable environment for newborn neurons, potentially leading to further cell loss.

1357. Deng-Bryant, Y., et al. (2016). "Methods of Drug Delivery in Neurotrauma." Methods in molecular biology (Clifton, N.J.) 1462: 89-100.

The central nervous system (CNS) is protected by blood-brain barrier (BBB) and blood-cerebrospinal-fluid (CSF) barrier that limit toxic agents and most molecules from penetrating the brain and spinal cord. However, these barriers also prevent most pharmaceuticals from entering into the CNS. Drug delivery to the CNS following neurotrauma is complicated. Although studies have shown BBB permeability increases in various TBI models, it remains as the key mitigating factor for delivering drugs into the CNS. The commonly used methods for drug delivery in preclinical neurotrauma studies include intraperitoneal, subcutaneous, intravenous, and intracerebroventricular delivery. It should be noted that for a drug to be successfully translated into the clinic, it needs to be administered preclinically as it would be anticipated to be administered to patients. And this likely leads to better dose selection of the drug, as well as recognition of any possible side effects, prior to transition into a clinical trial. Additionally, novel approach that is noninvasive and yet circumvents BBB, such as drug delivery through nerve pathways innervating the nasal passages, needs to be investigated in animal models, as it may provide a viable drug delivery method for patients who sustain mild CNS injury or require chronic treatments. Therefore, the focus of this chapter is to present rationales and methods for delivering drugs by IV infusion via the jugular vein, and intranasally in preclinical studies.

1358. Deng-Bryant, Y., et al. (2015). "Treatment with amnion-derived cellular cytokine solution (ACCS) induces persistent motor improvement and ameliorates neuroinflammation in a rat model of penetrating ballistic-like brain injury." Restorative neurology and neuroscience 33(2): 189-203.

PURPOSE: The present work compared the behavioral outcomes of ACCS therapy delivered either intravenously (i.v.) or intracerebroventricularly (i.c.v.) after penetrating ballistic-like brain injury (PBBI). Histological markers for neuroinflammation and neurodegeneration were employed to investigate the potential therapeutic mechanism of ACCS., METHODS: Experiment-1, ACCS was administered either i.v. or i.c.v. for 1 week post-PBBI. Outcome metrics included behavioral (rotarod and Morris water maze) and gross morphological assessments. Experiment-2, rats received ACCS i.c.v for either 1 or 2 weeks post-PBBI. The inflammatory response was determined by immunohistochemistry for neutrophils and microglia reactivity. Neurodegeneration was visualized using silver staining., RESULTS: Both i.v. and i.c.v. delivery of ACCS improved motor outcome but failed to improve cognitive outcome or tissue sparing. Importantly, only i.c.v. ACCS treatment produced persistent motor improvements at a later endpoint. The i.c.v. ACCS treatment significantly reduced PBBI-induced increase in myeloperoxidase (MPO) and ionized calcium binding adaptor molecule 1 (Iba1) expression. Concomitant reduction of both Iba1 and silver staining were detected in corpus callosum with i.c.v. ACCS treatment., CONCLUSIONS: ACCS, as a treatment for TBI, showed promise with regard to functional (motor) recovery and demonstrated strong capability to modulate

neuroinflammatory responses that may underline functional recovery. However, the majority of beneficial effects appear restricted to the i.c.v. route of ACCS delivery, which warrants future studies examining delivery routes (e.g. intranasal delivery) which are more clinically viable for the treatment of TBI.

1359. Deng-Bryant, Y., et al. (2012). "Comparison of intravenous and intracerebroventricular administration of amnion-derived cellular cytokine solution in a rat model of penetrating ballistic-like brain injury." Journal of neurotrauma 29(10): A171-A172.

Introduction Previous work indicates that the neuroprotective effects of Amnionderived Multipotent Progenitor (AMP) cells may be mediated through the sustained secretion of AMP cell-secreted factors (Amnion-derived Cellular Cytokine Solution; ACCS). This study compared the neuroprotective efficacy of different routes of ACCS administration following penetrating ballistic-like brain injury (PBBI). Methods Isoflurane-anesthetized rats received either sham or PBBI surgery. ACCS was delivered directly into the CSF (intracerebroventricular; i.c.v.) or intravenously (i.v.) within 15m post-PBBI. Chronic i.c.v. infusion of ACCS was delivered via Alzet osmotic pumps using a continuous flow rate of 1ll/hr (∗100 ll/kg daily) for 1 week. For i.v. administration, PBBI animals were given bolus infusions of ACCS (2 ml/kg) at 15m and 6h post-injury and twice daily thereafter (∗4 ml/kg daily) for 5 consecutive days. Motor and cognitive outcome were assessed on the rotarod (7 and 14 days post-injury) and Morris water maze (MWM; 14-18 days post-injury) tasks respectively. Results Results showed that the continuous i.c.v. infusion of ACCS into the CSF significantly improved motor outcome on the rotarod task as evidenced by an increased latency to fall ($p < 0.05$). In contrast, i.v. administration of ACCS failed to produce significant improvement in motor outcome. Under these test conditions, neither the i.c.v. or i.v. route of ACCS administration showed efficacy on improving cognitive performance on the MWM task. Conclusions Overall the results of this study indicate that chronic i.c.v. ACCS delivery improves motor but not cognitive outcome in the PBBI model. However, the beneficial effects of ACCS were not apparent following i.v. delivery indicating that blood-brain-barrier (BBB) permeability may be a mitigating factor. Further work evaluating (1) intrathecal administration as an alternate CSF delivery route and (2) the ability of ACCS to penetrate both the intact and compromised BBB is ongoing.

1360. Denneny, J. C., 3rd and W. D. Davidson (1987). "Combined otolaryngological and neurosurgical approach in treating sinus fractures." The Laryngoscope 97(5): 633-637.

Frontal sinus injury in patients with closed head trauma is significant. Fractures of the anterior and posterior table as well as injury to the nasofrontal duct system requiring exploration, and often times obliteration of the frontal sinus, are not uncommon. Some patients present with frontal sinus damage along with intracranial pathology that requires craniotomy for treatment of the intracranial problem. In these patients, the neurosurgeon typically performs a bifrontal scalp flap to expose the cranium. A bone flap that transects the superior margin of the frontal sinus is then elevated and removed. This allows direct visualization of the anterior and posterior sinus walls and both nasofrontal ducts, subsequently facilitating reduction of fractures, debridement, and obliteration or ablation, if necessary, without creating another bone flap. The surgeon gets an overall picture of the sinus without the added trauma associated with the creation of an osteoplastic flap.

