Posttraumatic secondary infarction (PTCI) is a common secondary injury following severe traumatic brain injury (sTBI). Several risk factors for PTCI have been identified including low admission GCS, raised ICP, herniation and decompression surgery but no known early CT signs predicting PTCI have been identified yet. Existing CT classifications (e.g., Marshall Classification and Rotterdam Score) predict overall prognosis, but have not been validated for predicting PTCI. We aimed to identify early CT signs as risk factors of PTCI. A prospective convenience controlled cohort study enrolled 131 adult patients with sTBI. CT scans were evaluated retrospectively for the presence of secondary infarcts, third ventricular compression, contralateral ventricular compression in relation to primary mass lesion, intra-ventricular hemorrhage, basal and cortical subarachnoid hemorrhage in patients with and without secondary infarcts. Fifteen of 131 patients (11.4%) developed secondary infarcts. Third ventricular compression and contralateral ventricular compression on initial CT scan was seen more frequently in patients with PTCI: 14/15 vs 55/116 (OR = 15.5; 95%CI 1.98-121.98 $p < 0.01$) and 10/15 vs 20/ 116 (OR = 9.6; 95%CI 2.96-31.14 $p < 0.01$), respectively. Contralateral and 3rd ventricular compression were found to correlate with the development of PTCI. These CT signs can be considered as surrogate markers of CSF volume loss, an early compensatory step in intracranial swelling often seen in sTBI. Subsequent rise in ICP can lead to herniation, vessel compression and ultimately secondary infarcts. Identification of these early CT signs may lead to intensified treatment and to reduced risk of secondary infarcts.

4406. Rabb, C. H. (1995). "Options for cerebral protection after penetrating head injury." Neurosurgery clinics of North America **6**(4): 643-656.

The medical management of secondary brain injury is entering a new era in which the fruits of labor in the laboratory are paying off in the form of legitimate agents for use in human trials. As more about pathophysiology of traumatic-ischemic brain injury becomes known, more effective means for pharmacologic intervention and neuronal salvage will emerge, and optimism is high that we are approaching an era that will witness improvements in functional survival that have been heretofore unwitnessed.

4407. Rabbani, C. C., et al. (2020). "The association of weather, temperature, and holidays on pediatric maxillofacial trauma." Laryngoscope Investigative Otolaryngology **5**(5): 846-852.

Objective: To evaluate the association of weather, seasons, months and holidays on the frequency and pattern of pediatric facial fractures. Methods: Retrospective review of pediatric patients treated for facial fractures at two Level I

trauma centers in a midsize Midwestern US city over a 5-year period. Patients were included only if presentation was within 3 hours of inciting trauma, transfers from other facilities were excluded. Demographic characteristics, fracture patterns, operative interventions, weather data, and local public school schedules were acquired and associations were analyzed with unpaired t tests, χ2, multivariate and binomial regression model analyses. Results: Two hundred and sixty patients were included. The average age (SD) was 11.8 (5.0) years, with 173 males and 87 females. The highest distribution of presentations occurred in the summer season (35.0%), on weekends and holidays (58.1%), and when the weather was described as clear (48.5%). The most common mechanisms of injury were motor vehicle collisions (25.8%), followed by sports—(21.5%) and assault—(16.5%) related injuries. Mechanisms were significantly associated with certain fracture patterns. Older age was associated with fewer orbital fractures (P <.01). Seventy-five patients (28.8%) required operative intervention. Age was found to impact the likelihood of operative intervention (Exp(β) = 1.081, P =.03) while weather, temperature, and mechanism did not. Conclusion: Pediatric facial fractures are linked to warmer weather with clear skies and warmer season. Age predicts some fracture patterns and need for operative intervention. These results can be used to inform public health interventions, policymaking, and trauma staffing. Level of Evidence: Level 2b (retrospective cohort).

4408. Rabinovich, Y., et al. (2005). "Survival with intact cerebral function after gunshot injury to both internal carotid arteries." Journal of vascular surgery **42**(3): 567-569.

A 24-year-old man was admitted after sustaining a single gunshot wound to the neck with an expanding hematoma on the left. Computed tomography angiography demonstrated bilateral internal carotid artery pseudoaneurysms, with disruption of flow on the left and a carotid-jugular fistula on the right. At operation, transection of the left internal carotid artery necessitated ligation of the artery. No injuries to the trachea or larynx were found, but the pharynx was lacerated and was repaired. The patient was transferred to the angiography suite where a stent graft was placed in the right internal carotid artery. This served to close the pseudoaneurysm and the arteriovenous fistula while preserving distal flow. The patient recovered with intact cerebral function and with mild paresis of the tongue related to hypoglossal nerve injury. He was discharged home after 7 days.

4409. Rabinowitz, M. P. and S. M. Goldstein (2013). "Diesel fuel injury to the orbit." Ophthalmic plastic and reconstructive surgery **29**(1): e31-33.

A 48-year-old man was seen in the Wills Eye Institute emergency room for pain and decreased vision after having a diesel engine fuel cylinder explosion in his face. Clinical examination showed proptosis, decreased extraocular motility, and increased intraocular pressure; CT scan imaging revealed hypodense areas within the orbit. His orbital signs rapidly worsened despite aggressive antibiotics, steroids, and surgical intervention. Two orbitotomies revealed diesel fuel infiltration of the intraconal and extraconal spaces that proved impossible to evacuate completely. The patient ended up losing vision from an intense chemical cellulitis with subsequent orbital compartment syndrome and optic neuropathy. This case highlights the severity of orbital chemical injuries and their variable prognoses despite aggressive management.

4410. Rabiu, T. (2011). "Posttraumatic seizures in a new rural neurosurgery service: Patterns and risk factors." Epilepsia **52**: 133.

Purpose: Traumatic brain injury (TBI) is a well recognized risk factor for seizures. Whereas TBI is a common occurence in Nigeria, a developing economy, there is paucity of literature on posttraumatic seizures (PTS) in the Nigerian population with TBI. We have recently pioneered a rural neurosurgical service in a Nigerian tertiary health centre in the country. This study provides our preliminary report on the profile and pattern of PTS in TBI patients. Method: A prospective observational study of TBI patients was carried out between November 2010 and March 2011. Patients demographics, nature of TBI, type of seizure (early or late), seizure semiology and cranial computerized tomography (CT) findings were assessed. Simple descriptive data analysis was done. Result: Forty-five patients were managed for TBI within the study period. Of these, 39(86.7%) were males while 6 (13.3%) were females. Eight (17.8%) of the patients were children. There were 25 (55.5%), 8 (17.8%), and 12 (26.7%) cases of mild, moderate and severe head injury respectively. Three (6.7%) patients had open depressed skull fracture while 2 (4.4%) had gunshot wound to the head (GSWH). There were 4 (8.9%) cases of early PTS and these were in patients with severe head injury, 3 (75%) of whom had acute subdural hematoma on CT scan while the fourth had GSWH. Seizure occured in three of them within 24 h of

trauma while it occured on the 5th day posttrauma in the other. Only two of them required anticonvulsant therapy because of recurrence but none progressed to late PTS. One patient who was managed for mild head injury a year previously presented with late posttraumatic seizures that were well-controlled with anticonvulsant. Conclusion: Most cases of PTS are associated with severe TBI, acute subdural hematoma and GSWH. Progression of early to late PTS is rare.

4411. Rabl, W., et al. (1998). "Ballistic aspects of tandem-loaded cartridges of identical caliber." International journal of legal medicine **112**(1): 58-61.

Tandem loading of a cartridge of the same caliber is possible only if the diameter of the barrel is sufficiently wide. This requirement is met by the .22 long shot Anschutz miniature clay pigeon gun. Ballistic experiments with tandem-loaded cartridges of the same caliber as those loaded in the normal way showed the bullet of the regularly loaded cartridge to impact the muzzle-loaded cartridge. On firing a shot, the bullet of the posterior cartridge penetrates the anterior one, expanding the case of the first cartridge to the diameter of the barrel and disintegrating the bullet. Regardless of whether the muzzle-loaded cartridge is ignited or not, the discharge speed of the projectiles (v0) is considerably below that of single shots. Calculations yielded a theoretical reduction by about 60%. In accordance with the formula E=1/2*m*v2, in terms of the energy released, the elevated mass of the projectile is of secondary importance compared with the reduction of v0. Although the "projectile" mass is more than twice the normal rate, the energy density is significantly reduced and the biological effect is attenuated. This also became apparent in the failed suicide attempt of a 43-year-old male who used a miniature clay pigeon gun to shoot himself in the forehead at a range of a few centimeters. He had inserted a second cartridge, base to head with the first cartridge, in the factory-bored barrel of the gun. The leading cartridge was destroyed by the regularly loaded one. The pierced and expanded case of the leading cartridge was found nearby the injured man and was at first taken to be the jacket of a larger-caliber bullet.

4412. Racadio, J. M., et al. (2006). "Three-dimensional rotational angiography of neurovascular lesions in pediatric patients." AJR. American journal of roentgenology **186**(1): 75-84.

OBJECTIVE: In this pictorial essay, we review the 3D rotational angiography (RA) studies of six pediatric patients; in these cases, the information obtained with 3D RA was uniquely beneficial in diagnosis and treatment planning., CONCLUSION: Three-dimensional RA is an excellent tool for the evaluation of a number of intracranial lesions in pediatric patients: There is less total radiation exposure from a single rotational run than from CT or a conventional angiography examination that involves more than one view and the study is quick, with data acquisition requiring less than 8 sec and fully rendered 3D reconstructions generated within 180 sec.

4413. Racette, S. and A. Sauvageau (2008). "Suicide by drowning after two gunshots to the head: a case report." Medicine, science, and the law **48**(2): 170-172.

Differentiation between suicide and homicide can be problematic for forensic pathologists, especially when a complex method of suicide is used by the victim. Multiple gunshot suicides have been previously reported in the forensic literature. However, multiple gunshots combined with other suicidal methods are rare. In this article the authors report the unusual case of a floating body recovered from a river, with two gunshot wounds to the head. The autopsy showed that both gunshot wounds were nonlethal and the cause of death was attributed to drowning. Though homicide was strongly suspected at first, the manner of death was later established as suicide.

4414. Radabaugh, H., et al. (2022). "HARMONIZING DATA ACROSS OPERATION BRAIN TRAUMA THERAPY IDENTIFIES DISTINCT, BIOMARKERPROJECTED MULTIMODAL PROFILES OF THREE TYPES OF EXPERIMENTAL TRAUMATIC BRAIN INJURY." Journal of neurotrauma **39**(11-12): A75.

The multi-center Operation Brain Trauma Therapy (OBTT) consortium generated a large dataset comparing outcomes across animal models. We explored the potential utility of harmonizing data from 531 male rats subjected to one of three TBI models (fluid percussion injury [FPI], controlled cortical impact [CCI], and penetrating ballistic-like brain injury [PBBI]) and the predictive value of bloodbased biomarkers. One-month of testing including blood biomarkers (glial fibrillary acidic protein [GFAP] and Ubiquitin carboxy-terminal hydrolase-L1 [UCH-L1]), behavior, and histology followed injury. Applying common data elements, variables from each center were harmonized. The stats and syndRomics R

packages were used for analysis and interpretation. We observed associations between biomarkers, behavior, and histology explaining 96.2% of the variance. PC loadings found these associations to be injury-type dependent. The best behavior and least severe histological measures exhibited an exaggerated GFAP 4h response dissipating by 24h. UCH-L1 impact was near-zero. Rats in the middle of behavioral and histological severity showed increased UCH-L1 (both time points) and increased GFAP at 24h. The most impaired behavior and severe histology were associated with both UCH-L1 time points but never GFAP. Plotting each rat across PC1 and PC2 revealed these profiles corresponded to FPI, CCI, and PBBI, respectively. We report successful harmonization of data across OBTT, demonstrating that TBI models yield identifiably distinct injuries. This work also emphasizes the importance of data sharing and interoperability approaches to identify phenotypebiomarker associations and develop innovative data-driven strategies for precision medicine in TBI.

4415. Radford, G. E., et al. (2016). "Simulating backspatter of blood from cranial gunshot wounds using pig models." International journal of legal medicine **130**(4): 985-994.

Few studies have examined the biomechanical basis for backspatter from cranial gunshot wounds. Backspatter is material which travels against the direction of fire following ejection from a gunshot entrance wound. Our paper focuses on the use of animals for reconstructing this phenomenon. Five live pigs and several slaughtered pigs were shot using either 9 x 19 mm, 115 grain, full metal jacketed ammunition or .22 long rifle, 40 grain, lead, round-nose ammunition. A high-speed camera was used to record the entrance wound formation and backspatter. A small amount of backspattered material was produced with all targets, and blood backspatter was seen in a few cases. However, we conclude that our model provides an understanding of the phenomenon of backspatter and the physical mechanisms associated with it. The various components of the mechanism of backspatter formation are complex and overlap. The principle mechanism observed in pig cranial gunshots was the high-speed impact response of the skin overlying the skull bone. This study has also produced evidence supporting the view that backspatter can result from the splashing of superficial blood if it is already present on the skin. Subcutaneous gas effects have been demonstrated for backspatter from contact shots. There has been no clear evidence of the role of the collapse of a temporary cavity within the brain.

4416. Radu, A. and M. P. Horan (2017). "Implant success rate in head and neck pathology patients reconstructed with a free flap graft." Journal of oral and maxillofacial surgery **75**(10): e372-e373.

Patients treated for head and neck pathology often undergo extensive treatment including surgical resection of the mandible/maxilla, reconstruction with free flap grafts, chemotherapy and radiation therapy. Following their treatment, these patients, albeit disease free, find themselves unable to perform basic functions, such as speaking or chewing. Therefore, restoring these patients to full function and esthetics is an equally important aspect of treating them. The reconstruction of maxillomandibular defects following ablation for tumors or osteoradionecrosis with free flaps has been demonstrated to be a reliable technique1. The purpose of this study was to analyze the success rate for dental implants in sites that have been altered through surgery or radiation therapy. It was hypothesized that there is no difference in the success rate for dental implant placement between patients with free flap reconstruction and patients with dental implants placed in native maxillofacial bones. This is an IRB approved study that retrospectively investigates the success rate of implant placement in free flap grafts in patients who were reconstructed for either benign or malignant pathology. We analyzed records from the Oral and Maxillofacial Surgery department at the Cleveland Clinic in Cleveland, OH starting from January 2012 to January 2017. The data was analyzed using Microsoft Excel data analysis tool pack. Also, descriptive statistics were used to evaluate the qualitative aspect of the data. The medical record data was obtained through chart review of the electronic medical record. The primary study aims were to determine the success rate of dental implants in patients with free flap reconstruction in a single institution over the past 5 years, to investigate the reasons for failure of implants that were deemed unsuccessful in patients with free flap reconstruction, and to understand the differences in surgical procedures between placing implants in patients with native mandibular or maxillary bone vs free flap grafts. Ten patients were included in this investigation, 5 females (50%) and 5 males (50%), with the average age of 65 (range 14-72). For each patient, the demographic information was gathered (age, gender, race) together with the medical and surgical history. One patient (10%) had a anteriolateral free flap, one patient (10%) has a radial free flap, and 8 patients (80%) had a free fibula flap reconstruction. One patient (10%) was reconstructed after suffering a gun shot wound to the face, one patient (10%) suffered from a benign neoplasm, and 8 patients (80%) suffered from malignant neoplasms. Fifty four implants were placed in the osseous segment of the free flap, with 12 implants (22.2%) placed in the maxilla and 42 implants (77.8%) placed in the mandible. Ten implants (18.5%) in three patients (33.3%) were removed due to lack of osseointegration. The success rate was calculated to be 80.5% which is

lower than the 94.5% success rate2 reported in previous studies in this patient population. Besides implant failure, the most common complication experienced was the persistence of hyperplastic soft tissue that had to be removed in 4 patients (40%) prior to delivery of the prosthesis. Based on this study, it was concluded that restoring patients with dental implants in vascularized bone grafts is a reliable method to restore function and esthetics.

4417. Rafaels, K. A., et al. (2015). "Injuries of the head from backface deformation of ballistic protective helmets under ballistic impact." Journal of forensic sciences **60**(1): 219-225.

Modern ballistic helmets defeat penetrating bullets by energy transfer from the projectile to the helmet, producing helmet deformation. This deformation may cause severe injuries without completely perforating the helmet, termed "behind armor blunt trauma" (BABT). As helmets become lighter, the likelihood of larger helmet backface deformation under ballistic impact increases. To characterize the potential for BABT, seven postmortem human head/neck specimens wearing a ballistic protective helmet were exposed to nonperforating impact, using a 9 mm, full metal jacket, 124 grain bullet with velocities of 400-460 m/s. An increasing trend of injury severity was observed, ranging from simple linear fractures to combinations of linear and depressed fractures. Overall, the ability to identify skull fractures resulting from BABT can be used in forensic investigations. Our results demonstrate a high risk of skull fracture due to BABT and necessitate the prevention of BABT as a design factor in future generations of protective gear.

4418. Rafique, M. B., et al. (2008). "Difficult airway due to sprinkler spike in the head." Paediatric anaesthesia **18**(9): 903-904.

4419. Ragab, T., et al. (2018). "Pattern and outcomes of head injuries in egypt: A study of the egyptian revolution." Indian Journal of Forensic Medicine and Toxicology **12**(3): 25-30.

Like many other traumas, head injuries is a growing health problem and is attributed to deaths among the young and productive population. The intention of this study was to compare the difference in the pattern and outcome of head injuries between year 2010 versus 2011. A retrospective comparative study carried out based upon data collected from medical records of patient with head injuries admitted to emergency room, El-Demerdash, Ain Shams University Hospitals starting from January 2010 to December 2011. Socio-demographic, full history, clinical examination and criteria of severity were collected from the sheets for the study. During the study period, the total number of head injured cases received by EL-Demerdash hospital was 1020; 407 in 2010 and 613 in 2011.Due to in-completed sheets 206 of the head injured patients were discarded from the study, 72 in 2010 and 134 in 2011, out of the 134 cases 69 were head gunshots. So the actual numbers of cases subjected to this study were 335 cases in 2010 and 479 in 2011. The male percentage was higher than female in both years. In 2011, the mean age was 24.63 ± 19.19. In 2010, Post-concussion state was in 82.4% of patients, while poly-trauma were present in only 17.6% and no cases of head gunshot were present. In 2011, poly-trauma were 53.03%, while post-concussion were present in 34.86% and head gunshots in 12.11% of cases. In 2010, fall 37.6% followed by motor car accidents (28.4%).

4420. Ragel, B. T., et al. (2010). "Wartime decompressive craniectomy: technique and lessons learned." Neurosurgical focus **28**(5): E2.

OBJECT: Decompressive craniectomy (DC) with dural expansion is a life-saving neurosurgical procedure performed for recalcitrant intracranial hypertension due to trauma, stroke, and a multitude of other etiologies. Illustratively, we describe technique and lessons learned using DC for battlefield trauma., METHODS: Neurosurgical operative logs from service (October 2007 to September 2009) in Afghanistan that detail DC cases for trauma were analyzed. Illustrative examples of frontotemporoparietal and bifrontal DC that depict battlefield experience performing these procedures are presented with attention drawn to the L.G. Kempe hemispherectomy incision, brainstem decompression techniques, and dural onlay substitutes., RESULTS: Ninety craniotomies were performed for trauma over the time period analyzed. Of these, 28 (31%) were DCs. Of the 28 DCs, 24 (86%) were frontotemporoparietal DCs, 7 (25%) were bifrontal DCs, and 2 (7%) were suboccipital DCs. Decompressive craniectomies were performed for 19 penetrating head injuries (13 gunshot wounds and 6 explosions) and 9 severe closed head injuries (6 war-related explosions and 3 others)., CONCLUSIONS: Thirty-one percent of craniotomies performed for trauma were DCs.

Battlefield neurosurgeons use DC to allow for safe transfer of neurologically ill patients to tertiary military hospitals, which can be located 8-18 hours from a war zone. The authors recommend the L.G. Kempe incision for blood supply preservation, large craniectomies to prevent brain strangulation over bone edges, minimal brain debridement, adequate brainstem decompression, and dural onlay substitutes for dural closure.

4421. Ragel, B. T. and R. R. McCafferty (2008). "Indirect gunshot wound to the head." Acta neurochirurgica **150**(12): 1311-1312.

BACKGROUND: An Afghani man presented to a U.S. military facility in Afghanistan with a 3-month history of clear fluid from his left naris and frequent sinusitis. Eleven years earlier, he had been struck in the forehead by an object falling from the sky., MATERIALS AND METHODS: Neurologic examination revealed decreased sensation in V1 and V2 on the left side. Imaging revealed a large bullet lodged in the left maxillary sinus., FINDINGS: The bullet was removed via sublabial incision and opening of the anterior bony wall of the maxillary sinus., CONCLUSIONS: In Afghanistan, indirect gunshot wounds to the head are not uncommon because of the constant war conditions since the invasion by the former Soviet Union in 1979 and the tradition of firing rounds into the air during cultural celebrations.

4422. Rahamimov, N., et al. (2010). "Cerebrospinal fluid leakage and pneumocephalus secondary to spine stab wounds." Journal of orthopaedics and traumatology : official journal of the Italian Society of Orthopaedics and Traumatology **11**(1): 57-59.

Cerebro-spinal fluid leakage from a spinal stab wound is rare, and usually not a life-threatening injury. Pneumocephalus, a possible rare complication of traumatic cerebro-spinal fluid leakage, can potentially lead to intracranial hemorrhage and death. We describe two cases of spinal stab wounds complicated by cerebro-spinal fluid leakage, one of them developing into severe pneumocephalus. Both patients recovered completely with the following treatment protocol: (a) trendelenburg positioning of the patient, (b) insertion of a continuous-drainage cerebro-spinal fluid catheter into the lumbar thecal sac, (c) primary suture of the leaking skin wound, (d) IV antibiotic therapy.

4423. Rahimi, R., et al. (2015). "A fire death with a rare finding: anthracosis or soot embolism?" The Malaysian journal of pathology **37**(1): 57-61.

Charred human remains were found in the smoking ambers of a dying fire in an oil palm plantation in Selangor, Malaysia in the midnight of January 28, 2013. Investigations showed that palm fronds and rubber tires were used to light and sustain the blaze. At least four to five tires were estimated to be used based on the residual burnt metal wires at the site. The remains were brought to the Department of Forensic Medicine, Hospital Sungai Buloh, Selangor for post-mortem examination. Pre-autopsy imaging showed a fractured skull with presence of a bullet in the head. The body belonged to a male with unrecognizable facial features, pugilistic attitude, and reduced body size caused by fire damage with sparing of the posterior surface. A large fracture was present at the skull vault. An entry gunshot wound was observed on the left side of the body of mandible, which was associated with base of skull fracture. Heat-related fractures were also noted on the right side of the frontal bone. A projectile was retrieved from the right side of the occipital lobe. Further examination showed presence of soot and hyperaemic larynx, trachea, main bronchi, and oesophagus. Black spots measuring 1 to 2 mm were present on the surface and parenchyma of the heart, liver, pancreas and kidneys. Histopathology examination showed black particles within the vessels in the affected organs. We report this rare finding in a charred body and present a discussion based on published literature on this issue.

4424. Rahimi-Movaghar, V., et al. (2013). "Lessons learned from war: a comprehensive review of the published experiences of the Iranian neurosurgeons during the Iraq-Iran conflict and review of the related literature." World neurosurgery **79**(2): 346-358.

BACKGROUND: This study sought to review the articles published by Iranian neurosurgeons regarding their experiences during the Iraq-Iran conflict and compare them with reports from other conflicts., METHODS: We searched databases (MEDLINE and 2 Iranian databases, namely IranMedex and Scientific Information Database, up to December 2011) and references for relevant studies. The search terms included Iran, Iraq, conflict, battle, war, traumatic aneurysm (TA), posttraumatic epilepsy (PTE), brain infection, penetrating head wound (PHW), cerebrospinal fluid (CSF) leakage, spine injury, and peripheral nerve injury., RESULTS: Twenty-eight articles were found that presented PHW, development

of TA, infections, PTE, and peripheral nerve injuries. There were 2 different protocols for management of PHWs: radical surgery and minimal debridement protocol. The overall central nervous system infection rate was 10%. The cumulated incidence of TA was 6%., CONCLUSIONS: Conservative minimal debridement of the wounds is indicated in patients with small entrance wounds, or those with Glasgow Coma Scale score >= 8 and no progressive neurological deficit. To diagnose TA before rupture, angiography is indicated in patients who have shells or bone fragments pass through the crowded vasculature, or have large/delayed hematoma, or if the surgeon has high index of suspicion based on neuroimaging and early debridement surgery. Surgery in a well-equipped nearby hospital after quick and safe evacuation of the victims by trained salvaging ancillary groups and the administration of broad-spectrum antibiotics and proper antiepileptics decrease the morbidity and mortality of casualties after PHW in war situations. The biases of the case selection, data collection, and confounders, and decreasing biases by conducting blinded controlled clinical trials, are discussed.

4425. Rahimizadeh, A. (2019). "Intracranial Migration of a Broken Rod After Orbitocranial Injury in an Adult." World neurosurgery **121**: 232-238.

BACKGROUND: Craniocerebral injuries due to the induction of sharp objects are relatively rare and are nearly always observed in the pediatric rather than the adult population. Orbitocranial injuries involving a piece of smooth steel rod are extremely rare and to our knowledge have yet to be reported in previous publications. When this particular category of injury does occur, the invading intracranial foreign body usually remains lodged within its entry position. This is most often near the entry point and within the frontal lobe after penetrating the orbit. Migration of the penetrating object far from the initial entry point is quite rare and has been historically confined to low-velocity bullet wounds., CASE DESCRIPTION: An adult man was injured on the right eyelid by a section of steel rod. The rod had entered the cranium through the right orbital roof and was lodged within the corresponding right frontal lobe. An initial plain radiograph showed that the rod was within the right frontal lobe. However, computed tomographic angiography of the brain performed during the second day of admission demonstrated displacement of the rod to the left hemisphere. This finding was clearly demonstrated through subsequent imaging. As a result of the migration, the rod could be distracted fairly easily through a left parasagittal and interhemispheric approach. Postoperatively, the patient made a full recovery., CONCLUSIONS: Migration of traumatically introduced intracranial foreign bodies far from their initial entry places should be suspected in objects possessing sufficient weight and a smooth surface. This means that a correct assessment of the final position of such objects is necessary before surgery, even while the patient is on the operating table.

4426. Rahimizadeh, A., et al. (1987). "Traumatic cerebral aneurysms caused by shell fragments. Report of four cases and review of the literature." Acta neurochirurgica **84**(3-4): 93-98.

Traumatic aneurysms of the cerebral arteries of penetrating origin are rare but a well recognized entity and their development in military practice have not been adequately discribed. In the review of the literature we encountered only 24 cases of traumatic aneurysms after penetrating brain wounds. In view of their rarity, we are adding four new cases. The need for routine angiography in the evaluation of the vascular state in penetrating brain wounds as well as the necessity of their prompt surgical intervention is emphasized.

4427. Rahman, N. U., et al. (1997). "Orbito-cranial injury caused by penetrating metallic foreign bodies: report of two cases." International ophthalmology **21**(1): 13-17.

Two cases of orbito-cranial injury caused by foreign bodies (FBs) penetrating the lateral wall and roof of the orbit are described. In the first patient, a long rusted nail acted as a missile and was only detected by X-rays and CT scan. The nail penetrated the orbit, the eyeball, the lateral orbital wall, and the temporal lobe of the brain. Lodged partly in the orbit and partly in the brain, this nail caused leakage of cerebrospinal fluid (CSF) through eye and led to orbital cellulitis and localized meningitis. The foreign body (FB) was removed through an extradural pterional approach with rapid resolution of orbital cellulitis and meningitis. In the second patient, large metallic FB, having penetrated the orbital roof was lodged intracranially above the chiasma. This was removed via frontal craniotomy. Mechanism of such injuries and appropriate surgical approaches are described as well.

4428. Rahmat, H., et al. (1984). "Pulsating unilateral exophthalmos due to traumatic aneurysm of the intraorbital ophthalmic artery. Case report." Journal of neurosurgery **60**(3): 630-632.

A case of pulsating unilateral exophthalmos is presented. It was caused by a traumatic aneurysm of the intraorbital ophthalmic artery, secondary to missile injury. Evolution of the aneurysm was observed clinically, by angiography, and by computerized tomography. The differential diagnosis of pulsating exophthalmos and the pathogenesis of such aneurysms are briefly discussed.

4429. Rahmathulla, G., et al. (2022). "PENETRATING BRAIN INJURIES - EVALUATION OF PATIENT OUTCOMES AND A CARE ALGORITHM FROM A LEVEL 1 TRAUMA CENTER." Journal of neurotrauma **39**(11-12): A42-A43.

Penetrating Brain injuries are less prevalent than closed head injury but carry a worse prognosis. Management of these complex injuries continues to present controversies and challenges as outcomes are variable and there are no specific recommendations to guide practice. Material & methods: At our institution , University of Florida, Jacksonville , a level 1 trauma center , we performed an IRB approved retrospective study of patients with penetrating head trauma treated since 2013. Data from 139 patients was collected. The type of penetrating injury, correlation with radiological findings, neurological presentation at admission and long term outcome are discussed Results: 139 patients have been brought to the emergency department at UF Health Jacksonville after suffering penetrating brain injuries (PBIs). Mean age at presentation was 31.3 years (4 - 95) with male (n = 109) and females (n = 30). Outcomes are correlated with degree of injury and GCS at presentation with a possible scoring system to enable determination of outcomes and survival Conclusion: penetrating brain injury patients have to be treated individually as one size does not fit all patients. A majority of these patients are young male and can benefit from surgical intervention and intensive management resulting in satisfactory to good outcomes.

4430. Rahmatullah, M. I., et al. (2021). "Unintentional penetrating brain injuries caused by air rifles in teenagers: Two case report." Interdisciplinary Neurosurgery: Advanced Techniques and Case Management **25**.

Pellet guns are non-powder guns but their related injuries have been reported worldwide. They represent a significant cause of injury especially among children and teenagers. We present two cases of non-powder firearms. First case was a 13-year old male with a chief complaint of headache following gunshot accident towards his head. The bullet's entry point was from the buccal region, going upwards fracturing the orbital roof, hitting the inner table of the frontal skull and ricocheted towards the parietal region. Second case was a 14-year old male who presented with cerebrospinal leakage, pulsating at the bullet's entry point in the frontal area. Despite several opinions existed for these type of injuries, aggressive management for surgical extraction of the foreign body is the largely accepted treatment. The leaded bullet had to be extracted to avoid future damage from the metal's known neurotoxicity. Often under-appreciated, we found difficulties in our experience for increasing the understanding and awareness for potentially fatal outcome regarding the gunshot wound brain injury. This obstacle often hinders the patient of consenting to surgical intervention in our population.

4431. Rahpeyma, A. and S. Khajehahmadi (2016). "Nasolabial flap in maxillofacial gunshot trauma: A case series." Archives of Trauma Research **5**(1).

Introduction: The nasolabial flap (NLF) has many advantages in oromaxillary reconstruction, but the majority of cases are reconstructions after pathologic resections. Its usage in trauma surgery, especially in the management of gunshot wounds, is rarely mentioned. Case Presentation: Three cases involving gunshot injuries to the face are presented: one for reconstruction of the nasal ala, another for bone graft coverage in mandibular reconstruction, and the third for the repair of premaxillary hard and soft tissue avulsive defects. Conclusions: The NLF is a thin, pliable flap and is useful for intraoral and facial reconstruction of trauma patients with small to moderate soft tissue loss.

4432. Rahpeyma, A. and S. Khajehahmadi (2018). "Reconstruction of lateral mandibular defects with soft tissue loss: The role of the submental flap." Iranian Journal of Otorhinolaryngology **30**(4): 203-207.

Introduction: Mandibular continuity defects after pathologic resections or traumatic events are difficult cases for reconstruction. Defects involving both hard and soft tissue loss are more challenging, because of problems in soft tissue coverage. The role of the submental flap in this regard is presented. Materials and Methods: In a retrospective study

from the archived files of Ghaem Hospital, Mashhad, Iran between 2007-2016, lateral mandibular defects that were managed with submental flap for soft tissue coverage were selected. Results: Ten patients had been treated, of whom four cases were due to trauma/gunshot events and six cases were defined as pathologic resection; five patients with malignant lesions and one with benign intraosseous pathology, but with soft tissue invasion. There was one complication overall, concerning orocutaneous fistula formation. Conclusion: Submental flap is indicated for coverage of the reconstruction plate when the lateral mandible is resected/avulsed with soft tissue loss limited to the oral cavity or due to through and through defects in the lower third of the face.

4433. Rai, A., et al. (2012). "Comparative assessment between eyelet wiring and direct interdental wiring for achieving intermaxillary fixation: a prospective randomized clinical study." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **70**(8): 1914-1917.

PURPOSE: The intention of this study was to compare the efficacy of eyelet wiring and direct interdental (Gilmer) wiring for achieving intermaxillary fixation (IMF)., MATERIALS AND METHODS: This study was a prospective randomized clinical trial. The study sample was derived from the population of patients who underwent IMF at the Department of Oral and Maxillofacial Surgery, Sharad Pawar Dental College, Wardha, India, between October 2008 and September 2010. The time required for placement and removal (in minutes) was compared between the eyelet wiring and direct interdental wiring techniques. Postoperative stability after achieving IMF was analyzed in the 2 groups. The plaque accumulation in both groups was evaluated using the Turesky-Gilmore-Glickman modification of the Quigley-Hein plaque index. Complications in the form of soft tissue injury, glove puncture, and trauma to the operator's finger were also recorded. Statistical analysis was performed with SPSS statistical software for Windows, version 8.0 (SPSS, Chicago, IL) using the chi(2) test and Student t test., RESULTS: The mean working time for placement and removal of eyelet wiring (group I) was 18.00 minutes and 9.67 minutes, respectively. For direct interdental wiring (group II), it was 30.50 minutes and 23.12 minutes, respectively. The mean plaque index values were 1.78 and 2.54 for groups I and II, respectively, which signifies a higher plaque deposition in group II. No occlusal disturbance was seen in either group. The incidences of glove perforation, soft tissue trauma, and trauma to the operator's finger were higher in group II., CONCLUSIONS: Eyelet wiring is preferable to direct interdental wiring as evidenced by fewer complications, and requires a shorter operating time in patients with minimally displaced fractures.

4434. Rai, J. K., et al. (2013). "Embolization in post-traumatic vascular injury in head and neck region." Cardiovascular and interventional radiology **36**: S284.

Background: Head and neck injuries are most commonly secondary to road traffic accidents; however, they are also associated with penetrating injuries and surgery. Interventional therapy for head and neck trauma could be embolization or stent grafting (e.g., carotid blow out) Embolization could be performed with coils/particles/liquid agents depending on the lesion. Clinical Findings/Procedure: Twenty-four patients who presented with active bleeding in the head and neck region following trauma were studied. All patients underwent digital subtraction angiography of the internal/external carotid system and/or vertebral arteries. The culprit vessels were embolized after studying the collateral supply. Microcatheters are used whenever a distal single vessel is the culprit or external and internal carotid artery communication is seen. Coils are not preferred in external carotid artery bleeders because extensive collateralization may cause re-bleeding. Further, in ECA territory bleeding, particle embolization of bilateral vessels may sometimes be required. Period of study: 20 years; total number of cases: 24; etiology: noniatrogenic trauma, 19; iatrogenic, 5; post-tonsillectomy, 2; post-maxillary surgery, 1; post-CA tongue radical dissection, 1; dental extraction in a polycythemic patient, 1. Embolization material used: particles, 16; coils, 4; coils and glue, 1; coils and particles, 3; technical success, 100%. Complications: 1 patient had a puncture site complication (hematoma), 5 patients had transient neck pain. Conclusion: Exploratory angiography and therapeutic embolization is an excellent modality in the treatment of post-traumatic vascular injuries of the head and neck.

4435. Rai, K. M., et al. (2004). "Treatment of casualties in a forward hospital of Indian Army: Nine year experience." Medical Journal Armed Forces India **60**(1): 20-24.

Background: To analyze the outcome of the management of casualties in a level II trauma centre of a forward hospital of Armed Forces over a nine year period. Retrospective analysis of all casualties received in a single forward

hospital of Indian Army was carried out. Method: During 9 years (1990-1998), a total of 5737 casualties were received in a single level II zonal hospital of the Army in a forward area. Majority of the injuries were caused by bullets, or by fragments of improvised explosive devices. A policy of aggressive resuscitation and early primary repair of injuries was followed. General surgeons routinely performed craniotomies, thoracotomies, laparotomies, stabilization of fractures by fixators and repair of vascular injuries. Result: 38% of patients had injuries to several body parts (polytrauma), resulting in a total of 8578 injuries. Region-wise distribution of injuries was as follows : 14.2% head and neck injuries, 13.3% chest wounds, 13.5% abdominal injury and 59% extremity wounds. The overall mortality rate was 3.6%. The complication rate was about 7% with infection as the major complication. The results of primary repair of colonic injuries were similar to those of staged repairs. The results after primary closure of war wounds were better than those treated with delayed primary closure in selected cases. Conclusion: Prompt evacuation, speedy resuscitation and early definitive repair of war injuries results in low mortality and morbidity. A motivated and dedicated team and adequate availability of blood and ancillary services adds to the excellent outcome. The policy of primary repair of colonic and selected soft tissue injuries appears justified in selected cases.

4436. Raimondi, A. J. and G. H. Samuelson (1970). "Craniocerebral gunshot wounds in civilian practice." Journal of neurosurgery **32**(6): 647-653.

4437. Rainov, N. G. and W. L. Burkert (1994). "An unusual suicide attempt using a circular saw." International journal of legal medicine **106**(4): 223-224.