Introduction: Various neuroregenerative procedures have been recently employed along with neurorehabilitation programs to promote neurological function after Spinal Cord Injury (SCI), and recently most of them have focused on the acute stage of spinal cord injury. In this report, we present a case of acute SCI treated with neuroprotective treatments in conjunction with conventional rehabilitation program. Methods: A case of acute penetrative SCI (gunshot wound), 40 years old, was treated with intrathecal bone marrow derived stem cells and parenteral Granulocyte-Colony Stimulating Factor (G-CSF) along with rehabilitation program. The neurological outcomes as well as safety issues have been reported. Results: Assessment with American Spinal Injury Association (ASIA), showed neurological improvement, meanwhile he reported neuropathic pain, which was amenable to oral medication. Discussion: In the acute setting, combination therapy of G-CSF and intrathecal Mesenchymal Stem Cells (MSCs) was safe in our case as an adjunct to conventional rehabilitation programs. Further controlled studies are needed to find possible side effects, and establish net efficacy.

1364. Derdyn, C., et al. (1990). "Craniofacial trauma: an assessment of risk related to timing of surgery." Plastic and reconstructive surgery 86(2): 238-237.

Following the retrospective analysis of approximately 4000 head-injury patients, 49 were identified with a combination of displaced facial fractures and significant cerebral trauma. The purpose of this study was to define clinical and radiographic features in these patients that are associated with a poor prognosis, which in turn might influence the timing of facial fracture repair. The presence of an upper-level facial fracture, low Glasgow coma score, intracranial hemorrhage, displacement of normally midline cerebral structures, and multisystem trauma was associated with a statistically significant poorer prognosis. Additionally, in demographically similar groups of patients (age, sex, concomitant injury) preselected for intracranial pressures of less than 15 mmHg at the time of surgery, no significant difference in survival was appreciated in patients who underwent early (0 to 3 days), middle (4 to 7 days), or late (greater than 7 days) surgical repair. Early surgical repair of facial fractures in these circumstances does not appear to have a negative impact on recovery.

1365. D'Errico, S., et al. (2011). "A novel macabre ritual of the Italian Mafia ('Ndrangheta): covering hands with gloves and burying the corpse with burnt lime after execution." The American journal of forensic medicine and pathology 32(1): 44-46.

'Ndrangheta is one of the famous "4 Mafias," which typically insists in Southern Italy. A particular case of 'Ndrangheta-related homicide double execution by means of multiple gunshots is presented. To the best of our knowledge, this is the first report of `Ndrangheta's homicidal modality (covering hands with gloves and burying) as a macabre ritual. In homicides committed by criminal organization, the method used as well as the positioning of the body follow a macabre ritual laden with significance and intending to be an admonition to other persons.

1366. Derums, V. I. (1980). "[X-ray morphological characteristics of the traumatic bone injuries and wounds of the inhabitants of the ancient Baltic region]." Rentgenomorfologicheskaia kharakteristika travmaticheskikh povrezhdenii i ranenii kostei zhitelei drevnei Pribaltiki. 42(2): 64-68.

Altogether 4492 skeletons of the people who inhabited the Baltic region during various epochs--from the end of the mesolithic period up to the XVIII century A. D. were examined. A total of 30 injuries, 15 wounds, 10 cranial trepanations and 78 bone fractures were revealed. Most of the injuries and wounds showed signs of regeneration, knitting consolidation was quite adequate that is partially accounted for by proficiency of people's doctors. It was established that lances and arrows of ancient inhabitants of the Baltic region were of great penetrative strength.

1367. Desai, R., et al. (2021). "Removal of a penetrating tree branch in the orbitofrontal region: A unique application of an orbitofrontal craniotomy through a supraciliary brow approach." Journal of Neurological Surgery Part B: Skull Base 82(SUPPL 2).

Orbitocranial penetrating injury (OPI) including with wooden objects is a well-described mechanism of brain injury. Thisreport describes unique application of an orbitofrontal craniotomy through a supraciliary brow approach to remove awooden stick penetrating through the orbit into the frontal lobe. A 51-year-old male presented after a traumatic event inwhich tree branch penetrated his face beneath the left eye, through the left orbit and into his frontal lobes. He did notexperience loss of consciousness and was neurologically intact with preserved vision and ocular motility. Computedtomography (CT) and CT angiogram of the head revealed an isodense hollow cylindrical object penetrating though the leftorbit through the left frontal lobe extending into the frontal horn of the right lateral ventricle abutting the left anteriorcerebral artery with minimal intraventricular hemorrhage and no evidence of arterial injuries. The patient was treated with broad spectrum antibiotic and antifungal coverage and underwent an orbitofrontal craniotomythrough a supraciliary brow approach for extraction of the foreign body, with incisions and positioning as below. The lateralbold curvilinear marking is the position of the supraciliary incision in a prominent forehead skin crease (single arrow). Thefurthest lateral dotted marking (double arrows) approximates the position of the branch of the left facial nerve to thefrontalis muscle. The medial curvilinear marking (white arrowhead) is the estimated lateral limit of frontal sinus which wasoutlined with the surgical navigation system to avoid entry into the frontal sinus. The lateral curvilinear incision (redarrows) is the planned incision for a larger frontotemporal craniotomy if additional exposure was necessary, a small portionof which was used in this case to harvest temporalis fascia for dural closure. After placement of a lumbar drain, a left orbitofrontal craniotomy was performed and an extradural, subfrontal dissection ofthe anterior fossa floor revealed the wooden stick traversing intracranially. In conjunction with the oculoplastics teamworking extracranially, the wooden stick was removed in two pieces by delivery through the puncture wound inferior to theorbit. Postoperative 3D CT reconstruction portrays the minimally invasive craniotomy with affixed plating and cranioplasty withoutsignificant bony defect. Postoperatively, the patient had a right frontalis palsy that resolved within 10 weeks. Intraoperative cultures grew Enterococcus casseliflavus , Bacillus cereus , Pseudomonas abietaniphila , and fungal species including Aspergillus niger , Alternaria species , and an unidentified dematiaceous mold. He was treated with an extended course of antimicrobialtherapy which included an initial intravenous course of vancomycin, ertapenem, and posaconazole transitioned to oraldoxycycline, ciprofloxacin, and isavuconazole after MRI 1 month postoperatively demonstrated source control. At 6 monthspostoperatively, the patient was prescribed lifelong suppressive isavuconazole. He remains neurologically intact at mostrecent postoperative visit, approximately 14 months postoperatively.

1368. Desai, R., et al. (2021). "Removal of a Penetrating Tree Branch in the Orbitofrontal Region-A Unique Application of an Orbitofrontal Craniotomy Through a Supraciliary Brow Approach." Operative neurosurgery (Hagerstown, Md.) 21(4): E386-E391.