The case of a suicide attempt of a depressed male using a circular saw is reported and discussed. There was a hesitation injury that is seldom described in this type of power tool suicide. A deviation in the position of the superior sagittal sinus allowed the life of the victim to be saved by a neurosurgical operation.

4438. Raiteb, M., et al. (2021). "Neglected ballistic trauma of the face in a young subject: A case report." Annals of medicine and surgery (2012) **70**: 102852.

Injuries by ballistic projectiles concern nowadays more and more frequently civilian populations. If the vital prognosis is rarely put at risk, the functional after-effects are frequent and important. The management of these injuries follows specific rules that must be known because they are sometimes different from the usual traumatology. However, it is important for any surgeon to understand the basic principles of ballistic injury. Indeed, the knowledge of the trajectory of the bullet and its final location allows to consider the potential injuries and to evaluate the management of the patient. CT is the examination of choice for penetrating foreign bodies, allowing for viewing of the entry site, bullet trajectory, possible scattered fragments, and, most importantly, a possible skull base breach, as well as providing useful information for planning the surgical procedure and, generally, for prognosis. The primary surgery must ensure an early and rigorous trimming associated with antibiotic therapy because the quality of the initial trimming significantly influences the final result, so this approach to the removal of the foreign body depends on its size, its anatomical location, the structures involved and the preference of the surgeon.

4439. Ralph, J. K. and T. Lowes (2009). "Neurointensive care." Journal of the Royal Army Medical Corps **155**(2): 147-151.

The majority of neurological admissions to military Intensive Care will be for Traumatic Brain Injury (TBI). These injuries will be either penetrating from fragmentation or missiles or blunt due to blast or impact. Intensive Care management of TBI is focused on the prevention of secondary brain injury due to insults such as hypoxia, hypotension and low Cerebral Perfusion Pressure. This management is based largely on comprehensive evidence based guidelines produced by the Brain Trauma Foundation. The most significant dilemma faced by UK military intensivists is whether we should be measuring Intracranial Pressure in patient with severe TBI in the deployed setting; and if so what technique should be used.

4440. Ram, E., et al. (2019). "Improved long-term outcomes after heart transplantation utilizing donors with a traumatic mode of brain death." Journal of cardiothoracic surgery **14**(1): 138.

BACKGROUND: The donor's mode of brain death (BD), being associated with impairment of myocardial function and hemodynamic performance, impacts the prognosis of the heart transplantation (HTx) recipient., METHODS: All patients who underwent HTx between 1996 and 2017 were categorized according to donor's BD mechanism: traumatic BD (TBD) versus non-traumatic BD (NTBD)., RESULTS: The TBD group included 105 recipients, and the NTBD group, 85 recipients. Kaplan-Meier survival analysis showed that overall survival was significantly higher for recipients of TBD hearts (10-year survival 58.1 vs. 37.6%, p = 0.044). Consistently, multivariate analysis showed that TBD was independently associated with a significant 43% reduction in mortality [95% confidence interval (CI) 0.42-0.75, p = 0.033]. Rejection rate was lower in the TBD group (total rejection score 0.44 +/- 0.32 vs. 0.51 +/- 0.38, p = 0.04; any rejection score 0.38 +/- 0.26 vs. 0.45 +/- 0.31, p = 0.030), and freedom from cardiac allograft vasculopathy (CAV) was significantly higher in recipients of traumatic vs. non-traumatic donors (10 years: 82.9 vs. 62.4%, log-rank p-value = 0.024). Multivariate analysis showed a significant 42% reduction in CAV [hazard ratio (HR) = 0.58, 95% CI 0.51-0.85, p = 0.022)., CONCLUSION: Mode of brain death significantly impacts HTx outcomes, with TBD being associated with reduced mortality, rejections and CAV.

4441. Ramasamy, A., et al. (2009). "Penetrating missile injuries during the Iraqi insurgency." Annals of the Royal College of Surgeons of England **91**(7): 551-558.

INTRODUCTION: Since the invasion of Iraq in 2003, the conflict has evolved from asymmetric warfare to a counter-insurgency operation. This study investigates the pattern of wounding and types of injuries seen in casualties of hostile action presenting to a British military field hospital during the present conflict., PATIENTS AND METHODS: Data were prospectively collected on 100 consecutive patients either injured or killed from hostile action from January 2006 who presented to the sole coalition field hospital in southern Iraq., RESULTS: Eighty-two casualties presented with penetrating missile injuries from hostile action. Three subsequently died of wounds (3.7%). Forty-six (56.1%) casualties had their initial surgery performed by British military surgeons. Twenty casualties (24.4%) sustained gunshot wounds, 62 (75.6%) suffered injuries from fragmentation weapons. These 82 casualties were injured in 55 incidents (mean, 1.49 casualties; range 1-6 casualties) and sustained a total 236 wounds (mean, 2.88 wounds) affecting a mean 2.4 body regions per patient. Improvised explosive devices were responsible for a mean 2.31 casualties (range, 1-4 casualties) per incident., CONCLUSIONS: The current insurgency in Iraq illustrates the likely evolution of modern, low-intensity, urban conflict. Improvised explosive devices employed against both military and civilian targets have become a major cause of injury. With the current global threat from terrorist bombings, both military and civilian surgeons should be aware of the spectrum and emergent management of the injuries caused by these weapons.

4442. Rambo, W. M. and R. K. Simpson (1993). "Carotid-cavernous sinus fistula complicating shotgun injuries to the head." Neurochirurgia **36**(3): 96-100.

Two cases of carotid artery injury due to shotgun blast are presented, one of which resulted in a carotid-cavernous sinus fistula. The diagnosis, natural history, and treatment of this condition is discussed, with emphasis on patient management.

4443. Ramirez-Ferrer, E., et al. (2022). "Cerebrospinal fluid leak following penetrating trauma to the spine without neurological deficit: A case report." Surgical neurology international **13**.

Background: Posttraumatic spinal cerebrospinal fluid leak (CSFL) without neurological deficit is a rare entity. Historically, the first-line treatment is a nonsurgical approach, which includes Trendelenburg positioning, carbonic anhydrase inhibitor (acetazolamide), and subarachnoid catheter, with a high successful rate of leak correction. However, in some cases, this first-line treatment could fail, being necessary the surgical approach. Case Description: A 23-year-old male with a recent stab wound to his lumbar region, complained of positional headache and fluid outflow through his wound. On physical examination, an active CSFL was detected without evidence of neurologic deficit. Imaging studies showed a CSF collection extending from the right L4 lamina to the subcutaneous tissue. CSF studies revealed bacterial meningitis. The treatment with carbonic anhydrase inhibitors, Trendelenburg position, lumbar subarachnoid catheter, and antibiotics was initiated. Failure of conservative measures prompted a surgical treatment to resolve the CSFL. Intraoperatively, a dura mater defect was identified, and an autologous paravertebral muscle flap was used for water-tight closure of the defect. The patient recovered without further complications and with CSFL resolution. Conclusion: Even though the nonsurgical approach is the first-line of treatment of traumatic CSFL cases, failures can occur. The

evidence of a CSF trajectory in imaging studies could be a predictor of treatment failure of the nonsurgical treatment. The surgical treatment as second-line treatment has outstanding results regarding CSFL correction and should be considered when the prediction rate to nonsurgical approach failure is high.

4444. Rammo, R. A., et al. (2012). "Management of migrating intracranial bullets: lessons learned from surviving an AK-47 bullet through the lateral brainstem." World neurosurgery **77**(3-4): 591.e519-524.

OBJECTIVE: Survival after a gunshot wound (GSW) to the head is becoming more common, with an accompanying increase in spontaneous migration of these intracranial bullet fragments. This phenomenon is well described in current literature and is a potentially life-threatening delayed complication of GSW to the head., METHODS: We present the case of a 17-year-old boy who survived a penetrating GSW to the cranium and cerebellum after an accident involving an AK (Automatic Kalashnikov)-47 (7.62 mm)., RESULTS: Following initial attempts to remove the bullet and associated hematoma from the cerebellar hemisphere, intraoperative fluoroscopy revealed that the bullet had migrated to lie within the right middle cerebellar peduncle with the development of intraoperative cardiac arrhythmia. The bullet could not be retrieved without risk of damage to the superior and inferior cerebellar arteries. The patient then developed bacterial meningitis, and further imaging revealed the bullet had again migrated under the cerebellar cortex to an accessible location. The infection was treated with aggressive antibiotic therapy and the bullet was removed from the posterior fossa, thus preventing recurrence of infection and further migration. The patient regained full motor, speech, and proprioceptive function within months after injury., CONCLUSION: The potential for spontaneous migration exists with any penetrating brain injury involving a retained foreign body. When a retained intracranial foreign body is unable to be safely extracted during initial debridement, close clinical evaluation is essential and plain-film or computed tomographic imaging should be considered in order to enhance the early detection of delayed-onset life-threatening deterioration, such as meningitis and occlusion of cerebrospinal fluid drainage, because of spontaneous migration.

4445. Ramneesh, G., et al. (2014). "A retrospective audit of hundred patients of orbitozygomatic fractures with brain injury." Journal of Clinical and Diagnostic Research **8**(7): NC04-NC06.

Background: Orbitozygomatic fracture that most commonly accompanies craniofacial injury is a challenge for medical science to reduce complications and to attain aesthetically satisfying results. Objective: To summarize our experiences with the optimum management of orbito-zygomatic fractures Materials and Methods: This retrospective study was aimed at investigating indications and surgical approaches for orbito-zygomatic fractures with clinical follow-up, particularly with regard to postoperative complications. Since 2010, 100 cases with facio-maxillary injury were assessed for Orbitozygomatic fractures with the help of physical examination, non-invasive investigations including computed tomography of the orbit. Patients were retrospectively analysed for data, such as mechanism of injury, classification of fracture, and complications. Results: Amongst 100 consecutive patients with orbito-zygomatic fractures an overwhelming majority were males (n=83). In the age distribution a great majority (45%) were in 30-45 years age group, followed by 15-30 years (22%) and 45-60 years (18%). So in the productive age group i.e. 15-60 years age group were affected mostly (85%) in our series. Among different injury mechanism, Road traffic accident affected most (69%) that landed up in orbito-zygomatic fractures followed by altercations (22%). We preferred Open reduction and internal fixation (ORIF) for 68% of the patients with orbito- zygomatic fractures, followed by closed reduction (12%). Conclusion: Ophthalmology consultation is recommended for all patients presenting with orbitozygomatic fractures, and is essential for patients with orbital blowout fractures, based on the high incidence of clinical ocular findings and injuries in this subgroup of patients.

4446. Ramos, J. G., et al. (2013). "Craniocerebral gunshot wounds in pediatric population." Child's Nervous System **29**(9): 1776.

Objective: There has been an increase in civilian gun violence since the last decade, with a disproportionately high increase occurring the pediatric population. The objective of this study is to describe and analyze a series of pediatric patients who underwent surgery for craniocerebral gunshot wounds. Material and method: The study is a retrospective review of the clinical charts of patients with cranial gunshot injuries at Hospital de Pediatria “Prof Dr Juan P Garrahan”. Neurological and radiological findings were studied as well as the outcome of the patients. Results: Fifty one patients were admitted and 48 were operated on always with general anesthesia.Mean age of the children was 7

years. Thirty five patients were male and sixteen female. Thirteen children sustained transhemipheric injuries, thirteen extradural injuries, 11 tangential injuries, 6 bihemipheric injuries and 4 transventricular injuries, 2 posterior fossa injuries. Child's age or gender, the mode of injury and the presence of extracerebral injuries were not found to be significantly associated with deaths. Mortality rate was 21% with a mean follow-up of 48 months. Conclusion: The pediatric population tends to demonstrate more favorable outcomes following intracranial gunshot injury when compared with the adult population. We conclude that almost all cranial gunshot patients should initially receive aggressive surgical therapy with a previous CT scan.

4447. Ramos P, J. P., et al. (2021). "First trauma registry in Chile. 2 years analysis in a public hospital." Revista de Cirugia **73**(1): 59-65.

Introduction: Trauma represents a real challenge for health systems because is a major public health problem. In Chile, the management of polytrauma patients is unknown. Aim: Describe the results of the first online trauma registry; in patients treated at the Dr. Sótero del Río Hospital during the first two years of implementation. Materials and Method: Prospective information is collected in a network registry, about trauma victims, admitted to Dr. Sótero del Río Hospital for two years. These variables involve the entire clinical care process from admission to discharge or death. Results: 3.515 admissions of trauma victims are registered in two years. Among these, 81.3% are men. 27% suffered penetrating trauma and 59% closed. They emphasize larger injuries by firearm than by bladed weapon. 18.4% of admitted patients have ISS greater than 15 points. 34 patients enter cardio-respiratory arrest and 7.3% make it hypotensive. 1,856 CT scans are performed and 54.4% require emergency surgery. They admitted 692 thoracic trauma, 654 abdominal, 1550 limb, 687 skull injuries and 190 cervical trauma. The massive transfusion protocol is activated at 3.1% of the admissions. 8.3% use the critical patient unit and mortality is 2.9%, with cranial brain trauma as the first cause and hemorrhagic shock as a second cause. Conclusions: Our hospital has a high incidence of trauma. The RT implementation allows us to know the dimension and assess the care process about the trauma patient. It is necessary to direct resources and implement training in high-volume trauma centers, as well as continuing with the extension of the tool as a multi-center monitoring strategy.

4448. Ramos, R., et al. (2017). "Penetrating head trauma injury with an excellent outcome." BMJ case reports **2017**.

4449. Ran, Y., et al. (2010). "Anatomic distribution of bullet head injuries in combat fatalities." The Journal of trauma **69**(3): 541-543.

BACKGROUND: Gun-shot wound head injury comprises a substantial fraction of combat injuries and a major cause of death in the battlefield. Current shielding gear is totally ineffective against bullets, because bullet-proof materials are too heavy to be worn on the head. The aim of this work was to describe the anatomic distribution of bullet entry wounds to the head in combat fatalities and to discern whether distribution is random (null hypothesis) or not., METHODS: We retrospectively examined the forensic external examination reports of all Israeli Defense Forces combat fatalities during the years 2000 to 2004, the Second Lebanon War (2006), and Operation Cast Lead (2009) and mapped the exact anatomic location of all bullet entry wounds to the calvaria., RESULTS: We found 76 gun-shot entry wounds to the heads of 49 fatalities. Among these wounds, the occipital and anterior-temporal regions were found to be hit significantly more often than expected compared with their relative surface area ($p < 0.001$ and $p < 0.001$, respectively). Fifty-five percent of all injuries occurred within 15% of the surface area of skull., CONCLUSIONS: These findings imply that gun-shot entry wounds to the head are unevenly distributed. A partially bullet-proof protective helmet may prevent a substantial fraction of injuries (and fatalities) without a significant weight addition to the helmet.

4450. Rana, M., et al. (2014). "Management of comminuted but continuous mandible defects after gunshot injuries." Injury **45**(1): 206-211.

INTRODUCTION: Firearm injuries continue as a major public health problem, contributing significant morbidity, mortality, and expense to our society. There are four main steps in the management of patients with gunshot wounds to the face: securing an airway, controlling haemorrhage, identifying other injuries and definitive repair of the traumatic facial deformities. The objective of this study was to determine late outcome of two treatment options by open reduction and internal fixation versus closed reduction and maxillomandibular fixation (MMF) in the treatment of

gunshot injuries of the mandible., METHODS: Sixty patients of gunshot injury were randomly allocated in two groups. In group A, 30 patients were treated by open reduction and internal fixation and in group B, 30 patients were treated by closed reduction and maxillomandibular fixation. Patients were discharged as the treatment completed and recalled for follow up. Up to 3 months after injury, fortnightly complications like infection, malocclusion, malunion of fractured fragments, facial asymmetry, sequestration of bone and exposed plates were evaluated and the differences between two groups were assessed. The follow-up period ranged from 3 months to 10 months., RESULTS: Patients treated by open reduction tended to have less complications as compared to closed reduction., CONCLUSION: Based on this study open reduction and internal fixation is the best available method for the treatment of gunshot mandible fractures without continuity defect.

4451. Rana, M., et al. (2014). "Management of comminuted but continuous mandible defects after gunshot injuries." Injury **45**(1): 206.

INTRODUCTION: Firearm injuries continue as a major public health problem, contributing significant morbidity, mortality, and expense to our society. There are four main steps in the management of patients with gunshot wounds to the face: securing an airway, controlling haemorrhage, identifying other injuries and definitive repair of the traumatic facial deformities. The objective of this study was to determine late outcome of two treatment options by open reduction and internal fixation versus closed reduction and maxillomandibular fixation (MMF) in the treatment of gunshot injuries of the mandible., METHODS: Sixty patients of gunshot injury were randomly allocated in two groups. In group A, 30 patients were treated by open reduction and internal fixation and in group B, 30 patients were treated by closed reduction and maxillomandibular fixation. Patients were discharged as the treatment completed and recalled for follow up. Up to 3 months after injury, fortnightly complications like infection, malocclusion, malunion of fractured fragments, facial asymmetry, sequestration of bone and exposed plates were evaluated and the differences between two groups were assessed. The follow-up period ranged from 3 months to 10 months., RESULTS: Patients treated by open reduction tended to have less complications as compared to closed reduction., CONCLUSION: Based on this study open reduction and internal fixation is the best available method for the treatment of gunshot mandible fractures without continuity defect.

4452. Rana, T. M., et al. (2016). "Pneumocephalus and neurologic deficit due to neck stabwound in a twenty nine-year-old man." Razavi International Journal of Medicine **4**(4).

Introduction: The presence of air within the intracranial cavity, due to the entry of air secondary to an abnormal communication after a dural tear, is defined as pneumocephalus and intraventricular pneumocephalus also known as pneumoventricle. Obviously, common etiologies of pneumocephalus are head injury and cranial surgery. Also, less common non-traumatic causes of pneumocephalus are neoplasm or from a gas-forming organism infection. Although pneumocephalus after spinal penetrating injuries is rare,it was reported. The object of this report is to describe the case of patient with pneumoventricle after neck spinal stab wound. Case Presentation: A 29-year-old man presented to ED with complaint of two stab wounds, one of them was located at the right back chest and the other at the midline neck. Because of the respiratory distress and decreased breath sounds, after taking a chest X-ray, we realized hemothorax in right hemithorax and placed the chest tube in ED. In addition, in requested neck CT scan, there was a defuse air in neck spine that spread to his brain. Furthermore, neurologic examination showed weakness in left leg motor function and loss of pain and temperature sensation in the other leg, which was based on brown-sequard syndrome. Mentioned patient admitted in neurosurgery department for further follow-up. Conclusions: Pneumoventricle is rare but it can be established after spinal trauma. By awareness of such possibility, accurate diagnosis by clinical examination and imaging is essential for these types of injuries.

4453. Randhawa, G. (1998). "Procuring organs for transplantation -- a European perspective." European journal of public health **8**(4): 299-304.

4454. Rangaraju, S., et al. (2017). "Preclinical and clinical efficacy of entrectinib in primary and metastatic brain tumors harboring NTRK, ROS1, or ALK gene fusions." Neuro-Oncology **19**: iii106.

Targeted therapies that effectively cross the blood-brain barrier to treat primary and metastatic brain tumors represent a critical unmet medical need in neuro-oncology. NTRK, ROS1, and ALK gene fusions are seen in over 40 primary solid tumor histologies, many of which may be complicated by brain metastases. An inhibitor with demonstrated brain tumor efficacy could be beneficial for these patient populations. Entrectinib (RXDX-101), an orally available, selective and potent kinase inhibitor of TRK, ROS1, and ALK, is specifically designed to cross the blood-brain barrier and is being developed in part to address this need. STARTRK-2 (Studies of Tumor Alterations Responsive to Targeting Receptor Kinases-2) (NCT02568267) is an open-label, multi-center, global phase 2 pivotal basket study of oral entrectinib in adult patients with locally advanced or metastatic solid tumors, including primary and secondary brain lesions, harboring a gene fusion in NTRK, ROS1, or ALK. While NTRK, ROS1, or ALK gene fusions are rare in non-small cell lung cancer (NSCLC), colorectal cancer, and primary brain tumors, NTRK fusions are more frequent in rare cancers such as infantile fibrosarcoma, secretory breast cancer and mammary analog secretory carcinoma (MASC) of the salivary gland. We report the activity of entrectinib against metastatic brain lesions in preclinical models and clinical subjects bearing these gene fusions. Entrectinib demonstrated a CNS penetration with a brain/blood ratio of 0.4 in mouse, 0.6-1.0 in rat, and 1.4-2.2 in dog. In a mouse model of intracranial ALK-fusion-driven lung cancer, entrectinib led to a survival benefit of 57 days vs. 34 days ($p < 5x10e-4$), after 10 days of oral treatment. In phase 1 clinical studies of entrectinib, a total of 119 patients have been treated with entrectinib (as of March 7, 2016). In the subpopulation of 24 patients positive for NTRK, ROS1, or ALK gene fusions who were naïve to prior TRK-inhibitor treatment specific for their respective fusion, effective therapeutic dosing of entrectinib resulted in a 79% response rate, with a well-tolerated safety profile. Regression of primary and metastatic brain tumors was demonstrated in 100% of NTRK fusion positive patients with CNS disease (3/3). In an NSCLC patient with SQSTM1-NTRK1 gene fusion, entrectinib treatment led to a rapid and sustained clinical response systemically and in 15-20 secondary brain lesions. In multiple ROS1-rearranged NSCLC patients, entrectinib treatment also resulted in robust regression of metastatic brain lesions. Finally, compassionate use of entrectinib in a young patient with infantile fibrosarcoma harboring an ETV6-NTRK3 fusion led to a confirmed RECIST response of multiple CNS metastases. Together, these data provide compelling evidence to identify patients with primary or metastatic brain tumors harboring NTRK, ROS1, or ALK fusions for enrollment in the STARTRK-2 trial.

4455. Rangeard, O., et al. (2007). "Relationship between procalcitonin values and infection in brain-dead organ donors." Transplantation proceedings **39**(10): 2970-2974.

BACKGROUND AND AIMS: An association between the inflammatory reactions estimated by several biomarkers and organ dysfunction has been reported in brain-dead organ donors (BDOD). Procalcitonin (PCT), a biomarker of inflammation due to bacterial infection, is increased among BDOD. However, is not known whether infection changes PCT values in BDOD., MATERIALS AND METHODS: We retrospectively analyzed 82 BDOD including several demographic and clinical parameters, bacterial culture results, antibiotics prescription, and plasma values of PCT measured before organ harvesting. Infection was diagnosed to be either a positive bacterial culture (restricted definition) and/or prescription of antibiotics (extended definition)., RESULTS: The median PCT value was 1.5 (interquartile range [IQR], 0.4 to 6.9; range, 0 to 526 ng/mL; n=82). Thirty-eight (46%) and 24 (29%) patients had PCT values>2 ng/mL and >5 ng/mL, respectively. Median PCT values among infected (1.18; IQR, 0.27 to 6.55 ng/mL) versus noninfected (1.57; IQR, 0.53 to 7.15 ng/mL) BDOD (restricted definition) were not different (P=.36). The area under the receiver operating characteristic curve using PCT to predict infection (restricted definition) was 0.52. Specificity of PCT to predict infection was above 80% at PCT values>9 ng/mL., CONCLUSION: Our results confirmed PCT values are increased in BDOD, suggesting that this was not related to an infectious cause (whatever definition was used) unless PCT values are high.

4456. Rankow, R. M. and F. V. Mignogna (1978). "Ankylosis of the temporalis-coronoid complex of the mandible." Annals of plastic surgery **1**(3): 280-285.

Ankylosis of the temporalis-coronoid complex is a clinical entity. The etiology is usually direct trauma to the temporalis muscle or coronoid process of the mandible. It is difficult to differentiate diagnostically from ankylosis of the adjacent temporomandibular joint, and should always be considered in the differential diagnosis of inability to open the mouth. The treatment is always surgical and the intraoral approach is favored. The cure rate with this modality of therapy has been gratifying.

4457. Rao, L. P., et al. (2014). "A 'pen' in the neck: an unusual foreign body and an unusual path of entry." Indian journal of dental research : official publication of Indian Society for Dental Research **25**(1): 111-114.

Penetrating injuries to head and neck region with varying objects have been reported in the literature. Majority of these injuries occur in interpersonal violence or bomb blasts or road traffic accidents. Despite the improvement in imaging technologies and surgical methods, penetrating injuries to head and neck with impacted foreign bodies are very challenging due to the proximity to vital structures and/or difficulties in accessing them for the removal. Following injury the normal anatomy could be altered because of edema or tissue destruction, which makes the diagnosis or retrieval more difficult. Parapharyngeal or prevertebral space is an unusual place for lodgment of foreign bodies and in these cases the usual point of entry is the oral cavity, cheek or neck. Here, we report a case of a ball point pen extending to the prevertebral region at the level of C1-C2 vertebrae from point of entry at the suprazygomatic region in the temporal fossa.

4458. Rao, P. M., et al. (1995). "Open extremity fracture penetrating the skull." Emergency radiology **2**(5): 303-304.

We present a case in which an open fracture of the ulna penetrated the skull and caused a comminuted, depressed skull fracture with a large intraparenchymal hematoma containing bone fragments.

4459. Rao, V. J. and C. V. Wetli (1988). "The forensic significance of conjunctival petechiae." The American journal of forensic medicine and pathology **9**(1): 32-34.

Conjunctival petechiae were mentioned in 227 (4.5%) of 5,000 consecutive autopsy reports of the Dade County Medical Examiner Department. They were most frequently observed in those who had died natural deaths (particularly due to cardiovascular disease), followed by those who had died from asphyxia, head injury, and central nervous system disorders. The incidence of conjunctival petechiae in victims of homicidal asphyxiation was 78%. These data suggest that conjunctival petechiae most often are the result of hypoxia coupled with an acute increase in cephalic vascular pressure. The latter factor may be the consequence of mechanical vascular obstruction or acute right heart failure.

4460. Raphael, B., et al. (2010). "[Repair of nose, lips and chin mutilations. The customary repairs versus allografts]." Reparation des mutilations du triangle nasolabio-mentonnier. Plasties conventionnelles versus allogreffes. **55**(4): 267-271.

Central-facial mutilations, located within the nose lips and chin triangle, require great quality repairs regarding morphology and function. Plastic surgery history affords the ideas evolution in this field crossing over nose and lips reconstructions, which were the subject of successive reports within our society, in 1994 (nose reconstruction) and 2002 (lips reconstruction). Now a day, following this progress, the plastic surgeon has a large choice of reliable techniques. His choice is dictated by a precise evaluation of the limits of the substance loss to repair, according to a (mapping) classification of the nose-lip and chin triangle. This classification defines three units (nose-labial, bilabial and chin-labial) as reflexion bases to the therapeutic indications. This anatomical and surgical approach was built starting from a retrospective study of 195 central-facial mutilations caused by ballistic damage and dog bites. The results evaluation makes possible to carry out a reflexion on the potential indications regarding allograft as a therapeutic alternative to the traditional reconstructions of this territory.

4461. Rapkiewicz, A. V., et al. (2014). "Fatal wounds sustained from "falling bullets": maintaining a high index of suspicion in a forensic setting." Journal of forensic sciences **59**(1): 268-270.

Celebratory gunfire injuries from "falling bullets" occur when guns are fired into the air during celebrations without realizing that this can cause serious injuries or even fatalities. Fatal celebratory gunfire injury is an uncommonly reported event in the continental United States. Our electronic database was queried for homicides occurring within days of July 4th and December 31st over a 14-year period. We describe two cases of fatal gunfire injury due to celebratory gunfire occurring during New Year's Eve in Southern Florida. The relevant literature is reviewed. These case reports illustrate that fatal gunfire injuries sustained from "falling bullets" may pose as an unexpected mimic to sudden natural deaths especially in patients with prior medical history. A high index of suspicion to recognize such injury is required particularly during holidays.

4462. Rapoport, B. I., et al. (2014). "Cranial neuropathy due to intradural disc herniation." Neurosurgery **74**(5): E561-565.

BACKGROUND AND IMPORTANCE: Herniated intervertebral disc fragments rarely penetrate the thecal sac, and intracranial hypotension attributable to such penetrating fragments is even more unusual. We describe the first reported case of a cranial neuropathy due to intradural herniation of a disc fragment, in which intracranial hypotension from a resulting cerebrospinal fluid leak caused bilateral abducens palsies., CLINICAL PRESENTATION: A 45-year-old man presented with a positional headache after having experienced a "popping" sensation in his back while lifting a heavy object. He also reported blurred vision and was noted to have lateral gaze palsies bilaterally. Magnetic resonance imaging (MRI) of the brain revealed bilateral subdural collections, abnormal pachymeningeal enhancement, and cerebellar tonsillar herniation, suggesting intracranial hypotension. T2-weighted MRI of the spine revealed extrusion of the T12-L1 disc and suggested the presence of a disc fragment in the intradural space, displacing the caudal nerve roots. A myelogram demonstrated a filling defect extending into the subarachnoid space adjacent to the disc herniation, consistent with a free disc fragment in the intradural space. A diagnosis of intracranial hypotension due to a cerebrospinal fluid leak resulting from an intradural herniated disc was made. The diagnosis was confirmed intraoperatively., CONCLUSION: Surgical removal of the herniated disc fragment and repair of the dural defect resulted in complete resolution of the cranial neuropathy. This rare etiology of a cranial neuropathy, arising from pathology in the thoracolumbar spine, illustrates the clinical teaching that the sixth cranial nerve is highly sensitive to deformation induced by intracranial hypotension.

4463. Rappaport, Z. H., et al. (1984). "Computerized tomography in combat-related craniocerebral penetrating missile injuries." Israel journal of medical sciences **20**(8): 668-671.

Our experience in the use of computerized tomography (CT) in the evaluation and treatment of combat-related penetrating missile injuries of the head in 12 cases is summarized. Advantages observed in the use of CT include accurate delineation of in-driven bony and metallic fragments, the relation of hematomas to the missile tract and detection of brain abscesses. The availability of a CT scanner for use in military medicine may further reduce the mortality and morbidity due to combat-related cranial missile injuries.

4464. Rashid, B. A., et al. (2010). "Analysis of 3794 civilian craniocerebral missile injuries - Results from 20 years of Kashmir conflict." Pan Arab Journal of Neurosurgery **14**(1): 24-32+140.

An analysis of 3794 craniocerebral missile injuries managed, monitored and treated by the Sher-i-Kashmir Institute of Medical Sciences (SKIMS), India, over a period of 20 years from September 1988 - December 2008 was analyzed. It revealed an overall mortality of 88% (3327 out of 3794) and a good survival of 5% (176 out of 3794). Most of the deaths occurred within 30 minutes of the patient's arrival to the hospital and only 694 patients lived beyond one hour of arrival. All patients with an admission Glasgow Coma Scale (GCS) of 3 and the majority of those with 4 died. No deaths occurred in the group of patients with GCS score 9 - 15. Poor and delayed mode of transportation accounted for up to 90% of deaths. Predictors of poor outcome were low admission GCS score, fixed and dilated pupils, poor and delayed mode of transportation, haemodynamic instability, abnormal breathing at admission, coagulopathy and disseminated intravascular coagulation, CT visualisation of subarachnoid haemorrhage, ventricular haemorrhage, midline shift, bihemispheric and multilobar injuries and scalp wounds at occipital, temporal and frontal areas. However, retained missile and bone fragments were less harmful than retained wooden (pulped mulberry stem) and cardboard wads and pneumocephalus in causing infections, cortical atrophy and seizures in the long run.

4465. Rashid, B. A., et al. (2010). "Comparative outcome of non-metallic and metallic craniocerebral missile injuries." Current Neurobiology **1**(2): 151-160.

We ought to sought the comparative outcome related to 694 non-metallic and metallic cra-niocerebral missile injuries who lived at 2 hours and beyond the time of injury in a retrospective and prospective analysis in the Department of Neurosurgery at Sher-I-Kashmir Institute of Medical Sciences (SKIMS) Kashmir, India, over a period of 21 years from September 1988 to March, 2010. The study revealed an overall mortality of 32.70% (227 out of 694). A total of 664 adults and 30 children (mostly teenagers) were studied. The 79.1% (549 out of 694) patients were metallic missile (metal

bullets, grenade, bomb and improvised explosive device (IED) blasts, shrapnels, bolts, splinters and pellets used by shotgun etc) injuries whereas 20.8% (145 out of 694) patients were non-metallic missile injuries. The non-metallic missile injury group mostly (72.4% i.e.; 105 out of 145) had low GCS (Glasgow Coma Scale) score and overall worse prognosis with zero good-recovery, 47.5% disabilities and 52.4% mortality as compared to the metallic missile injury group. The non-metallic group comprised of 60% (18 out of 30) children which resulted in only one death. The metallic missile injury deaths amounted to 21.75% (151 out of 694 patients) and non-metallic missile injuries accounted for 10.95% (76 out of 694 patients) of total deaths. Predictors of poor outcome were low admission GCS score, non-metallic penetrating injury due to tear-gas cartridges, rubber bullets and stone-bullets, perforating metallic missile injuries and delayed and maltransportation. Most complications i.e. 287 complications in only 145 patients, mostly infective were found in non-metallic missile injuries with worst outcome. The common non-metallic missiles used were stone balls (stone-bullets) and spherical glass balls (locally Buanta) fired by Gulail (modified catapult) or slingshot, red rubber bullets, plastic tear gas shells and cartridges, wooden (pulped mulberry stem) and card-board wads used in shotguns (pellet-guns). The stone pelting, throwing stone projectiles (stone-bullets and glass-bullets) by Gulail and manually has become a common way to inflict head and eye injuries in Kashmir. The non-metallic missiles are not less-lethal and have high disabling, killing and infective.

4466. Raska, G. M., et al. (2007). "Management of penetrating trauma to the soft palate: a case report." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **65**(7): 1279-1285.

4467. Rasouli, J., et al. (2012). "Attenuation of interleukin-1beta by pulsed electromagnetic fields after traumatic brain injury." Neuroscience letters **519**(1): 4-8.

Traumatic Brain Injury (TBI) is a major cause of morbidity and mortality in civilian and military populations. Interleukin-1beta (IL-1beta) is a pro-inflammatory cytokine with a key role in the inflammatory response following TBI and studies indicate that attenuation of this cytokine improves behavioral outcomes. Pulsed electromagnetic fields (PEMF) can reduce inflammation after soft tissue injuries in animals and humans. Therefore, we explored whether PEMF signals could alter the course of IL-1beta production in rats subjected to closed-head contusive weight-drop injuries (Marmarou method) and penetrating needle-stick brain injuries. Protein levels, measured by the Biorad assay, were not altered by injuries or PEMF treatment. In addition, we verified that IL-1beta levels in cerebrospinal fluid (CSF) were proportional to injury severity in the contusion model. Results demonstrate that PEMF treatment attenuated IL-1beta levels up to 10-fold in CSF within 6h after contusive injury and also significantly suppressed IL-1beta within 17-24h after penetrating injury. In contrast, no differences in IL-1beta were seen between PEMF-treated and control groups in brain homogenates. To the authors' knowledge, this is the first report of the use of PEMF to modulate an inflammatory cytokine after TBI. These results warrant further studies to assess the effects of PEMF on other inflammatory markers and functional outcomes.

4468. Ratcliff, G. (1979). "Spatial thought, mental rotation and the right cerebral hemisphere." Neuropsychologia **17**(1): 49-54.

4469. Ratcliff, G. and F. Newcombe (1973). "Spatial orientation in man: effects of left, right, and bilateral posterior cerebral lesions." Journal of neurology, neurosurgery, and psychiatry **36**(3): 448-454.

Men with chronic, penetrating missile wounds of the brain were examined with two `spatial' tasks: a visually-guided stylus maze and a locomotor map-reading task. Men whose lesions involved the posterior part of the right cerebral hemisphere were significantly worse than those with left posterior lesions at stylus maze-learning. On the locomotor task, however, a highly significant deficit was found in the group of men with bilateral posterior cerebral lesions, while those with unilateral lesions of either hemisphere and those with bilateral frontal lesions were unimpaired. The contributions of the two cerebral hemispheres to the analysis of spatial information are discussed in the light of these results and it is suggested that, while the right hemisphere has a special role in the perception of space, it does not bear exclusive responsibility for the maintenance of spatial orientation.

4470. Rathore, F. A., et al. (2012). "Pneumorrhachis of thoracic spine after gunshot wound." Journal of the College of Physicians and Surgeons--Pakistan : JCPSP **22**(8): 529-530.

Air in the spinal canal (Pneumorrhachis) is a rare complication of traumatic spinal injuries reported at various levels of the spinal canal. Pneumorrhachis resolves spontaneously most of the times. Rarely, it may cause cord compression. It is important to rule out potentially serious causes like basilar skull fracture, injury to lungs, mediastinum, mastoid air cells, frontal sinuses or intestine. We present a case of pneumorrhachis in a young soldier who sustained gunshot wound in neck, resulting in spinal cord injury, He was managed conservatively and pneumorrhachis resolved spontaneously without complications. Pathogenesis along with review of relevant literature is presented.

4471. Ratilal, B. and L. C. Vara (2004). "Moving bullet syndrome." Neurology India **52**(3): 407.

4472. Ratilal, B. O., et al. "Antibiotic prophylaxis for preventing meningitis in patients with basilar skull fractures." (4).