BACKGROUND AND IMPORTANCE: Orbitocranial penetrating injury (OPI) is associated with neurological, infectious, and vascular sequalae. This report describes unique application of an orbitofrontal craniotomy through a supraciliary approach to remove a wooden stick penetrating through the orbit and frontal lobe, postoperative management, and antimicrobial therapy., CLINICAL PRESENTATION: A 51-yr-old male presented after a tree branch penetrated beneath his eye. He had no loss of consciousness and was neurologically intact with preserved vision and ocular motility. Computed tomography (CT) and CT angiogram revealed an isodense hollow cylindrical object penetrating though the left orbit and left frontal lobe. The object extended into the right lateral ventricle, abutting the left anterior cerebral artery. There was minimal intraventricular hemorrhage without arterial injury. The patient was treated with broad-spectrum antimicrobial coverage. The foreign body was removed and the

dural defect repaired via an orbitofrontal craniotomy through a supraciliary eyebrow incision. He was treated with an extended course of antimicrobial therapy, and after 18 mo remained neurologically intact., CONCLUSION: OPI are a subset of penetrating brain injuries with potential for immediate injury to neurovascular structures and delayed complications including cerebrospinal fluid leak and infection. Treatment includes attempted complete removal of the foreign body and antimicrobial therapy. An orbitofrontal craniotomy through a supraciliary eyebrow incision may be effective in selected patients.

1369. Desai, U. R., et al. (1993). "Perfluorocarbon liquid in traumatic vitreous hemorrhage and retinal detachment." Ophthalmic surgery 24(8): 537-541.

Patients with penetrating ocular trauma also may have severe vitreous hemorrhage and associated retinal detachment. Removing the hemorrhage and repairing the detachment can be a difficult surgical problem. Besides the limited surgical view due to the hemorrhage, an incomplete separation of the posterior hyaloid membrane can allow the detached retina to be drawn toward the port of the vitrectomy instrument, producing an inadvertent retinal tear. We have used perfluoroperhydrophenanthrene (Vitreon) to manage three cases of penetrating ocular trauma with concurrent retinal detachment and a partial vitreous detachment, either at the time of surgery or as noted ultrasonographically. The perfluorocarbon liquid helped to separate the partially detached posterior hyaloid membrane and flatten the detached retina. This maneuver simplified removal of the vitreous hemorrhage and management of the retinal detachment.

1371. DesChamps, G. T., Jr. and J. U. Morano (1991). "Intracranial bullet migration--a sign of brain abscess: case report." The Journal of trauma 31(2): 293-295.

An unusual case of migration of an intracranial bullet fragment within a brain abscess is reported. Movement of the bullet was first detected on skull films, and the significance of this finding on plain radiographs is emphasized.

1372. DeSoucy, E. S., et al. (2017). "Review of 54 Cases of Prolonged Field Care." Journal of special operations medicine : a peer reviewed journal for SOF medical professionals 17(1): 121-129.

BACKGROUND: Prolonged field care (PFC) is field medical care applied beyond doctrinal planning time-lines. As current and future medical operations must include deliberate and contingency planning for such events, data are lacking to support efforts. A case review was conducted to define the epidemiology, environment, and operational factors that affect PFC outcomes., METHODS: A survey distributed to US military medical providers solicited details of PFC encounters lasting more than 4 hours and included patient demographics, environmental descriptors, provider training, modes of transportation, injuries, mechanism of injury, vital signs, treatments, equipment and resources used, duration of PFC, and morbidity and mortality status on delivery to the next level of care. Descriptive statistics were used to analyze survey responses., RESULTS: Surveys from 54 patients treated during 41 missions were analyzed. The PFC provider was on scene at time of injury or illness for 40.7% (22/54) of cases. The environment was described as remote or austere for 96.3% (52/54) of cases. Enemy activity or weather also contributed to need for PFC in 37.0% (20/54) of cases. Care was provided primarily outdoors (37.0%; 20/54) and in hardened nonmedical structures (37.0%; 20/54) with 42.6% (23/54) of cases managed in two or more locations or transport platforms. Teleconsultation was obtained in 14.8% (8/54) of cases. The prehospital time of care ranged from 4 to 120 hours (median 10 hours), and five (9.3%) patients died prior to transport to next level of care., CONCLUSION: PFC in the prehospital

setting is a vital area of military medicine about which data are sparse. This review was a novel initial analysis of recent US military PFC experiences, with descriptive findings that should prove helpful for future efforts to include defining unique skillsets and capabilities needed to effectively respond to a variety of PFC contingencies. Copyright 2017.

1373. D'Esposito, M., et al. (1995). "Amnesia following traumatic bilateral fornix transection." Neurology 45(8): 1546-1550.

There is controversy regarding the effect of isolated fornix damage on human memory. We report a patient who suffered a traumatic penetrating head injury that resulted in a significant and persistent anterograde amnesia. CT revealed a lesion that involved the region of the proximal, posterior portion of both fornices without evidence of damage to other hippocampal pathways or to other structures known to be critical for memory, such as the hippocampus, thalamus, or basal forebrain. The unique location of the lesion in this patient provides evidence supporting the role of isolated fornix lesions in amnesia.

1374. Detorakis, E. T., et al. (2004). "Pneumocephalus and presumed meningitis following inconspicuous penetrating periocular trauma." Acta ophthalmologica Scandinavica 82(5): 603-605.

PURPOSE: To report a case of serious intracranial complications in an adolescent youth following a seemingly trivial periocular injury., METHODS: An adolescent youth was examined and discharged after a small penetrating injury to his left medial canthus. He later presented with blurred vision, nausea and mild pyrexia and underwent a computed tomography (CT) scan of the head and orbits as well as a lumbar puncture., RESULTS: The CT scan revealed a fracture in the cribriform plate of the ethmoid bone and the medial orbital wall, as well as pneumocephalus. The lumbar puncture revealed 3000 white cells/mm3 in the cerebrospinal fluid (CSF). After treatment with meningitic doses of intravenous antibiotics, a significant improvement was noted., CONCLUSIONS: A CT scan, instead of an ordinary head radiograph, may be considered as a first-choice mode of diagnosis in evaluating even inconspicuous penetrating periocular wounds. Early administration of meningitic doses of antibiotics may significantly improve prognosis.

1375. Detorakis, E. T., et al. (2012). "Unexpected finding in ocular surface trauma: a large intraorbital foreign body (bullet)." Acta medica (Hradec Kralove) 55(2): 100-103.

Sometimes intraorbital foreign bodies lead to unexpected findings. A 16-year old boy was referred due to ocular surface trauma. A conjunctival laceration was detected at the level of the left caruncle with associated left exotropia, reduced adduction as well as a preretinal hemorrhage along the nasal periphery of the fundus. A blow-out fracture of the medial orbital wall was suspected and a CT scan of the orbits was scheduled which revealed the presence of a large intraorbital foreign body. The removal of the intraorbital foreign body (which proved to be a bullet) and precautionary laser photocoagulation along the nasal periphery of the left eye were performed. Ocular surface trauma may reveal unexpected findings, such as an intraorbital foreign body, requiring investigation by a CT scan.

1376. Devi, B. I., et al. (1993). "Penetrating orbitocranial injuries--report of two cases." Indian journal of ophthalmology 41(2): 84-86.