Background, Basilar skull fractures predispose patients to meningitis because of the possible direct contact of bacteria in the paranasal sinuses, nasopharynx or middle ear with the central nervous system (CNS). Cerebrospinal fluid (CSF) leakage has been associated with a greater risk of contracting meningitis. Antibiotics are often given prophylactically, although their role in preventing bacterial meningitis has not been established., Objectives, To evaluate the effectiveness of prophylactic antibiotics for preventing meningitis in patients with basilar skull fractures., Search methods, We searched CENTRAL (2014, Issue 5), MEDLINE (1966 to June week 1, 2014), EMBASE (1974 to June 2014) and LILACS (1982 to June 2014). We also performed an electronic search of meeting proceedings from the American Association of Neurological Surgeons (1997 to September 2005) and handsearched the abstracts of meeting proceedings of the European Association of Neurosurgical Societies (1995, 1999 and 2003)., Selection criteria, Randomised controlled trials (RCTs) comparing any antibiotic versus placebo or no intervention. We also identified non-RCTs to perform a separate meta-analysis in order to compare results., Data collection and analysis, Three review authors independently screened and selected trials, assessed risk of bias and extracted data. We sought clarification with trial authors when needed. We pooled risk ratios (RRs) for dichotomous data with their 95% confidence intervals (CIs) using a random-effects model. We assessed the overall quality of evidence using the GRADE (Grades of Recommendation, Assessment, Development and Evaluation) approach., Main results, In this update we did not identify any new trials for inclusion. We included five RCTs with 208 participants in the review and meta-analysis. We also identified 17 non-RCTs comparing different types of antibiotic prophylaxis with placebo or no intervention in patients with basilar skull fractures. Most trials presented insufficient methodological detail. All studies included meningitis in their primary outcome. When we evaluated the five included RCTs, there were no significant differences between antibiotic prophylaxis groups and control groups in terms of reduction of the frequency of meningitis, all-cause mortality, meningitis-related mortality and need for surgical correction in patients with CSF leakage. There were no reported adverse effects of antibiotic administration, although one of the five RCTs reported an induced change in the posterior nasopharyngeal flora towards potentially more pathogenic organisms resistant to the antibiotic regimen used in prophylaxis. We performed a subgroup analysis to evaluate the primary outcome in patients with and without CSF leakage. We also completed a meta-analysis of all the identified controlled non-RCTs (enrolling a total of 2168 patients), which produced results consistent with the randomised data from the included studies., Authors' conclusions, Currently available evidence from RCTs does not support prophylactic antibiotic use in patients with basilar skull fractures, whether there is evidence of CSF leakage or not. Until more research is available, the effectiveness of antibiotics in patients with basilar skull fractures cannot be determined because studies published to date are flawed by biases. Large, appropriately designed RCTs are needed.

4473. Ratiu, P. and I.-F. Talos (2004). "Images in clinical medicine. The tale of Phineas Gage, digitally remastered." The New England journal of medicine **351**(23): e21.

4474. Ratiu, P., et al. (2004). "The tale of Phineas Gage, digitally remastered." Journal of neurotrauma **21**(5): 637-643.

The injury of Phineas Gage has fueled research on and fascination with the localization of cerebral functions in the past century and a half. Most physicians and anatomists believed that Gage sustained a largely bilateral injury to the

frontal lobes. However, previous studies seem to have overlooked a few less obvious, but essential details. This has led us to reanalyze the injury using three-dimensional reconstruction and quantitative computer-aided techniques and to propose a new biomechanical model, in order to determine the location and extent of the injury and explain Gage's improbable survival. Unlike previous studies on this subject, our findings are based on computer-generated three-dimensional reconstructions of a thin-slice computed tomography scan (CAT) of Phineas Gage's skull. The results of our image analysis were corroborated with the clinical findings, thoroughly recorded by Dr. Harlow in 1848, as well as with a systematic examination of the original skull specimen. Our results show that the cerebral injury was limited to the left frontal lobe, did not extend to the contralateral side, did not affect the ventricular system, and did not involve vital intracranial vascular structures. Although modern neuroscience has perhaps outgrown the speculations prompted by this famous case, it is still a living part of the medical folklore and education. Setting the record straight based on clinical reasoning, observation of the physical evidence, and sound quantitative computational methods is more than mere minutia and of interest for the broad medical community.

4475. Rau, A., et al. (2018). "The mechanics of corneal deformation and rupture for penetrating injury in the human eye." Injury **49**(2): 230-235.

Penetrating eye injuries are surgical emergencies with guarded visual prognosis. The purpose of the current study was to determine the force required to rupture the cornea with a penetrating object, and to study how this force is affected by the object geometry. Thirty-six human cadaveric eyes from donors of various ages were characterized for diameter, axial length, and pre-test intraocular pressure. In order to investigate the effects of specimen storage time on the tissue response, half of the specimens were tested within two weeks of donor expiration, and half of the specimens were stored at -4degreeC for 12-18 months. Indenters of three different diameters (1.0, 1.5, and 2.0mm) were lowered into the apex of the cornea until rupture. Resistance to displacement (stiffness), displacement at failure, and the force at failure were determined. Multi-variable regression analysis was used to determine associations of the input variables (indenter size, test speed, and tissue postmortem time) on the mechanics of the tissue response. Twenty-nine of the 36 specimens failed at the indenter location in the cornea, four failed at the limbus, and three failed in the sclera near sites of muscle attachment. The average force at failure caused by the 1.0mm, 1.5mm, and 2.0mm indenters increased from 30.5+/-5.5N to 40.5+/-8.3N to 58.2+/-14.5N, respectively ($p<0.002$). The force at failure was associated with the donor age ($p<0.001$), and globe diameter ($p<0.041$), but was not associated with pre-test intraocular pressure, tissue postmortem time, axial length, or speed of the indenter. This study has quantified the force-displacement and failure response of a large series of human cadaveric eyes subjected to penetrating indentation loads on the cornea. The results provide useful data for characterizing the relationship between corneal rupture and the geometry of a penetrating object.

4476. Raul, J.-S., et al. (2002). "Penetration of a piece of World War II rifle grenade initially suspected as a stab wound." The American journal of forensic medicine and pathology **23**(3): 277-280.

The authors report the case of a 58-year-old man found dead by his son in the forest where he had gone to cut wood for winter. Initial examination showed an upper left laterocervical wound compatible with a stab wound. Radiography and autopsy performed the next day showed a piece of metal located in the left part of the occipital bone, associated with a half-ring fracture of the occipital bone and consequent diffuse subarachnoid hemorrhage. Death was attributed to a spinal shock after impact at the cervicocephalic junction. Investigators returned to the scene and found a few more metal elements and also a 20-cm deep and 40-cm wide crater underneath a fire the deceased had set. Army experts concluded that the metal pieces belonged to an ATM 9 antitank rifle grenade used by the U.S. Army during World War II. Death was considered accidental, the deceased having unfortunately set a fire over the grenade.

4477. Raul, J.-S., et al. (2007). "A finite element model investigation of gunshot injury." International journal of legal medicine **121**(2): 143-146.

Multiple gunshot suicide can be a controversial subject mainly because of wrong opinions concerning immediate incapacitation or alleged backwards hurling. For the last 20 years, experts in medicine and physics have tried to demonstrate what really happens during a gunshot wound. Different methods have been used to achieve this aim such as basic physics or the use of empirical evidence. In this paper, using a finite element model of the human head, we

demonstrate that no incapacitation or backwards hurling can occur from a gunshot fired between the eyes which did not enter the cerebrum.

4478. Raulin, C. and T. Emonds (1998). "[Removal of dirt tattooing with Q-switched laser]." Entfernung von Schmutztatowierungen durch gutegeschaltete Laser. **69**(11): 1270-1274.

In present times treatment of traumatic tattoos with Q-switched laser systems is an alternative to conventional therapy. In our study, 19 patients were treated with the Q-switched ruby laser, including 4 patients with explosive trauma and 2 after pointed pencil penetration. One patient was treated with the Q-switched Nd:YAG-laser, while we tried both systems on another one. Pigmentation after abrasive trauma is easily removed or improved. Deeper penetration of foreign bodies demands more intensive and more frequent therapy. Immediate removal of foreign bodies after an accident is the best treatment.

4479. Rautio, J. and P. Paavolainen (1988). "Afghan war wounded: experience with 200 cases." The Journal of trauma **28**(4): 523-525.

The injuries seen in 200 Afghan war wounded in the International Committee of the Red Cross (ICRC) hospital in Quetta are reported. Evacuation took several days and no proper initial first aid was available. Therefore few of those reaching us had serious multiple injuries. The anatomic distribution of wounds was remarkably similar to that seen in other conflicts: 38% of the injuries were caused by bullets, 50% by fragmentation weapons, and 10% by mines. Two thirds of the patients had limb injuries. Of all wounded, patients with fractures of long bones needed the greatest number of repeated operations and the longest hospitalization time. Twenty-five patients had abdominal or perineal wounds and 12 needed laparotomy. Of 25 with head injuries 14 had penetrating brain trauma. Thoracic, vascular, and burn injuries were rare. The eight patients with spinal cord injury could fortunately be referred to the ICRC rehabilitation center in Peshawar within a week. Wound sepsis was the major problem due to the extraordinarly long delay in the initiation of treatment. In spite of the often grossly infected wounds, radical debridement usually led to good recovery for most patients, with a hospital mortality rate of only 2.5%.

4480. Raveenthiran, V. (2004). "Comment on "Penetrating head injury caused by bear claws: case report"." The Journal of trauma **57**(5): 1141.

4481. Ravelli, V., et al. (1987). "Unusual penetrating craniocerebral injuries. Report of three cases." Journal of neurosurgical sciences **31**(3): 153-156.

Three cases of penetrating cranio-cerebral injuries are reported. Two were caused by steel hooks shot by rotating blades: in one of these, the foreign body penetrated the brain through the eye-ball and in the second case the main injury was caused by a careless of extraction. In the third case, the foreign body, a key, penetrated the left parasagittal rolandic area following an under-water injury. All three patients were submitted to surgery and had good neurological recovery without complications of infection or seizures.

4482. Ravindra, K., et al. (2010). "Deceased donor utilization in hand transplantation: A single center experience." American Journal of Transplantation **10**: 417.

Background: With increasing success in solid organ transplantation, donor criteria have become far more liberal over the past decade. There is data to support the use of organs from extended criteria donors. Composite tissue allotransplantation (CTA) is still in infancy and there has been little discussion about donor quality and the risks of utilizing donors considered to be high risk or extended criteria in solid organ transplantation. Methods: Between 1999 and 2009, 5 patients underwent hand transplantation at the University of Louisville. We retrospectively analyzed the donor data in these patients and looked at factors considered in donor selection. Results: All the 5 donors were white men with ages 18, 20, 27, 49 and 59 respectively. Size (including X-ray for bone dimensions) and color matching played a significant role. All were brain dead donors; the cause of death being gunshot injury in 3 and drug overdose in 2. The only one with a medical illness was the 59 year old with hypertension. None had positive HIV or hepatitis serology. CMV mismatch was noted in 2 donor: recipient pairs; but was not a contraindication for donor selection. All required the use

of vasopressors for hypotension including 2 agents in 2 donors. The warm ischemia time ranged from 17 to 28 minutes and UW solution was used to preserve the graft. Brachial artery was also procured for utilization as vascular conduits at implantation in the last 2 donors. The transplant was successfully performed in all and the initial graft function was excellent. The reasons for turning down potential donors included history of hypertension requiring two or more drugs, Hepatitis B core antibody positivity and high risk status by CDC criteria. Conclusions: As the clinical volumes in CTA grow in the next decade, there will be greater need for using extended criteria donors. This is particularly relevant to CTA as the donation rates for hand or face will be lower than internal organs.The established criteria for solid organ transplant donation work well in CTA. There is a need for further research to address unanswered questions such as 1) the extent of warm ischemia tolerated by CTA, 2) the ideal perfusion solution, 3) the impact of age and systemic disease (hypertension, diabetes) on quality of CTA graft, 4) the risk of transmission of Hepatitis B with HB core antibody positive donors in CTA and 5) the role of non-heart beating and high risk donors (by CDC criteria) in CTA.

4483. Ravindra, V. M., et al. (2017). "Management of Penetrating Cerebrovascular Injuries in Pediatric Trauma: A Retrospective Multicenter Study." Neurosurgery **81**(3): 473-480.

BACKGROUND: Blunt cerebrovascular injury is uncommon in the pediatric population; penetrating cerebrovascular injuries are even rarer and are thus poorly understood., OBJECTIVE: To describe the diagnosis and management of penetrating cerebrovascular injuries and describe outcomes of available treatment modalities., METHODS: Clinical and radiographic data were collected retrospectively from a multicenter trauma registry for children screened for cerebrovascular injury during 2003 to 2013 at 4 academic pediatric trauma centers., RESULTS: Among 645 pediatric patients evaluated with computed tomography angiography with blunt cerebrovascular injury, 130 also had a penetrating trauma indication. Seven penetrating cerebrovascular injuries were diagnosed in 7 male patients (mean age 12.4 years, range 12-18 years). Focal neurological deficit and concomitant intracranial injury were each seen in 2 patients. There were 2 intracranial carotid artery injuries, 4 extracranial carotid artery injuries, and 1 vertebral artery injury. The majority of injuries were higher than grade I (5/7; 71%): 2 were grade I, 1 grade II, 2 grade III, and 2 grade IV. The 2 patients with grade III injuries required open surgery, and 1 patient with a grade IV injury underwent endovascular treatment. Two patients suffered immediate stroke secondary to the penetrating cerebrovascular injury. There were no delayed neurological deficits from the penetrating injuries, and no patients died as a result of the injuries., CONCLUSION: This is the largest series of penetrating cerebrovascular trauma in the pediatric literature. Although rare, penetrating cerebrovascular injuries can be high-grade injuries that require urgent recognition and may require aggressive endovascular and/or open surgery for treatment.

4484. Ray, B. R., et al. (2013). "Anaesthetic management of maxillofacial trauma." Trends in Anaesthesia and Critical Care **3**(5): 231-237.

Maxillofacial trauma, alone or as part of polytrauma, can pose a significant challenge to the anaesthesiologist in the emergency department, in the operating room and in the intensive care unit as it may hamper effective airway management in these patients. Detailed knowledge of maxillofacial and airway anatomy can help in understanding the mechanism, diagnosing the extent and severity of injury and formulating a proper airway management plan. Basic principles of trauma care should be followed at every step. Moreover, the presence of experienced personnel with adequate airway expertise is essential. Anaesthetic drugs and techniques should be optimally tailored to ensure maximal patient safety.

4485. Ray, J. M. (2013). "The treatment of maxillofacial trauma in austere conditions." Atlas of the oral and maxillofacial surgery clinics of North America **21**(1): 9-14.

Caring for severely injured patients, whether they be in the theater of combat or after natural disasters, can be a rewarding and even life-changing experience for all involved. Sound surgical principles and an attempt to achieve a high standard of care should still guide the treating surgeon. The surgical team undoubtedly face numerous obstacles, but with careful and considerate planning, many of these can be minimized.

4486. Rayess, N., et al. (2015). "Spectral-domain optical coherence tomography features of bilateral chorioretinitis sclopetaria." Ophthalmic surgery, lasers & imaging retina **46**(2): 253-255.

The authors report a case of bilateral chorioretinitis sclopetaria in a 31-year-old man who sustained a perforating gunshot trauma. On presentation, best corrected visual acuity was light perception in the right eye and counting fingers at 5 feet in the left eye. Funduscopic examination demonstrated bilateral peripapillary fibrogliotic lesions with associated pigmentation in the posterior pole. Spectral-domain optical coherence tomography scans revealed bilateral full-thickness hyperreflectivity consistent with chorioretinal disruption. The patient was closely monitored, and his vision remained stable at 6-week follow-up. Copyright 2015, SLACK Incorporated.

4487. Raymond, D., et al. (2009). "Tolerance of the skull to blunt ballistic temporo-parietal impact." Journal of biomechanics **42**(15): 2479-2485.

Less-lethal ballistic projectiles are used by police personnel to temporarily incapacitate suspects. While the frequency of these impacts to the head is low, they account for more serious injuries than impacts to any other body region. As a result, there is an urgent need to assess the tolerance of the head to such impacts. The focus of this study was to investigate the tolerance of the temporo-parietal skull to blunt ballistic impact and establish injury criteria for risk assessment. Seven unembalmed isolated cadaver heads were subjected to fourteen impacts. Specimens were instrumented with a nine-accelerometer array as well as strain gages surrounding the impact site. Impacts were performed with a 38 mm instrumented projectile at velocities ranging from 18 to 37 m/s. CT images and autopsies were performed to document resulting fractures. Peak fracture force for the seven resulting fractures was 5633+/-2095 N. Peak deformation for fracture-producing impacts was 7.8+/-3.2 mm. The blunt criterion (BC), peak force and principal strain were determined to be the best predictors of depressed comminuted fractures. Temporo-parietal tolerance levels were consistent with previous studies. An initial force tolerance level of 2346 N is established for the temporo-parietal region for blunt ballistic impact with a 38 mm diameter impactor.

4488. Raymont, V., et al. (2008). "Demographic, structural and genetic predictors of late cognitive decline after penetrating head injury." Brain : a journal of neurology **131**(Pt 2): 543-558.

We examined the relationship of pre-injury intelligence, demographic variables, lesion location, brain tissue volume loss and a number of genetic markers to long-term cognitive decline in a group of Vietnam veterans with predominantly penetrating head injury (PHI) suffered more than 30 years ago. Using linear and stepwise regression procedures, we found that those with PHI demonstrated a greater degree of cognitive decline overall during the years following recovery from injury compared with a control group of uninjured Vietnam veterans. This became increasingly significant later in life. We also found that pre-injury intelligence was the most consistent predictor of cognitive outcome across all phases of potential recovery and decline after such injuries. While laterality of lesion was not a factor, we did find some associations between atrophy and specific regions of tissue loss and long-term cognitive functioning. Finally, we found evidence for an association between level of cognitive decline following PHI and the possession of certain genetic markers that have been linked with brain injury and neurodegeneration. Thus exacerbated decline does occur in Vietnam veterans with PHI and it is apparently unrelated to dementia and is determined by multiple factors (most notably pre-injury intelligence).

4489. Raymont, V., et al. (2010). "Correlates of posttraumatic epilepsy 35 years following combat brain injury." Neurology **75**(3): 224-229.

BACKGROUND: The Vietnam Head Injury Study (VHIS) is a prospective, longitudinal follow-up of 1,221 Vietnam War veterans with mostly penetrating head injuries (PHIs). The high prevalence (45%-53%) of posttraumatic epilepsy (PTE) in this unique cohort makes it valuable for study., METHODS: A standardized multidisciplinary neurologic, cognitive, behavioral, and brain imaging evaluation was conducted on 199 VHIS veterans plus uninjured controls, some 30 to 35 years after injury, as part of phase 3 of this study., RESULTS: The prevalence of seizures (87 patients, 43.7%) was similar to that found during phase 2 evaluations 20 years earlier, but 11 of 87 (12.6%) reported very late onset of PTE after phase 2 (more than 14 years after injury). Those patients were not different from patients with earlier-onset PTE in any of the measures studied. Within the phase 3 cohort, the most common seizure type last experienced was complex partial seizures (31.0%), with increasing frequency after injury. Of subjects with PTE, 88% were receiving anticonvulsants. Left parietal lobe lesions and retained ferric metal fragments were associated with PTE in a logistic regression model. Total brain volume loss predicted seizure frequency., CONCLUSIONS: Patients with PHI carry a high

risk of PTE decades after their injury, and so require long-term medical follow-up. Lesion location, lesion size, and lesion type were predictors of PTE.

4490. Raza, S. and D. A. Redelmeier (2018). "Gunshot to the Head." The American journal of medicine **131**(1): e7-e8.

4491. Raza, S. S., et al. (2021). "A peculiar case of a gunshot wound to the abdomen." Journal of Investigative Medicine **69**(2): 480.

Case Report Discussion The prevalence of penetrating trauma is only seen in 3/100,000 live births. In these rare cases, the mainstay management of pregnant patients with trauma is to stabilize the mother to increase fetus viability. The primary assessment of hypovolemic shock required 2 large-bore IVs to administer a total of 6 units of PRBCs, 2 L of crystalloid, and 3 units of FFP. Pt's airway was secured, breathing noted as symmetric, and no disability appreciated. These measures were instrumental to stabilize the patient for surgery and limit organ hypoperfusion. Furthermore, immediate ultrasound of the fetus and HR monitoring is required; hence, the OB/Gyn team was consulted to assess fetal viability. In terms of management of trauma in pregnancy, bleeding needs to be localized and limited. With a uterine injury, it was beneficial to deliver the fetus, ligate the uterine arteries, and apply continuous uterine massage. REBOA was utilized to provide adequate circulation to vital organs. Zone 1 placement allowed initial stabilization and blood flow to the heart and brain. Shifting the REBOA to Zone 3 allowed for preserved circulation to the kidneys and liver. Focused approaches to restrict bleeding and provide adequate circulation eventually stabilized the patient and were imperative in recovery.

4492. Razek, T., et al. (2000). "Issues in potential organ donor management." The Surgical clinics of North America **80**(3): 1021-1032.

The shortage of organ donors has become a serious problem in modern medicine. Room for improvement exists in our ability to convert potential donors to actual donors based on the available numbers and a significant amount of recent research. A significant percentage of the potential donors represent head-injured patients, so a significant amount of responsibility falls on surgeons to optimize the opportunity for donation. There are clear steps along the pathway from potential to actual donor where physicians can have a significant effect on the rate of successful donation: 1. Identify all potential donors and institute a review system to verify that all potential donors are being identified in your area. 2. Establish an acceptable method to rapidly and accurately determine brain death in potential donors using the local available services. 3. Approach all potential donor families for consent, decouple death notification and consent request, use a member of the hospital team and an OPO representative to approach the family, and make the request in a private setting. 4. Use an aggressive, proactive approach to the medical management of the potential donor using the techniques described to limit the number of medical failures and maximize the number of organs donated per donor. Institute a review process to evaluate any medical failures that occur. Given the difference between the numbers of potential versus actual donors, the authors' significant contact with potential donors, and the clear opportunities for improvement in their approach, the surgical community must address these issues surrounding the optimal management of potential donors and their families.

4493. Rebić, J. and D. Charoulis (2019). "Biological base recoupment and implantoprosthetic treatment after a gunshot wound in the lateral mandible-a case report." Acta Stomatologica Croatica **53**(4): 394-395.

Vertical ridge augmentation represents one of the major challenges in modern implant dentistry and it can be solved with different techniques and with different materials. Hard and soft tissue diversity enables us to select the proper technique and material for each case individually. Furthermore, it affects the selection of the implant system that is to be used, whose characteristics can influence the long-term success of the rehabilitation. With today's broad spectrum of techniques, materials and implant systems our therapy plan must be assessed systematically in every detail. We will show a case with ridge augmentation and the following implantoprosthetic rehabilitation of insufficient bone volume 25 years after the patient suffered a gunshot wound in the mandibular region. Patient underwent several rehabilitation attempts using unilateral mobile devices which all failed due to the lack of underlying bony structure. Regarding the complexity of solving this kind of edentulism we were obliged to use all known concepts in order to obtain peri-implant tissues, as well as to ensure long term success of the therapy. Soft tissue management represents the core

of the long-term success from the aspect of hygiene maintenance and cortical bone preservation. Along with the bone augmentation, we will explain the importance of implant system se lection in it's surgical as well as prosthetic part. Methodology of the donor site, implant system and material selection will be explained through the presentation.

4494. Redd, K. T., et al. (2019). "Incidence and prevalence of headache in cranio-cervical artery dissection patients." Stroke **50**.

Introduction: Spontaneous craniocervical artery dissection (CeAD) occurs commonly in healthy individuals without known risk factors for stroke, whereas traumatic CeAD varies widely from penetrating trauma to motor vehicle crashes to minor movements of the neck. Headache (HA) and cervical pain occur in up to 75% of patients with CeAD. Yet, there are limited data on the incidence of new HA in CeAD patients after diagnosis. Methods: All patients from January 2015 to May 2017 consecutively identified by an electronic medical record-based application were enrolled in this prospective longitudinal registry. CeAD was confirmed by imaging during acute hospital visits. Patients were consented and followed for 12 months for HA status and HA Impact Test-6 (HIT-6) score (little to no impact: 49 or less, some impact: 50-55, substantial impact: 56-59, severe impact 60+). Results: The cohort included 111 CeAD patients (age 53 ± 15.9 years, 56% Caucasian, 50% female). Prevalence of reported HA at baseline was 40% (n=44) of enrolled patients; yet, there was no reportable difference between HA and no HA based on dissection location (carotid n=62; vertebral n=41; or basilar n=2; p=0.445). At baseline, 43% of patients categorized their HA as severely impacting their lives based on HIT-6. At the 3-month follow up, there was an incidence of 16% (n=11) who now reported HA but had no HA at baseline. At 3 months, 57% of patients categorized their HA as severely impacting on their life. At the 12-month follow up, there was an incidence of 7% (n=4) who now reported HA but no previous HA at baseline or 3 months. At 12 months, 58% of patients were classified into the severe impact category determined using HIT-6 calculations. HA status was not found to be associated with stroke or traumatic brain injury from CeAD (p = non-significant). Conclusions: We report the incidence and prevalence of HA within the CeAD population over a 12-month period. A high prevalence level was observed (40%) within the baseline history of CeAD diagnosis, with incremental incidence of new HA (16% and 7%) reported at 3 months and 12 months, respectively. There was no association found between HA status and stroke, dissection location or traumatic brain injury.

4495. Reddi, S. P., et al. (1999). "Hydroxyapatite cement in craniofacial trauma surgery: indications and early experience." The Journal of cranio-maxillofacial trauma **5**(1): 7-12.

BACKGROUND AND OBJECTIVES: Reconstruction of the nonstress-bearing portions of the craniofacial skeleton has recently utilized several alloplastic compounds. One such recent compound is hydroxyapatite cement (HAC)--a calcium-phosphate-based product. Its chemical structure consists primarily of calcium phosphate, as does human bone, and this similarity in the mineral structure renders it biocompatible., METHODS AND MATERIALS: Based on clinical indications for HAC, the authors have classified acquired craniofacial defects into four types. This article presents 5 clinical cases with craniofacial fractures, sustained in various accidents, in which hydroxyapatite cement was used to prevent cranial deformities or to reinstate contour., RESULTS AND/OR CONCLUSIONS: Complications were encountered in some of these cases, but all patients healed without any secondary complications. While the short-term experience using hydroxyapatite cement in craniofacial trauma surgery has been favorable, long-term studies in humans are required to validate the safety and efficacy of this product.

4496. Reddy, A. K., et al. (2014). "Survivors of self-inflicted gunshot wounds to the head: characterization of ocular injuries and health care costs." JAMA ophthalmology **132**(6): 730-736.

IMPORTANCE: Suicides and attempted suicides are major public health issues in the United States and around the world. Self-inflicted gunshot wounds (SIGSWs) are a common method of attempting suicide, the head being the most commonly injured body region; however, the literature lacks an overview of the orbital and ocular injuries as well as outcomes associated with SIGSWs., OBJECTIVES: To characterize the ocular and orbital injuries and outcomes of patients presenting with SIGSWs and to examine the cost associated with these injuries., DESIGN, SETTING, AND PARTICIPANTS: Retrospective medical record review was performed of all patients who presented to the University of Iowa Hospitals and Clinics between 2003 to 2013 with the admitting diagnosis of self-inflicted injuries via firearms. Patients with no periorbital or ocular injuries and/or those who did not survive for at least 2 months following the incident were excluded., MAIN OUTCOMES AND MEASURES: Ocular injuries and outcomes and health care costs and

reimbursements, which were generated by a financial report obtained from the hospital finance department that included data from both the hospital billing and cost accounting systems., RESULTS: All patients in this study (n = 18) were men with a mean age of 47.2 years. Eight patients (44.4%) displayed submental missile entry points, 7 (38.9%) displayed intraoral entry points, and 3 (16.7%) displayed pericranial entry points. Patients with pericranial entries sustained more severe ocular injuries and had poorer ocular outcomes. Seven patients (38.9%) were found at final follow-up to have visual acuity of 20/40 or better in each eye and all showed missile trajectories in the sagittal plane. The mean cost of treatment of these patients totaled $117,338 while the mean reimbursement amount was $124,388., CONCLUSIONS AND RELEVANCE: Data regarding ocular injuries and outcomes may assist ophthalmologists in the treatment of patients with SIGSWs in the future. Many patients had extremely functional vision at final follow-ups, which highlights the importance of specialists conducting examinations and reconstructive procedures promptly, carefully, and thoroughly. Cost and reimbursement data suggest that while these cases place a large financial burden on society, they may not burden hospital systems in the same way.

4497. Redell, J. B., et al. (2007). "Acutely increased cyclophilin a expression after brain injury: a role in blood-brain barrier function and tissue preservation." Journal of neuroscience research **85**(9): 1980-1988.

Blood-brain barrier (BBB) compromise is a significant pathologic event that manifests early following traumatic brain injury (TBI). Because many signaling cascades are initiated immediately after the traumatic event, we were interested in examining acute differential protein expression that may be involved in BBB function. At acute time points postinjury, altered protein expression may result from altered translation efficiency or turnover rate rather than from a genomic response. The application of tandem 2-D gel electrophoresis and mass spectrometry analysis is a powerful approach for directly screening differential protein expression following TBI. Using comparative 2-D gel analysis, we selected candidate protein spots with apparent altered expression and identified them by mass spectrometry. Cyclophilin A was selected for further analysis because it has been implicated in endothelial cell activation and inflammation, and studies have suggested cyclosporine A, an inhibitor of all cyclophilin isoforms, might be beneficial after TBI. We examined if altered expression of cyclophilin A in the brain vasculature might play a role in BBB function. We found significantly increased cyclophilin A levels in isolated brain microvessels 30 min following injury. Postinjury administration of cyclosporine A significantly attenuated BBB permeability measured 24 hr postinjury, suggesting cyclophilin activity after TBI may be detrimental. However, direct injection of purified recombinant cyclophilin A attenuated both BBB permeability and tissue damage in a stab wound model of injury. These findings suggest that increased expression of cyclophilin A may play a protective role after TBI, whereas other cyclophilin isoforms may be detrimental.

4498. Reeves, C., et al. (2019). "Spatiotemporal dynamics of PDGFRbeta expression in pericytes and glial scar formation in penetrating brain injuries in adults." Neuropathology and applied neurobiology **45**(6): 609-627.

AIMS: Understanding the spatiotemporal dynamics of reactive cell types following brain injury is important for future therapeutic interventions. We have previously used penetrating cortical injuries following intracranial recordings as a brain repair model to study scar-forming nestin-expressing cells. We now explore the relationship between nestin-expressing cells, PDGFRbeta+ pericytes and Olig2+ glia, including their proliferation and functional maturation., METHODS: In 32 cases, ranging from 3 to 461 days post injury (dpi), immunohistochemistry for PDGFRbeta, nestin, GFAP, Olig2, MCM2, Aquaporin 4 (Aq4), Glutamine Synthetase (GS) and Connexin 43 (Cx43) was quantified for cell densities, labelling index (LI) and cellular co-expression at the injury site compared to control regions., RESULTS: PDGFRbeta labelling highlighted both pericytes and multipolar parenchymal cells. PDGFRbeta LI and PDGFRbeta+ /MCM2+ cells significantly increased in injury Zones at 10-13 dpi with migration of pericytes away from vessels with increased co-localization of PDGRFbeta with nestin compared to control regions ($P < 0.005$). Olig2+ /MCM2+ cell populations peaked at 13 dpi with significantly higher cell densities at injury sites than in control regions ($P < 0.01$) and decreasing with dpi ($P < 0.05$). Cx43 LI was reduced in acute injuries but increased with dpi ($P < 0.05$) showing significant cellular co-localization with nestin and GFAP ($P < 0.005$ and $P < 0.0001$) but not PDGFRbeta., CONCLUSIONS: These findings indicate that PDGFRbeta+ and Olig2+ cells contribute to the proliferative fraction following penetrating brain injuries, with evidence of pericyte migration. Dynamic changes in Cx43 in glial cell types with dpi suggest functional alterations during temporal stages of brain repair.

4499. Reeves, P., et al. (2016). "Analysis of pediatric trauma in a combat zone to inform high-fidelity simulation training." Critical care medicine **44**(12): 466.

Learning Objectives: The military uses 'just in time' training for medical personnel to refresh skills to prior to deployments. Pre-deployment training for pediatric care has been extremely limited. Pediatric patients have been shown to account for over 10% of bed-days in Role 3 facilities. The goal of this study is to utilize both Role 3 and Role 2 patient records to enable the data-driven development of high-fidelity simulation training for the management of pediatric patients in the combat zone. Methods: Retrospective reviews were performed on the Department of Defense Joint Trauma Registry for Role 3 patients and the Role 2 Registry of pediatric patients (<18 years) from 2001-2014. Three sub cohorts were determined using commercially available models: Group 1: <1 year, Group 2: 1-8 years, Group 3: >8 years. The groups were analyzed according to demographic data and were further sub-stratified based on management. Comparative analyses included: T-Test for continuous data; Chi Squared for dichotomous data. Results: 6045 patients were analyzed: 8.9 years±4.58, 76% male, Glasgow Coma scale 11 ± 5, 8% overall mortality. Injury type: Penetrating (55%), Blunt (31%), Burn (12%). Group 1 patients (n=115, 2%) were admitted for Traumatic Brain Injury (TBI) (30%), Penetrating Abdomen (23%). Field care: intravenous fluids (IVF) (11%), 15% transfused. Surgical procedures: orthopedic (15%), laparotomy (10%), and neurosurgery (4%). Group 2 patients (n=2617, 43%) were admitted for Penetrating abdomen (38%), TBI (37%). Field interventions: IVF (16%), c-collar (7%), 22% transfused. Surgical procedures: orthopedic (43%), laparotomy (32%), and neurosurgery (19%). Group 3 patients (n=3313, 55%) were admitted for Penetrating abdomen (45%), TBI (26%), penetrating extremities (25%). Field interventions: IVF (18%), c-collar (9%), 27% transfused. Surgical procedures: orthopedic (68%), laparotomy (38%), neurosurgery (16%). Conclusions: Operations in Middle East over past 15 years demonstrate the importance of pediatric trauma care in combat zone. This data will help design high-fidelity simulations for pre-deployment training of providers.

4500. Regasa, L. E., et al. (2018). "Mortality Following Hospital Admission for US Active Duty Service Members Diagnosed With Penetrating Traumatic Brain Injury, 2004-2014." The Journal of head trauma rehabilitation **33**(2): 123-132.

OBJECTIVE: To examine mortality among active duty US military service members (SMs) with the diagnosis of penetrating traumatic brain injury (PTBI) and a hospital admission between 2004 and 2014., DESIGN: Data on SMs with PTBI and an admission to a military or civilian hospital were obtained from the 2004 to 2014 Military Health System data repository. After applying exclusion criteria, data on 1226 SMs were analyzed., MAIN MEASURES: The number of observed deaths per 100 identified patients with PTBI and time to death from admission were used as main measures., RESULTS: Approximately 25% of the 1226 patients with PTBI included in this study died following admission, with 44.6% of the all deaths occurring within a day following hospital admission and 75% occurring within the first week. Severe comorbid conditions and intentionally self-inflicted injuries are associated with higher mortality rate. SMs' gender, age, year of hospital admission, and service were significantly associated with likelihood of death following PTBI hospitalization. Males had a higher likelihood of dying following hospital admission compared with females (odds ratio = 2.7, confidence interval = 1.03-7.9). SMs in the 35- to 44-year-old and 45- to 64-year-old groups had up to a 2.6 times higher odds of death following their admission compared with the 25- to 34-year-old group. Age, admission year, service, and rank were significantly associated with SMs' time to death from hospitalization. Patients between the ages of 45 and 64 years were significantly more likely to die earlier than other age groups. Furthermore, cases in the Navy Afloat group had a higher fatality rate and were more likely to die earlier than patients in other services. PTBI comorbid conditions and injury type did not significantly affect time to death., CONCLUSION: This study quantifies case fatality rate among hospitalized US SMs with the diagnosis of PTBI. We report a 23.1% crude case fatality rate among the current cohort. Early intensive care for these patients may be the key to improving survival rates.

4501. Regev, E., et al. (1990). "Penetrating craniocerebral injury caused by a metal rod: an unusual case report." Injury **21**(6): 414-415.

4502. Reguera-Teba, A., et al. (2021). "Eight-year analysis of bullfighting injuries in Spain, Portugal and southern France." Scientific reports **11**(1): 16006.

Improving knowledge on the epidemiology and analysing the prognostic factors of severity for injuries caused by fighting bulls in Spain, Portugal and southern France. Observational retrospective study including 1239 patients with a

reported history of bull horn injuries between January 2012 and November 2019 in Spain, Portugal or southern France. A multiple logistic regression test was used to analyse the prognostic factors of severity and mortality rate of these lesions. The mean accident rate was 9.13% and the mortality rate was 0.48%. The most frequent mechanism of trauma was goring, and the commonest locations of the lesions were thigh and groin. Vascular lesion was found in 20% of thigh/groin gorings. Prognostic factors of severity were vascular lesion, head trauma, fracture, goring injuries and age of the animal. The most reliable prognostic factors of mortality were vascular lesion and goring in the back. Lesions caused by fighting bulls are common in the bullfighting events held in Spain, Portugal and southern France. Although the mortality rate is low, there is a higher morbidity rate, which is conditioned by vascular lesion. All medical teams should include a surgeon experienced in vascular surgery and an anaesthesiologist. Copyright © 2021. The Author(s).

4503. Regunath, K., et al. (2012). "Penetrating injury to the head: case reviews." The Medical journal of Malaysia **67**(6): 622-624.

Penetrating injury to the head is considered a form of severe traumatic brain injury. Although uncommon, most neurosurgical centres would have experienced treating patients with such an injury. Despite the presence of well written guidelines for managing these cases, surgical treatment requires an individualized approach tailored to the situation at hand. We describe a collection of three cases of non-missile penetrating head injury which were managed in two main Neurosurgical centres within Malaysia and the unique management approaches for each of these cases.

4504. Rehman, A., et al. (2014). "The human mandible shattered to a hundred pieces: A disastrous consequence of firearm injury." Journal of Pioneering Medical Sciences **4**(4): 171-173.

Firearm injuries can lead to grave consequences, especially if suffered to the facial region. Patients who survive these injuries have an enduring impact on their quality of life. In this article, we present a case of a 35-year-old police officer who suffered a firearm injury to his face after being attacked by bandits. He was subsequently managed at our hospital with multiple procedures. At one-year follow-up visit, he was found to have major depressive disorder, facial deformity, difficulty chewing chewing solid foods and inability to resume his job. We describe how firearm injuries in the facial region have profound psychological and socioeconomic implications for the patient, extending wider than the physical damage and are easily.

4505. Rehman, T.-U., et al. (2007). "Intracranial penetration of a TASER dart." The American journal of emergency medicine **25**(6): 733.e733-734.

4506. Reichert, L., et al. (2017). "Radial Artery Compression with Threatened Transection: Catfish Injury in a Pediatric Patient." Annals of vascular surgery **39**: 288.e281-288.e283.

Marine animal injuries are rare causes of emergency room visits and vascular injuries worldwide. Penetrating injuries from marine animals risk damage to vasculature, and physicians must be alert to such possibilities. We report a 7-year-old boy with penetrating trauma and retained foreign body in the forearm from a catfish injury. Initial imaging suggested transection of the radial artery, but on exposure in a controlled setting the foreign body was found to compress the artery without any vascular injury. No vascular repair was needed after foreign body removal. Copyright © 2016 Elsevier Inc. All rights reserved.

4507. Reid, A., et al. (2014). "Age at traumatic brain injury affects excitability and seizure susceptibility." Epilepsy Currents **14**: 315-316.

Rationale: Human studies suggest younger age at time of traumatic brain injury (TBI) is a risk factor for early post-traumatic seizures while older age may be a risk factor for post-traumatic epilepsy (PTE). We used lateral fluid percussion injury (LFPI) in rats to determine whether age at injury has an effect on the development of PTE or other electrical kindling-related measures of brain excitability and seizure susceptibility. Methods: Male rats underwent moderate-severe LFPI or sham injury at post-natal day 19 or as an adult. Recording and stimulating electrodes were implanted two months later. Baseline EEG was recorded for one week to detect spontaneous seizures. Rats with LFPI were then divided to TBI/PTE- or TBI/PTE+ groups. After-discharge threshold and duration (ADT and ADD) were

determined in response to callosal stimulation, then rats underwent 20 daily sessions of kindling. We studied kindling progression and the occurrence of secondary ADs (SAD), thought to originate from the hippocampus. Statistical analyses were performed on raw data to compare within Pup (P) or Adult (A) groups, and on data normalized to their respective Sham group to make comparisons across age. Results: Rats were divided into groups based on time of injury and baseline EEG: P/Sham; P/TBI/PTE-; P/TBI/PTE+; A/Sham; A/TBI/PTE-; and A/TBI/PTE+. Injury severity was not different in any TBI group (Table 1). P/TBI/PTE+ and A/TBI/PTE+ both had seizures originating from perilesional neocortex, but A/TBI/PTE+ had more frequent, longer duration seizures. Both P and A TBI/PTE+ had lower ADTs and longer ADDs versus their respective Shams and TBI/PTE- (Table 1). Normalized ADTs and ADDs were not different between PTE+ groups (Fig 1A, B). The number of stage 4/5 seizures during kindling was lower in PTBI/PTE+ versus P/Shams and P/TBI/PTE-, while A/TBI/PTE+ had more stage 4/5 seizures than A/Shams and P/TBI/PTE- (Table 1, Fig 1C). There were no differences between P groups in the latency to initial SAD, although A/TBI/PTE+ had a shorter latency to initial SAD than A/Shams and P/TBI/PTE+ (Table 1, Fig 1D). Conclusions: Some long term effects of LFPI on seizures and epilepsy are age-related, and appear to be linked to the development of PTE itself, not just TBI. LFPI at P19 or in adults caused PTE in the same proportion of rats, but seizures were more frequent and longer duration when injury occurred in adults. Injury at either age was associated with lower ADTs and longer ADDs, but the severity and progression of kindling-induced seizures increased in A/TBI/PTE+ and decreased in P/TBI/PTE+, suggesting younger brains have a greater capacity to withstand trauma-induced alterations that support PTE. The effect of LFPI on SADs only after adult injury suggests there may be hippocampal involvement with LFPI at an older age, supporting previous findings that the developing hippocampus is not as susceptible to injury. Future studies of the brain after LFPI may help lead to further understanding of the epileptogenic process occurring after TBI at different ages, and whether different interventions may be needed to prevent PTE in children versus adults. 316 All values are presented as Mean ± SEM Figure 1. A) ADT values for TBI/PTE- and TBI/PTE+ were normalized to their respective Shams. P/TBI/PTE+ and A/TBI/PTE+ had significantly lower ADTs compared with their Shams and TBI/PTE- (∗p<0.05). B) ADD values for TBI/PTE- and TBI/PTE+ were normalized to their respective Shams. P/TBI/PTE+ and A/TBI/PTE+ had significantly longer ADDs compared with their Shams and TBI/PTE- (∗p<0.05). C) The number of stage 4/5 seizures during kindling for TBI/PTE- and TBI/PTE+ was normalized to the respective Shams. P/TBI/PTE+ had significantly less stage 4/5 seizures than P/Sham and P/TBI/PTE- (∗p<0.05), while A/TBI/PTE+ had significantly more stage 4/5 seizures than A/Sham and P/TBI/PTE+ (#p<0.05). D) The number of the kindling session when the first SAD occurred for TBI/PTE- and TBI/PTE+ was normalized to the respective Shams. There were no difference between any of the Pu groups. The first SAD occurred significantly earlier in A/TBI/PTE+ compared with A/Sham and P/TBI/PTE+ (#p<0.05). (Table Presented)(Figure Presented).

4508. Reid, R. H., et al. (1990). "Cerebral perfusion imaging with technetium-99m HMPAO following cerebral trauma. Initial experience." Clinical nuclear medicine **15**(6): 383-388.

Thirteen patients with cerebral trauma were studied for cerebral perfusion by the use of Tc-99m HMPAO scanning. CT imaging was performed on nine patients. Because of their clinical condition, four patients were scanned only in the planar mode to help establish the diagnosis of brain death. Other indications for study included gunshot wound and blunt or sharp object trauma with or without skull fracture. In all cases, HMPAO scans showed defects with a quality equivalent to or greater than that demonstrated by CT. Our initial results suggest that HMPAO may predict the degree of permanent damage and which patients may develop post-traumatic headache. A diagnosis of brain death can be established without the withdrawal of medical therapy.

4509. Reid, T. D., et al. (2018). "Anatomic Location and Mechanism of Injury Correlating with Prehospital Deaths in Sub-Saharan Africa." World journal of surgery **42**(9): 2738-2744.

INTRODUCTION: Trauma is a large contributor to morbidity and mortality in developing countries. We sought to determine which anatomic injury locations and mechanisms of injury predispose to prehospital mortality in Malawi to help target preventive and therapeutic interventions. We hypothesized that head injury would result in the highest prehospital mortality., METHODS: This was a retrospective analysis of all trauma patients presenting to Kamuzu Central Hospital in Lilongwe, Malawi, from 2008 to 2015. Independent variables included baseline characteristics, anatomic location of primary injury, mechanism of injury, and severity of secondary injuries. Multivariable logistic regression was used to assess the effect of primary injury location and injury mechanism on prehospital death, after adjusting for confounders. Effect measure modification of the primary injury site/prehospital death relationship by injury mechanism (stratified into intentional and unintentional injury) was assessed., RESULTS: Of 85,806 patients, 701 died in transit

(0.8%). Five hundred and five (72%) of these patients sustained a primary head injury. After adjustment, head injury was the anatomic location most associated with prehospital death (OR 11.81 (95% CI 6.96-20.06, p < 0.0001). The mechanisms of injury most associated with prehospital death were gunshot wounds (OR 38.23, 95% CI 17.66-87.78, p < 0.0001) and pedestrian hit by vehicle (OR 2.62, 95% CI 1.92-3.55, p < 0.0001). Among head injury patients, the odds of prehospital mortality were higher with unintentional injuries., CONCLUSIONS: Head injuries are the most common causes of prehospital death in Malawi, while pedestrians hit by vehicles are the most common mechanisms. In a resource-poor setting, preventive measures are critical in averting mortality.

4510. Reider-Groswasser, I. I., et al. (2002). "Quantitive imaging in late traumatic brain injury. Part I: late imaging parameters in closed and penetrating head injuries." Brain injury **16**(6): 517-525.

OBJECTIVE: To ascertain the value of relatively simple quantitative radiologic measurements after head injury. Despite major advances in neuroradiology, analysis and reporting of imaging studies is based primarily on individual subjective and local experience, rather than on reproducible, standardized parameters; reliance on newer technologies can improve care, but also raises diagnostic costs., DESIGN: Blinded, retrospective, quantitative assessment of computerized tomography studies done some 14 years post-injury., OUTCOME MEASURES: Frontal horn width (FHW); septum-caudate distance (SCD); temporal horn width (THW); interuncal distance (IUD); third ventricle width (3VW); ventricular score (VS); sulcal width (SW); gray-white matter discriminability (GWMD) and subjective assessment of atrophy (SAOA)., RESULTS: Diffuse and frontal damage was noted in both closed (CHI) and penetrating (PHI) head injury groups. Enlargement of frontal lobe parameters (septum caudate distance and frontal horn width suggest frontal injury in both closed and penetrating traumatic brain injury (TBI). Temporal horn width and inter-uncal distance were related to VS, 3VW and FHW in closed, but not in penetrating head injury., CONCLUSIONS: Simple linear CSF space measurements are correlated with volumetric and parenchymal measures, and can represent valuable and reliable low-cost quantitative measures of long term brain damage after TBI.

4512. Reines, H. D., et al. (1980). "Neurogenic pulmonary edema and missile emboli." The Journal of trauma **20**(8): 698-701.

A case of missile emboli to a major intracranial vessel resulting in fulminant pulmonary edema is reported. A discussion of the etiology of neurogenic pulmonary edema (NPE) is presented. The cause is thought to be a marked increase in pulmonary artery pressure, due to a massive catechol release in the CNS, and possibly secondary to post-capillary sphincteric constriction. Missile emboli to the cerebral arteries should be removed in order to avoid distal embolization and infarction. The case reported appears to represent the first documented case of missile emboli causing NPE.

4513. Reinges, M. H., et al. (1998). "Minimally invasive bedside craniotomy using a self-controlling pre-adjustable mechanical twist drill trephine." Surgical neurology **50**(3): 226-230.

BACKGROUND: Craniotomy with a mechanical twist drill is a standard, minimally invasive procedure in neurosurgery, widely used for the drainage of chronic subdural hematomas and the placement of ventricular drains. Nevertheless, the use of a standard twist drill trephine bears the risk of causing cerebral lesions., METHOD: A commercially available mechanical twist drill system has been modified by a special self-controlling drill and a pre-adjustable distance holder that limits intracerebral penetration. After initial cadaver testing, the modified trephine has been used for 65 trephinations in patients (37 chronic subdural hematomas, 21 external ventricular drains, 6 frontal hygromas, 1 tumor cyst)., RESULTS: There were no complications related to the modified trephine; cerebral lesions caused by drilling too deeply or by uncontrolled penetration were safely prevented. In our series no procedure related infections occurred, and the drilling time was reduced significantly., CONCLUSION: The described modified mechanical twist drill enables fast, easy, and safe craniotomy without jeopardizing the advantages of a mechanical twist drill. Therefore, it can be recommended particularly for difficult emergency conditions.

4515. Reiss, M. and E. Pilling (1996). "[Diagnostic and therapeutic problems in gunshot wounds]." Diagnostische und therapeutische Probleme bei Schussverletzungen. **75**(7): 426-432.

BACKGROUND: Bullet wounds are a rare occurrence during times of peace. Recently, however, there has been a general increase in the relative number and severity of this type of trauma. In times of peace, gunshot wounds may be mainly caused by suicide attempts, negligent handling of firearms and especially violent conflicts. Bullet wounds, in contrast to wounds caused by a blow or impact to the viscerocranium, are characterised by an irregular path, entry and exit wounds, as well as localised demolition of bones with the associated defects., PATIENTS: 30 patients with gunshot wounds were treated during the past 35 years. Basing on four case reports, problems of interdisciplinary treatment approach to gunshot wounds are discussed, as well as the diagnostic and therapeutic consequences., RESULTS AND CONCLUSIONS: The first case concerns a retained missile in the left fossa pterygopalatina. Intraoperative removal caused a rupture of the A. maxillaris. Preoperative angiography could have provided valuable information. In the second case, an injury caused by a shot from a blank cartridge pistol in the left facial area resulted in extensive wounds with several surgical revisions. The third case was a shot injury to the tongue with an unexpected wound and bleeding. The fourth case describes a child with a bullet in a hyperplastic adenoid tonsil. Primary careful treatment is of greatest significance for functional and cosmetic results due to extensive rupturing and wounds.

4516. Reiss, M., et al. (1998). "[Gunshot injuries in the head-neck area--basic principles, diagnosis and management]." Schussverletzungen im Kopf-Hals-Bereich--Grundlagen, Diagnostik und Versorgung. **87**(24): 832-838.

Bullet wounds are a rare occurrence during times of peace. Recently, however, there has been a general increase in the number and severity of this type of trauma in our case load. First, the possible firearms and the individual types of ammunition will be discussed. Based on this background, the possible types of wounds are presented. Principally, one distinguishes ricocheting shots from grazing ones, and those leaving bullets lodged in the body from those with perforating wounds. The extent of tissue damage depends on internal lacerations, on the compression of the tissue and on the temporary cavitation along the projectile path. In contrast to other types of injuries, which are caused by a blow or impact to the face or skull, gunshot traumas are characterized by an irregular path, as well as, by localized destruction of bones with associated effects. In this connection, the severity of the bullet wound also depends upon the extent of involvement of the viscerocranium. As causes of gunshot wounds during times of peace, suicidal intent, the negligent handling of firearms and especially brutal crimes are those which come into consideration first and foremost. The diagnostic aspect of firearm wounds, beside anamnesis, comprises comprehensive X-ray diagnostics for a complete picture. From the therapeutic side, tetanus serum and antibiotics as a prophylactic are recommended initially. The operative treatment should take place depending on the injury with the removal of a possible projectile. Bullet wounds always require an interdisciplinary approach to treatment.

4517. Reith, W. (2008). "[Traumatic lesions of the orbit]." Traumatische Lasionen der Orbita. **48**(12): 1150-1154.

Complex and sometimes severe lesions of the orbit can be caused by a variety of injury mechanisms, such as fractures, hemorrhages and foreign bodies. Imaging techniques play an extremely important role in the treatment of various diagnostic question marks, such as direct sequelae of trauma, localization of fractures and soft tissue damage.

4518. Remsen, K., et al. (1983). "Unusual presentations of penetrating foreign bodies of the upper aerodigestive tract." The Annals of otology, rhinology & laryngology. Supplement **105**: 32-44.

Only a small number of ingested foreign bodies perforate the esophagus and even a smaller fraction migrate extraluminally. Four such penetrating and migrating foreign bodies of the upper aerodigestive tract are presented. Review of the literature revealed 321 cases of penetrating ingested foreign bodies, of which 252 remained intraluminal and 43 were found extraluminally, with the status of the remainder indeterminate. Analysis revealed that an intraluminal penetrating foreign body carried a higher overall mortality than one that migrated extraluminally. Although intraluminal and extraluminal penetrating foreign bodies may remain quiescent for years before presenting a complication, no correlation existed between mortality and the duration of the foreign bodies' retention. The greatest

mortality was seen with vascular complications followed by diffuse and local suppurative processes. The overall mortality was significantly reduced in the post-antibiotic era.

4519. Ren, C., et al. (2008). "An ultrastructural study on indirect injury of dental pulp caused by high-speed missile projectile to mandible in dogs." Dental traumatology : official publication of International Association for Dental Traumatology **24**(6): 633-639.

The aim of this study was to evaluate the characteristics of indirect injury of dental pulp caused by high-speed missile projectile to mandible in dogs. Eighteen dogs aged 12-13 months were divided equally into six groups (n = 3 in each group) with random allocation, then a high-speed missile projectile (a ball bearing of stainless steel, phi6.0 mm, 0.88 g) was shot at right mandible body (the wound tract was below the fourth premolar, 1 cm or so to the root tips) of each dog, but the teeth were not wounded directly. The dogs were killed 6 h (n = 3), 24 h (n = 3), 3 days (n = 3), 7 days (n = 3), 2 weeks (n = 3) and 4 weeks (n = 3) after the wound, respectively; then ultrastructural change of dental pulp of the fourth premolar and the second premolar of right mandible, and the second premolar of left mandible was observed through transmission electron microscope. The results showed that mean initial velocity of projectiles was 778.0 +/- 33.2 m s(-1) and mean projection energy was 266.1 +/- 19.1 J, which were in conformity with parameters of gunshot wound. On the wound side, dental pulp of the fourth mandibular premolar was injured seriously and irreversible necrosis happened in the end; yet, dental pulp of the second mandibular premolar was injured less seriously, reversibly; on the opposite side, dental pulp of the second mandibular premolar was injured slightly and temporarily. It may be concluded that there are several characteristics in indirect injury of dental pulp caused by high-speed missile projectile to dogs' mandible: the injured area is relatively extensive; traumatic degree decreases progressively and sharply with the distance to the wound tract increasing; ultrastructural change of nerval damage takes place in early stage after wound, etc.

4521. Renfrow, J. J., et al. (2017). "Evaluation of a Traumatic Vertebral Artery Occlusion." World neurosurgery **101**: 815.e813-815.e817.

Background Penetrating neck injury occurs in 5%–10% of all trauma cases and carries a significant burden of morbidity and mortality (15%). We describe the evaluation and management of a 25-year-old man shot in the neck with occlusion of the left vertebral artery from its origin to C6. This is a case report in which medical data were analyzed retrospectively with institutional review board approval. Case Description Neurologic examination revealed paresthesias and dysesthesias in a left C8 dermatomal distribution. Computed tomography angiography of the neck demonstrated no opacification of the left vertebral artery from its origin to C6. Magnetic resonance imaging of the cervical spine revealed an acute infarct in the left cerebellum. A cerebral angiogram highlighted hemodynamic compromise, and the patient was felt to be at significant risk of further cerebral infarction. Augmenting flow to the posterior circulation would mitigate that risk. The patient was taken to the operating room for a transposition of the vertebral artery to the common carotid artery. Conclusions The patient presented with silent cerebellar infarction due to a vertebral artery injury and impending vertebrobasilar insufficiency. This case demonstrates clinical evaluation of the posterior circulation and treatment with a bypass technique through mobilization of the vertebral artery from the boney vertebral foramen with anastomosis to the common carotid.

4523. Rennert, R. C., et al. (2016). "Ventricular Tract Hemorrhage Following Intracranial Nail Removal: Utility of Real-time Endovascular Assistance." Frontiers in neurology **7**: 112.

Penetrating brain trauma commonly results in occult neurovascular injury. Detailed cerebrovascular imaging can evaluate the relationship of intracranial foreign bodies to major vascular structures, assess for traumatic

pseudoaneurysms, and ensure hemostasis during surgical removal. We report a case of a self-inflicted intracranial nail gun injury causing a communicating ventricular tract hemorrhage upon removal, as well as a delayed pseudoaneurysm. Pre- and post-operative vascular imaging, as well as intra-operative endovascular assistance, was critical to successful foreign body removal in this patient. This report demonstrates the utility of endovascular techniques for the assessment and treatment of occult cerebrovascular injuries from intracranial foreign bodies.

4524. Rennert, R. C., et al. (2016). "Ventricular tract hemorrhage following intracranial nail removal: Utility of real-time endovascular assistance." Frontiers in neurology **7**(JUL).

Penetrating brain trauma commonly results in occult neurovascular injury. Detailed cerebrovascular imaging can evaluate the relationship of intracranial foreign bodies to major vascular structures, assess for traumatic pseudoaneurysms, and ensure hemostasis during surgical removal. We report a case of a self-inflicted intracranial nail gun injury causing a communicating ventricular tract hemorrhage upon removal, as well as a delayed pseudoaneurysm. Pre- and post-operative vascular imaging, as well as intra-operative endovascular assistance, was critical to successful foreign body removal in this patient. This report demonstrates the utility of endovascular techniques for the assessment and treatment of occult cerebrovascular injuries from intracranial foreign bodies. Penetrating brain trauma is less common than closed head injury, with outcomes dependent on the penetrating object (1, 2). Gunshot wounds to the head comprise the majority of penetrating head traumas and are the most lethal due to their ballistic properties (1, 3). Accidental or intentional penetrating brain injuries from nail guns are a well-described phenomenon (4-8). Although nail guns are capable of firing projectiles at high speeds (up to 427 m/s), intracranial nails tend to act more like low-velocity missiles and cause only limited local injury (4). Aside from infection, a major concern with nail gun and other low-velocity penetrating head trauma is vascular injury. These situations necessitate detailed cerebrovascular imaging to evaluate the relationship of the missile to major vascular structures and to assess for traumatic pseudoaneurysms. We report here clinical and neuroimaging findings from a patient with an intracranial nail gun injury, a communicating ventricular tract hemorrhage upon nail removal, and a delayed pseudoaneurysm, whose treatment was augmented with neuroendovascular techniques.

4526. Rerolle, C., et al. (2015). "Contribution of Antemortem Computed Tomography Findings to Cause of Death Determination: An Unusual Fatal Stroke." Journal of forensic sciences **60**(4): 1095-1098.

In the case reported here, the antemortem computed tomography scan (CT scan) was essential in the forensic investigation. A 32-year-old man was found fully awake with a facial abrasion, after what seemed to be a car accident. He lost consciousness suddenly one hour after initial management. Successive CT scan showed a facial fracture and a metallic foreign body in the carotid canal associated with an occlusion/dissection of the left internal carotid, a pseudoaneurysm, and a carotid-cavernous fistula. The victim died from a stroke. Autopsy confirmed that the facial abrasion was a gunshot entrance wound, the metallic foreign body being a projectile. Intracranial vascular injuries linked with gunshot wounds are most of the time isolated and due to pelet embolism. The observed vascular injury association has never been described in the existing literature. The CT scan provided a better understanding of the chronology of events that led to death.

4527. Resnick, S., et al. (2017). "Early declaration of death by neurologic criteria results in greater organ donor potential." The Journal of surgical research **218**: 29-34.

BACKGROUND: Aggressive management of patients prior to and after determination of death by neurologic criteria (DNC) is necessary to optimize organ recovery, transplantation, and increase the number of organs transplanted per donor (OTPD). The effects of time management are understudied but potentially pivotal component. The objective of this study was to analyze specific time points (time to DNC, time to procurement) and the time intervals between them to better characterize the optimal timeline of organ donation., METHODS: Using data over a 5-year time period (2011-2015) from the largest US OPO, all patients with catastrophic brain injury and donated transplantable organs were retrospectively reviewed. Active smokers were excluded. Maximum donor potential was seven organs (heart, lungs [2],

kidneys [2], liver, and pancreas). Time from admission to declaration of DNC and donation was calculated. Mean time points stratified by specific organ procurement rates and overall OTPD were compared using unpaired t-test., RESULTS: Of 1719 Declaration of Death by Neurologic Criteria organ donors, 381 were secondary to head trauma. Smokers and organs recovered but not transplanted were excluded leaving 297 patients. Males comprised 78.8%, the mean age was 36.0 (+/-16.8) years, and 87.6% were treated at a trauma center. Higher donor potential (>4 OTPD) was associated with shorter average times from admission to brain death; 66.6 versus 82.2 hours, P = 0.04. Lung donors were also associated with shorter average times from admission to brain death; 61.6 versus 83.6 hours, P = 0.004. The time interval from DNC to donation varied minimally among groups and did not affect donation rates., CONCLUSIONS: A shorter time interval between admission and declaration of DNC was associated with increased OTPD, especially lungs. Further research to identify what role timing plays in the management of the potential organ donor and how that relates to donor management goals is needed.

4528. Reuhl, J., et al. (2000). "[Self-impalement after thoracic stab wound. An unusual method of suicide in psychotic symptomatology]." Selbst-Pfahlung nach Thoraxstichen. Eine ungewohnliche Suizid-Methode bei psychotischer Symptomatik. **205**(5-6): 152-161.

A 35 year-old male was found dead within a vast collection of garbage in his parent's house with 13 stab wounds of the thorax. 6 years before death he had suffered from a severe cerebral trauma with intracranial hemorrhage, after which an organic psychosis had ensued. At autopsy besides the stab wounds measuring 1-3.5 cm in length and partly exhibiting a so-called "fish-tail" formation a piece of wood was detected, having penetrated the fourth intercostal space along the sternal border and lacerated the pericardium, right pulmonary hilum and the pleura parietalis at the paravertebral line between the eight and ninth rib. There the leading part of the tool had apparently broken and bent to the left in a nearly 90 degrees angle, thus penetrating the left pleural cavity with a slight laceration of the lower lobe of the lung. From the forensic pathologist's point of view this case of multiple stabbing and additional impalement was at least remarkable and at first sight might have raised a suspicion of homicide due to the extent of the rib penetrations and especially the intrusion of the wooden device, which had been pushed by substantial force into an already existing wound. The police presupposed a suicide based on the personal history and situation at the site, where no traces suggesting an activity of somebody else could be ascertained. Reconstruction of the case and resulting differential diagnostic considerations are to be discussed.

4529. Rey, J. W., et al. (2015). "[Catch me if you can: endoscopic remove of a needle from the jejunum]." Catch me if you can: Endoskopische Bergung einer Sicherheitsnadel aus dem tiefen Dunndarm. **53**(8): 794-797.

INTRODUCTION: The ingestion of foreign bodies is a frequently observed problem in daily clinical practice. In order to avoid complications such as perforation, endoscopic removal of potentially penetrating foreign bodies should be attempted quickly. The use of various endoscopic techniques has been reported for this purpose. However, extraction of foreign bodies from the mid gastrointestinal tract has rarely been reported., CASE REPORT: We present the case of a patient who had swallowed a safety needle which could safely be removed from the jejunum by means of double-balloon enteroscopy (DBE). The combination of a thin p-type enteroscope with a thick t-type overtube was used in order to improve the manoeuvrability of the endoscope. The needle was pulled into the overtube which served as a protective shield during the retrieval of the endoscope., CONCLUSION: Our case report describes the potential of removing foreign bodies from the deep small bowel by pulling them into the overtube of a double-balloon enteroscope. If the suspicion of foreign body impaction in the small bowel is made, it may be advisable to primarily choose a balloon enteroscopy system. Through this, quick and deep insertion can be combined with a safe removal of the foreign body.

4530. Reychler, H. and R. Olszewski (2010). "Intracerebral penetration of a zygomatic dental implant and consequent therapeutic dilemmas: case report." The International journal of oral & maxillofacial implants **25**(2): 416-418.

This case report describes a unique intracerebral penetration of a zygomatic implant inserted in the pterygoid region. A 47-year-old female patient developed severe persistent headaches immediately after two zygomatic and two standard implants were inserted under general anesthesia. However, no additional treatment or radiologic assessment was performed at that time by the treating surgeon. The maxilla was rehabilitated with an implant-supported fixed denture 3 months after the implants were placed. An episode of acute left maxillary sinusitis occurred shortly after

insertion of the fixed denture. Treatment with antibiotics was insufficient, and the patient developed chronic left maxillary sinusitis. The patient presented herself to a neurologist with symptoms of chronic fatigue and severe headaches. Cerebral magnetic resonance imaging demonstrated the intracerebral penetration of a foreign body that resembled a dental implant. The authors sought to resolve the intracerebral penetration of the foreign body, along with the persistent maxillary chronic sinusitis with its concomitant risk of ascending cerebral infection. Computer-assisted preoperative planning associated with computer-assisted three-dimensional transfer should be used to avoid such a dangerous complication. Postoperative computed tomography assessment should be performed after zygomatic implant surgery. Finally, any neurologic impairment of the patient after pterygoid implantation should also be treated immediately.

4531. Reyes, C. and C. A. Solares (2015). "Endoscopic Repair of Frontal Sinus Cerebrospinal Fluid Leaks after Firearm Injuries: Report of Two Cases." Journal of neurological surgery reports **76**(1): e8-e12.

Objectives To describe two cases of cerebrospinal fluid (CSF) leak repair after gunshot wound to the head. Design Retrospective review of two cases. Settings A large regional tertiary care facility. Participants Two patients with gunshot wounds to the skull base. Main Outcome Measures Preoperative and postoperative physical and radiologic findings. Results Patients in this series underwent endoscopic surgery, debridement, and repair of CSF leaks after gunshot wounds to the head. To date, the patients are without CSF leak. Conclusions Endoscopic closure of anterior skull base CSF leaks in patients with gunshot wounds can be safe and effective. Treatment should be decided by the severity of neurologic deterioration throughout the emergency period and the existence or absence of associated intracranial lesions. Timing for surgery should be decided with great care and with a multidisciplinary approach.

4532. Reyes, S., et al. (2015). "Developments in intracerebral stem cell grafts." Cell Transplantation **24**(4): 770.

The field of stem cell therapy has emerged as a promising research area for brain repair. Optimizing the safety and efficacy of the therapy for clinical trials will require revisiting transplantation protocols. The cell delivery route stands as a key translational item that warrants careful consideration in facilitating the success of stem cell therapy in the clinic. Intracerebral administration, compared to the peripheral route, requires an invasive procedure to directly implant stem cells into the injured brain. Although invasive, intracerebral transplantation circumvents the prohibitive blood-brain barrier in allowing grafted cells when delivered peripherally to penetrate the brain and reach the discreet damaged brain tissues. In this presentation, we will highlight milestone discoveries in cell therapy for neurological disorders, with emphasis on intracerebral transplantation in relevant animal models and provide insights necessary to optimize the safety and efficacy of cell therapy for the treatment of Parkinson's disease, Huntington's disease, stroke, and traumatic brain injury. Despite scientific advances that led to limited clinical applications of cell therapy, the challenges of implementing large-scale stem cell therapy in the clinic remain, requiring transplant regimen optimization and investigations into mechanisms of action underlying this treatment. The cellular and molecular changes in the brain microenvironment that accompany the progression of the disease warrant a careful consideration of the cell delivery route that will facilitate enhanced regeneration of the injured brain. A review of experimental and clinical data is deemed critical in guiding scientists in finding the most effective and safe transplant methodologies in an effort to improve outcomes in both animal models and patients with neurological disorders.

4533. Reynolds, M. R., et al. (2018). "Transorbital intracranial penetrating trauma with carotid artery injury: a multidisciplinary approach to management." Journal of neurosurgical sciences **62**(1): 89-91.

4534. Rezae, L., et al. (2014). "Case report on the successful removal of an organic penetrating object into the orbit." Journal of injury & violence research **6**(1): 50-52.

The penetration of objects into the orbit can lead to blindness and even to the death of the patient. The penetration of organic objects longer than 7 cm into the eye is a rare phenomenon. In this study, we report a case in which a 6-year-old boy fell on a pencil which penetrated the upper side of his right eye orbit. Because of the agitation of the child and the lack of access, it was not possible to perform a brain or orbital computed tomography (CT) scan, but an X-ray showed that the object had gone directly into the retro-orbital space. As the result of a clinical diagnosis, it was possible to ascertain that the globe was severely hypertonic. Throughout this process the child was extremely agitated.

After consultation with the neurosurgery service, the patient was rushed to the operation room. After anesthesia and superanasal peritomy, the pencil was removed slowly from the orbit. Neurology and CT scans after surgery didn't show any ocular or brain symptoms. Once the patient's general condition had improved sufficiently and his visual acuity had returned to 10/10, he was discharged from the hospital. This case shows that even without specialized tests, such as CT scans, an organ can be saved.

4535. Rezai, A. R., et al. (1994). "Traumatic posterior cerebral artery aneurysm secondary to an intracranial nail: case report." Surgical neurology **42**(4): 312-315.

We present the case of a traumatic posterior cerebral artery aneurysm from a self-inflicted pneumatic nail-gun missile injury through the roof of the mouth. The patient presented to us in a coma with subarachanoid and intraventricular hemorrhage. Cerebral angiography revealed an aneurysm of the left posterior cerebral artery with no distal filling. The patient died 6 days after admission. At autopsy, a pseudoaneurysm of the posterior cerebral artery was seen. This aneurysm resulted from direct disruption of the arterial wall by the intracranial nail.

4539. Rheinboldt, M., et al. (2014). "Terson syndrome in conjunction with ruptured intracranial aneurysm and penetrating intracranial injury: a review of two cases." Emergency radiology **21**(2): 215-218.

Terson syndrome, the presence of intraocular hemorrhage in the setting of acutely elevated intracranial pressure, was historically described in conjunction with acute subarachnoid hemorrhage; however, more recently, it has been associated with a gamut of intracranial pathophysiology ranging from blunt or penetrating injury to neurosurgical procedures. We describe two cases of profound intracranial injury, secondary to ballistic injury, and a ruptured intracranial aneurysm, in which posterior chamber ocular hemorrhage was noted on CT imaging. Though the outcome in such cases, as with ours, is often poor, the findings are germane to clinical care as the presence of Terson syndrome has been noted to be a negative prognostic factor in multiple clinical reviews. Additionally, clinical recovery can be impacted adversely by lasting visual deficits or retinal degradation in the absence of timely ophthalmologic intervention.

4540. Rhine, J. S. and B. K. Curran (1990). "Multiple gunshot wounds of the head: an anthropological view." Journal of forensic sciences **35**(5): 1236-1245.

A decomposed body was judged at the scene to have two gunshot wounds of the thorax and three of the head. Confirmed at autopsy, the condition of the remains precluded conclusions about the precise nature of the defects. Preparation and reconstruction of the skull disclosed seven large cranial defects and a series of fractures. This preparation allowed the application of well-known principles of gunshot wound analysis. Although the analysis of specific gunshot wound defects is well covered in the literature, there are few examples of the application of gunshot wound principles to complex wound cases. Three entrances and three exits were identified. A seventh defect resulted from bullet passage. Finally, the wounds were sequenced.

4541. Riabukha, N. P. (1992). "[The diagnosis and treatment of open craniocerebral trauma]." Diagnostika i lechenie otkrytoi cherepno-mozgovoi travmy. **148**(2): 197-202.

An analysis of findings of complex clinical examinations and treatment of 46 patients with open cranio-cerebral traumas was made. Specific features of clinical manifestations are shown which are substantially different from closed cranio-cerebral traumas. They are primary infection of the cranio-cerebral wound, haemorrhage, liquorrhea, foreign bodies in the cranial cavity. Curative measures for the first aid, indications and contraindications for early surgical treatment, its technique are elucidated.

4542. Ribeiro, C. J. N., et al. (2018). "Pain assessment of traumatic brain injury victims using the Brazilian version of the Behavioral Pain Scale." Avaliacao da dor de vitimas de traumatismo craniencefalico pela versao brasileira da Behavioral Pain Scale. **30**(1): 42-49.

OBJECTIVE: To evaluate the validity and reliability of the Brazilian version of the Behavioral Pain Scale (BPS-Br) in victims of traumatic brain injury., METHODS: Observational prospective study with paired and repeated measures conducted at two intensive care units (clinical and surgical) of a large general hospital. The convenience sample consisted of adult victims of moderate or severe penetrating or blunt craniocerebral trauma who were sedated and mechanically ventilated. A total of 432 paired observations were performed by independent evaluators simultaneously, prior to eye cleaning, during eye cleaning, during tracheal aspiration and after tracheal aspiration. Sociodemographic, clinical, trauma-related, sedoanalgesia and physiological parameter data (heart rate, systolic and diastolic blood pressure) were collected. The discriminant validity was tested using the Friedman and Wilcoxon paired tests. The intraclass correlation coefficient and Cohen's Kappa coefficient were used to evaluate the reliability. The Spearman correlation test was used to test the association between clinical variables and BPS-Br scores during tracheal aspiration., RESULTS: There was a significant increase in the physiological parameters during tracheal aspiration, but without correlation with the BPS-Br scores. Pain was significantly more intense during tracheal aspiration ($p < 0.005$). Satisfactory interobserver agreement was found, with an intraclass correlation coefficient of 0.95 (0.90 - 0.98) and Kappa coefficient of 0.70., CONCLUSION: Brazilian version of the Behavioral Pain Scale scores increased during tracheal aspiration. The Brazilian version of the scale was valid and reliable for pain assessment of traumatic brain injury victims undergoing tracheal aspiration.

4543. Ricci, M. R. (1999). "The arrow-head which went through the brain." East African medical journal **76**(7): 411-413.

An 18-year old man was admitted into hospital being fully conscious, with a thirteen centimetre long metal arrow-head entirely lodged intracranially, having entered through the right orbit. Pre- and post-operative neurological condition, treatment and investigations are described. The arrow-head was removed through a partial occipital craniectomy without any major haemorrhage. The patient not only survived the operation, but was also discharged in an astonishing improved neurological condition.

4544. Rice, M. W., et al. (2018). "Cannabidiol-rich hemp extract reduces edema following severe, penetrating brain injury." Journal of neurotrauma **35**(16): A217.