1377. Devulapalli, K. K., et al. (2018). "Utility of Repeat Head CT in Patients with Blunt Traumatic Brain Injury Presenting with Small Isolated Falcine or Tentorial Subdural Hematomas." AJNR. American journal of neuroradiology 39(4): 654-657.

BACKGROUND AND PURPOSE: In blunt traumatic brain injury with isolated falcotentorial subdural hematoma not amenable to neurosurgical intervention, the routinely performed, nonvalidated practice of serial head CT scans frequently necessitates increased hospital resources and exposure to ionizing radiation. The study goal was to evaluate clinical and imaging features of isolated falcotentorial subdural hematoma at presentation and short-term follow-up., MATERIALS AND METHODS: We performed a retrospective analysis of patients presenting to a level 1 trauma center from January 2013 to March 2015 undergoing initial and short-term follow-up CT with initial findings positive for isolated subdural hematoma along the falx and/or tentorium. Patients with penetrating trauma, other sites of intracranial hemorrhage, or depressed skull fractures were excluded. Patient sex, age, Glasgow Coma Scale score, and anticoagulation history were obtained through review of the electronic medical records., RESULTS: Eighty patients met the inclusion criteria (53 males; 27 females; median age, 61 years). Of subdural hematomas, 57.1% were falcine, 33.8% were tentorial, and 9.1% were mixed. The mean initial Glasgow Coma Scale score was 14.2 (range, 6-15). Isolated falcotentorial subdural hematomas were small (mean, 2.8 mm; range, 1-8 mm) without mass effect and significant change on follow-up CT (mean, 2.7 mm; range, 0-8 mm; P = .06), with an average follow-up time of 10.3 hours (range, 3.9-192 hours). All repeat CTs demonstrated no change or decreased size of the initial subdural hematoma. No new intracranial hemorrhages were seen on follow-up CT., CONCLUSIONS: Isolated falcotentorial subdural hematomas in blunt traumatic brain injury average 2.8 mm in thickness and do not increase in size on short-term follow-up CT. Present data suggest that repeat CT in patients with mild traumatic brain injury with isolated falcotentorial subdural hematoma may not be necessary.

1378. Dewangan, N. K. and A. Sharma (2021). "Validation of the Revised Neuroimaging Radiological Interpretation System for Acute Traumatic Brain Injury in Adult and Pediatric Population." Indian Journal of Neurotrauma 18(1): 32-37.

Aim Our study aimed to validate the revised neuroimaging radiological interpretation system (NIRIS), which would standardize the interpretation of noncontrast head CT of acute traumatic brain injury (TBI) patient and consolidate imaging finding into ordinal severity categories that would not only inform specific patient management actions but could also be used as a clinical decision support tool. Methods We retrospectively studied dispositions and their outcomes of consecutive patients brought to the Sawai Man Singh Hospital Trauma Centre, Jaipur, India, by any means of transport and who underwent a noncontrast CT scan for suspected TBI between April and December 2018. Results The revised NIRIS correctly predicted disposition and outcome in 62.9% (750/1192) of patients. After excluding patients with OMEI (other major extracranial injuries) and OMII (other major intracranial injuries), a correct prediction was observed in 88.3% (670/758) of patients. After excluding OMEI and OMII, the predictability of revised NIRIS in the adult population is 87.6% (446/509), while predictability in the pediatric population is 92.1% (224/249). Conclusion Revised NIRIS is a good tool for predicting patient dispositions, to specific management categories, and outcomes in TBI patients after noncontrast CT head.

1379. DeWeese, W. O., et al. (1976). "Pellet-gun brain wound complicated by Clostridium Perfringens meningitis." Surgical neurology 5(4): 253-254.

A ten-year-old male was hospitalized for a pellet-gun wound to the brain. He developed Clostridial meningitis within eighteen hours in spite of radical debridement and prophylactic antibiotics. However, successful recovery was obtained with high levels of penicillin and chloromycetin antibiotic therapy.

1380. Deyle, S., et al. (2011). "Collateral damage--penetrating head injury and orbital injury: a case report." The American journal of forensic medicine and pathology 32(3): 215-218.

We report a case of an accidental death or potential suicide by revolver with subsequent injury of another person. A 44-year-old man shot himself in the head while manipulating his .38 caliber special revolver in the kitchen in the presence of his wife, standing approximately 1.5 m next to him. After passing through the husband's head, the lead round-nose bullet entered the region underneath his wife's left eye. When the bullet left the man's head, it retained the energy to penetrate the soft tissue at this distance, including the skin and thin bone plates like the orbital wall. Owing to the low energy of the projectile, the entry wound was of atypical in shape and without loss of tissue. Only a small line--resembling a cut--was externally visible. The man died in the hospital from his injuries; his wife suffered visual loss of her left eye.

1381. D'Hermies, F., et al. (2001). "[Orbital wooden foreign body]." Corps etranger vegetal intra-orbitaire. 24(5): 517-521.

A 76-year-old-female patient fell in her garden, inducing a right orbital wound in which no foreign body was primarily found. As pain and diplopia followed the orbital trauma, a CT-scan was performed, disclosing a linear external foreign body in the right orbit. An anterior orbitotomy was performed to remove an 18-mm-long wooden foreign body. Histopathology of the tissue surrounding the foreign body showed an inflammatory fibrous tissue with small granulomas around telluric particles. Improvement after the operation was dramatic with complete disappearance of diplopia the day following surgery. Antibiotics were prescribed and tetanus prophylaxis was performed.

1382. Di Prospero, N. A., et al. (1998). "Suramin disrupts the gliotic response following a stab wound injury to the adult rat brain." Journal of neurocytology 27(7): 491-506.

Reactive gliosis, observed in numerous pathological states, leads to the formation of a glial scar that is believed to impede axonal regeneration. Astrocyte reactivity can be initiated both in vitro and in vivo by various cytokines. Thus, the aim of this study was to investigate if suramin, a polysulfonated napthylurea that has been shown to inhibit the binding of many different cytokines to their cell surface receptors, could attenuate the glial response after brain injury. A single dose of suramin (5 microl, 75 microM) or saline vehicle was injected intracerebrally through the same needle used to make the stab wound at the time of lesioning. Suramin-treated animals showed an obvious reduction in several parameters of CNS inflammation: cellular proliferation, GFAP levels, and tenascin-C immunoreactivity were reduced in suramin-treated as compared to control animals at early time points. GFAP immunoreactivity was strikingly reduced at 3 days after injury, as confirmed by Western blot analysis. This reduction was transient, however, in that the difference in GFAP expression between suramin-treated and control animals was less apparent at 7 days and had disappeared by 30 days after injury. Likewise, fewer BrdU-positive cells were noted in treated versus control tissue at 1 and 3 days, but this difference was not significant by 7 days. Moreover, tenascin immunoreactivity was significantly diminished at 24 h as confirmed by Western blot analysis in suramin-treated lesion areas, which is analogous to our observations that suramin can antagonize tenascin expression by cultured astrocytes treated with bFGF. In addition, examination of the corpus callosum of saline-treated animals 30 days post-trauma revealed a disruption of the fiber tract within the lesion site, while suramin-treated animals displayed numerous fibers spanning the lesion. These results demonstrate that a single injection of suramin transiently inhibits the gliotic response, which may be sufficient to ameliorate subsequent tissue damage.