Cerebral edema following traumatic brain injury (TBI) results in higher rates of morbidity and mortality. Activation of the cannabinoid system shows promise in regulating brain edema following ischemia and mild to moderate brain injury, however, no investigation has yet examined the results of cannabinoid administration in a severe, penetrating TBI model. This study aimed to evaluate the efficacy of a hemp extract high in cannabidiol (CBD) for reducing edema in an animal model of penetrating ballistic-like brain injury (PBBI). Rats were randomly divided into four groups: PBBI-CBD 75mg/kg, PBBI-No Treatment, PBBIVEH (extra virgin olive oil), or Sham (no craniectomy). CBD and VEH treatments were administered via oral gavage beginning at 15 minutes post-injury and continuing for twice a day out to 72 hours post-injury. Within two hours following the final treatment, animals were euthanized with CO2 and rapidly decapitated. Brains were then placed in a brain-block device, cut into 4mm sections, and hemisected. Three blocks constituting the entirety of the ipsilateral side, as well as the block containing the middle portion of the contralateral side of the cortex were collected. Edema was measured as the difference in percent water content ([fresh weight - dry weight]/fresh weight) between fresh tissue blocks and those same blocks following exposure of the tissue to 607deg;C in a vacuum oven for seven days. Oral administration of the CBD high-content hemp oil resulted in a significant decrease in edema as compared to PBBI-No Treatment and PBBI-VEH animals in the anterior-ipsilateral portion of the brain, the entry site of our penetrating injury. However, treatment did not return edema to baseline levels. In mid-ipsilateral tissue blocks, a significant increase in edema between our PBBI groups as compared to Sham was observed, which was not

significantly ameliorated by the 75mg/kg CBD treatment. As expected, no significant differences in edema were observed among our groups at either the poster-ipsilateral or mid-contralateral portions of the brain. In summary, this investigation reveals that cannabinoids were able to reduce some aspects of brain swelling, warranting additional study. Further investigations into the neuropathology are upcoming and will be presented at the conference.

4546. Richardson, R., et al. (1992). "Neurologic consequences of cerebrovascular injury." The Journal of trauma **32**(6): 755-760.

Because of ongoing controversy, the issue of vascular repair or ligation for patients with cerebrovascular injuries and preoperative central neurologic deficits is frequently debated. A total of 133 patients with penetrating cerebrovascular injuries were analyzed. The frequency of preoperative neurologic deficit was 20% (27 patients). The common carotid and internal carotid arteries were the most frequently injured structures, with a 29% and 15% incidence of preoperative neurologic deficits, respectively. The results of carotid repair in all patients whose preoperative deficit was limited to weakness or paralysis were favorable (seven patients normal or improved, two patients unchanged). The results of repair in patients whose preoperative deficit was characterized by obtundation were variable (four patients improved, four patients worsened or died). The results of carotid ligation were also variable (one improved, one unchanged, three worsened or died). Limited numbers of patients with preoperative neurologic deficits and the retrospective nature of this review prohibit definite conclusions. Therefore a multicenter, prospective, randomized trial of ligation or vascular repair for comatose patients with cerebrovascular injuries is proposed.

4547. Rickert, C. H., et al. (1998). "A unique case of cerebral spleen." The American journal of surgical pathology **22**(7): 894-896.

We present the first case of cerebral splenosis, occurring in a 20-year-old man 15 years after posttraumatic splenectomy. He became symptomatic through seizures and was operated on for suspected meningioma of the right occipital pole. Histologic evaluation of the lesion revealed splenic tissue with matching immunohistochemical results. Because no penetrating head injuries were reported at the time of trauma, a hematogenous spread of splenic tissue has to be assumed.

4548. Rickman, J. M. and M. J. Smith (2014). "Scanning electron microscope analysis of gunshot defects to bone: an underutilized source of information on ballistic trauma." Journal of forensic sciences **59**(6): 1473-1486.

Recent years have seen increasing involvement by forensic anthropologists in the interpretation of skeletal trauma. With regard to ballistic injuries, there is now a large literature detailing gross features of such trauma; however, less attention has been given to microscopic characteristics. This article presents analysis of experimentally induced gunshot trauma in animal bone (Bos taurus scapulae) using full metal jacket (FMJ), soft point (SP), and captive bolt projectiles. The results were examined using scanning electron microscopy (SEM). Additional analysis was conducted on a purported parietal gunshot lesion in a human cranial specimen. A range of features was observed in these samples suggesting that fibrolamellar bone response to projectile impact is analogous to that observed in synthetic composite laminates. The results indicate that direction of bullet travel can be discerned microscopically even when it is ambiguous on gross examination. It was also possible to distinguish SP from FMJ lesions. SEM analysis is therefore recommended as a previously underexploited tool in the analysis of ballistic trauma.

4549. Ricks, W. A. and H. Alemayehu (2020). "Aspiration of a bullet after a gunshot wound to the face." Journal of Pediatric Surgery Case Reports **61**.

There are very few reports of penetrating injuries to the head and neck resulting in aspiration of and retained intrabronchial foreign bodies. We present a pediatric patient who sustained a gunshot injury to the face with

subsequent aspiration of the bullet. Removal of the retained bullet was achieved with flexible bronchoscopy. Additionally, we review the available literature on this rare injury pattern.

4550. Riefkohl, R., et al. (1986). "Chain saw injuries to the face." Annals of plastic surgery **16**(2): 87-89.

Chain saws may produce devastating facial injuries when the blade kicks back after striking a hard object. A review of experience with 12 male patients indicates that in addition to extensive ragged lacerations of skin and soft tissues, bone and teeth are frequently fractured. Eye injuries are rare, but the eyelids may be extensively damaged. Management includes debridement and exploration of the wounds, repair of soft tissues, removal of fractured roots, and application of arch bars if the jaw is fractured.

4551. Riepert, T., et al. (2001). "[Postmortem roentgen diagnosis of the skull]." Zur postmortalen Rontgendiagnostik des Schadels. **208**(3-4): 65-71.

In this prospective study, skulls of 164 dead bodies were x-rayed in two different planes. The findings were assessed independent to the results of the subsequent autopsy, however afterwards compared with the autopsy findings. In 86 cases (53.4%) x-ray findings were significant. Dislocated calvarium fractures were clearly visible on the x-rays, however non-dislocated calvarium fractures as well as fractures of the visceral cranium and skull base were difficult to detect. Gas and foreign bodies could easily be observed. Similar to the clinical assessment the indication for a post-mortem x-ray of the skull must consider the case history and the respective condition of the corpse (for example putrefaction, charred body).

4553. Rikken, Q. G. H., et al. (2022). "Epidemiology of penetrating injury in an urban versus rural level 1 trauma center in the Netherlands." Hong Kong Journal of Emergency Medicine **29**(1): 38-45.

Background: Penetrating injury can encompass a large spectrum of injuries dependent on the penetrating object, the location of entry, and the trajectory of the object through the human body. Therefore, the management of penetrating injuries can be challenging and often requires rapid assessment and intervention. No universal definition of penetrating injury exists in the literature and little is known about the demographics and outcome of penetrating injury in the Netherlands. Objective: A research was carried out to ascertain the size and outcome of penetrating injuries in two level-one trauma centers in the Netherlands. Methods: Using the trauma registry of the Radboud University Medical Center in Nijmegen and VU University Medical Center in Amsterdam, all patients with penetrating injury were identified who were admitted to these level 1 trauma centers in the period between January 1, 2009, and January 1, 2014. Penetrating injury was defined as an injury that caused disruption of the body surface and extended into the underlying tissue or into a body cavity. Data concerning age, gender, mechanism of injury, Glasgow Coma Scale, number of injuries, type of injury, and Injury Severity Score were collected and analyzed. Patient results were stratified by Injury Severity Score. Results: In total, 354 patients were identified, making up around 2% of all admitted trauma patients 3.1% (VU Medical Center) and 1.6% (Radboud Medical Center). Patients were overwhelmingly male (83.1%) and median age was 36 years (range = 1–88 years). Most injuries were caused by stabbings (51.1%) followed by shootings (26.3%). Admission to the intensive care unit occurred in 41.1% of all patients. Median stay in the intensive care unit was 5.1 days (range = 1–96 days) and median total hospital stay was 8 days (range = 1–95 days). Mortality among these patients was 7.1%, ranging from 0% among patients with Injury Severity Score 1–8 to 100% in patients with Injury Severity Score > 34. High mortality figures were associated with injuries caused by firearms (19.4%), injuries to the head (27.9%), and alleged assaults (10.9%). Differences in demographics between the two centers were not significant. Conclusion: Penetrating injury is a relative rare occurrence in the Netherlands compared with other countries. It is associated with high mortality and substantial hospital costs. The incidence of penetrating injuries is higher in metropolitan areas than in rural areas. A universal definition of penetrating trauma should be agreed upon in order to ensure that future studies remain free of bias, and also to ensure that data remain homogeneous.

4554. Riley, J. P., et al. (2017). "The Role of Intraoperative Cerebral Angiography in Transorbital Intracranial Penetrating Trauma: A Case Report and Literature Review." World neurosurgery **97**: 761.e765-761.e710.

BACKGROUND: Transorbital intracranial penetrating trauma with a retained intracranial foreign body is a rare event lacking a widely accepted diagnostic and therapeutic algorithm. Intraoperative catheter angiography (IOA) has been advocated by some authorities to rule out cerebrovascular injury before and/or after removal of the object, but no standard of care currently exists., CASE DESCRIPTION: A 19-year-old man was involved in a construction site accident whereby a framing nail penetrated the left globe, traversed the lateral bony orbit, and terminated in the midtemporal lobe. No hematoma or injury to the middle cerebral arteries (MCAs) was apparent on noncontrast head computed tomography (CT) or CT angiography, respectively. The foreign body was removed in the operating room under direct visualization after a frontotemporal craniotomy without incident. No significant venous or arterial bleeding was encountered. All visualized MCA branches appeared intact. Indocyanine green videoangiography performed immediately after object removal showed adequate filling of the MCA branches. Given these uneventful clinical and radiographic findings, IOA was not performed. Postoperative head CT and CT angiography showed no obvious neurovascular injury. On postoperative day 2, the patient was noted to have an expressive aphasia. Cerebral angiography showed absent antegrade filling of the angular artery with some retrograde perfusion. Magnetic resonance imaging confirmed an ischemic infarction in the midtemporal lobe. The patient's expressive aphasia improved to near baseline during his hospitalization and he made an excellent clinical recovery., CONCLUSIONS: In transorbital intracranial penetrating trauma with a retained intracranial object, we advocate microsurgical removal of the object under direct visualization followed immediately by IOA. IOA should be strongly considered even in the setting of minimal intraoperative bleeding and normal findings on videoangiography (a course of action that was not followed in the present case). Given that CT angiography and intraoperative videoangiography may miss a potentially treatable traumatic arterial injury, IOA can help determine whether cerebral revascularization may be necessary.

4555. Rinaldi, A., et al. (2000). "Cranio-orbital missile wound and bullet migration. Case report." Journal of neurosurgical sciences **44**(2): 107-112.

An unusual case of craniocerebral missile injury, with orbital roof perforation and spontaneous bullet migration into the maxillary sinus, is reported. Emergency treatment consisted in wide craniectomy around the bullet entry point, blood and foreign bodies debridement. Subsequent procedures were necessary for abscess evacuation, transmaxillary bullet removal and later cranial vault reconstruction. Challenging aspects were the treatment of the infectious complications, following cerebrospinal fluid fistula through the wound, and the onset of post-traumatic epilepsy, scarcely responsive to common antiepileptic drugs. The treatment of the abscess by combined systemic and intracavitary antibiotic therapy and of the chronic seizures by progressive adjustment with new protocols of antiepileptic drugs under EEG and brain mapping revealed successful.

4556. Rincon, S., et al. (2016). "Imaging of head trauma." Handbook of clinical neurology **135**: 447-477.

Imaging is an indispensable part of the initial assessment and subsequent management of patients with head trauma. Initially, it is important for diagnosing the extent of injury and the prompt recognition of treatable injuries to reduce mortality. Subsequently, imaging is useful in following the sequelae of trauma. In this chapter, we review indications for neuroimaging and typical computed tomography (CT) and magnetic resonance imaging (MRI) protocols used in the evaluation of a patient with head trauma. We review the role of CT), the imaging modality of choice in the acute setting, and the role of MRI in the evaluation of patients with head trauma. We describe an organized and consistent approach to the interpretation of imaging of these patients. Important topics in head trauma, including fundamental concepts related to skull fractures, intracranial hemorrhage, parenchymal injury, penetrating trauma, cerebrovascular injuries, and secondary effects of trauma, are reviewed. The chapter concludes with advanced neuroimaging techniques for the evaluation of traumatic brain injury, including use of diffusion tensor imaging (DTI), functional MRI (fMRI), and MR spectroscopy (MRS), techniques which are still under development.

4557. Ringos Beach, P., et al. (2011). "Organ donation after circulatory death: vital partnerships." The American journal of nursing **111**(5): 32-40.

OVERVIEW: The authors present the case of a woman in her mid-50s who sustained extensive brain injury in an accident but wasn't declared brain dead. The case highlights some of the clinical and ethical considerations of organ donation after circulatory death (also known as non-heart-beating donation and donation after cardiac death). It also illustrates the interdisciplinary teamwork necessary for organ donation in such cases, involving nurses and other clinicians in the ICU, palliative care, and the local organ procurement organization, among others., KEYWORDS: cardiac death, circulatory death, donation after cardiac death, end-of-life care, ethics, non-heart-beating donation, organ donation, organ donation after circulatory death, organ transplantation, palliative care.

4558. Ripley, D., et al. (2016). "The physiological basis of fatigue after traumatic brain injury." Brain injury **30**(5-6): 713.

Objectives: Fatigue represents one of the most common complaints of individuals following traumatic brain injury (TBI). The complaint of fatigue following TBI differs from fatigue experienced by uninjured individuals, suggesting an underlying physiological cause. There have been many theories of the basis of fatigue, none of which fully explain the phenomenon. The objective of this study was to explore the association between physiological, psychological and physical factors contributing to fatigue in a small population of individuals following TBI, in order to determine foci for interventional trials. Methods: Twelve subjects who were between the ages of 18-65, with a prior hospitalization for non-penetrating moderate- to-severe TBI that occurred at least 1 year prior, underwent a week-long evaluation including brief neuropsychological assessment, evaluation of resting energy expenditure using indirect calorimetry, serum electrolyte and hormone screening, MRI including resting state fMRI, activity monitoring and sleep monitoring using actigraphy, diet and exercise logs, all compared to subjective fatigue, as measured by the fatigue sub-scale of the TBI-QoL. Results: Increased fatigue as measured by the fatigue sub-scale of the TBI-QoL was correlated with greater resting energy expenditure [REE] ($r = 0.6210$, $p = 0.0414$), increased Cortisol ($r = 0.63$, $p = 0.037$) and increased score on the Depression Sub-scale of the Neurobehavioural Functioning Inventory ($r = 0.721$, $p = 0.008$). Trends were observed towards correlations between duration of wakefulness after sleep onset (WASO) ($r = 0.5812$, $p = 0.0608$) and increased IGF-1 ($r = 0.57$, $p = 0.06$). We used LASSO (Least Absolute Shrinkage and Selection Operator) regularized linear regression, a method that automatically selects the variables in the model that contributes to the response (fatigue on TBI-QoL) through cross-validation. Contributing factors in this model that predicted Fatigue were serum Cortisol, Sleep Disturbance and the Depression Sub-scale score of the NFI. There was no association between physical activity and fatigue. Conclusions: Fatigue following TBI is a multifactorial phenomenon, with Cortisol, Emotional Status (increased depression) and Sleep Disturbance being important contributors. Although an association was seen between REE and fatigue, this did not contribute significantly in the final model. Neither did IGF-1, which was additionally found to have an opposite relationship than reported in prior studies. It is felt that Cortisol may be elevated due to Stress or Anxiety, which has been reported to be associated with fatigue in other studies. These results lead to the suggestion that emotional factors strongly drive subjective fatigue and actually may be related to the other variables, such as increased Cortisol due to endogenous stress, poorer sleep and higher resting energy expenditure. These results will need to be confirmed in a larger study and may form the basis for an interventional trial.

4559. Rish, B. L., et al. (1981). "Analysis of brain abscess after penetrating craniocerebral injuries in Vietnam." Neurosurgery **9**(5): 535-541.

A population of 1221 patients from the Vietnam War with penetrating craniocerebral trauma was analyzed. Thirty-seven cases of brain abscess were documented (incidence 3%). This sequela occurred more frequently in association with extensive, deep penetrating injuries; deep, prolonged coma; cerebrospinal fluid fistulas; wound infections; facio-orbital cranial/air sinus injuries; and retained bone fragments. The mortality rate was 54%, and, of the patients who survived, 82% had significant morbidity. This is the last large population study of brain abscess after penetrating craniocerebral trauma before the availability of computed tomographic scanning and more comprehensive coma care. It should serve as base line data against which we can measure improvement.

4560. Rish, B. L., et al. (1980). "Evolution of craniotomy as a debridement technique for penetrating craniocerebral injuries." Journal of neurosurgery **53**(6): 772-775.

A craniotomy debridement technique was recommended for penetrating craniocerebral injuries as early as 1940, in World War II. However, with due consideration for the bacterial contamination of penetrating injuries, the safety of this technique was questionable. The technique has been recommended in each succeeding war, but no data

substantiating the safety or eventual sequelae have been available. Analysis of the data from the large Head Injury Registry of Vietnam casualties indicates that, in properly selected cases, debridement by craniotomy technique can be safe and efficacious.

4561. Rish, B. L., et al. (1979). "Cranioplasty: a review of 1030 cases of penetrating head injury." Neurosurgery **4**(5): 381-385.

A total of 491 cranioplasties performed in a population of 1030 cases of penetrating head injury are reviewed. The morbidity rate was 5.5%, and the mortality rate was 0.2%. The clinical criteria of improving cosmetic defects and restoring craniocerebral protection are established, based on the location and size of the skull defect. Cranioplasty after penetrating head injury should be deferred for a minimum of 1 year to control morbidity. Complication of the original injury and surgical debridement increase the morbidity rate of cranioplasty. Post-traumatic epilepsy is not related to skull defects per se; neither is it affected by cranioplasty. Acrylic is an acceptable cranioplasty material if there is strict adherence to good surgical technique.

4562. Rish, B. L., et al. (1983). "Mortality following penetrating craniocerebral injuries. An analysis of the deaths in the Vietnam Head Injury Registry population." Journal of neurosurgery **59**(5): 775-780.

A population of 1127 men with penetrating craniocerebral injuries who were alive 1 week after their injuries has been followed for 15 years. During this time, 90 deaths (8%) occurred. Most of the deaths occurred early in the 1st year after trauma and were secondary to the direct effects of brain injury or the sequelae of coma. Complications, particularly infections, were significant mortality factors. Coma was the best prognostic guideline. Posttraumatic epilepsy was not related to mortality except for the risks accompanying each ictus. The population now appears to be approaching the actuarial norm of their peers.

4563. Risling, M., et al. (2012). "Alteration in bdnf and its receptors, fulllength and truncated TrkB and p75NTR following penetrating traumatic brain injury." Journal of neurotrauma **29**(10): A53-A54.

Introduction BDNF exerts multiple functions during CNS development and after injury. We have recently shown that the polymorphism of human BDNF gene predicts the cognitive recovery and outcome following penetrating TBI. In this study we have examined the expression of BDNF and its receptors in a rat model for penetrating TBI. Methods We used new model for penetrating TBI model in rat. The injury is produced by a controlled penetration of 2mm thick needle shaped object, which is accelerated with a bullet from air gun or a pendulum. We used in situ hybridization and investigated the mRNA expression of BDNF and its receptors, the full-length and the truncated TrkB and p75NTR, from 1 day to 8 weeks following penetrating TBI. In addition, the protein level of BDNF in cortex and hippocampus was measured following injury by reverse phase protein microarray (RPPM). Results The mRNA expression of BDNF and its receptors decreased in the penumbra zone ipsilateral to the injury while there was an increase in mRNA expression at the contralateral side of injury. The increase of BDNF mRNA expression in the hippocampus sustained for 2 weeks following injury. The most affected area was CA3. Furthermore, the protein analysis by RPPM showed increased levels of BDNF in the cortex and the hippocampus up to 2 weeks after TBI. At 8 weeks following injury the there was an intense labeling of the truncated TrkB receptor in the area surrounding the cavity. Also the mRNA expression of p75NTR was continuously increased around the cavity 8 weeks after injury. Conclusions Our study is the first report on the expression of BDNF and its receptors following penetrating TBI and suggests that their expression is altered long after the acute phase of injury. Further studies are needed to investigate if these late expressions of these receptors are beneficial or deleterious. In either case it raises the possibility to influence the recovery of brain injury during the chronic phase and the development of treatments that may improve TBI patients outcome.

4564. Ritchie, A. J. (1992). "Plastic bullets: significant risk of serious injury above the diaphragm." Injury **23**(4): 265-266.

A series of 123 patients who attended a district general hospital in Belfast over a 14-year period from 1975, sustained 126 plastic bullet injuries, resulting in one death and several serious injuries. This report shows the significant association of serious injury and/or death from plastic bullets in which the impact is above diaphragmatic level.

4565. Ritchie, E. C., et al. (1989). "Bullet in the brain: a case of organic psychosis." The Journal of neuropsychiatry and clinical neurosciences **1**(4): 449-451.

4566. Ritter, C. and G. Adebahr (1986). "[Stab injuries of the skull and brain]." Stichverletzung von Schadel und Gehirn. **96**(3): 229-234.

A few cases of skull and brain stab wounds are described and the clinicodiagnostic problems discussed. The injuries often remain unrecognized because the external wound often appears harmless, there are no neurological symptoms, or the clinical picture is interpreted as drunkenness, blunt injury or as another disease. The importance of a precise physical examination of the whole patient's head is pointed out. The refined methods used in modern radiodiagnostics of the skull are the most helpful in correctly recognizing these injuries; there are reports of patients with severe injuries who recovered when the correct diagnosis had been established.

4567. Riva, F., et al. (2021). "Practical application of synthetic head models in real ballistic cases." International journal of legal medicine **135**(6): 2567-2579.

In shooting crimes, ballistics tests are often recommended in order to reproduce the wound characteristics of the involved persons. For this purpose, several "simulants" can be used. However, despite the efforts in the research of "surrogates" in the field of forensic ballistic, the development of synthetic models needs still to be improved through a validation process based on specific real caseworks. This study has been triggered by the findings observed during the autopsy performed on two victims killed in the same shooting incident, with similar wounding characteristics; namely two retained head shots with ricochet against the interior wall of the skull; both projectiles have been recovered during the autopsies after migration in the brain parenchyma. The thickness of the different tissues and structures along the bullets trajectories as well as the incident angles between the bullets paths and the skull walls have been measured and reproduced during the assemblage of the synthetic head models. Two different types of models ("open shape" and "spherical") have been assembled using leather, polyurethane and gelatine to simulate respectively skin, bone and soft tissues. Six shots have been performed in total. The results of the models have been compared to the findings of post-mortem computed tomography (PMCT) and the autopsy findings.Out of the six shots, two perforated the models and four were retained. When the projectile was retained, the use of both models allowed reproducing the wounds characteristics observed on both victims in terms of penetration and ricochet behaviour. However, the projectiles recovered from the models showed less deformation than the bullets collected during the autopsies. The "open shape" model allowed a better controlling on the shooting parameters than the "spherical" model. Finally, the difference in bullet deformation could be caused by the choice of the bone simulant, which might under-represent either the strength or the density of the human bone. In our opinion, it would be worth to develop a new, more representative material for ballistic which simulates the human bone.

4568. Riva, F., et al. (2019). "Individual synthetic head models in wound ballistics - A feasibility study based on real cases." Forensic science international **294**: 150-159.

Synthetic models, also called "surrogates", are commonly used in wound ballistics in order to simulate human tissues. Despite several surrogates are worldwide accepted and used; some of them have not been yet fully validated and their limits for forensic reconstructions have not been deeply investigated yet. In this work we present a homicide/suicide case involving three gunshots to the head with bullets retained in the skull or beneath the scalp. Reconstruction of these cases was performed preparing three individual synthetic head models based on post-mortem computed tomography (PMCT) measurements. Ballistic soap, polyurethane plates and 10% ballistic gelatine at 4degreeC were used as simulants in individually adapted thickness. Ballistic tests were performed using the questioned firearm and ammunition type. The damages on the synthetic models have been compared to the findings in PMCT and autopsy of the victims. Although the results highlighted general similarities in terms of injury characteristics, some of the experimental shots overpenetrated. Furthermore, the bullets recovered in the synthetic models did not show the same quality of deformations as the questioned bullets. This lack of bullet deformation in the synthetic models might be mainly attributed to the physical difference between real bones and polyurethane surrogate.

4569. Rivara, F. P. (1983). "Epidemiology of violent deaths in children and adolescents in the United States." Pediatrician **12**(1): 3-10.

Injuries are the largest cause of death in children and adolescents after the first year of life. Injuries more than any other disease result in 3.5 million years of potential life lost. Poor children are particularly at risk of dying from trauma, particularly fires and drownings. The patterns of different types of childhood injuries are discussed, including motor vehicle occupants, pedestrian, bicycle and motorcycle injuries, fire and flame injuries, drownings and firearm deaths. For each of these, possible preventive strategies suggested by injury epidemiology are given. Intentional injuries from suicide and homicide are included because of similarities in epidemiology and prevention. The article also outlines areas where few effective strategies are available and where further research should be concentrated.

4570. Rivas, L., et al. (2022). "Early Chemoprophylaxis Against Venous Thromboembolism in Patients With Traumatic Brain Injury." The American surgeon **88**(2): 187-193.

INTRODUCTION: Timing to start of chemoprophylaxis for venous thromboembolism (VTE) in patients with traumatic brain injury (TBI) remains controversial. We hypothesize that early administration is not associated with increased intracranial hemorrhage., METHODS: A retrospective study of adult patients with TBI following blunt injury was performed. Patients with penetrating brain injury, any moderate/severe organ injury other than the brain, need for craniotomy/craniectomy, death within 24 hours of admission, or progression of bleed on 6 hour follow-up head computed tomography scan were excluded. Patients were divided into early (<=24 hours) and late (>24 hours) cohorts based on time to initiation of chemoprophylaxis. Progression of bleed was the primary outcome., RESULTS: 264 patients were enrolled, 40% of whom were in the early cohort. The average time to VTE prophylaxis initiation was 17 hours and 47 hours in the early and late groups, respectively (P < .0001). There was no difference in progression of bleed (5.6% vs. 7%, P = .67), craniectomy/-craniotomy rate (1.9% vs. 2.5%, P = .81), or VTE rate (0% vs. 2.5%, P = .1)., CONCLUSION: Early chemoprophylaxis is not associated with progression of hemorrhage or need for neurosurgical intervention in patients with TBI and a stable head CT 7 hours following injury.

4571. Rivera, G., et al. (2021). "Management of life-threatening post-traumatic otorrhagia." Clinical Case Reports **9**(1): 5-7.

Otorrhagia can be life-threatening, and acute control of the hemorrhage using easily accessible and practical techniques in the otolaryngology field such as Merocel packing and Kerlix gauze pressure dressing is essential to manage this complication.

4572. Rivera, G. A., et al. (2019). "A novel approach for controlling life-threatening post-traumatic otorrhagia." Otolaryngology - Head and Neck Surgery **161**(2): P183.

Objectives: To describe the presentation and acute management of severe life-threatening otorrhagia using an accessible and practical technique on the otolaryngology field. Methods: A case report and literature review are presented. Results: A 39-year-old man presented to the emergency room after suffering a gunshot wound to the left postauricular region over the mastoid bone. Initial otoscopic evaluation showed abundant soft tissue collapsing into the external auditory canal (EAC) with fresh bright red blood as well as blood clots within the canal without active bleeding. A nonabsorb-able hollow stent was placed in the EAC to maintain patency. A temporal bone imaging study demonstrated a complex temporal bone fracture extending to the carotid canal. A computed tomography angiogram showed a posttraumatic external carotid pseudoaneurysm. Soon after the study, the patient had a sudden onset of profuse uncontrollable left otorrhagia resulting in hemorrhagic shock. The EAC stent was removed, and hemostasis was successfully accomplished using a Merocel packing followed by a mastoid dressing. The neuroendovas-cular service proceeded to coil embolize the pseudoaneurysm controlling the hemorrhage. Conclusions: Otorrhagia will continue to be a common and self-limiting otolaryngology complaint. However, it can be life-threatening, and acute control of the hemorrhage using accessible otolaryngology equipment for novel cases can be crucial and a safe tool to manage this complication.

4573. Rivera-Lara, L., et al. (2010). "The “perfect storm” after nail gun penetration: Combined blast and vessel injury resulting in severe cerebral vasospasm." Neurocritical care **13**: S187.

Introduction Cerebral vasospasm (CVSP) is commonly seen after aneurysmal subarachnoid hemorrhage (SAH), but may also be seen after trauma. Vascular injury with SAH is the most intuitive etiology for traumatic CVSP. Blast injury - although a common cause for traumatic CVSP in the battle field - is rarely seen in civilians. We present a patient with a penetrating nail-gun brain injury in whom the blast and vessel injury combination lead to severe CVSP. Methods Case report. Results A 46 year-old man suffered a nail-gun induced penetrating brain injury through the foramen magnum. Head CT revealed two nails through the calvarium and left pons with tips in the left temporal lobe, SAH with intraventricular extension and a left temporal hematoma. A four-vessel angiogram (angio) revealed the nails adjacent to the left posterior cerebral artery (PCA) with PCA laceration and pseudoaneurysm formation. He underwent a successful craniotomy for removal of the two nails. On post-operative day (POD)# 6, his exam deteriorated. An angio revealed severe CVSP throughout, even in areas where no SAH was present, and intra-arterial nicardipine was given. NeuroICU treatment included nimodipine and hypervolemic but not hypertensive therapy because of a presumed increased risk of pseudoaneurysm rupture. On POD# 7, a repeat angio showed persistent CVSP, requiring intraarterial nicardipine and balloon angioplasty. To prevent rupture of the enlarging pseudoaneurysm, the left distal PCA was endovascularly occluded. A follow-up angio on POD# 10 revealed the resolution of CVSP. Four months after discharge, the patient was oriented, able to answer questions, walking with assistance, but was left with behavioral problems, several cranial nerve palsies and right arm weakness. Conclusions Although we do not know the exact mechanism of CVSP in this patient, we suspect that SAH alone could not explain the diffuse nature of the CVSP. Blast injury contributing to traumatic CVPS should be considered even in civilians when the vessel injury with SAH is remote from the CVPS vessel territories. When recognized early and treated aggressively, early death and severe disability may be prevented in traumatic CVSP.

4574. Rivers, J., et al. (2020). "Impact of a Devastating Brain Injury Pathway on Outcomes, Resources, and Organ Donation: 3 Years' Experience in a Regional Neurosciences ICU." Neurocritical care **33**(1): 165-172.

OBJECTIVE: To assess the impact of introducing a devastating brain injury (DBI) pathway on patient outcome, intensive care unit (ICU) resources, and organ donation practice in the first 3 years of implementation in a regional neurosciences ICU in the South West of England., METHODS: Patients with DBI admitted to our ICU between 2015 and 2018 were identified from our ICU database and their outcomes compared to those of non-DBI patients. Data were also obtained from the national potential donor audit to compare organ donation metrics before and after the introduction of the DBI pathway. Organ donation metrics in DBI patients and non-DBI patients were compared once the pathway had been implemented., RESULTS: We admitted 85 DBI patients (1.3% of all admissions), with a significantly shorter median length of ICU stay than in non-DBI patients, 1.14 versus 2.93 days ($p < 0.001$). Decisions for withdraw life-sustaining treatments (WLST) were made significantly earlier in DBI patients, median 26.2 versus 84.8 h ($p < 0.001$). Over 8% of DBI patients survived, while 31% progressed to brain death compared to 7.1% in the general population ($p < 0.001$), and 25% become solid organ donors compared to 1.3% of the general population ($p < 0.001$). There was an increase in the proportion of donors after brain death (DBD) to donors after circulatory death (DCD) in the 3 years following the introduction of the DBI pathway ($p = 0.024$). There was also an increased proportion of DBD donors to DCD donors of 76% versus 24% in the DBI group compared to 62% versus 38% ($p = 0,002$) in the non-DBI population. Prognostic scoring systems do not provide accurate estimates of survival rate in this population., CONCLUSIONS: Admitting patients with perceived DBI to ICU and avoiding the early WLST allows identification of unexpected survivors and gives families more time in decision making at the end of life. The DBI pathway increases the potential for organ donation and increases the proportion of DBD donors. These benefits outweigh the small impact of a DBI pathway on ICU resources.

4575. Rizwan, M., et al. (2016). "Pattern of maxilofacial trauma in patients reporting at Liaquat University Hospital Hyderabad." Medical Forum Monthly **27**(10): 65-67.

Objective: The aim of present study was to evaluate the pattern of maxillofacial trauma in patients reporting at Liaquat University Hospital Hyderabad. Study Design: Observational/descriptive/cross sectional study Place and Duration of Study: This study was conducted at the Oral and Maxillofacial Surgery Outpatient Department of Liaquat University Hospital from 01-01-2014 to 31-12-2015. Materials and Methods: This study was to analyze the age, gender and site of facial fracture of patients due to road traffic accidents, assault, falls, gunshot and sports injuries. Data relating to 136 patients was collected. The diagnosis of the maxillofacial trauma was done on the basis of history, clinical features and appropriate radiographs. All the relevant information was recorded on proforma. Results: Most prevalent age of trauma was 21-30 years teenagers, male 104 (76%) outnumbered the female 32 (24%) with ratio of 4:1. The most common fractured bone of midface was zygomatic bone n=52 (38.3%) and the most common region of mandibular fracture was

parasymphysis n=34(25.0%). Conclusion: Trauma is a main cause of fracture of facial bones especially in the young male population of Pakistan. Zygomatic bone fracture and parasymphseal regions are most common fracture site.

4576. Roa, J., et al. (2022). "USE OF RESPONSIVE NEUROSTIMULATION FOR TREATMENT OF REFRACTORY EPILEPSY AFTER TRAUMATIC BRAIN INJURY: A CASE SERIES." Journal of neurotrauma **39**(11-12): A77.

Introduction: Refractory post-traumatic epilepsy (RPTE) is a debilitating sequela of about 10% of traumatic brain injury (TBI) cases. RPTE refers to seizures that persist >1 week after TBI despite appropriate trials of two or more medications. Responsive neurostimulation (RNS), a closed-loop system that provides stimulation when epileptiform activity is detected, has shown promising results in refractory epilepsy. Objective: To assess outcomes of RNS in RPTE. Methods: Patients who underwent RNS for RPTE between 2014 and 2021 at our institution were included. TBI severity was classified as mild (loss of consciousness (LOC) <30min + normal neuroimaging), moderate (LOC >30 minutes and <24h +/- skull fracture), or severe (LOC >24h hours + contusion/hematoma). Outcomes were assessed using Engel classification and improvement in seizure frequency, duration, severity, post-ictal recovery, and medication reduction. Results: Six patients underwent RNS for RPTE. Mechanisms of TBI included motor vehicle accidents in three patients (2 severe, 1 moderate), one motor pedestrian collision (severe), one gunshot wound to the head (severe), and one assault (moderate). Seizure onset zones included bilateral temporal (3 cases), temporal plus (2 cases), and multilobar (1 case). After a year patients experienced 50% or higher improvement in all categories: 3 patients achieved Engel Class III (50-90% improvement), 2 with Engel Class II (90-99% improvement), and 1 with Engel Class I (seizure-free). No complications were reported. Conclusions: RNS is a safe and effective treatment for RPTE. Patients carefully selected by adequate characterization of the seizure onset zone may benefit from this technology.

4577. Robaei, D., et al. (2004). "Orbitocranial penetration by a fragment of wood." The Medical journal of Australia **181**(6): 329-330.

4578. Robakis, D., et al. (2015). "A case of “prodromal” huntington's disease with neuropathology." Neurology **84**.

OBJECTIVE: To present the first case of neuropathologically confirmed “prodromal” Huntington's disease (HD). BACKGROUND: HD is neurodegenerative disorder inherited in an autosomal dominant manner. The current diagnostic criteria based exclusively on motor signs have been questioned recently by Reilmann et al., who proposed new criteria that incorporate historical information including behavioral and cognitive changes, and drew a distinction between presymptomatic and prodromal cases. Perhaps biased by current definitions, clinicopathologic studies to date have examined either asymptomatic (presymptomatic) HD or manifest HD of several years duration, of which relatively few have grade 1 neuropathology (16 cases in total; Gomez-Tortosa et al, Myers et al, Pillai et al), but to our knowledge, no cases of “prodromal” HD have been published with neuropathology. DESIGN/METHODS: The patient was a brain donor to the New York Brain Bank at Columbia University. History was obtained post-mortem through family members. Neuropathologic grade was assigned according to the Vonsattel HD grading scale. RESULTS: A 29-year old male with a maternal history of HD presented to autopsy after suffering lethal gunshot wounds in an altercation. Two weeks prior to death a family member familiar with HD noted an unsteady gait, dropping of objects, and apathy. The patient had become unemployed several months prior. He was not aware of deficits, did not present to a neurologist, and was not tested for CAG-repeat length. Neuropathology revealed grade 1 HD. The head and body of the caudate nucleus were atrophic; there was mild atrophy in the putamen and external segment of the globus pallidus. CONCLUSIONS: 1) Brain donation pre-plans are essential to capturing unexpected deaths associated with early HD. 2) The clinical course presented here is consistent with our current understanding of HD, and supports the use of a “prodromal” diagnostic category 3) Prodromal HD may correlate with grade 1 disease neuropathologically.

4579. Robb, J. D. and J. G. Matthews (1971). "The injuries and management of riot casualties admitted to the Belfast hospital wards, August to October, 1969." The British journal of surgery **58**(6): 413-419.

4580. Roberson, J. B. and W. S. Rosenberg (1997). "Traumatic cranial defects reconstructed with the HTR-PMI cranioplastic implant." The Journal of cranio-maxillofacial trauma **3**(2): 8-13.

Titanium mesh, polymethyl methacrylate application, and autogenous bone grafting have been used to reconstruct traumatic cranial defects, with varying success. A more recent technique utilizing hard tissue replacement-patient matched implants (HTR-PMIs) involves the production of a cranioplastic implant using three-dimensional computed tomography imaging. It has proven less time-consuming and provides an excellent cosmetic result for the patient. The authors present two case reports using this technique to correct traumatic cranial defects. Both patients exhibited satisfactory results and no postoperative complications. The authors believe this relatively new technique represents an advance in the management of large cranial defects.