1383. Di Rita, A., et al. (2022). "Airgun Wound with Superior Sagittal Sinus Involvement in a Child: Case Report and Review of the Literature." Pediatric neurosurgery 57(2): 133-137.

INTRODUCTION: Although still considered quite harmless, nonpowder guns (NPG) may cause severe head injuries in children. We present the case of a depressed skull fracture with superior sagittal sinus involvement following NPG injury. Decision-making and surgical management are discussed, and

the current literature concerning NPG-related pediatric head injuries is reviewed., CASE PRESENTATION: A 4-year-old boy hit by a compressed-air rifle came to our center. CT scan showed a depressed skull fracture of the occipital bone on the midline and intracranial penetration of some fragments of the pellet. CT angiography documented a compression of the superior sagittal sinus without thrombosis. Soon after hospital admission, the patient showed deterioration of the neurological status suggesting intracranial hypertension. Surgery was performed with fracture elevation, removal of metal fragments, and wound debridement. The patient had a full recovery without subsequent neurological deficits., DISCUSSION/CONCLUSION: Modern airguns may produce severe penetrating head injuries in children. Parents and physicians should be aware of the danger of NPG. Depressed skull fracture and dural venous sinus involvement can occur, and even a stable neurological condition may worsen. In such instances, a thorough preoperative assessment including vascular imaging is mandatory. The surgical risk is not negligible due to the possible injury of the sinus wall and subsequent intraoperative bleeding. This has to be weighted against potential complications of the penetrating injury, such as infection, sinus thrombosis, and intracranial hypertension. Our case suggests that prompt surgical treatment can be a safe and effective option.

1384. Di Roio, C., et al. (2000). "Craniocerebral injury resulting from transorbital stick penetration in children." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery 16(8): 503-507.

OBJECTS: Two children were admitted to hospital for treatment of craniocerebral injury with transorbital penetration., METHODS: One child aged 6 years and 6 months had poked a chopstick in his orbit. There was no report of either a palpebral or an ocular wound. He had subsequently developed a meningeal syndrome with a cerebral abscess managed by needle aspiration biopsy and intravenous antibiotics. The other child, aged 4, had fallen onto a metal rod. He presented with a palpebral wound, motor disorders and coma, all due to a frontal intracerebral hematoma. There was an improvement in outcome without complications of an infectious nature or motor sequelae., CONCLUSIONS: Such head injuries are rare. Clinical, radiological and ophthalmological investigations must be performed, including computed tomography (CT) scan or cerebral magnetic resonance imaging (MRI) with antibiotic treatment for suspected microorganisms.

1386. Dias, J., et al. (2021). "Thromboelastography for the evaluation and management of patients with traumatic brain injury." Research and Practice in Thrombosis and Haemostasis 5(SUPPL 2).

Background : Traumatic brain injury (TBI) is frequently associated with coagulopathy and increased mortality risk. Thromboelastography can provide rapid coagulation assessment and may be particularly useful in distinguishing coagulapathic TBI (CTBI) profiles and severity, aiding goal-directed treatment of CTBI patients. Aims : To conduct a systematic review and outcomes analysis to assess the utility of thromboelastography for evaluation and management of CTBI patients. Methods : A systematic literature search was performed on PubMed and EMBASE to identify clinical studies of adult patients with TBI assessed using thromboelastography. Articles were screened using predefined inclusion and exclusion criteria. Demographic, diagnostic, laboratory, treatment, and outcome data were extracted for comparison and an aggregate analysis performed to compare the effect of CTBI management with thromboelastography versus conventional coagulation assays (CCA) on 28-day mortality. Results : Searches identified 303 non-duplicate publications with seven additional manuscripts identified by the authors. After screening and review, 29 publications were identified with relevant data on the use of thromboelastography in CTBI patients. Results showed that thromboelastography identified hypercoagulable patterns in TBI patients. Notably, the K-value, α angle

and MA values consistently differed from established reference ranges. Furthermore, thromboelastography parameters differed between TBI subtypes; penetrating TBI was associated with increased likelihood of coagulopathy, evidenced by significant differences in all TEG parameters (except R time), compared with blunt TBI. Thromboelastography assays were also able to predict a range of clinical outcomes including mortality, neurosurgical intervention, and bleeding complications, with evidence for improved outcomes following thromboelastography guided blood transfusion in TBI patients. Two studies were identified for an aggregate analysis, and demonstrated a significant mortality benefit of using viscoelastic testing to guide resuscitation in TBI patients compared to CCA (Figure 1). Conclusions : Thromboelastography may have an important role in both the diagnosis and management of patients with TBI. Further studies are needed to define optimal use.

1387. Diaz, J., et al. (2011). "Changes in brain and ventricle volumes after decompressive craniectomy in patients with severe traumatic brain injuries." Journal of neurotrauma 28(6): A93.

Fluctuations in brain volume are apparent in patients with severe traumatic brain injuries (TBI) who have undergone decompressive craniectomy (DC). Here we describe the changes in brain and ventricular volumes that result fromDC during the acute phase of the injury.Wholebrain CT scans were compiled for decompressed patients with severe non-penetrating TBI (Glasgow Comma Scale<8 n=9, female=1, mean age=36.7). Brain and ventricular volumes were quantified for week one post-DC using the software Analyze 10.0. Preliminary data do not reveal significant variations in brain volume during the first postoperatory week, and indicate a significant decrease in ventricular volume at the second post-operatory day (p=0.004, paired samples t-test). No significant correlations were found between changes in brain and ventricular volumes (r=-0.139, n=36, p=0.420, Pearson's correlation test). Further evaluations will reassess the present results in a larger patient pool, and will examine the contributions of edema, hemorrhage, and extra-ventricular cerebrospinal fluid to brain herniation.

1388. Diaz-Arrastia, R., et al. (2009). "Posttraumatic epilepsy: the endophenotypes of a human model of epileptogenesis." Epilepsia 50 Suppl 2: 14-20.