4581. Roberts, D. J., et al. (2009). "Effect of acute inflammatory brain injury on accumulation of morphine and morphine 3- and 6-glucuronide in the human brain." Critical care medicine **37**(10): 2767-2774.

OBJECTIVE: In animals, central nervous system inflammation increases drug accumulation in the brain partly due to a loss of central nervous system drug efflux transporter function at the blood-brain barrier. To determine whether a similar loss of active drug efflux occurs in humans after acute inflammatory brain injury., DESIGN: Observational human pharmacokinetic study., SETTING: Medical-surgical-neurosurgical intensive care unit at a university-affiliated, Canadian tertiary care center., PATIENTS: Patients with acute inflammatory brain injury, including subarachnoid hemorrhage (n = 10), intracerebral and/or intraventricular hemorrhage (n = 4), or closed head trauma (n = 2) who received morphine intravenously after being fitted with cerebrospinal fluid ventriculostomy and peripheral arterial catheters., INTERVENTIONS: We correlated the cerebrospinal fluid distribution of morphine, morphine-3-glucuronide, and morphine-6-glucuronide with the cerebrospinal fluid and plasma concentration of the proinflammatory cytokine interleukin-6 and the passive marker of blood-brain barrier permeability, albumin., MEASUREMENTS AND MAIN RESULTS: Acute brain injury produced a robust inflammatory response in the central nervous system as reflected by the elevated concentration of interleukin-6 in cerebrospinal fluid. Penetration of morphine metabolites into the central nervous system increased in proportion to the neuroinflammatory response as demonstrated by the positive correlation between cerebrospinal fluid interleukin-6 exposure and the area under the curve cerebrospinal fluid/plasma ratio for morphine-3-glucuronide ($r = .49$, $p < .001$) and morphine-6-glucuronide ($r = .51$, $p < .001$). In contrast, distribution of morphine into the brain was not linked with cerebrospinal fluid interleukin-6 exposure ($r = .073$, $p = .54$). Albumin concentrations in plasma and cerebrospinal fluid were consistently in the normal range, indicating that the physical integrity of the blood-brain barrier was likely undisturbed., CONCLUSIONS: Our results suggest that central nervous system inflammation following acute brain injury may selectively inhibit the activity of specific drug efflux transporters within the blood-brain barrier. This finding may have significant implications for patients with neuroinflammatory conditions when administered centrally acting drugs normally excluded from the brain by such transporters.

4582. Roberts, E., et al. (2012). "Anti-seizure prophylaxis is unnecessary after traumatic brain injury." Brain injury **26**(4-5): 318-319.

Objective: The purpose of this study was to examine the effectiveness of prophylactic antiepileptic drugs during the early post-injury period (first seven days after traumatic brain injury [TBI]) in preventing post-injury seizures. Methods: The records of adult (age>16) patients with TBI from Jan 2005 to Jan 2010 at a Level I trauma center were retrospectively reviewed using NTRACS. Admission GCS, mechanism of injury (blunt vs. penetrating TBI), age, ISS, AIS, computed tomography (CT) scan of the head, day of seizure, and type of prophylaxis (Dilantin (Phenytoin), Keppra (Levetiracetam), or none) were all reviewed. Statistical analysis was performed using mean, and Chi-square test, accepting $p<0.05$ as significant. Results: 2061 adult patients with CT scan positive TBI after blunt and penetrating mechanisms were identified of which only 14 (0.68%) patients had a seizure during the early post-injury period. Patients were divided into two groups based on anti-seizure prophylaxis: No Prophylaxis (NP) (1383) and With Prophylaxis (WP) (Dilantin and Keppra) (678). For blunt and penetrating TBI, comparing NP vs. WP groups, no significant difference in seizure rate occurred regardless of GCS: GCS (3-15) [0.65% vs. 0.74%, p=0.82], GCS (9-15) [0.73% vs. 0.69%, p=0.94], and GCS(≤8) [0.47% vs. 0.82%, p=0.58]. For just blunt TBI, comparing NP vs. WP groups, again no significant difference in seizure rate occurred regardless of GCS: GCS (3-15) [0.55% vs. 0.47%, p=0.83], GCS (9-15) [0.76% vs. 0.74%, p=0.97], and GCS (≤8) [0.57% vs. 0.88%, p=0.66]. For just penetrating trauma patients there were no seizures in both the NP (n=105) vs. WP (n=42) group (p=1). Conclusions: Significantly lower overall seizure rate was noted as compared to previously reported (0.68% vs. 4-25%). Regardless of mechanism of injury (blunt or penetrating) or severity of TBI, [GCS (3-15), GCS (9 - 15), or GCS (≤8)] no significant difference in the seizure rate was found between NP and P groups. Therefore, seizure prophylaxis may not be necessary during the early post-injury (first seven days) period after TBI.

4583. Roberts, I., et al. (2017). "Tranexamic acid in bleeding trauma patients: an exploration of benefits and harms." Trials **18**(1): 48.

BACKGROUND: The CRASH-2 trial showed that tranexamic acid (TXA) administration reduces mortality in bleeding trauma patients. However, the effect appeared to depend on how soon after injury TXA treatment was started. Treatment within 3 h reduced bleeding deaths whereas treatment after 3 h increased the risk. We examine how patient characteristics vary by time to treatment and explore whether any such variations explain the time-dependent treatment effect., METHODS: Exploratory analysis were carried out, including per-protocol analyses, of data from the CRASH-2 trial, a randomised placebo-controlled trial of the effect of TXA on mortality in 20,211 trauma patients with, or at risk of, significant bleeding. We examine how patient characteristics (age, type of injury, presence or absence of head injury, Glasgow coma scale (GCS), systolic blood pressure and capillary refill time) vary with time to treatment and use univariable (restriction) and multivariable methods to examine whether any such variations explain the time-dependent effect of TXA. If not explained by differences in patient characteristics, we planned to conduct separate prespecified subgroup analyses for the early benefit and late harm., RESULTS: There was no substantial variation in age or capillary refill by time to treatment. However, the proportion of patients with blunt trauma, the proportion with head injury and mean systolic blood pressure increased as time to treatment increased. Mean GCS decreased as time to treatment increased. Analyses restricted to patients with blunt trauma, those without head injury and those with a systolic blood pressure <100 mmHg showed that these characteristics did not explain the time-dependent treatment effect. In a multivariable analysis the interaction with time to treatment remained highly significant (p < 0.0001). Separate subgroup analyses that examine how the benefits of early TXA treatment and the harms of late TXA treatment vary by systolic blood pressure (⩽75, 76-89, >89 mmHg); GCS (severe 3-8, moderate 9-12, mild 13-15); and type of injury (penetrating versus blunt) showed no significant heterogeneity., CONCLUSIONS: The time-dependent effect of TXA in bleeding trauma patients is not explained by the type of injury, the presence or absence of head injury or systolic blood pressure. When given within 3 h of injury, TXA reduces death due to bleeding regardless of type of injury, GCS or blood pressure., TRIAL REGISTRATION: ClinicalTrials.gov, NCT00375258 . Registered on 11 September 2006.

4584. Roberts, I., et al. (2013). "The CRASH-2 trial: a randomised controlled trial and economic evaluation of the effects of tranexamic acid on death, vascular occlusive events and transfusion requirement in bleeding trauma patients." Health technology assessment (Winchester, England) **17**(10): 1-79.

BACKGROUND: Among trauma patients who survive to reach hospital, exsanguination is a common cause of death. A widely practicable treatment that reduces blood loss after trauma could prevent thousands of premature deaths each year. The CRASH-2 trial aimed to determine the effect of the early administration of tranexamic acid on death and transfusion requirement in bleeding trauma patients. In addition, the effort of tranexamic acid on the risk of vascular occlusive events was assessed., OBJECTIVE: Tranexamic acid (TXA) reduces bleeding in patients undergoing elective surgery. We assessed the effects and cost-effectiveness of the early administration of a short course of TXA on death, vascular occlusive events and the receipt of blood transfusion in trauma patients., DESIGN: Randomised placebo-controlled trial and economic evaluation. Randomisation was balanced by centre, with an allocation sequence based on a block size of eight, generated with a computer random number generator. Both participants and study staff (site investigators and trial co-ordinating centre staff) were masked to treatment allocation. All analyses were by intention to treat. A Markov model was used to assess cost-effectiveness. The health outcome was the number of life-years (LYs) gained. Cost data were obtained from hospitals, the World Health Organization database and UK reference costs. Cost-effectiveness was measured in international dollars ($) per LY. Deterministic and probabilistic sensitivity analyses were performed to test the robustness of the results to model assumptions., SETTING: Two hundred and seventy-four hospitals in 40 countries., PARTICIPANTS: Adult trauma patients (n = 20,211) with, or at risk of, significant bleeding who were within 8 hours of injury., INTERVENTIONS: Tranexamic acid (loading dose 1 g over 10 minutes then infusion of 1 g over 8 hours) or matching placebo., MAIN OUTCOME MEASURES: The primary outcome was death in hospital within 4 weeks of injury, and was described with the following categories: bleeding, vascular occlusion (myocardial infarction, stroke and pulmonary embolism), multiorgan failure, head injury and other., RESULTS: Patients were allocated to TXA (n = 10,096) and to placebo (n = 10,115), of whom 10,060 and 10,067 patients, respectively, were analysed. All-cause mortality at 28 days was significantly reduced by TXA [1463 patients (14.5%) in the TXA group vs 1613 patients (16.0%) in the placebo group; relative risk (RR) 0.91; 95% confidence interval (CI) 0.85 to 0.97; p = 0.0035]. The risk of death due to bleeding was significantly reduced [489 patients (4.9%) died in the TXA group vs 574 patients (5.7%) in the placebo

group; RR 0.85; 95% CI 0.76 to 0.96; p = 0.0077]. We recorded strong evidence that the effect of TXA on death due to bleeding varied according to the time from injury to treatment (test for interaction p < 0.0001). Early treatment (<= 1 hour from injury) significantly reduced the risk of death due to bleeding [198 out of 3747 patients (5.3%) died in the TXA group vs 286 out of 3704 patients (7.7%) in the placebo group; RR 0.68; 95% CI 0.57 to 0.82; p < 0.0001]. Treatment given between 1 and 3 hours also reduced the risk of death due to bleeding [147 out of 3037 patients (4.8%) died in the TXA group vs 184 out of 2996 patients (6.1%) in the placebo group; RR 0.79; 95% CI 0.64 to 0.97; p = 0.03]. Treatment given after 3 hours seemed to increase the risk of death due to bleeding [144 out of 3272 patients (4.4%) died in the TXA group vs 103 out of 3362 patients (3.1%) in the placebo group; RR 1.44; 95% CI1.12 to 1.84; p = 0.004]. We recorded no evidence that the effect of TXA on death due to bleeding varied by systolic blood pressure, Glasgow Coma Scale score or type of injury. Administering TXA to bleeding trauma patients within 3 hours of injury saved an estimated 755 LYs per 1000 trauma patients in the UK. The cost of giving TXA to 1000 patients was estimated at $30,830. The incremental cost of giving TXA compared with not giving TXA was $48,002. The incremental cost per LY gained of administering TXA was $64., CONCLUSIONS: Early administration of TXA safely reduced the risk of death in bleeding trauma patients and is highly cost-effective. Treatment beyond 3 hours of injury is unlikely to be effective. Future work [the Clinical Randomisation of an Antifibrinolytic in Significant Head injury-3 (CRASH-3) trial] will evaluate the effectiveness and safety of TXA in the treatments of isolated traumatic brain injury (http://crash3.lshtm.ac.uk/)., TRIAL REGISTRATION: Current Controlled Trials ISRCTN86750102, ClinicalTrials.gov NCT00375258 and South African Clinical Trial Register DOH-27-0607-1919., FUNDING: The project was funded by the Bupa Foundation, the J P Moulton Charitable Foundation and the NIHR Health Technology Assessment programme and will be published in full in Health Technology Assessment; Vol. 17, No. 10. See HTA programme website for further project information.

4585. Roberts, P. (2002). "Patterns of injury in military operations." Current Anaesthesia and Critical Care **13**(5): 243-248.

The predominant causes of injury in peace are markedly different from those occurring in times of conflict. In peace, the majority of injuries are caused by blunt trauma. In war, penetrating injuries are by far the most common with blunt, blast and thermal injuries also arising. Penetrating injuries may be caused not only by bullets but by fragments and the actual mortality depends to, a large extent, on the site which is hit, brain, mediastinum and abdomen carrying the highest rate of lethality. Of particular importance with any penetrating injury is the energy transfer from the missile to the tissue which it enters.This review examines all of these issues together with the various strategies of management and likely outcomes.

4586. Roberts, P. A., et al. (2005). "Pneumoperitoneum after percutaneous endoscopic gastrostomy: a case report and review." The Journal of emergency medicine **28**(1): 45-48.

A complication of percutaneous endoscopic gastrostomy (PEG) is perforation of a hollow viscus. This is typically detected by finding of pneumoperitoneum (PP) on radiographs. However, PP can occasionally be a benign finding. A review of the literature shows many causes for a benign PP, and it has been noted to occur frequently after PEG placement. In the absence of signs or symptoms of peritoneal inflammation, PP usually requires no further investigation or treatment.

4587. Roberts, R. M., et al. (2014). "Diffusion Tensor Imaging (DTI) findings following pediatric non-penetrating TBI: a meta-analysis." Developmental neuropsychology **39**(8): 600-637.

This study meta-analyzed research examining Diffusion Tensor Imaging following pediatric non-penetrating traumatic brain injury to identify the location and extent of white matter changes. Fractional anisotropy (FA) and apparent diffusion coefficient (ADC) data from 20 studies were analyzed. FA increased and ADC decreased in most white matter tracts in the short-term (moderate-to-large effects), and FA decreased and ADC increased in the medium- to long-term (moderate-to-very-large effects). Whole brain (short-term), cerebellum and corpus callosum (medium- to long-term) FA values have diagnostic potential, but the impact of age/developmental stage and injury severity on FA/ADC, and the predictive value, is unclear.

4588. Roberts, S. A. G., et al. (2016). "Decompressive craniectomy and cranioplasty: experience and outcomes in deployed UK military personnel." British journal of neurosurgery **30**(5): 529-535.

OBJECT: In recent conflicts, many UK personnel sustained head injuries requiring damage-control surgery and aeromedical transfer to the UK. This study aims to examine indications, complications and outcomes of UK military casualties undergoing craniectomy and cranioplasty from conflicts in Afghanistan and Iraq., METHODS: The UK military Joint Theatre Trauma Registry (JTTR) was searched for all UK survivors in Afghanistan and Iraq between 2004 and 2014 requiring craniectomy and cranioplasty resulting from trauma., RESULTS: Fourteen decompressive craniectomies and cranioplasties were performed with blast and gunshot wounds equally responsible for head injury. Ten survivors (71%) had an Injury Severity Score (ISS) of 75, normally designated as 'unsurvivable'. Most were operated on the day of injury. Seventy-one percent received a reverse question mark incision and 7% received a bicoronal incision. Seventy-nine percent had bone flaps discarded. Overall infection rate was 43%. Acinetobacter spp was the causative organism in 50% of cases. Median Glasgow Outcome Scale (GOS) at final follow-up was 4. All casualties had a GOS score greater than 3., CONCLUSIONS: Timely neurosurgical intervention is imperative for military personnel given high survival rates in those sustaining what are designated 'un-survivable' injuries. Early decompression facilitates safe aeromedical evacuation of casualties. Excellent outcomes validate the UK military trauma system and the stepwise performance gains throughout recent conflicts however trauma registers most evolving to have specific relevance to military casualties. In high-energy trauma with contamination and soft-tissue destruction, surgery should be conducted with regard for future soft tissue reconstruction. Bone flaps should be discarded and cranioplasty performed according to local preference. Facilities receiving military casualties should have specialist microbiological input mindful of the difficulties treating unusual microbes.

4589. Robertson, B. C. and P. N. Manson (1999). "High-energy ballistic and avulsive injuries. A management protocol for the next millennium." The Surgical clinics of North America **79**(6): 1489-xi.

This article discusses high-energy ballistic and avulsive injuries, which are a formidable challenge to the reconstructive surgeon. Management protocols are provided for the next millennium.

4590. Robertson, C. (1993). "Desaturation episodes after severe head injury: influence on outcome." Acta neurochirurgica. Supplementum **59**: 98-101.

The relationship of jugular venous desaturation and neurological outcome was examined in 116 patients with severe head injury. Seventy-six episodes of jugular venous desaturation were prospectively identified in 46 (40%) of the patients. The etiology of the desaturations varied, including both systemic and cerebral causes. A poor neurological outcome was strongly associated with the occurrence of jugular venous desaturation.

4591. Robertson, C. (1993). "Measurements of cerebral blood flow and metabolism in severe head injury using the Kety-Schmidt technique." Acta neurochirurgica. Supplementum **59**: 25-27.

Global cerebral blood flow (CBF) was measured serially for up to 10 days after severe head injury, and related to outcome. Twenty-five of the patients had a reduced CBF, 47 had a normal CBF, and 30 had an elevated CBF. Patients with a reduced CBF had a poorer outcome than patients with a normal or elevated CBF. There were no differences in the type of injury, initial GCS, severity of intracranial hypertension in each CBF group. Systemic factors did not significantly contribute to the differences in CBF among the 3 groups. A logistic regression model of the effect of CBF on neurological outcome was developed. When adjusted of variables which were found to be significant confounders, including age, initial Glasgow Coma Score, hemoglobin, cerebral perfusion pressure, and cerebral oxygen consumption, a reduced CBF remained significantly associated with an unfavorable neurological outcome.

4592. Robertson, D. P. and R. K. Simpson (1992). "Penetrating injuries restricted to the cauda equina: a retrospective review." Neurosurgery **31**(2): 265-270.

Thirty-three patients with penetrating injuries to the cauda equina were admitted to Ben Taub General Hospital (1980-1989). Thirty received gunshot injuries, and three had stab wounds. The average age was 30 years, and 30 patients were male. All patients had been admitted within 1 hour of injury and received spine films, myelography, or computed tomography. Deficits were "complete" if total loss of function existed and were "incomplete" if any function remained below the level of injury. Improvement at the end of followup was defined as any recovery of motor strength or regaining of a unilateral sensory level. Twenty-nine (88%) patients had incomplete neurological deficits. Of these, 15

(52%) had surgery, and of this patient group, 7 (47%) improved, 7 (47%) showed no change, and 1 (6%) worsened. Fourteen (48%) patients with incomplete deficits were treated conservatively; 10 (71%) improved, and 4 (29%) had no change. Four patients (12%) had complete deficits, 3 of whom had surgery, and all improved. One patient with a complete deficit was treated conservatively and did not improve. Ten (34%) patients had bowel or bladder dysfunction, and none improved regardless of the type of treatment. Complications (cerebrospinal fluid leak, pseudomeningocele, or wound infection) occurred in 5 (28%) operative patients and 1 (7%) conservatively treated patient. Early neurosurgical intervention for penetrating injuries of the cauda equina may be beneficial but carries an increased risk of complication.

4593. Robinson, B., et al. (2021). "Outcomes of stab wounds presenting to Kamuzu Central Hospital in Malawi." Malawi medical journal : the journal of Medical Association of Malawi **33**(1): 1-6.

Introduction: Injuries are a leading cause of morbidity and mortality worldwide, necessitating that we understand the local burden of injury to improve injury-related trauma care and patient outcomes. The characteristics, outcomes, and risk factors for mortality following stab wounds in Malawi are poorly delineated., Methods: This is a retrospective, descriptive analysis of patients presenting to Kamuzu Central Hospital in Lilongwe, Malawi, with stab wounds from February 2008 to May 2018. Univariate and bivariate analyses were performed to compare patient and injury characteristics based on mortality. We performed Poisson multivariate regression to predict the factors that increase the relative risk of mortality., Results: During the study, 32,297 patients presented with assault. Of those patients, 2,352 (7.3%) presented with stab wounds resulting in a 3.2% (n=74) overall mortality. The majority of wounds were to the head or cervical spine (n=1,043, 44.6%), while injuries to the chest (n=319, 13.7%) were less frequent. We found an increased relative risk of mortality in patients who presented with an injury to the chest (RR 3.95, 95% CI 1.79-8.72, p=0.001) and who were brought in by the police (RR 33.24, 95% CI 11.23-98.35, p<0.001)., Conclusion: In this study, stab wounds accounted for 7.3% of all assault cases, with a 3.2% mortality. Though the commonest site of stab was the head, wounds to the chest conferred the highest relative risk of mortality. A multifaceted approach to reducing mortality is needed. Incorporating training of first responders in basic life support, including the police, may reduce stab-related mortality.

4594. Robinson, P. D., et al. (1997). "Unlikely foreign bodies in unusual facial sites." The British journal of oral & maxillofacial surgery **35**(1): 36-39.

Two cases are reported in which retained wooden foreign bodies in the facial tissues posed considerable diagnostic difficulty and were the source of persistent and distressing symptoms. In both patients the embedded foreign material defied radiological identification and in case 1 the time between injury and final removal of the foreign body was 9 years. The cases are described to highlight the problems in managing penetrating injuries when there is the possibility that radiolucent material is implanted in the wound.

4595. Robiony, M. (2013). "Minimally invasive surgery: Endoscopic removal of a bullet from the orbital apex." Orbit **32**(3): 203-205.

I present an endoscopic approach to removal of a bullet from the orbital apex in an attempted suicide, emphasising the importance of fast, minimally invasive surgery, performing endoscopy through the bullet entrance hole, to prevent major complications and to ensure a speedy recovery.

4596. Robles, L. A. (2012). "High-velocity gunshot to the head presenting as initial minor head injury: things are not what they seem." The American journal of emergency medicine **30**(9): 2089.e2085-2087.

Tangential gunshots to the head are a special type of injury in which the bullet or bullet fragments do not penetrate the inner table of the skull. Most of patients experiencing this kind of injuries usually have a benign clinical presentation. We describe the case of a 22-year-old soldier who had a tangential gunshot to the head caused by a high-velocity projectile. Initially, the patient was neurologically intact, progressing to profound coma in the next 2 hours. The characteristics of the wound and initial neurologic condition led to first contact physicians to treat this injury as a case of mild head trauma. This case shows us that gunshots to the head caused by high-velocity missiles must be treated aggressively like a severe head injury, even when the initial neurologic examination is normal.

4597. Robles, L. A. (2022). "Orbito-cranial gunshot injury: the case of the missing entrance wound." British journal of neurosurgery **36**(1): 105-107.

This paper presents the case of a 68 years old male who was admitted to the hospital after being attacked by another person. The main clinical signs were confusion and severe periorbital edema, findings of gunshot injury were not evident initially. However, a CT scan showed findings compatible with an orbito-cranial perforating gunshot injury. To the best of the author's knowledge, cases like this have not been reported in the literature. This report shows us that an orbito-cranial gunshot injury should be ruled out in cases of severe periorbital edema, especially if the cause of the injury remains unidentified.

4598. Rocca, A., et al. (1987). "Penetrating craniocerebral injuries. Report of two unusual cases." Journal of neurosurgical sciences **31**(1): 19-21.

Two unusual cases of craniocerebral injury caused by a fishing harpoon trident are reported. Both patients, in spite of the apparent seriousness of the lesions, recovered satisfactorily.

4599. Rocker, G. M., et al. (2006). "Brief review: Practice variation in end of life care in the ICU: implications for patients with severe brain injury." Canadian journal of anaesthesia = Journal canadien d'anesthesie **53**(8): 814-819.

PURPOSE: To review end of life care issues in the intensive care unit (ICU) and how practice variation might affect the ultimate outcome of acute brain injury., SOURCES: Bibliographic literature search and personal files., FINDINGS: In Canada, 10-20% of critically ill adults die in the ICU. Many of these deaths follow acute brain injury in the setting of clinical deterioration, life support limitation and brain death. This brief review addresses some key elements of end of life care for critically ill brain injured patients, including family interactions, making survival predictions, and factors influencing decision-making about cardiopulmonary resuscitation and withdrawal of mechanical ventilation., CONCLUSIONS: Provision of compassionate high quality end of life care should be standard of practice for brain injured and all other critically ill patients who cannot survive. Inconsistencies in end of life care may affect where, when and how patients die, the quality of their death and whether or not they are considered for organ and tissue donation.

4601. Rodenas-Lozano, R., et al. (2019). "[Paradoxical arterial gas embolism following a direct incisive injury to the skull]." Embolismo arterial gaseoso paradojico tras una herida incisa craneal directa. **69**(3): 109-112.

INTRODUCTION: An arterial gas embolism is defined as the presence of air in the arterial circulation. This is an extremely rare cause of stroke that has been described in a multitude of clinical scenarios, generally related to iatrogenic processes. A clinical case is reported in which the arterial gas embolism occurred after a traumatic brain injury, and the most relevant aspects of diagnosis and aetiopathogenesis are reviewed., CASE REPORT: We report the case of a 52-year-old woman with an open craniofacial wound resulting from an attack with an axe. The initial CT scan found fractures in the left zygomatic, sphenoidal and maxillary arches, as well as pneumocephalus in the cavernous sinuses and the right carotid canal. One hour later, the patient showed a neurological deficit in the right hemisphere, and so a new cranial computed tomography scan with multimodal vascular study was urgently requested, which revealed the mobilisation of the pneumocephalus and ruled out a large vessel arterial occlusion. A shunt study using transcranial Doppler and echocardiography showed the presence of a patent foramen ovale to be the cause of arteriovenous communication that justified an arterial gas embolism. The follow-up CT scan at 48 hours confirmed the appearance of a right parietal ischaemic lesion., CONCLUSION: This case reflects the simultaneous presence of air in the arterial and venous circulation of the brain, as well as the peripheral communication through a patent foramen ovale. This production mechanism is poorly documented in the literature.

4602. Rodiek, S. O. (1984). "[Computed tomographic classification of gunshot wounds of the head]." Computertomographische Klassifikation von Kopfschussverletzungen. **141**(1): 11-17.

Twenty-four patients following head bullet injuries were analyzed by CT. The major part, concerning 10 patients, refers to acute perforating lesions. Five cases showed penetrating injuries, 3 cases bolt injuries, the other ones lesions of the facial skull and residues of former bullet injuries. Because of a tempory cavitation the bullet track is wider than the bullet itself. The position of the skull fragments gives a hint to the shot direction. A reconstruction of intracranial bullet movements and spontaneous bullet dislocations is made possible by CT. It further shows secondary posttraumatic lesions.

4603. Rodionov, N. F., et al. (2015). "[The successful treatment of the combined penetrating gunshot wound of the orbit, ethmoidal labyrinth cells, and sphenoidal sinus containing a foreign body]." Vestnik otorinolaringologii **80**(2): 73-74.

4604. Rodiukova, E. N., et al. (1992). "[Changes in the cellular immunity factors in suppurative complications of penetrating craniocerebral trauma]." Izmenenie faktorov kletochnogo immuniteta pri gnoinykh oslozhneniiakh pronikaiushchei cherepno-mozgovoi travmy.(2-3): 12-15.

The authors examined patients with penetrating cerebrocranial trauma (CCT) and uneventful course of traumatic disease (30) and those with CCT complicated by intracranial purulent process (24 persons). A direct correlation of the marked character and severity of the clinical course of the posttraumatic period and the changes in the immune system was revealed. Increase of the level of neutrophil rosette formation, indices of the NST test, the activity and intensity of neutrophil phagocytosis in penetrating CCT allows the development of an intracranial purulent process to be predicted at an early stage before the appearance of clinical sings. Decrease of the number of spontaneous rosette-forming and formazan-positive neutrophils is an indication of an unfavourable course of an intracranial purulent complication with a fatal outcome.

4605. Rodriguez, E. D., et al. (2007). "Microsurgical reconstruction of posttraumatic high-energy maxillary defects: establishing the effectiveness of early reconstruction." Plastic and reconstructive surgery **120**(7 Suppl 2): 103S-117S.

BACKGROUND: Posttraumatic, high-energy defects of the midface can be challenging to reconstruct because they involve extensive composite tissue loss and result in significant permanent functional and cosmetic deformity. These injuries require replacement of the bony framework, external soft tissue, and intraoral mucosa. Local skin flaps and nonvascularized bone grafts have been used for reconstruction, but bony resorption and the associated soft-tissue collapse limit long-term viability. The authors present a classification of maxillary defects following high-energy trauma and a treatment algorithm using vascularized bone flaps., METHODS: Fourteen patients with significant maxillary loss from high-energy trauma underwent reconstruction with composite vascularized bone flaps. Eight patients had fibula flaps and six had iliac crest flaps. There were five women and nine men, with a mean age of 36.3 years (range, 21 to 48 years) and a mean follow-up of 18 months (range, 5 to 54 months)., RESULTS: Thirteen of the 14 flaps survived. Nine patients had additional procedures. Nine patients had oronasal fistulas and eight were dependent on gastrostomy tubes preoperatively. All patients were able to feed orally without nasal regurgitation postoperatively. All patients achieved stable restoration of the midfacial architecture., CONCLUSIONS: The classification scheme presented centers on the missing maxillary subunits. The reconstructive algorithm is based on the type of defect, tissue requirement, and donor tissues necessary to restore facial projection and prosthodontic rehabilitation. Iliac crest and fibula bone free flaps are ideal for restoring a variety of traumatic maxillary defects. The authors advocate early reconstructive intervention using vascularized bone flaps to achieve superior functional and cosmetic outcomes.

4606. Rodríguez Ríos, Y. D. R., et al. (2005). "Deaths by human vascular trauma." Anales de Cirugia Cardiaca y Vascular **11**(2): 64-68.

Vascular trauma is cause of high mortality inside variety of traumas that the population suffers. This is indirect relationship to the caliber and place of the affected vessels, as well as the time lapsed between the trauma and medical action. The analysis of the data gathered in 291 deaths by human vascular trauma was the objective of this study carried out in a 10 - year's period. The highest percentage was present during the weekends especially during the evening from 6 pm to 6 am with 66.6% of the cases. Those produced by knife cut, represented 64.7%, followed by traffic accident and firearms recorded 22.6% and 8.9% respectively. The greatest number of cases, 227, died in situ, 51 died in the hospital and 13 died on the way to health unit. Homicides represented 58.1% and the suicidal attempts 5.8%. The wounds of the

thoracic vessels whit 41.9% greatest number of the deaths, followed by lesser abdominal wounds with 24.7%, skull and extremities in 15.1% and the facial skull wounds in 3.2%. The data offered show the incidence of vascular trauma as the cause of mortality in the population, as well as the danger of the weekends and evening schedule. Surveillance and safety measures protection to the population should be reforced to avoid the production of human vascular trauma.

4607. Rofail, M., et al. (2005). "Suicide-related perforating injury of globe with nail gun." Clinical & experimental ophthalmology **33**(3): 294-295.

A case is reported of nail gun injury due to suicide attempt involving both orbits, frontal lobe and abdomen, which resulted in an unusual posterior perforation of the left globe. Injury was inflicted with a total of eight nails. Three nails entered the left orbit, one of which perforated the posterior aspect of the left globe. One nail entered the right orbit involving the optic nerve and crossed the midline to finish in the left sphenoid sinus. Three nails entered the frontal lobe near the midline and the final nail pierced the left lobe of the liver. The left eye underwent primary repair, lensectomy and vitrectomy with silicone oil and achieved a visual acuity of 6/60, 3 months post removal of oil with sutured posterior chamber intraocular lens. The right eye suffered traumatic optic neuropathy and currently has a visual acuity of 6/36 due to senile cataract formation. No other serious sequelae resulted from the other injuries and the patient has recovered from his episode of depression.

4608. Roganovic, Z. (2004). "Missile-caused ulnar nerve injuries: outcomes of 128 repairs." Neurosurgery **55**(5): 1120-1129.

OBJECTIVE: This prospective study presents repair results after missile-caused ulnar nerve ruptures as well as factors influencing the outcomes., METHODS: Between 1991 and 1994, 128 casualties with missile-caused complete ulnar nerve injury were managed surgically in the Neurosurgical Department of the Belgrade Military Medical Academy. At least 4 years after surgery, we scored sensorimotor recovery, neurophysiological recovery, and patient judgment of the outcome. On the basis of the total score, we defined the final outcome as poor, insufficient, good, or excellent. The last two outcomes were considered to be successful., RESULTS: A successful outcome was obtained in 0% of high-level, 33.8% of intermediate-level, and 77.3% of low-level repairs ($P < 0.001$). On average, the nerve defect, preoperative interval, and patient age were lower for patients with a successful outcome than for those with an unsuccessful outcome ($P = 0.004$, $P = 0.032$, and $P = 0.003$, respectively). Worsening of the outcome was related to nerve defect longer than 4.5 cm, preoperative interval longer than 5.5 months, and age older than 23 years ($P = 0.002$, $P = 0.034$, and $P = 0.023$, respectively). A successful outcome occurred in 48.8% of patients repaired with direct suture and in 41.2% of patients repaired with a nerve graft ($P > 0.05$). A successful outcome also occurred 22.2% of combined ulnar-median nerve repairs and in 49.5% of isolated ulnar nerve repairs ($P = 0.011$). Repair level ($P < 0.001$), preoperative interval ($P = 0.001$), length of the nerve defect ($P < 0.001$), and associated median nerve rupture ($P = 0.028$) were independent predictors of a successful outcome., CONCLUSION: The outcome of ulnar nerve repair depends significantly on the repair level, preoperative interval, associated median nerve injury, length of the nerve defect, and age of the patient. High-level ulnar nerve repair is probably useless if performed in the classic manner.

4609. Roge, D. (2012). "Bilateral foot and ankle paresis following a gunshot wound to the head with a bullet lodged in the superior sagittal sinus: A case report." PM and R **4**(10): S338.

Case Description: A 15-year-old patient presented with bilateral foot and ankle paresis and numbness after suffering a gunshot wound to the apex of his skull. There was no loss of consciousness, trauma to his spine or to the lower extremities. He denied radicular pain in his legs, saddle anesthesia or bowel or bladder dysfunction. On physical examination he had no strength in ankle dorsiflexors, plantarflexors or foot muscles. Sensory deficits were present in a non peripheral nerve and non dermatomal distribution. Proximal lower extremity and hip musculature was preserved. His patellar and Achilles reflexes were present. CT imaging of the head with and without contrast revealed “comminuted depressed skull fracture of the parietal bone at the midline of the vertex of the calvarium causing mass effect focally narrowing the superior sagittal sinus without evidence of sagittal sinus occlusion, thrombosis, or extravasation.” Setting: Tertiary-care pediatric hospital. Results or Clinical Course: Differential diagnosis included bilateral peripheral nerve injury to the sciatic nerve, spinal cord injury or a focal midline lesion to the primary motor cortex. In this patient, his deficits were best explained by a focal midline injury to the motor cortex based on history, detailed physical examination and neuroimaging studies available. Bullet was removed surgically. Sensory deficits improved but weakness remained. By

discharge the patient was able to ambulate independently with carbon fiber anklefoot orthosis. Discussion: To our knowledge, this is the first reported case of bilateral foot and ankle weakness following focal midline trauma to the head irritating the primary motor cortex. This case also underscores the importance of correlating clinical history and physical examination to imaging studies for functional neuro-anatomical localization of a lesion. Such a practice yields appropriate and cost-effective diagnostic and therapeutic interventions. Conclusions: Bilateral focal motor deficits are possible after penetrating head injury when the lesion is located midline in the motor strip.

4610. Rohrich, R. J., et al. (2021). "The Assassination of JFK: A Plastic Surgery Perspective 50 Years Later." Plastic and reconstructive surgery **148**(5S): 82S-85S.

4611. Roisentul, A., et al. (2011). "Remote penetrating orbital trauma due to a snooker cue through the mouth." Dental traumatology : official publication of International Association for Dental Traumatology **27**(3): 247-249.

PURPOSE: This is a unique case report of a self-inflicted orbital injury that presented as a simple upper vestibulum laceration. A 43-year-old man presented to the Oral and Maxillofacial Surgery Unit with a small laceration in his mouth and complaints of pain in his left eye due to a snooker cue penetration. Upon admission, clinical findings included a small laceration on the upper left vestibulum and a subdermal hematoma in the left eye lid with restricted movements of the left eye. Further examination revealed remote trauma to the orbit, penetrating through the oral cavity, passing the maxillary sinus, and the orbital floor causing traumatic optic neuropathy with partial visual loss. The patient was treated conservatively with antibiotics and corticosteroids and a 6-week follow up., CONCLUSION: In cases of remote penetrating injury, meticulous examination revealing precise injury mechanism is crucial. All cases of Dento-maxillofacial trauma should include a high degree of clinical suspicion for ocular injury, requiring early diagnosis and treatment to reduce risk of visual loss.

4612. Roitbak, T. and E. Sykova (1999). "Diffusion barriers evoked in the rat cortex by reactive astrogliosis." Glia **28**(1): 40-48.

Changes in extracellular space (ECS) diffusion parameters in astrogliotic tissue around a unilateral cortical stab wound were determined from concentration-time profiles of tetramethylammonium (TMA(+)) using TMA(+)-selective microelectrodes. Three diffusion parameters-ECS volume fraction alpha (alpha = ECS volume/ total tissue volume), tortuosity lambda (lambda(2) = D/ADC; where D is the free and ADC is the apparent diffusion coefficient of TMA(+) in the brain), and nonspecific TMA(+)uptake k'-were determined at 3, 7, 21, and 35 days postwounding (dpw), in the hemispheres ipsilateral and contralateral to the lesion. Following diffusion experiments, tissue sections were immunostained for glial fibrillary acidic protein (GFAP) and chondroitin-sulphate proteoglycans (CSPG). In the area 300-1000 micron around the wound, alpha was increased at 3, 7, and 21 dpw by about 20% but returned to control values at 35 dpw; lambda was increased at all four intervals, reaching a maximum at 7 dpw. k' was lower than in the contralateral hemisphere at 7, 21, and 35 dpw. Measurements 1,500-2,000 micron from the wound revealed only an increase in lambda at 7 dpw. The time course of changes in ECS diffusion parameters closely correlated with increased staining for GFAP and CSPG. Our results show that astrogliosis significantly changes the diffusion properties of nervous tissue, making it less permissive. Both hypertrophied astrocytic processes and an enhanced formation of some extracellular matrix molecules could affect, through changes in the diffusion of molecules in the ECS, neuron-glia communication, "cross-talk" between synapses, extrasynaptic transmission, and regenerative processes.