Posttraumatic epilepsy is a common complication of traumatic brain injury (TBI), occurring in up to 15-20% of patients with severe brain trauma. Trauma accounts for approximately 5% of chronic epilepsy in the community. Because it is a common condition, and because of the relatively short latency period between injury and onset of chronic seizures, posttraumatic epilepsy represents a good model to test antiepileptogenic therapies. However, several well-conducted clinical trials have failed to demonstrate antiepileptogenic efficacy for several common anticonvulsants. Posttraumatic epilepsy can arise through a number of mechanisms, which often coexist within a single patient. Penetrating brain injury produces a cicatrix in the cortex and is associated with a risk of posttraumatic epilepsy of approximately 50%, whereas nonpenetrating head injury may produce focal contusions and intracranial hemorrhages, and is associated with a risk of posttraumatic epilepsy of up to 30%. Furthermore, closed head injury often produces diffuse concussive injury, with shearing of axons and selective damage to vulnerable brain regions, such as the hippocampus. The clinical, neurophysiologic, imaging, and neuropathologic features or epileptogenicity differ between these alternate mechanisms. It is likely that better understanding of the subtypes of epilepsy resulting from brain trauma will be required to successfully identify antiepileptogenic therapies.

1389. Diaz-Daza, O., et al. (2003). "Endovascular therapy of traumatic vascular lesions of the head and neck." Cardiovascular and interventional radiology 26(3): 213-221.

Pseudoaneurysm and fistula formation are well-documented complications of arterial vascular injury and may be associated with significant morbidity and mortality. The purpose of this manuscript is to review the presentation and therapy of patients with traumatic vascular injuries of the head and neck. Eight patients were admitted to a Level 1 Trauma Center and diagnostic angiography of the carotid

artery and vertebral circulation was performed. The mechanisms of injury included motor vehicle accident, gunshot wound, stab wound and aggravated assault. Cause of trauma, vascular lesion, endovascular therapy and outcome were analyzed retrospectively. The angiographic findings, clinical presentation and hospital course were reviewed. There were eight patients, seven males and one female, aged 17-65. Four patients (50%) had multiple lesions; four had pseudoaneurysms, two with fistula formation and two with active arterial hemorrhage. A total of 17 lesions were embolized using coils. Polyvinyl Alcohol (PVA), Gelfoam or a combination. Two of the 17 lesions received stents. Six of the eight patients remained clinically improved or stable at varying follow-up intervals. One of the four patients who presented with penetrating trauma and neurological deficits had resolution of right hemiplegia at the 8th month follow-up. One of the four patients who sustained blunt trauma and carotid-cavernous fistula presented with a new pseudoaneurysm at the 2-month post-embolization follow-up. The evolution of diagnostic neuroangiographic techniques provides opportunities for endovascular therapy of traumatic vascular lesions of the head and neck that are minimally invasive, attractive options in selected cases.

1390. Dichtel, W. J., et al. (1984). "Lateral mandibulotomy: a technique of exposure for penetrating injuries of the internal carotid artery at the base of the skull." The Laryngoscope 94(9): 1140-1144.

Injuries to the internal carotid artery are rare but are frequently fatal or associated with significant neurologic sequelae. Exposure for surgical repair of penetrating injuries to the internal carotid artery at the base of the skull is difficult because of the overlying ramus of the mandible and the facial nerve. In the past, these injuries have been treated by techniques such as occlusion of the artery with a Fogarty balloon catheter, or subluxation of the temporomandibular joint to gain access to the arterial injury. Based on techniques previously reported for extirpation of parapharyngeal space tumors, we describe lateral mandibulotomy for exposure of penetrating carotid artery injuries at the base of the skull. The technique affords relatively rapid and adequate exposure of these injuries allowing ligation, or in selected cases, arterial repair.

UNLABELLED: The use of blunt cannulas for retrobulbar injection (retro) is recommended to reduce the risk of retrobulbar hemorrhage and globe perforation. Retro cannulas with blunt tips--so-called Atkinson needles--are commercially available. They can also be produced by being blunted on a sterile surface immediately before injection., METHODS: In a prospective study, all retro cannulas (0.5 x 40 mm, Steriseal) used over 8 days in our hospital were collected after being blunted on a sterile Petri dish, followed by injection. Subsequently, scanning electron microscopic examination was performed. 20 unused retro needles were examined for control., RESULTS: 62% (n = 54) of the 87 used retro cannulas were satisfactory, i.e., the tips were blunted, exhibiting no undesirable hooks. 29% (n = 25) of the retro cannulas demonstrated moderate deformation, 9% (n = 8) stronger deformation of the needle tip. No complications occurred after any of the 87 injections., CONCLUSIONS: Blunting of retro cannulas immediately before injection is a possible alternative to commercially available needles with blunt tips. However, this procedure has to be performed carefully to avoid potential detrimental deformation of the needle tip, which can be detected in a low percentage by means of the scanning electron microscope.

1392. Dielert, E. and P. Stroinigg (1978). "[Consequences of gunshot injuries of the face (author's transl)]." Folgezustande nach Schussverletzungen im Kiefer-Gesichtsbereich. 26(12): 414-418.

During a 5 year period 59 patients with gunshot wounds were treated in the Department of Maxillo-facial Surgery at Munich University. Two patients, who developed local problems secondary to

latent infection due to missiles retained for 31 and 32 years, are presented. These missiles were surgically removed. Today, compared to the past, the interval between the gunshot injury and the surgical removal of the missile from the mandible because of the use of antibiotics and improved surgery may be considerable.

1393. Dieterich, H.-J., et al. (2003). "Penetration of intravenous hydroxyethyl starch into the cerebrospinal fluid in patients with impaired blood-brain barrier function." Anesthesia and analgesia 96(4): 1150-1154.

UNLABELLED: Hypovolemic patients with impairment of the blood-brain barrier may receive IV hydroxyethyl starch (HES) to stabilize cardiovascular function and to increase cerebral perfusion pressure. It is not known whether HES can penetrate into the cerebrospinal fluid (CSF) under those conditions. We investigated plasma and CSF levels of HES after IV infusion in patients with suspected disturbance of the blood-brain barrier. Eight adult patients were studied who were being treated for head trauma or subarachnoid hemorrhage, with an external CSF drain in place. All patients exhibited radiographic signs of blood-brain barrier impairment diagnosed by cerebral computed tomography. After IV infusion of 500 to 1000 mL of HES 200,000/0.5, plasma HES levels were measured. Additionally, all CSF that was drained within 8 h after the HES infusion was collected, and HES concentrations were measured. All patients had detectable HES plasma concentrations (3.41 to 9.95 mg/mL). In contrast, no HES could be detected in the CSF of any patient. These data indicate that IV HES 200,000/0.5 does not penetrate into the CSF in patients with disturbed blood-brain barrier function after subarachnoid hemorrhage or head trauma. Further study is required to determine whether HES penetrates into the intracranial interstitium, despite the absence of HES in the CSF., IMPLICATIONS: Patients may receive IV hydroxyethyl starch (HES) after head trauma or subarachnoid hemorrhage. The results of the present study indicate that in patients with suspected blood-brain barrier impairment, HES does not penetrate from the plasma into the cerebrospinal fluid.

1394. Dietz, H. (1980). "[Perforating orbito-frontal injuries (author's transl)]." Uber orbito-frontale perforierende Verletzungen. 23(6): 219-223.

In spite of the severity of the injury, perforating orbito-frontal injuries have often been overlooked on account of their very scanty clinical symptoms. For this reason they are particularly dangerous. The historic, aetiological, diagnostic and clinical aspects of the lesion are discussed. Experiences from the literature are reported as well as our own observations. In nearly all of our 15 personal cases there was initially a CSF fistula and a brain injury; in all six of the late cases there had been three or more attacks of meningitis and in five the diagnosis was only made after a brain abscess had developed.

1396. Dijkstra, S., et al. (2000). "Up-regulation of CD81 (target of the antiproliferative antibody; TAPA) by reactive microglia and astrocytes after spinal cord injury in the rat." The Journal of comparative neurology 428(2): 266-277.

We examined the expression of CD81 (also known as TAPA, or target of the antiproliferative antibody) after traumatic spinal cord injury in the rat. CD81, a member of the tetraspanin family of proteins, is thought to be involved in reactive gliosis. This is based on the antiproliferative and antiadhesive effects of antibodies against CD81 on cultured astrocytes, as well as its up-regulation after penetrating brain injury. CD81 expression following dorsal hemisection of the spinal cord was determined immunohistochemically at time points ranging from 1 day to 2 months postlesion (p.l.). In

the unlesioned cord a low background level of CD81 was observed, with the exception of the ependyma of the central canal and the pia mater, which were strongly CD81-positive. One day p.l., CD81 was diffusely up-regulated in the spinal cord parenchyma surrounding the lesion site. From 3 days onward, intensely CD81-positive round cells entered the lesion site, completely filling it by 7 days p.l. Staining with the microglial markers OX-42 and Iba1 revealed that these cells were reactive microglia/macrophages. At this time, no significant CD81 expression by GFAP-positive reactive astrocytes was noted. From the second week onward, CD81 was gradually down-regulated; i.e., its spatial distribution became more restricted. The CD81-positive microglia/macrophages disappeared from the lesion site, leaving behind large cavities. After 2 months, astrocytes that formed the wall of these cavities were strongly CD81-positive. In addition, CD81 was present on reactive astrocytes in the dorsal funiculus distal from the lesion in degenerated white matter tracts. In conclusion, the spatiotemporal expression pattern of CD81 by reactive microglia and astrocytes indicates that CD81 is involved in the glial response to spinal cord injury. 1397. Dikmen, S. S., et al. (2009). "Cognitive outcome following traumatic brain injury." The Journal of head trauma rehabilitation 24(6): 430-438.

OBJECTIVE: To determine whether an association exists between traumatic brain injury (TBI) sustained in adulthood and cognitive impairment 6 months or longer after injury., DESIGN: Systematic review of the published, peer-reviewed literature., RESULTS: From 430 articles, we identified 11 primary and 22 secondary studies that examined cognitive impairment by using performance measures for adults who were at least 6 months post-TBI. There was clear evidence of an association between penetrating brain injury and impaired cognitive function. Factors that modified this association included preinjury intelligence, volume of brain tissue lost, and brain region injured. There was also suggestive evidence that penetrating brain injury may exacerbate the cognitive effects of normal aging. We found clear evidence for long-term cognitive deficits associated with severe TBI. There was suggestive evidence that moderately severe brain injuries are associated with cognitive impairments. There was inadequate/insufficient evidence to determine whether an association exists between a single, mild TBI and cognitive deficits 6 months or longer postinjury., CONCLUSION: In adults, penetrating, moderate, and severe TBIs are associated with cognitive deficits 6 months or longer postinjury. There is insufficient evidence to determine whether mild TBI is associated with cognitive deficits 6 months or longer postinjury.

1398. Di-Luciano, A., et al. (2019). "Challenging Surgical Approach to a Lost Inferior Rectus Muscle Following Penetrating Orbital Trauma." Journal of pediatric ophthalmology and strabismus 56: e49-e52.

A 37-year-old man suffered a penetrating left orbital injury with rupture of the inferior rectus muscle and avulsion of the optic nerve. The orbit was explored and the inferior rectus muscle stump was identified 25 mm from the limbus. Despite this, the muscle was successfully reattached and the patient achieved satisfactory postoperative alignment. [J Pediatr Ophthalmol Strabismus. 2019;56:e49-e52.]. 1399. DiMaio, V. J., et al. (1987). "Use of scanning electron microscopy and energy dispersive X-ray analysis (SEM-EDXA) in identification of foreign material on bullets." Journal of forensic sciences 32(1): 38-47.

The authors report two cases in which examination of foreign material embedded in or adherent to bullets provided critical information in the reconstruction of a crime scene. Analysis of small particles by scanning electron microscopy (SEM) and energy dispersive X-ray analysis (EDXA) can be accomplished without destruction or injury of the particles. In one case, the detection and identification of mineral fragments embedded near the nose of a bullet provided conclusive evidence that the bullet had ricocheted from a fireplace before striking the victim. In the second case, analysis of particles from

two bullets identified them as them as bone fragments, thus proving which shots fired from a police officer's gun had killed a suspected burglar. SEM-EDXA has not been widely used to identify such material on bullets, but should be considered a potentially powerful tool in forensic science.

1400. Dimitrov, M., et al. (1996). "The effects of frontal lobe damage on everyday problem solving." Cortex; a journal devoted to the study of the nervous system and behavior 32(2): 357-366.

The prefrontal cortex plays an especially important role in human social-cognitive behavior. It has been difficult to quantify deficits in this domain in patients with frontal lobe lesions using standardized psychological instruments. We administered the Everyday Problem Solving Inventory (EPSI), which is composed of a range of scenarios depicting everyday social problems and their possible solutions, to a group of patients with frontal lobe lesions who were required to rate each of 4 possible solutions to each problem for their effectiveness. Our sample consisted of 27 normal controls (NCs), 33 patients with focal frontal lobe lesions (FLL), and 3 patients with frontal lobe dementia (FLD). The performance of the FLL patients on the EPSI instrument was also compared with their performance on traditional neuropsychological tests. The results indicated that the FLD patients' EPSI rank ordering of social problem solutions was uncorrelated with the performance of NCs and about half of the FLL patients EPSI rank orderings of solutions also varied substantially from those of the NCs. These same FLL patients also had the lowest scores, compared to FLL patients whose judgements on the EPSI were similar to that of the NCs, on a set of neuropsychological tasks sensitive to frontal lobe dysfunction. There was no obvious relationship between locus of lesion within the frontal lobes and performance on the EPSI. These results suggest that some patients with prefrontal lobe lesions may have impaired social judgement that can be directly revealed through the use of a conventional psychological inventory such as the EPSI.

1401. Dimopoulou, I., et al. (2003). "High prevalence of decreased cortisol reserve in brain-dead potential organ donors." Critical care medicine 31(4): 1113-1117.