4613. Rojas, A. (2011). "The epidemiology study of mandibular fractures treated in two general hospitals. Caracas-Venezuela. A review of 585 cases in 8 years (2001-2008)." International journal of oral and maxillofacial surgery **40**(10): 1107.

Purpose: In Venezuela there are few studies that report the epidemiological pattern of Mandibular Fractures. Materials and methods: The medical records and radiographs for 585 patients treated for mandibular fracture in Caracas, Venezuela, over a 8-year period were reviewed. Variables such as age, gender, etiology, fracture type, treatment techniques, anesthetics and complications. The statistical methodology used was: frequency, percentages, mean, standard deviation, chi-square, t of Student and Fisher. Results: The male shows was 478 patients (81.7%) and female 107 (18.3%), with a ratio of 4:1. The average age was 28.79 years. The most common range was between 21 to

30 years (38%), followed by 11 to 20 and 31 to 40 with equal numbers of patients, (22.65%) each. Most fractures were caused by physical violence (46.3%), traffic accidents (25.1%), gunshot (17.6%), falls (10.6%) and sporting activities (0,3%). The expressions of physical violence were (44.27%), stroke (41.3%), assault (39.4%) and blunt objects (19.3%). Traffic accidents were (24.78%), automobile (49.0%), motorcycles (35.2%), bicycle (10.3%) and coil (5.5%). As for the location was in body (23.1%), angle (15.6%) condyle (3.9%), symphysis (3.6%), sub-condylar (3.3%), alveolar (3.3%), parasymphysis (2.9%), raw (1.7%) and coronoid (0.3%). The (97.9%) had not complications. Discussion: Young people are the most susceptible to the mandibular fractures. The violence and traffic accidents are the most frequent etiological factors, and there is a predisposition ofwomen to the falls and men the gunshot. Body and angle are the most fractured, and are more displaced than non-displaced. Post surgical complications were rare.

4614. Roland, J. T., Jr., et al. (1994). "Management of traumatic facial nerve paralysis with carotid artery cavernous sinus fistula." European archives of oto-rhino-laryngology : official journal of the European Federation of Oto-Rhino-Laryngological Societies (EUFOS) : affiliated with the German Society for Oto-Rhino-Laryngology - Head and Neck Surgery **251**(1): 57-60.

Massive skull base injuries require detailed preoperative neurological and neurovascular assessment prior to undertaking surgical repair of isolated cranial nerve deficits. We present the management of a patient with traumatic facial paralysis, cerebrospinal fluid leak, and carotid artery cavernous sinus fistula as the result of a gunshot wound to the skull base. The carotid artery cavernous sinus fistula was ultimately controlled with super-selective embolization via the vertebral artery. The facial nerve injury was then safely treated with mobilization of the labyrinthine and vertical segments to allow a primary anastomosis.

4615. Roldan, M. and P. A. Kyriacou (2021). "Near-Infrared Spectroscopy (NIRS) in Traumatic Brain Injury (TBI)." Sensors (Basel, Switzerland) **21**(5).

Traumatic brain injury (TBI) occurs when a sudden trauma causes damage to the brain. TBI can result when the head suddenly and violently impacts an object or when an object pierces the skull and enters brain tissue. Secondary injuries after traumatic brain injury (TBI) can lead to impairments on cerebral oxygenation and autoregulation. Considering that secondary brain injuries often take place within the first hours after the trauma, noninvasive monitoring might be helpful in providing early information on the brain's condition. Near-infrared spectroscopy (NIRS) is an emerging noninvasive monitoring modality based on chromophore absorption of infrared light with the capability of monitoring perfusion of the brain. This review investigates the main applications of NIRS in TBI monitoring and presents a thorough revision of those applications on oxygenation and autoregulation monitoring. Databases such as PubMed, EMBASE, Web of Science, Scopus, and Cochrane library were utilized in identifying 72 publications spanning between 1977 and 2020 which were directly relevant to this review. The majority of the evidence found used NIRS for diagnosis applications, especially in oxygenation and autoregulation monitoring (59%). It was not surprising that nearly all the patients were male adults with severe trauma who were monitored mostly with continue wave NIRS or spatially resolved spectroscopy NIRS and an invasive monitoring device. In general, a high proportion of the assessed papers have concluded that NIRS could be a potential noninvasive technique for assessing TBI, despite the various methodological and technological limitations of NIRS.

4616. Rolle, M. and A.-C. Duhaime (2021). "Pediatric Gunshot Wound to Visual Cortex with Retained Bullet: Case Report and Review of the Literature." Pediatric neurosurgery **56**(1): 94-98.

INTRODUCTION: Pediatric gunshot wounds (GSWs) to the head are not well studied in the literature, especially in civilians. With a dearth of case-based and clinically relevant information, pediatric neurosurgeons may be challenged when considering the risks and benefits of removing retained bullet fragments in different intracranial locations. We explore the literature and highlight the key factors in the surgical decision-making case of a 16-year-old girl with GSW to the visual cortex., CASE REPORT: A 16-year-old girl was shot in the head in a parieto-occipital trajectory with the bullet crossing midline, lodging in the occipital lobe into the straight sinus. Her initial Glasgow Coma Scale was 7, and she was urgently stabilized with intracranial pressure monitoring and external ventricular drainage. She underwent craniectomy, debridement, and irrigation and then a reoperation for further debridement and culture 2 weeks later for persistent fevers; cultures remained negative. The retained bullet was not removed. At 18 months post-injury, she had normal speech and motor function, moderate memory dysfunction, and 3-quadrant field loss with retained macular vision.,

DISCUSSION/CONCLUSION: Pediatric penetrating GSWs to the head may be challenging to manage since literature is sparse. In this case, the primary focus of management was to maintain normal intracranial pressure, reduce risk of infection, and preserve potentially viable visual cortex. In the civilian context of available antibiotics and serial imaging, it may be possible to manage retained bullets conservatively without delayed complications.

4617. Roman, F., et al. (2003). "Neuropsychological deficits in a child with a left penetrating brain injury." Brain injury **17**(8): 695-700.

This case study reports neuropsychological and structural magnetic resonance (MRI) studies of a 10-year-old girl with a left hemisphere lesion, caused by an underwater fishing harpoon penetrating her head when she was 6 years old. The patient showed a marked deficit in the acquisition of reading, writing and arithmetic, as well as an attentional deficit. Magnetic resonance images revealed left cortical lesions in the orbital region and the gyrus angularis, as well as in the caudate and putamen nuclei and longitudinal inferior fascicle. Neuropsychological assessment showed frontal and parietal lobe dysfunctions consistent with the lesional data. The structural data explain the neuropsychological impairment and suggest that, although the left lesion was early and relatively small, plasticity was incomplete.

4618. Romano, F., et al. (2008). "Complex craniofacial trauma resulting from fireworks blast." The Journal of craniofacial surgery **19**(2): 322-327.

The authors report the case of a patient who sustained a complex craniofacial trauma secondary to a recreational fireworks blast. Initial assessment and management were performed with a multidisciplinary approach to achieve control of cerebral hemorrhage, debridement of wounds and brain, isolation of the brain from the external environment, reconstruction of the cranial base floor, and orbital and facial reconstruction. Modification of multiple conventional approaches, along with a multispecialty surgical team, were used to deal effectively with this unusual patient who was treated by single-stage immediate management. Reconstruction of both the intracranial and extracranial compartments was considered successful with a satisfactory cosmetic result.

4619. Romboy, M., et al. (2020). "A case of congenital central hypoventilation syndrome complicated by intracranial hemorrhage." Journal of Investigative Medicine **68**(1): A215.

Background Congenital Central Hypoventilation Syndrome (CCHS) is a rare cause of apnea in the neonate. We present a unique case of CCHS to demonstrate that a high index of suspicion for CCHS is necessary to avoid a delay in diagnosis. Case A full term baby boy was born to a healthy 25-year-old G1P1 via caesarean section with vacuum-assist due to failed induction. Patient required positive pressure ventilation at birth due to poor respiratory effort. At 3 hours of life, patient had a cyanotic episode and was admitted to the NICU. He required intubation due to apnea. Due to history of traumatic delivery, head CT was done and demonstrated bilateral sub-dural hemorrhages and a non-displaced skull fracture. MRI showed posterior subdural bleed. Neurology and neurosurgery were consulted to help explain the frequent apneic episodes. Patient was extubated and maintained on nasal non-invasive ventilation but continued to have frequent apnea. He failed a trial of caffeine and required reintubation due to respiratory acidosis. Subsequently, a sleep study was done revealing multiple episodes of central apneas and hypopneas. Genetic testing for CCHS was ordered and was positive for a mutation in the PHOX2B gene. Patient underwent tracheostomy and was discharged on a home ventilator. Discussion CCHS is a rare disorder of respiratory and auto-nomic dysregulation estimated to affect 1:200,000 people. It is classically characterized by hypercapnia and hypoxe-mia during sleep. Most patients require tracheostomy and lifelong ventilatory support. Apnea in the neonate has a broad differential including cardiac, pulmonary, infectious and neurogenic causes. CCHS is often overlooked because of overlap with more common disease processes and low incidence of the disease. Our patient had a neurological explanation for apnea (head trauma with intracranial hemorrhage) and thus CCHS was not initially considered as a diagnosis. Only when our patient was unable to be extu-bated due to persistent respiratory acidosis was genetic testing done. Due to the availability of genetic testing for CCHS, we recommend considering CCHS as a diagnosis in all term neonates with central apnea despite presence of confounding findings.

4620. Romero Pareja, R., et al. (2020). "Prehospital triage for mass casualty incidents using the META method for early surgical assessment: retrospective validation of a hospital trauma registry." European journal of trauma and emergency surgery : official publication of the European Trauma Society **46**(2): 425-433.

BACKGROUND: In mass casualty incidents (MCI), death usually occurs within the first few hours and thus early transfer to a trauma centre can be crucial in selected cases. However, most triage systems designed to prioritize the transfer to hospital of these patients do not assess the need for surgery, in part due to inconclusive evidence regarding the value of such an assessment. Therefore, the aim of the present study was to evaluate the capacity of a new triage system-the Prehospital Advanced Triage Method (META)-to identify victims who could benefit from urgent surgical assessment in case of MCI., METHODS: Retrospective, descriptive, observational study of a multipurpose cohort of patients included in the severe trauma registry of the Gregorio Maranon University General Hospital (Spain) between June 1993 and December 2011. All data were prospectively evaluated. All patients were evaluated with the META system to determine whether they met the criteria for urgent transfer. The META defines patients in need of urgent surgical assessment: (a) All penetrating injuries to head, neck, torso and extremities proximal to elbow or knee, (b) Open pelvic fracture, (c) Closed pelvic fracture with mechanical or haemodynamic instability and (d) Blunt torso trauma with haemodynamic instability. Patients who fulfilled these criteria were designated as "Urgent Evacuation for Surgical Assessment" (UESA) cases; all other cases were designated as non-UESA. The following variables were assessed: patient status at the scene; severity scales [RTS, Shock index, MGAP (Mechanism, Glasgow coma scale, Age, pressure), GCS]; need for surgery and/or interventional procedure to control bleeding (UESA); and mortality. The two groups (UESA vs. non-UESA) were then compared., RESULTS: A total of 1882 cases from the database were included in the study. Mean age was 39.2 years and most (77%) patients were male. UESA patients presented significantly worse on-scene hemodynamic parameters (systolic blood pressure and heart rate) and greater injury severity (RTS, shock index, and MGAP scales). No differences were observed for respiratory rate, need for orotracheal intubation, or GCS scores. The anatomical injuries of patients in the UESA group were less severe but these patients had a greater need for urgent surgery and higher mortality rates., CONCLUSION: These findings suggest that the META triage classification system could be beneficial to help identify patients with severe trauma and/or in need of urgent surgical assessment at the scene of injury in case of MCI. These findings demonstrate that, in this cohort, the META fulfils the purpose for which it was designed.

4621. Ronen, O., et al. (2017). "[HIGH VELOCITY PENETRATING HEAD AND NECK INJURIES OF SYRIAN CIVIL WAR CASUALTIES TREATED IN THE GALILEE MEDICAL CENTER]." Harefuah **156**(5): 315-317.

INTRODUCTION: For two years the State of Israel has been treating casualties from the Syrian civil war. The Galilee Medical Center in Nahariya is the main hospital for this humanitarian mission. Objectives: To evaluate the demographic and clinical characteristics of the casualties that were treated in our department., METHODS: Information from medical records of all Syrian casualties evacuated to the Galilee Medical Center were evaluated., RESULTS: Between March 2013 and December 2014, 450 casualties were evacuated to the Galilee Medical Center. Of those, 45 were treated in the Department of Otolaryngology - Head and Neck Surgery. Of the 45 cases, 43 were male (95.5%) and the mean age was 30.4 years (range 1-79 years). There was a significant difference in terms of gender ($p < 0.0001$). The majority of cases (42.1%) were aged 21-27 years. The most common cause of injury was a gunshot wound. Thirty five patients (77.7%) suffered from multiple trauma, and complex injuries of the maxillofacial bones and upper respiratory tract. Eight (18%) of the cases arrived at the medical center with a tracheotomy. The average length of hospital stay was 15 days (range: 1-141). Of the 450 cases, 97.3% were discharged back to Syria, and 12 died., CONCLUSIONS: Of all Syrian injured treated in the ENT department, the vast majority were young men. The main cause of injury was gunshot wounds., DISCUSSION: It is likely that the lack of protective gear that exist in western armies is a factor in the complex injuries treated at the Galilee Medical Center.

4622. Roosen, K. and H. Weichert -Chr (1979). "Gunshot injury of the brain as seen in the axial CT scan." Aktuelle Traumatologie **9**(4): 205-207.

The article reports on a patient with an open craniocerebral lesion due to a through-and-through bullet wound. The significance of the CT scan for theray and prognosis of the disease is discussed.

4623. Ropposch, T., et al. (2013). "The effect of steroids in combination with optic nerve decompression surgery in traumatic optic neuropathy." The Laryngoscope **123**(5): 1082-1086.

OBJECTIVES/HYPOTHESIS: Traumatic optic neuropathy (TON) is an important cause of severe visual impairment following blunt or penetrating head trauma. Treatment options include steroids, decompression, or both. Studies have failed to show a clear benefit for either steroids or surgery or a combined therapy. This study describes the visual outcome in surgically managed patients with or without steroid treatment., STUDY DESIGN: Retrospective analysis., METHODS: In a retrospective chart review we included patients (n = 42) with TON who were managed with optic nerve decompression surgery with or without steroids. Comparison of initial and final visual acuity was the primary outcome parameter., RESULTS: In 42 consecutive patients, steroids were used in 21 cases (50%). Ten patients received a high-dose systemic regimen of more than 500 mg methylprednisolone initial dose, and 11 patients were treated with a lower dose. The overall visual improvement rate was 33%, no change was noted in 50%, and no outcome data were available in 17%. The visual improvement rate of patients treated with decompression surgery and steroids was lower (29%, 6 of 21) than those treated with surgery alone (53%, 8 of 15). Comparing both groups, additional steroids had no beneficial effect on the visual outcome (P = .97). There was no case with a deterioration of visual function due to therapy., CONCLUSIONS: In patients with traumatic optic neuropathy who were treated with optic nerve decompression surgery, steroids had no beneficial effect on the visual outcome., LEVEL OF EVIDENCE: 2c.

4624. Rose, C. E., 3rd, et al. (2008). "Brain abscess caused by Streptomyces infection following penetration trauma: case report and results of susceptibility analysis of 92 isolates of Streptomyces species submitted to the CDC from 2000 to 2004." Journal of clinical microbiology **46**(2): 821-823.

The case of a patient who presented with a brain abscess caused by Streptomyces infection following penetrating cerebral trauma with a soil-contaminated object generated an interest in optimizing antimicrobial therapy. Collaboration with the Centers for Disease Control and Prevention led to the analysis of susceptibility data for Streptomyces isolates that suggested that amikacin (100% susceptibility for 92 isolates tested) and linezolid, an oxazolidinone (100% susceptibility for 41 isolates tested), offer reliable activity against all isolates.

4625. Rosen, P., et al. (2006). "Difficult airway management." Internal and emergency medicine **1**(2): 139-147.

Airway management is unequivocally the most important responsibility of the emergency physician. No matter how prepared for the task, no matter what technologies are utilized, there will be cases that are difficult. The most important part of success in the management of a difficult airway is preparation. When the patient is encountered, it is too late to check whether appropriate equipment is available, whether a rescue plan has been in place, and what alternative strategies are available for an immediate response. The following article will review the principles of airway management with an emphasis upon preparation, strategies for preventing or avoiding difficulties, and recommended technical details that hopefully will encourage the reader to be more prepared and technically skillful in practice.

4626. Rosen, T., et al. (2016). "Geriatric assault victims treated at U.S. trauma centers: Five-year analysis of the national trauma data bank." Injury **47**(12): 2671-2678.

INTRODUCTION: While geriatric trauma patients have begun to receive increased attention, little research has investigated assault-related injuries among older adults. Our goal was to describe characteristics, treatment, and outcomes of geriatric assault victims and compare them both to geriatric victims of accidental injury and younger assault victims., PATIENTS AND METHODS: We conducted a retrospective analysis of the 2008-2012 National Trauma Data Bank. We identified cases of assault-related injury admitted to trauma centers in patients aged >=60 using the variable "intent of injury.", RESULTS: 3564 victims of assault-related injury in patients aged >=60 were identified and compared to 200,194 geriatric accident victims and 94,511 assault victims aged 18-59. Geriatric assault victims were more likely than geriatric accidental injury victims to be male (81% vs. 47%) and were younger than accidental injury victims (67+/-7 vs. 74+/-9 years). More geriatric assault victims tested positive for alcohol or drugs than geriatric accident victims (30% vs. 9%). Injuries for geriatric assault victims were more commonly on the face (30%) and head (27%) than for either comparison group. Traumatic brain injury (34%) and penetrating injury (32%) occurred commonly. The median injury severity score (ISS) for geriatric assault victims was 9, with 34% having severe trauma (ISS>=16). Median length of stay was 3 days, 39% required ICU care, and in-hospital mortality was 8%. Injury severity was greater in geriatric than

younger adult assault victims, and, even when controlling for injury severity, in-hospital mortality, length of hospitalization, and need for ICU-level care were significantly higher in older adults., CONCLUSIONS: Geriatric assault victims have characteristics and injury patterns that differ significantly from geriatric accidental injury victims. These victims also have more severe injuries, higher mortality, and poorer outcomes than younger victims. Additional research is necessary to improve identification of these victims and inform treatment strategies for this unique population.

4627. Rosenbaum, K., et al. (2021). "A national analysis of pediatric firearm violence and the effects of race and insurance status on risk of mortality." American journal of surgery **222**(3): 654-658.

OBJECTIVES: To perform a national analysis of pediatric firearm violence (PFV), hypothesizing that black and uninsured patients would have higher risk of mortality., METHODS: The Trauma Quality Improvement Program (2014-2016) was queried for PFV patients <=16 years-old. Multivariable logistic regression models on all patients and a subset excluding severe brain injuries were performed., RESULTS: The PFV mortality rate was 11.2%. 66.5% of PFV patients were black ($p < 0.001$). Deceased patients were more likely to be uninsured (14.5% vs. 5.3%, $p < 0.001$). Black race was an associated risk factor for mortality in patients without severe brain injury (OR 5.26, CI 1.00-27.47, $p = 0.049$) but not for the overall population (OR 1.32, CI 0.68-2.56, $p = 0.39$)., CONCLUSION: Nearly two-thirds of PFV patients were black. Contrary to previous studies, black and uninsured pediatric patients did not have an increased risk of mortality overall. However, in a subset of patients without severe brain injury, black race was associated with increased mortality risk., SUMMARY: Between 2014 and 2016 the mortality rate for pediatric firearm violence (PFV) in children 16 years and younger was 11.2%. Although two-thirds of PFV patients were black, black race and lack of insurance were not risk factors of mortality for the overall population. Once patients with severe brain injury were excluded, black race and became associated with an increased risk of mortality.

4628. Rosenblum, W. I. and F. El-Sabban (1977). "Effects of combined parenchymal and vascular injury on platelet aggregation in pial arterioles of living mice: evidence for release of aggregate-inhibiting materials." Stroke **8**(6): 691-693.

Platelet aggregation was produced in pial arterioles by exposing them to appropriately filtered light from a mercury lamp, following intravascular injection of sodium fluorescein. The dye acted as a target for the radiant energy and initiated a sequence of events resulting in the platelet aggregation. The aggregates adhered to the vessel in which they first appeared. When a microneedle punctured the brain adjacent to a subsequently irradiated arteriole, platelet aggregation was inhibited, even though the arteriole was not touched by the microneedle. Inhibition was manifested by prolongation of the exposure time required for the light-dye stimulus to initiate an adherent aggregate and by lengthening the time required for the aggregate to grow and totally block erythrocyte flow in the affected vessel. It is suggested that a material(s) diffuses from the zone of brain puncture, to and through the arteriolar wall, with a resultant inhibition of aggregation. It is noted that the inhibiting effect is reduced as the distance between puncture and wall increases.

4630. Rosenbohm, A., et al. (2014). "Can lesions to the motor cortex induce amyotrophic lateral sclerosis?" Journal of neurology **261**(2): 283-290.

A recent staging effort for amyotrophic lateral sclerosis (ALS) has demonstrated that the TDP-43 neuropathology may initiate focally in the motor cortex in the majority of patients. We searched our data bank for patients with lesions of the motor cortex which preceded disease onset. We performed a search of our patient- and MRI-data bank and screened 1,835 patients with amyotrophic lateral sclerosis for frontal lobe/motor cortex lesions. We found 18 patients with definite ALS who had documented and defined lesions of the motor cortex, which preceded the initial ALS symptoms by 8-42 years. In the vast majority (15/18) of the patients, the onset of ALS was closely related to the focal lesion since it started in a body region reflecting the damaged cortical area. The findings suggest that initial lesions to the motor cortex may be a contributing initiating factor in some patients with ALS or determine the site of onset in individuals pre-disposed to ALS.

4631. Rosenfeld, J. V. (2002). "Gunshot injury to the head and spine." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **9**(1): 9-16.

The principles of management of civilian gunshot wounds (GSWs) to the head and spine have evolved directly from the experience gained in war by military neurosurgeons. The type of craniocerebral wounds being produced in urban gang warfare and suicide at tempts using handguns or rifles at close range vary considerably from the lower velocity fragment injuries which are common in modern warfare. Civilian craniocerebral GSWs are often devastating. The in-hospital mortality for civilians with penetrating craniocerebral injury is 52-95% depending on the proportion of suicide victims in the series. The most important predictive factor is the post-resuscitation Glasgow Coma Score (GCS). Many civilian victims (47%) present with GCS 3-5 and only approximately 8.1% survive. Of these survivors, 1.4% will have nil, mild or moderate disability without surgery and 4.8% with surgery. Higher post-resuscitation GCS is associated with a significantly improved survival: GCS 6-8, 35.6% and GCS 9-15, 90.5%. A selective treatment policy is recommended for the patients with GCS 3-5. There are many clinical and radiological correlates with poor outcome that help the neurosurgeon decide on operative versus supportive treatment. Early aggressive resuscitation, surgery and vigorous control of intracranial pressure offers the best chance of achieving a satisfactory outcome. Spinal GSWs are uncommon and the neurosurgeon should be aware of the principles of management and prognosis. The indication for acute spinal cord decompression is deteriorating neurological status. Steroids are not indicated for these injuries. Neurosurgeons should take an active role in formulating and supporting public policy which aims to reduce possession and usage of firearms and therefore the prevalence of gunshot injuries. Copyright 2002 Harcourt Publishers Ltd.

4632. Rosenfeld, J. V. (2006). "A neurosurgeon in Iraq: a personal perspective." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **13**(10): 986-990.

The practice of neurosurgery in a war zone provides enormous challenges and risks for the individual surgeon working in such an austere and hostile environment, but also provides a unique opportunity to treat a high volume of severe penetrating and blast injuries to the head, neck and the spine. The purpose of this article is to present the author's personal experiences and perspective as a military neurosurgeon working in the US Airforce Hospital in Balad (the 332nd Expeditionary Medical Group) Iraq in for 3 months in 2004. Strategies for managing the mass casualties, and the severe penetrating craniofacial trauma are presented and the reasons for the low mortality of troops injured in Iraq are discussed.

4633. Rosenfeld, J. V., et al. (2015). "Current concepts in penetrating and blast injury to the central nervous system." World journal of surgery **39**(6): 1352-1362.

AIM: To review the current management, prognostic factors and outcomes of penetrating and blast injuries to the central nervous system and highlight the differences between gunshot wound, blast injury and stabbing., METHODS: A review of the current literature was performed., RESULTS: Of patients with craniocerebral GSW, 66-90% die before reaching hospital. Of those who are admitted to hospital, up to 51% survive. The patient age, GCS, pupil size and reaction, ballistics and CT features are important factors in the decision to operate and in prognostication. Blast injury to the brain is a component of multisystem polytrauma and has become a common injury encountered in war zones and following urban terrorist events. GSW to the spine account for 13-17% of all gunshot injuries., CONCLUSIONS: Urgent resuscitation, correction of coagulopathy and early surgery with wide cranial decompression may improve the outcome in selected patients with severe craniocerebral GSW. More limited surgery is undertaken for focal brain injury due to GSW. A non-operative approach may be taken if the clinical status is very poor (GCS 3, fixed dilated pupils) or GCS 4-5 with adverse CT findings or where there is a high likelihood of death or poor outcome. Civilian spinal GSWs are usually stable neurologically and biomechanically and do not require exploration. The indications for exploration are as follows: (1) compressive lesions with partial spinal cord or cauda equina injury, (2) mechanical instability and (3) complications. The principles of management of blast injury to the head and spine are the same as for GSW. Multidisciplinary specialist management is required for these complex injuries.

4635. Rosenwasser, R. H., et al. (1991). "Penetrating craniocerebral trauma." The Surgical clinics of North America **71**(2): 305-316.

The authors review the pathophysiology of penetrating and perforating cranial wounds. Radiologic evaluation includes computed tomography and angiography. Operative technique and perioperative critical care are discussed, with special emphasis on the control of the intracranial pressure. Other problems such as fluid and electrolyte disorders and nutrition are discussed in relation to neurosurgery.

4636. Rosinski, C. L., et al. (2019). "Autologous Bone Cranioplasty: A Retrospective Comparative Analysis of Frozen and Subcutaneous Bone Flap Storage Methods." World neurosurgery **131**: e312-e320.

OBJECTIVE: The use of autologous bone for cranioplasty offers superior cosmesis and cost-effectiveness compared with synthetic materials. The choice between 2 common autograft storage mechanisms (subcutaneous vs. frozen) remains controversial and dictated by surgeon preference. We compared surgical outcomes after autologous bone cranioplasty between patients with cryopreserved and subcutaneously stored autografts., METHODS: Ten-year retrospective comparative analysis of patients undergoing cranioplasty with autologous bone stored subcutaneously or frozen at a tertiary academic medical center., RESULTS: Ninety-four patients were studied, with 34 (36.2%) bone flaps stored subcutaneously and 59 (62.8%) frozen. The 2 groups were similar in demographics, comorbidities, and craniectomy indication, with only body mass index and race differing statistically. The mean operation time was greater within the subcutaneous group ($P < 0.001$), which also had a greater number of ventriculoperitoneal shunt (VPS) placements ($P = 0.02$). There were no significant differences in complications, readmissions, unplanned reoperations, or length of stay between the 2 groups. VPS placement during cranioplasty increased length of stay ($P < 0.001$), and placement prior to cranioplasty increased both length of stay ($P = 0.009$) and incidence of hospital-acquired infection ($P = 0.03$)., CONCLUSIONS: Subcutaneous and frozen storage of autologous bone result in similar surgical risk profiles. Cryopreservation may be preferred because of shorter operation time and avoidance of complications with the abdominal pocket, whereas the portability of subcutaneous storage remains favorable for patients undergoing cranioplasty at a different institution. VPS placement prior to cranioplasty should be avoided, if possible, due to the increased risk of hospital-acquired infection.

4637. Ross, A. H. (1996). "Caliber estimation from cranial entrance defect measurements." Journal of forensic sciences **41**(4): 629-633.

Caliber estimation from entrance defects has long been rejected by forensic scientists. This appears to be a consequence of soft tissue perspective of forensic pathologists. This study examined the relation between caliber and cranial entrance defects and maximum cranial thickness. The calibers considered in this inquiry were .22, .25, .32, and .38. The sample consisted of 73 specimens obtained at autopsy (thirty-seven of .22 caliber, five of .25, six of .32, and twenty-five of .38). To test the strength of the relation between caliber, minimum diameter, and maximum thickness Pearson correlation coefficients were conducted. The strongest relationship was observed between caliber and minimum diameter. A relationship between minimum diameter and maximum thickness was also observed. To test the null hypothesis that the mean minimum diameter is not significantly different between calibers an analysis of variance procedure was performed. The ANOVA yielded a strong relationship between dependent variable minimum diameter and caliber. Multiple regression analysis measuring the association between minimum diameter, caliber, and maximum thickness was also conducted. The $Pr > F$ .0001 suggests that the overall model is significant. Discriminant functions and canonical variables were obtained. Classification was first performed by using two values small and large calibers. The large caliber group consisted of .38, while the small caliber group included .22, .25, and .32. The correct classification rate using crossvalidation for large caliber is 86.96%, and 93.33% for the group small caliber. A narrower classification was also performed by using three values, .23 caliber (.22 and .25 calibers grouped), .32, and .38 as the criterion variable groups also using minimum diameter and maximum thickness as predictors. The correct classification rate using crossvalidation is 82.02% for .23 caliber, 73.94% for .38 caliber, and 16.67% for .32 caliber defects. The discriminant functions can be used with appropriate caution to classify observations into groups defined by caliber using minimum diameter and maximum thickness as the predictors. Caution is suggested when attempting to estimate caliber from defects that are not produced from the perpendicular entrance of a bullet.

4638. Rosselli, D. (2005). "[Phineas Gage, 'Tan' and the importance of case reports]." Phineas Gage, 'Tan' y la importancia de los casos clinicos. **40**(2): 122-124.

INTRODUCTION: The original descriptions of the frontal lobe injury of Phineas Gage (1848) and the slowly growing tumor of 'Tan', Broca's famous patient (1861), are examples of how a simple case report can teach important lessons, some of them still discussed a century and a half later., DEVELOPMENT: In this article, the original sources of both of these seminal cases, in Boston and Paris, have been reviewed and are briefly summarized. The lessons learned from them in the effort to localize brain functions are explained and set in the context of modern evidence-based medicine.

4639. Rossi, C., et al. (2018). "Cranial Backspatter Pattern Production Utilizing Human Cadavers." Journal of forensic sciences **63**(5): 1526-1532.

A backspatter pattern results from blood drops that travel retrograde to an applied external force. Historically, an array of animals and nonhuman objects have been used to create and study backspatter patterns. In this study, backspatter patterns captured on foam core targets that were placed 45.72 cm (18 in) behind the impact site (occipital area of the skull) were produced by cranial gunshots to human cadavers that were reinfused with fresh defibrinated bovine blood. These patterns were compared to the backspatter patterns produced by shooting blood-soaked sponges, a typical simulant used in controlled studies of backspatter pattern production and characteristics. The backspatter pattern produced by shooting an actual human head was found to be different than those of blood-soaked sponges in the number of stains produced, the size and size range of the stains, and the stain dispersion patterns.

4640. Rostami, E., et al. (2011). "Biomarkers in serumafter experimental diffuse and focal traumatic brain injury in rats." Journal of neurotrauma **28**(5): A11.

Background: Traumatic brain injury (TBI) biomarkers would be highly valuable in the diagnosis of various forms of TBI, and also in the evaluation and treatment of TBI patients, and may even provide prediction of the outcome of the future impairments of the patients. Here we analyzed brain and serum samples derived from rodent models of rotational and penetration TBI by reverse phase protein microarray (RPPM). Methods: The first model is a controlled penetration of 2-mmthick needle-shaped object, which is accelerated with a bullet from an air gun or a pendulum (pen-TBI). In the second model we produce diffuse axonal injury. The animal is subjected to high-speed sagittal rotation acceleration (rot-TBI). A total of 48 animals were used, grouped into normal controls, sham-operated, and injured animals. The rats were sacrificed at days 1, 3, and 14 post-injury, and serum samples were analyzed for Tau, NF200, MBP, N-cadherin, NSE, and S100B. Results: We found an increase in all proteins measured in both rotational and penetrating TBI. However, there were distinct temporal patterns of expression of protein markers in each TBI model. The results of tau and NF200 appear consistent with the injury mechanism in DAI (i.e., initial axonal distention followed by a secondary axotomy). The NSE and S100B showed a biphasic pattern in focal penetrating injury (pen-TBI), indicating a secondary injury. Conclusion: This information can be used to form a palette of biomarkers that can improve and contribute to diagnostic and therapeutic tools in TBI management.

4641. Rostami, E., et al. (2014). "Alteration in BDNF and its receptors, full-length and truncated TrkB and p75(NTR) following penetrating traumatic brain injury." Brain research **1542**: 195-205.

The evidence that BDNF is involved in neuroprotection, neuronal repair and recovery after traumatic brain injury (TBI) is substantial. We have previously shown that the polymorphism of the human BDNF gene predicts cognitive recovery and outcome following penetrating TBI. The distribution of expression of BDNF and its receptors after penetrating TBI has not been investigated. In this study we examined the expression of these genes in a rat model of penetrating TBI. The injury is produced by a controlled penetration of a 2mm thick needle-shaped object, which is accelerated with a pellet from an air gun. We used in situ hybridization and investigated the mRNA expression of BDNF and its receptors: the full-length and the truncated TrkB and p75(NTR), from 1 day to 8 weeks following penetrating TBI. In addition, the protein level of BDNF in frontal cortex and hippocampus was measured by reverse phase protein microarray (RPPM). The mRNA expression of BDNF and its receptors decreased in the hippocampus in the border zone ipsilateral to the injury while there was an increase in mRNA expression at the contralateral side. The increase in BDNF

mRNA expression in the hippocampus was sustained for 2 weeks following injury, with the highest expression noted in the CA3 cell layer. Furthermore, the protein analysis by RPPM showed increased levels of BDNF in the frontal cortex and the hippocampus up to 2 weeks after TBI. At 8 weeks following injury there was an intense labeling of the truncated TrkB receptor and the p75(NTR) in the area surrounding the cavity. Our study is the first report on the expression of BDNF and its receptors following penetrating TBI and suggests that their expression is altered long after the acute phase of injury. Further studies are needed to investigate if the late expressions of these receptors are beneficial or deleterious. In either case it indicates the possibility to influence the recovery after brain injury during the chronic phase and the development of treatments that may improve the outcome of TBI patients. Copyright © 2013 Published by Elsevier B.V.

4642. Rostami, E., et al. (2011). "BDNF polymorphism predicts general intelligence after penetrating traumatic brain injury." PloS one **6**(11): e27389.

Neuronal plasticity is a fundamental factor in cognitive outcome following traumatic brain injury. Brain-derived neurotrophic factor (BDNF), a member of the neurotrophin family, plays an important role in this process. While there are many ways to measure cognitive outcome, general cognitive intelligence is a strong predictor of everyday decision-making, occupational attainment, social mobility and job performance. Thus it is an excellent measure of cognitive outcome following traumatic brain injury (TBI). Although the importance of the single-nucleotide polymorphisms polymorphism on cognitive function has been previously addressed, its role in recovery of general intelligence following TBI is unknown. We genotyped male Caucasian Vietnam combat veterans with focal penetrating TBI (pTBI) (n = 109) and non-head injured controls (n = 38) for 7 BDNF single-nucleotide polymorphisms. Subjects were administrated the Armed Forces Qualification Test (AFQT) at three different time periods: pre-injury on induction into the military, Phase II (10-15 years post-injury, and Phase III (30-35 years post-injury). Two single-nucleotide polymorphisms, rs7124442 and rs1519480, were significantly associated with post-injury recovery of general cognitive intelligence with the most pronounced effect at the Phase II time point, indicating lesion-induced plasticity. The genotypes accounted for 5% of the variance of the AFQT scores, independently of other significant predictors such as pre-injury intelligence and percentage of brain volume loss. These data indicate that genetic variations in BDNF play a significant role in lesion-induced recovery following pTBI. Identifying the underlying mechanism of this brain-derived neurotrophic factor effect could provide insight into an important aspect of post-traumatic cognitive recovery.

4643. Rostomily, R. C., et al. (1997). "Gunshot wounds of the internal carotid artery at the skull base: management with vein bypass grafts and a review of the literature." The Journal of trauma **42**(1): 123-132.

BACKGROUND: Penetrating trauma to the skull base and distal cervical internal carotid artery (ICA) can result in occlusion or pseudoaneurysm formation. The appropriate management strategy for these rare lesions is controversial and includes observation, anticoagulation, carotid ligation, balloon occlusion, or revascularization., METHODS: We present the management and outcomes of four consecutive patients, two with pseudoaneurysms and two with acute occlusions, after injury to the distal cervical/petrous ICA from gunshot wounds. Preoperative assessment determined intracranial collateral flow patterns and the patency of the distal portion of the petrous ICA., RESULTS: Two patients underwent cervical-to-petrous ICA vein bypass grafts without neurologic complications. Both grafts remain patent without evidence of emboli at 2 years and 3 months, respectively. Both of the conservatively managed patients died, one from a massive cerebral infarction and the other from intracerebral hemorrhage., CONCLUSIONS: These cases underscore the need for an aggressive approach to the assessment and management of patients with penetrating vascular skull-base injuries. Although the optimal treatment of remains controversial, when the goal is exclusion of the injured portion of the carotid artery and revascularization, the cervical to petrous ICA vein bypass graft is a valuable management option that can reduce the potential morbidity and mortality from acute ischemic or delayed embolic or hemorrhagic complications, provide immediate restoration of high flow, and allow good surgical access with minimal risk to intracranial structures.