OBJECTIVE: To investigate the adrenocortical function in brain-dead patients, potential organ donors., DESIGN: Prospective study., SETTING: Intensive care units in two teaching hospitals., PATIENTS: A total of 37 patients (28 men, nine women) with severe brain injury, having a mean age of 42 +/- 18 yrs, were included in the study. Group A consisted of 20 brain-injured patients who did not deteriorate to brain death. Group B included 17 brain-injured patients who were brain dead; of these, ten patients developed brain death during ICU stay and seven patients were admitted to the ICU after clinical brain death., INTERVENTIONS: In all patients (group A and group B), a morning blood sample was obtained at admission to the ICU to determine baseline plasma cortisol. Subsequently, 1 microg of corticotropin (adrenocorticotropic hormone, Synacthen) was administered intravenously, and a blood sample was taken 30 mins after the injection. In group B patients who became brain dead while being treated in the ICU (n = 10), the same procedure was repeated the morning after the confirmation of brain death. Patients having a cortisol level of at least 18 microg/dL after the administration of adrenocorticotropic hormone were defined as responders., MEASUREMENTS AND MAIN RESULTS: After the occurrence of brain death, group B patients had significantly lower values for baseline (8.5 +/- 6.2 vs. 17.0 +/- 6.6 microg/dL, p <.001) and stimulated (16.9 +/- 6.3 vs. 23.9 +/- 5.7 microg/dL, p =.001) plasma cortisol compared with group A patients. Thirteen group B patients (76%) and two group A patients (10%) were nonresponders to adrenocorticotropic hormone (p <.001). In group B patients, baseline and stimulated cortisol concentrations were significantly related (r =.71, p =.001), whereas there was no correlation between baseline cortisol and the increment in cortisol (r = -.37, p =.15). Mean hormonal data of the ten brain-dead patients studied at admission in the ICU and after the occurrence of brain death were the following: baseline plasma cortisol (23.5 +/- 11.4 vs. 6.8 +/- 4.2 microg/dL, p =.003) and stimulated serum cortisol (28.8 +/- 9.9 vs. 16.3 +/- 4.3 microg/dL, p =.008)., CONCLUSIONS: Adrenal cortisol secretion after dynamic stimulation is deficient in a substantial proportion of brain-dead potential organ donors.

1402. Dinakaran, S. and P. J. Noble (1998). "Silent orbitocranial penetration by a pencil." Journal of accident & emergency medicine 15(4): 274-275.

OBJECTIVE: To emphasise the value of computed tomography even in the absence of symptoms in a case of penetrating injury of the upper eyelid., METHODS: Case report., RESULTS: Although clinically asymptomatic, penetration of upper eyelid was associated with intracranial penetration that left a track in the brain parenchyma., CONCLUSIONS: Computed tomography of orbit and brain is an important investigation, even in seemingly trivial eyelid injury, to reveal the full extent of the damage.

1403. Ding, K., et al. (2008). "Cerebral atrophy after traumatic white matter injury: correlation with acute neuroimaging and outcome." Journal of neurotrauma 25(12): 1433-1440.

Traumatic brain injury (TBI) is a pathologically heterogeneous disease, including injury to both neuronal cell bodies and axonal processes. Global atrophy of both gray and white matter is common after TBI. This study was designed to determine the relationship between neuroimaging markers of acute diffuse axonal injury (DAI) and cerebral atrophy months later. We performed high-resolution magnetic resonance imaging (MRI) at 3 Tesla (T) in 20 patients who suffered non-penetrating TBI, during the acute (within 1 month after the injury) and chronic stage (at least 6 months after the injury). Volume of abnormal fluid-attenuated inversion-recovery (FLAIR) signal seen in white matter in both acute and follow-up scans was quantified. White and gray matter volumes were also quantified. Functional outcome was measured using the Functional Status Examination (FSE) at the time of the chronic scan. Change in brain volumes, including whole brain volume (WBV), white matter volume (WMV), and gray matter volume (GMV), correlates significantly with acute DAI volume ($r = -0.69$, -0.59, -0.58, respectively; $p < 0.01$ for all). Volume of acute FLAIR hyperintensities correlates with volume of decreased FLAIR signal in the follow-up scans ($r = -0.86$, $p < 0.001$). FSE performance correlates with acute hyperintensity volume and chronic cerebral atrophy ($r = 0.53$, $p = 0.02$; $r = -0.45$, $p = 0.03$, respectively). Acute axonal lesions measured by FLAIR imaging are strongly predictive of post-traumatic cerebral atrophy. Our findings suggest that axonal pathology measured as white matter lesions following TBI can be identified using MRI, and may be a useful measure for DAI-directed therapies.

1404. Dinocourt, C., et al. (2006). "Injury-induced axonal sprouting in the hippocampus is initiated by activation of trkB receptors." The European journal of neuroscience 24(7): 1857-1866.

Penetrating head injuries are often accompanied by the delayed development of post-traumatic epilepsy. Schaffer collateral transection leads to axonal sprouting and hyperexcitability in area CA3 of hippocampal slice cultures. We used this model to test the hypothesis that the injury-induced axonal sprouting results from increased neurotrophin signaling via trkB receptors near the lesion. Using rats and mice, we established that sprouting CA3 pyramidal cell axons are labeled with an antibody to the growth-associated protein GAP-43. We observed two- to threefold increases in the level of brain-derived neurotrophic factor and trkB protein in area CA3 by 24-48 h after Schaffer collateral transection, preceding the onset of axonal sprouting. Finally, we demonstrated that injury-induced axonal sprouting of GAP-43-immunoreactive axons is impaired in hippocampal slice cultures from mice expressing low levels of trkB receptors. We conclude that injury-induced axonal sprouting is initiated by brain-derived neurotrophic factor-trkB signaling and suggest that this process may be critical for the genesis of post-traumatic epilepsy.

A case of traumatic middle cerebral artery aneurysm is presented. The case demonstrates some of the difficulties encountered when dealing with this type of aneurysm. The unusual surgical approach required for obliteration is described.

1408. Dittmann, W. (1986). "[Gunshot injuries of the brain caused by air pressure guns]." Gehirnschussverletzungen durch Luftdruckwaffen. 96(2): 119-131.

The article describes the historical and legal basis, as well as the ballistic criteria of injuries caused by air-rifle shots to the head. Six of our own cases of craniocerebral air-gun pellet injuries are discussed and critically assessed, using the results communicated in other papers as the basis of the discussion. The different post-traumatic complications, including the histopathological reaction of the brain to lead-pellets, are considered. The literature is reviewed and the indications for stereotactic removal or craniotomy of intracranial air-gun pellets are discussed. Air rifles, while occasionally the cause of serious head injuries, are rarely thought of as lethal weapons. However, this article illustrates the potential penetrating power of the air-gun pellet, a fact not always appreciated by physicians.