4644. Rostworowski, M., et al. (1997). "Astrogliosis in the neonatal and adult murine brain post-trauma: elevation of inflammatory cytokines and the lack of requirement for endogenous interferon-gamma." The Journal of neuroscience : the official journal of the Society for Neuroscience **17**(10): 3664-3674.

The relevance of astrogliosis remains controversial, especially with respect to the beneficial or detrimental influence of reactive astrocytes on CNS recovery. This dichotomy can be resolved if the mediators of astrogliosis are identified. We have measured the levels of transcripts encoding inflammatory cytokines in injury systems in which the presence or absence of astrogliosis could be produced selectively. A stab injury to the adult mouse brain using a piece of nitrocellulose (NC) membrane elicited a prompt and marked increase in levels of transcripts for interleukin (IL)-1alpha, IL-1beta, and tumor necrosis factor (TNF)-alpha, which are considered to be microglia/macrophage cytokines. The elevations preceded, or occurred concomitantly with, the rise in glial fibrillary acidic protein mRNA, an early manifestation of astrogliosis. In neonatal mice, IL-1 and TNF-alpha mRNA were elevated to a greater extent by an NC-implant injury, which produced astrogliosis, than after an NC-stab, with minimal astrogliosis. We determined whether endogenous interferon (IFN)-gamma could be responsible for the observed increases in IL-1 and TNF-alpha, because IFN-gamma is a potent microglia/macrophage activator, and because its exogenous administration to rodents enhanced astrogliosis after adult or neonatal insults. A lack of requirement for endogenous IFN-gamma was demonstrated by three lines of evidence. First, no increase in IFN-gamma transcripts could be found at injury. Second, the administration of a neutralizing antibody to IFN-gamma did not attenuate astrogliosis. Third, in IFN-gamma knockout adult mice, astrogliosis and increases in levels of IL-1alpha and TNF-alpha were induced rapidly by injury. The marked elevation of inflammatory cytokines is discussed in the context of astrogliosis and general CNS recovery.

4645. Roth, J., et al. (2005). "Brain injuries caused by spherical bolts." Journal of neurosurgery **102**(5): 864-869.

OBJECT: Metallic particles contained in antihuman bombs increase the number of fatalities. The ballistics of these particles depends on the explosive that is used, the distance from the explosion, the shape of the particle projected, and the biomechanics of the injured tissue. The authors present their experience with penetrating spherical bolt injuries to the brain., METHODS: The authors retrospectively reviewed clinical and radiological data obtained in eight patients with penetrating spherical bolt injuries to the cranium: four had Glasgow Coma Scale (GCS) scores less than 8 (three died, one from an unrelated injury) and four had a GCS score of 15 (all survived). Two of the latter patients suffered unique anatomical injuries attributed to the distinctive ballistics of spherical bolts: in one patient the bolt penetrated the cavernous sinus causing minimal cranial nerve injury, and in the other patient the bolt lodged in the fourth ventricle causing acute hydrocephalus without other neurological deficits., CONCLUSIONS: Penetrating spherical bolts to the brain may be lethal. Nevertheless, they have unique ballistics that cause highly delineated anatomical damage and minor neurological deficits.

4646. Roth, M., et al. (1989). "Penetrating injuries involving the anterior cranial fossa." Archives of oto-rhino-laryngology **246**(6): 411-416.

Penetrating injuries of the anterior cranial fossa may result in permanent neurologic changes or even death if injuries are unrecognized and remain untreated. The diverse etiologies of such injuries are reviewed, as well as their diagnosis, treatment and prognosis.

4647. Rothman, M. I., et al. (1998). "Superior blowout fracture of the orbit: the blowup fracture." AJNR. American journal of neuroradiology **19**(8): 1448-1449.

We describe a patient who sustained a blowout fracture of the superior orbital roof without an orbital rim fracture. The initial CT study (obtained with 10-mm-thick sections) did not show herniation of the intraorbital fat into the anterior cranial fossa; however, thin (3-mm-thick) direct orbital sections showed a fracture of the midportion of the superomedial orbital roof with displacement of the fracture fragment into the anterior cranial fossa.

4650. Rothschild, M. A. and D. M. Krause (1996). "[Blank firearms--an underestimated weapon class. Dangerousness, mechanical effect and legal classification]." Schreckschusswaffen--eine unterschatzte Waffengattung. Gefahrlichkeit, Wirkungsweise und strafrechtliche Einordnung. **197**(3-4): 65-75.

The dangers posed to individuals by blank-cartridge guns are frequently underestimated by German courts. A description is given to the effects, specific dangers and typical consequences of injuries caused by the use of these weapons, inclusion of blank guns in the catalogue of terms applying to weapons law and penal law as well as individual questions of penal decisions regarding their use against man. The paper comes to the conclusion that it is hardly possible to doubt any more the not insignificant probability and objective foreseeability of severe or even fatal injuries when blank guns are used against people.

4651. Rothschild, M. A. and H. Maxeiner (1994). "Unusual findings in a case of suicide with a gas weapon." International journal of legal medicine **106**(5): 274-276.

Case report on a suicide with a gas pistol loaded with 8 mm blank cartridges. A 58-year-old male shot himself in the right temple and then in the back of the neck. The contact shot wounds showed large wound cavities with interspersed powder particles. The soft tissues were injured solely by the pressure of the exploding powder. Death was due to an air/gas embolism in the right ventricle of the heart.

4652. Rothschild, M. A. and V. Schneider (2000). "Gunshot wound to the head with full recovery." International journal of legal medicine **113**(6): 349-351.

A 28-year-old man was shot in the back of the head at close range by a robber who then locked him in a room assuming that he was dead. The man was discovered 2 days later. The entrance wound of the bullet was in the left occipital region and it passed into the periphery of the right temporal lobe, where it lodged. The man was transferred to a rehabilitation centre 3 weeks later in relatively good health with only slight general EEG changes. The mild clinical course in this case is attributable to two major factors: firstly, no important brain structures were injured, and secondly, the kinetic energy of the silver-tip hollow-point bullet was probably rather low. Three years after the incident, the man still has slight sensory disturbances in the fingers of the left hand and left-sided homonymous hemianopia. He is now working again at his old profession (managing director) and the projectile is still lodged in the right temporal lobe.

4655. Roux, F. E. and M. Mejdoubi (2001). "[Potential neurosurgical damage of rubber bullets. Analysis of 2 pediatric cases]." Gravite neurochirurgicale potentielle des projectiles "caoutchouc". Analyse de 2 cas pediatriques. **47**(6): 576-579.

We present 2 cases of craniocerebral injuries in children caused by rubber bullets. The potential severity of these projectiles is discussed. The first case was an eleven-year-old boy who died a few days after having been injured by a rubber bullet during a riot. He presented with a bi-hemispheric fronto-parietal craniocerebral injury with massive intraventricular hemorrhage. The second case was a fourteen-year-old boy also injured by a similar rubber bullet with an important left fronto-temporal cerebral contusion. These projectiles were composed of a metal cylinder (length: 1.7 cm, diameter: 1.7 cm) covered by a 2 mm layer of rubber. The term "rubber bullet" could give the impression that these projectiles are harmless. But, based on these observations and on the literature, these rubber bullets (like their predecessors) can induce severe, or even fatal craniocerebral injuries.

4656. Roux, F.-E. and M. Reddy (2013). "Neurosurgical work during the Napoleonic wars: Baron Larrey's experience." Clinical neurology and neurosurgery **115**(12): 2438-2444.

OBJECTIVES: Considered as the most famous French military surgeon, Dominique-Jean Larrey (1766-1842), who joined all the campaigns of Napoleon, wrote his memoirs and several medical articles. This paper discusses how in the Napoleonic times, Larrey dealt with neurosurgical diseases or injuries., PATIENTS AND METHODS: We reviewed four main publications of Larrey published between 1812 and 1838 and analyzed the type of neurosurgical cases presented and their treatment., RESULTS: These works include his practice of what we call now "neurosurgery" since most injuries described concern the skull or spine. He seemed to treat patients with humanity, integrity and perseverance. Larrey dealt with many aspects of neurosurgery, such as cranial or spinal trauma surgery, and also infectious diseases. He saw many head injuries inflicted not only by muskets or artillery, but also with spears and sabers. Unlike some others, Larrey advocated the use of trepanation in many situations as practiced, for instance, in the treatment of depressed fractures or in presence of subdural collections. On the other hand, this surgeon who saw thousands of amputees during his career did not mention the phantom limb phenomenon in his memoirs. Similarly, the issue of cerebral localizations is only mentioned in his last work, published in 1838., CONCLUSIONS: In his work, Larrey (and all his contemporaries) dealt essentially with "cranial" surgery, as in skull fractures where the brain could potentially have been injured by bone fragments. The time for brain surgery had not come yet.

4657. Rovlias, A., et al. (2016). "The influence of the epidemiological and nontreatment variables on neurological outcome in severe head injury." Brain injury **30**(5-6): 492.

Objectives: It has long been recognized that the method of clinical management of severe head injuries often creates a remarkable difference in neurological outcome. Moreover, the development of advanced systems of emergency and primary care has minimized medical complications associated with severe traumatic brain injuries. Previous literature suggests the influence and contribution of several non-treatment factors, other than clinical protocols, on patients' outcome. This study analyzes nine prognostic epidemiological variables and their potential relationship to the late outcome in a series of patients with severe head injury. Methods: Our study is based on 280 patients admitted to Asclepeion Hospital, a regional trauma centre, with severe head injury. Patients with associated major chest, abdominal or orthopaedic trauma were excluded. The sample population was composed of 214 males and 66 females, with a mean age of 38 years; 16.42% of the patients had a history of alcohol intake with road traffic accident (83.21%) as the most common mode of brain injury. Over 50% of the patients were admitted to the hospital within 4 hours of injury; 47.14% of the patients were intubated within the first hour from the time of the accident. All patients underwent a CT scan as soon as possible after initial resuscitation. Only non-penetrating head injuries were included in this study. All variables were individually and simultaneously related to outcome. Neurological outcome was evaluated at 6 months according to Glasgow Outcome Score (GOS). Results: Severity of injury (GCS) was the best and strongest statistical predictor of outcome. Patient's age, type of head injury according to CT scan findings, time from accident to emergency room and time from accident to intubation had also a statistically significant impact on neurological outcome. Multivariate analysis indicated an overall multiple correlation of R = 0.73, generated primarily from the confounding influence of GCS score, age and CT scan findings. Conclusions: The type of patient most frequently encountered in this study was the young adult male, under 40 years of age, involved in a moving vehicular accident. This suggests a potential target group for any preventive measures directed at severe head injuries. In the arena of severe head trauma, where randomization and patient comparisons are frequently difficult, it is important to determine statistically whether reported differences in outcome are due to differences in patient groups or to more effective therapy or to other factors associated with outcome. Thus, predicting neurological outcome is an assimilative and integrative process of various pre-injury, injury and post-injury variables. These also suggest the necessity of continuing evaluative research on emergency care networks which can link together data relating to ambulances, paramedical personnel, physicians, community hospitals and trauma centres.

4658. Rowe, N. L. (1971). "The history of the treatment of maxillo-facial trauma." Annals of the Royal College of Surgeons of England **49**(5): 329-349.

4659. Rowell, S. E., et al. (2011). "Specific abbreviated injury scale values are responsible for the underestimation of mortality in penetrating trauma patients by the injury severity score." The Journal of trauma **71**(2 Suppl 3): S384-388.

BACKGROUND: The Injury Severity Score (ISS) is widely used as a method for rating severity of injury. The ISS is the sum of the squares of the three worst Abbreviated Injury Scale (AIS) values from three body regions. Patients with

penetrating injuries tend to have higher mortality rates for a given ISS than patients with blunt injuries. This is thought to be secondary to the increased prevalence of multiple severe injuries in the same body region in patients with penetrating injuries, which the ISS does not account for. We hypothesized that the mechanism-based difference in mortality could be attributed to certain ISS ranges and specific AIS values by body region., METHODS: Outcome and injury scoring data were obtained from transfused patients admitted to 23 Level I trauma centers. ISS values were grouped into categories, and a logistic regression model was created. Mortality for each ISS category was determined and compared with the ISS 1 to 15 group. An interaction term was added to evaluate the effect of mechanism. Additional logistic regression models were created to examine each AIS category individually., RESULTS: There were 2,292 patients in the cohort. An overall interaction between ISS and mechanism was observed (p = 0.049). Mortality rates between blunt and penetrating patients with an ISS between 25 and 40 were significantly different (23.6 vs. 36.1%; p = 0.022). Within this range, the magnitude of the difference in mortality was far higher for penetrating patients with head injuries (75% vs. 37% for blunt) than truncal injuries (26% vs. 17% for blunt). Penetrating trauma patients with an AIS head of 4 or 5, AIS abdomen of 3, or AIS extremity of 3 all had adjusted mortality rates higher than blunt trauma patients with those values., CONCLUSION: Significant differences in mortality between blunt and penetrating trauma patients exist at certain ISS and AIS category values. The mortality difference is greatest for head injured patients.

4660. Rowland, B. A., et al. (2018). "Aberrations in inflammation and fibrinolysis in the context of tbi and polytrauma." Shock **49**(6): 141-142.

Moderate to severe traumatic brain injury (TBI) is a leading cause of morbidity and mortality in our society. After the initial traumatic injury, secondary inflammatory insults to the CNS potentiate further brain injury. Moreover, early fibrinolysis is associated with progressive hemorrhagic injury (PHI)- the early expansion of intracranial hemorrhage. The pathophysiology underlying inflammatory and fibrinolytic processes in polytrauma with TBI are poorly understood, largely in part to a lack of studies exploring the phenomena. We predict that patients with severe TBI in the presence of polytrauma exhibit derangements in both fibrinolysis and acute inflammation. Methods: We conducted a single center retrospective study of a cohort of patients with polytrauma who were enrolled in the PROPPR study. These patients had blood samples prospectively collected at eight timepoints in the first 3 days of admission. Using radiological data to determine TBI, our polytrauma cohort was dichotomized into TBI or non-TBI groups. Patients with penetrating trauma were excluded. Inflammatory biomarkers and D-dimer were measured by ELISA and ACL TOP Coagulation Analyzer, respectively. Data across time were compared for TBI vs. non-TBI groups using Spearman correlation coefficients and Wilcoxon rank sum test. Results: TBI (n = 31) and non-TBI patients (n = 54) had similar demographic variables. The majority of patients were males. Patients with TBI had a higher median age (46 (IQR 24,61) vs. 36 (25,53) years) and injury severity score (ISS) (43 (34,50) vs. 29 (22,41); p-value < 0.001). Within the TBI group, 80% of patients developed PHI. Patients with TBI had higher (p-value < 0.001) 30-day mortality (51.6%) compared to patients without TBI (16.9%). Patients with TBI demonstrated increased inflammatory responses based on elevatedIL-6, IL-8, MCP-1, and G-CSF levels at each time point from 2-12 hours after admission, with peak differences occurring at 6 hours (IL-6, IL-8, MCP-1; p-value <0.05) (Figure). D-dimer were greater upon admission in patients with TBI. Unlike the pattern demonstrated for inflammatory markers, D-dimer levels were highest at admission and subsequently decreased across time. Among all patients, D-dimer and inflammatory cytokines were not correlated with each other across time (r<0.3, p-value >0.05). Conclusion: Peak inflammation and fibrinolysis were more pronounced in those polytrauma patients with TBI. The temporal onset of fibrinolysis and the subsequent inflammatory upregulation suggests that fibrinolytic products may potentiate inflammatory dysregulation. These data provide a molecular basis for understanding the relationship between fibrinolytic and inflammatory mechanisms found in polytrauma patients. An improved understanding of the underlying pathophysiology may provide novel opportunities for therapeutic intervention. (Figure Presented).

4661. Rowlands, H. E. and K. P. Morris (2007). "Management of severe traumatic brain injury." Paediatrics and Child Health **17**(3): 82-88.

Traumatic brain injury (TBI) causes significant morbidity and mortality in children. Physiological insults worsen morbidity and mortality and are particularly common in the pre-hospital setting. Management of severe TBI in the ICU is largely focused on the management of raised intracranial pressure and preservation of cerebral perfusion. Few randomised controlled trials have been undertaken in children with TBI. © 2007.

4662. Rowse, C. W. (1971). "Notes on interpretation of the orthopantomogram." British dental journal **130**(10): 425-434.

4663. Roy, B., et al. (2016). "Isolated tongue hemi-atrophy from hypoglossal-vertebral entrapment syndrome." Neurology **86**(16).

Objective: To review differential diagnosis of isolated hemi-atrophy of the tongue and present a case of hypoglossal-vertebral entrapment syndrome leading to unilateral hypoglossal nerve compression. Background: Isolated hemi-atrophy of the tongue, a rare neurological condition, is often a manifestation of peripheral hypoglossal nerve involvement. It can be associated with dysarthria and dysphagia. Skull base and neck tumors, schwannoma, gunshot wound related trauma, stroke, arterial dissection, multiple sclerosis, Guillain-Barré neuropathy, other inflammatory and infectious conditions can affect the nerve. Nerve can be affected along its course from caudal medulla, intracranial extramedullary portion, through the hypoglossal canal to its extracranial termination. Structural vascular anomaly leading to hypoglossal nerve compression is rare. Method: Case report presentation. Results: 44 year old male presented with isolated left sided hemi-atrophy of the tongue without any significant dysarthria or dysphagia. He did not have any neck trauma, or any recent infection. Review of systems did not suggest any other systemic or neurological illness. Neurological examination revealed left sided tongue atrophy with left deviation of the tongue on protrusion without any other cranial nerve involvement. Motor, sensory, coordination testing and reflexes were normal. Work up including complete blood count, comprehensive metabolic panel, cerebrospinal fluid (CSF) analysis, Lyme serology, angiotensin-converting enzyme level in CSF were unremarkable. MRI of the brain revealed compression of left hypoglossal nerve from left vertebral artery ectasia. A diagnosis of hypoglossal-vertebral entrapment syndrome was made based on clinical symptoms and radiological finding. Conclusion: Hypoglossal vertebral entrapment syndrome from a structural vascular anomaly or anomalous vascular course is an extremely rare cause of isolated hypoglossal nerve palsy. Only a few cases have been reported in the literature. Imaging studies and careful exclusion of other potential etiologies is essential to establish the diagnosis.

4664. Ruan, W.-S. and Y.-Q. Lu (2020). "The life-saving emergency thoracic endovascular aorta repair management on suspected aortoesophageal foreign body injury." World journal of emergency medicine **11**(3): 152-156.

BACKGROUND: Fatal aortic rupture caused by esophageal foreign body (EFB), is associated with a high mortality, but can be prevented by thoracic endovascular aorta repair (TEVAR) that performed increasingly as technology improves. This study aims to investigate the cause, management and prognosis of suspected penetrating aortoesophageal foreign body injury., METHODS: Twelve cases who met the criteria were enrolled in this study. The demographic and clinical data were reviewed for evaluating the characteristics of EFB., RESULTS: Among 12 cases enrolled, 7 were males and 5 were females, with an age 27-86 years. The distance of EFB from aorta (DFA) of 7 cases were less than or equal to 0 mm, 5 cases were 0-2 mm. Eleven cases were managed with TEVAR, only one case was with open surgery standby but finally treated by flexible endoscopy (FE) successfully, without TEVAR. In group with TEVAR, EFB of 7 cases were successfully removed by rigid endoscopy (RE), and one of them was failed at the first RE treatment. EFB of 2 cases were successfully removed by open surgery with TEVAR, and other 9 cases were managed by endoscopies with TEVAR. The mean length of stay of hospitalization (LOS) and length of ICU stay of patients treated by open surgery with TEVAR (18.50+/-2.12 days and 5.50+/-0.71 days) was significantly longer than those of patients treated by endoscopy with TEVAR (7.00+/-2.74 days and 1.33+/-1.12 days, $P<0.001$ and $P=0.001$, respectively). Five cases had severe complications., CONCLUSION: Rational application of TEVAR can be a life-saving management for aortoesophageal foreign body injury, and jointed with endoscopy is safe and effective with a shorter length of ICU or total hospital stay.

4665. Ruberti, R. F. (1997). "Cranioplasty with inner table of bone flap in children: Report of two cases." African Journal of Neurological Sciences **16**(2).

Cranioplasty is performed with various materials and autogenous bone. Since 1956 the Author has adopted the cranioplasty with acrilic resin in 149 consecutive cases and is satisfied with this technique in adult patients, less so in children where, due to the growing of the head and growing of the bone around the skull defect the acrilic cranioplasty can be displaced with bad cosmetic results so much that often it requires redoing. For this reasons the Author has adopted recently the cranioplasty with inner table of bone flap as described by KAZUHIKO et all in 1985. This technique has been used to repair the skull defect in two children with very satisfactory results. It is worth reporting this method of

grafting applicable in various situations. particularly in children and especially in Africa where acrilic resin may not be available.

4666. Rubiano, A. M., et al. (2019). "The Evolving Concept of Damage Control in Neurotrauma: Application of Military Protocols in Civilian Settings with Limited Resources." World neurosurgery **125**: e82-e93.

OBJECTIVE: The aim of the present review was to describe the evolution of the damage control concept in neurotrauma, including the surgical technique and medical postoperative care, from the lessons learned from civilian and military neurosurgeons who have applied the concept regularly in practice at military hospitals and civilian institutions in areas with limited resources., METHODS: The present narrative review was based on the experience of a group of neurosurgeons who participated in the development of the concept from their practice working in military theaters and low-resources settings with an important burden of blunt and penetrating cranial neurotrauma., RESULTS: Damage control surgery in neurotrauma has been described as a sequential therapeutic strategy that supports physiological restoration before anatomical repair in patients with critical injuries. The application of the concept has evolved since the early definitions in 1998. Current strategies have been supported by military neurosurgery experience, and the concept has been applied in civilian settings with limited resources., CONCLUSION: Damage control in neurotrauma is a therapeutic option for severe traumatic brain injury management in austere environments. To apply the concept while using an appropriate approach, lessons must be learned from experienced neurosurgeons who use this technique regularly.

4667. Rubinstein, A., et al. (2005). "Self-inserted intraorbital foreign bodies." Ophthalmic plastic and reconstructive surgery **21**(2): 156-157.

We report an unusual case of self-mutilation by insertion of multiple foreign bodies in the orbit. A 26-year-old female psychiatric patient with a severe emotionally unstable personality disorder was reviewed in the ophthalmology clinic. She had allegedly inserted a metal staple into her right eye 2 days previously and was complaining of pain around the right eye. Radiography showed multiple foreign bodies in the right orbit and one in the left orbit. Self-mutilation in psychiatric patients has been well documented. The management of nonorganic, nontoxic intraorbital foreign bodies is discussed. A low threshold for imaging in these cases is of vital importance.

4668. Rubio, A., et al. (2012). "The gunshot wound that wasn't: A case of foramina parietalia permagna in a skeletonized calvarium." Clinical neuropathology **31**(4): 304.

Introduction: Incidental autopsy findings can mimic clinical or traumatic conditions resulting in erroneous conclusions. It is the challenge and responsibility of the pathologist to gather additional information and interpret the findings in a multidisciplinary setting. Methods: Case report: A 78-year-old African-American man was found dead in his residence in a state of advanced decomposition, with partial skeletonization of the head and torso. Medical history included hypertension, perforated gastric ulcer, obesity, diabetes, prostatic cancer and hip replacement surgery. There was no history of significant trauma or neurosurgical procedures. Postmortem radiology did not reveal osseous trauma. Results: the skull was partially exposed and revealed bilateral defects involving the parietal bones. The defects were roughly symmetric, 6.4 cm to the left and 5.7 cm to the right of the sagittal suture, 7 cm anterior to the lambdoid suture and 5 over the temporal squame. The defect on the left side was round and measured 1.1 cm in diameter. The edge was smooth and rounded like a lip, giving the impression of outward beveling. The defect on the right consisted of a 1 cm area of skull thinning with a similarly smooth round lip and three 1 to 6 mm irregular orifices. X-rays of the cranium did not reveal ballistic evidence. One of the defects in the reported case was incomplete, ruling out the possibility of a true perforating gunshot wound. These defects were recognized as foramina parietaliapermagna (FPP). We present photographic documentation of the current case as well as other cases of FPP incidentally found during autopsy at our institution. Conclusions: FPP is a rare condition (estimated incidence of 1 in 15,000 to 25,000 individuals), transmitted in an autosomal dominant pattern. FPP in a skeletonized cranium closely resembles gunshot wounds, which could result in the incorrect diagnosis with untoward forensic and social consequences.

4669. Ruchholtz, S., et al. (2002). "A multidisciplinary quality management system for the early treatment of severely injured patients: implementation and results in two trauma centers." Intensive care medicine **28**(10): 1395-1404.

OBJECTIVE: The impact of a multidisciplinary quality management system (MQMS) on the early treatment of severely injured patients was tested., DESIGN AND SETTING: Prospective clinical study in two level 1 trauma centers., METHODS AND MATERIALS: MQMS comprised a protocol for documentation, 20 assessment criteria, and the judgement of data by a quality circle. After implementation in Munich (1st period, n=90; 2nd period, n=77) the validation took place in Essen (1st period, n=175; 2nd period, n=150)., RESULTS: Improvements in diagnostics were shown by significant time savings in radiological diagnostics and before computed tomography in severe traumatic brain injury. In patients with hemorrhagic shock there was a reduction in time before transfusion (49 to 14 min in Munich; 31 to 22 min in Essen) and before emergency operation (74 to 43 min in Munich; 69 to 45 min in Essen). The time before craniotomy was reduced from 97 to 67 min in Munich. The incidence of delayed diagnosis of life-threatening lesions was diminished from 6% to 3% in Munich (not found in Essen). The TRISS technique showed a reduction in mortality in both hospitals in the second period (Munich: 15.4% TRISS vs. 9.1% observed mortality; Essen: 17.8% vs. 11.3%)., CONCLUSIONS: MQMS improved early clinical treatment in severe injury with respect to therapeutic effectiveness and outcome. The effectiveness of the MQMS was shown at two different hospitals

4671. Ruddy, R. M. and G. R. Fleisher (1985). "Pediatric trauma: an approach to the injured child." Pediatric emergency care **1**(3): 151-159.

The approach to the injured child requires great care and clinical acumen to establish the diagnosis and institute appropriate treatment. Loss of life from occult internal hemorrhage or neurologic sequelae from a missed unstable cervical spine injury may be devastating. Yet, physicians in the ED must also know which children need only a careful physical examination, and when laboratory testing or admission is unnecessary. We have described a schema for providing appropriate care to children with trauma in such a way that specific issues about management can be reasonably approached by the emergency physician.

4672. Ruess, D., et al. (2013). "Pitfalls in brain death diagnosis: a case report." Journal of neurological surgery. Part A, Central European neurosurgery **74**(3): 192-196.

Although there are distinct guidelines in nearly all countries, a reliable secure assessment of brain death in cases with open head injury can be challenging. We present a case of a 32-year-old man with severe head injury after intracranial penetration of a grindstone fragment. As the injury led to destruction of nearly the whole greater wing of the right sphenoid bone and parts of the right orbit, the examination of brainstem reflexes and the confirmation of brain death was unfeasible. On day 2, all clinical criteria of brain death (coma, absence of brainstem reflexes, apnea) were fulfilled. In addition, there was an extinction of brainstem auditory (BAEP) and cerebral (N20) components of median nerve somatosensory evoked potentials, while electroencephalogram (EEG) activity was still present. In the following days, a persisting EEG activity was obtained. Thus, an irreversible loss of whole brain functions could not be proved. As the patient had agreed to organ donation in case of brain death several years ago, ancillary methods to test the cessation of cerebral blood flow were mandatory. However, in this patient these methods turned out either to be doubtful or unavailable. For example, values of transcranial Doppler ultrasonography are not reliable in cases with open head injury. Due to a progressive septic state, time was running out to get the radiopharmaceutical agent for a cerebral scintigraphy (delivery time about 7 days, as the radiopharmaceutical agent was not in stock). Referring to the actual German guidelines, we had no legitimating indication for a cerebral angiography. Finally, the patient died of sepsis. We discuss the widening of the German guidelines in assessing brain death with the fast and low-risk method of cerebral computed tomography-angiography (CTA) to confirm diagnosis of brain death. 4673. Ruiz, C., et al. (2013). "[Characteristics of trauma patients admitted to the intensive care unit of a general hospital in Chile]." Caracteristicas de los pacientes traumatizados que ingresan a la UCI de un hospital general en Chile. **141**(11): 1389-1394.

BACKGROUND: Trauma is an important cause of death among young adults., AIM: To determine the characteristics, treatments and evolution of trauma patients admitted to an intensive care unit (ICU) of a public hospital in Santiago, Chile., MATERIAL AND METHODS: All polytrauma (PT) and severely traumatized (ST) patients admitted to ICU were included. We recorded the type of trauma along with demographic and hemodynamic variables, treatments and complications. The evolution and treatments received by PT and ST patients were compared., RESULTS: We recorded data from 72 patients aged 43 +/- 21 years (93% males). Sixty two percent were PT and 24% had penetrating injuries. TBI (Trauma Brain Injury) was the most common trauma. On admission, acute Physiology and Chronic Health Evaluation II (APACHE II) score was 18.7 + 7.3, and Injury Severity Score (ISS) was 32.8 + 20.1. ICU stay was 7.8 + 6 days. Sixty seven per cent of patients required surgery and 58% received blood transfusions. No differences were found between PT and ST. ICU and hospital mortality rates were 15 and 25% respectively., CONCLUSIONS: The characteristics and evolution of PT and ST of this series of patients are similar to those described abroad. Mortality was in agreement with ISS and APACHE II scores.

4674. Ruiz, C., et al. (2019). "[Features of patients with trauma admitted to an emergency room of a general hospital]." Atencion de los pacientes con trauma grave durante los primeros dias: evolucion entre la urgencia, el pabellon y la unidad de cuidados intensivos. **147**(10): 1256-1265.

BACKGROUND: Trauma is the main cause of death among people aged 5 to 44 years., AIM: To describe features, treatment and evolution of trauma patients admitted to an emergency room., MATERIAL AND METHODS: Adult patients admitted in the emergency department of a public hospital due to severe trauma were studied and followed during their hospital stay., RESULTS: We included 114 patients aged 40 +/- 17 years (78%men) with an injury severity score of 21 +/- 11. Trauma was penetrating in 43%. Traumatic brain injury (TBI) was the most common diagnosis in 46%. In the emergency room, 8% had hypotension, 5% required vasopressors and 23% required mechanical ventilation. The initial lactate was 3.6 +/- 2.9 mmol/L. Sixty-five patients (57%) required emergency surgery. The intraoperative lactate was 3 +/- 1.7 mmol/L and 20% required vasopressors. Sixty-four patients (56%) were admitted to the ICU, with APACHEII and SOFA scores of 16 +/- 8 and 5 +/- 3, respectively. ICU lactate was 3.2+/-1.5 mmol/L. In the ICU 40% required vasopressors and 63% mechanical ventilation. Thirty two percent had coagulopathy, 43% received transfusions and 10% required massive transfusions. The hospital stay was 13 (6-32) days, being significantly longer in patients with TBI. ICU and hospital mortalities were 12.5 and 18.4% respectively. The only predictor for mortality was the APACHEII score (Hazard Ratio 1.18, 95% confidence intervals 1.03-1.36)., CONCLUSIONS: APACHE score was a predictor of mortality in this group of patients.

4675. Ruiz-Martin, M. M., et al. (2007). "[Penetrating orbitocranial injury after trivial eyelid trauma: a case report]." Lesion orbito-craneal penetrante tras traumatismo palpebral minimo: a proposito de un caso. **82**(12): 785-788.

CASE REPORT: We report a patient who, while in a drunken state, sustained a cerebral hemorrhage associated with an apparently trivial eyelid injury after an aggressive attack with a metallic object., DISCUSSION: Any apparently trivial eyelid injury may be associated with serious cerebral lesions. Making a correct diagnosis that distinguishes between that of drunkenness and an organic injury is essential, because failure to do so may result in both clinical and legal repercussions.

4676. Rummelt, V., et al. (1993). "Congenital nonpigmented epithelial iris cyst after amniocentesis. Clinicopathologic report on two children." Ophthalmology **100**(5): 776-781.

BACKGROUND: Congenital nonpigmented epithelial iris cysts are not common. They may arise spontaneously from developmental entrapment of surface ectodermal epithelium or from occult ocular trauma prenatally or at birth., PATIENTS AND METHODS: Between 1989 and 1991, an 8-month-old child and a 6-year-old child presented with large, progressive congenital epithelial iris cysts. Both children had a maternal history of diagnostic amniocentesis after an ultrasound scan, and there was no history of postnatal ocular trauma. The cysts were successfully removed by a modified block excision and tectonic corneoscleral grafting., RESULTS: A dense adherence of the cyst wall to Descemet's membrane resembled old anterior synechiae after occult perforation of the globe in both patients. On histopathologic examination, the epithelial lining of the cysts consisted of non-keratinizing stratified squamous epithelium with goblet cells resembling conjunctival epithelium. A perforating limbal scar with a corresponding break in Descemet's membrane could be detected in one eye. The long-term visual acuity of both children was encouraging, and there was no evidence

of recurrence of the iris cyst during the follow-up period (average, 23 months)., CONCLUSIONS: The authors conclude that the clinical and histopathologic features of these congenital iris cysts may be consistent with an occult intrauterine limbal perforation of the anterior chamber with a needle during amniocentesis. Amniocentesis, when not guided by a real-time ultrasound scan, may be a risk factor for prenatal ocular trauma, which should be considered in the differential diagnosis of congenital ocular disorders.

4677. Runge, J. W. (1993). "The cost of injury." Emergency medicine clinics of North America **11**(1): 241-253.

The public health problem of injury has an enormous impact on individuals and society, both as a health and economic issue. Prior to the last decade, little attention has been paid to the costs generated by injury, much of which is preventable. By looking at aggregate economic costs for different injuries and population groups, the physician can understand where the problems occur that need to be addressed to curb this staggering burden on society.

4678. Rungruangsak, K. and N. Poriswanish (2021). "Pathology of fatal diffuse brain injury in severe non-penetrating head trauma." Journal of forensic and legal medicine **82**: 102226.

Traumatic brain injury (TBI) is recognised as a serious global public health problem that imposes a heavy socioeconomic burden on society. The vast majority of cases result from road traffic accidents and falls, and the injuries are mainly attributed to velocity-related mechanisms. Lethal cases are mostly found to suffer from severe diffuse brain injuries (DBI), comprising diffuse vascular injury, diffuse axonal injury (DAI), generalized cerebral edema and ischemic-hypoxic injury. Coup and contrecoup brain contusions may also occur. This study set out to describe the pathological findings of severe DBI in terms of survival times and Abbreviated Injury Scale (AIS) severity scores. The autopsy data from 2 recent years (2018 and 2019) were reviewed to recruit over 800 cases presenting with severe head injuries. Many demographic characteristics of TBI were identified (for example, causes, victim genders and victim ages). These were revealed to be like those previously reported in the literature, confirming that there are shared risk factors across the globe. The hallmarks of severe TBI-such as a unimodal survival distribution and a period for detecting DAI via conventional staining-were also evident, as per previous reports. However, it was noticed that the histopathological detection rates of DAI surged after 72 h, which might be because these injuries are mediated by secondary axotomy. This study also analysed real brain weights to identify the time period for the development of cerebral edema in humans; this period seems to have never been reported. The increment time of cerebral edema reached a peak in 12 h, after which the condition sustained for at least 72 h. This may be a golden period in clinical practice as well as a prognostic factor in forensic medicine.

4679. Rupp, W. R., et al. (2001). "[Early post-mortem animal bites after suicidal gunshot wound to the head of a police dog handler]." Fruhpostmortaler Tierfrass nach suizidalem Kopfschuss eines polizeilichen Hundefuhrers. **207**(3-4): 73-80.

A 41-year-old police officer committed suicide in his office by firing a contact shot to the left temple. When the body was found 12 hours later, the German shepherd dog the officer had been in charge of had caused considerable damage on the lower half of the face and the adjacent parts of the neck. The clothing of the suicide was undamaged. Blood traces in the shape of paws were found at the place of death. The wound margins of the postmortem animal injury were nicked and jagged by the canine teeth. The entrance and exit wounds were not affected by the soft tissue defect. The findings gathered are discussed in reference to the relevant literature.

4680. Ruprecht, K. W. (1983). "[Emergency conditions in ophthalmology. First aid in general practice and in the clinic. 3: Leading symptoms "results of injury"--"unconsciousness"--"diplopia"]." Notfall-Situationen in der Ophthalmologie. Erstmassnahmen in der Praxis und Klinik--Schluss. Folge 3: Leitsymptome "Verletzungsfolgen"--"Bewusstlosigkeit"--"Diplopie". **101**(30): 1378-1385.

The emergency situations in ophthalmology are divided into the main symptoms (acute loss of sight, pain in the eye, "Red Eyes", injuries, unconsciousness, diplopia). Subjective symptom identification, diagnosis and current therapy are briefly outlined. For the general doctor the important preceding symptoms are emphasized as well as the prognosis according to clinical treatment.

4681. Rushworth, B. and L. Carter (2018). "Tetanus after a penetrating injury to the right globe: a case report." The British journal of oral & maxillofacial surgery **56**(5): 425-426.

A 24-year-old man attended the emergency department with a penetrating injury to the right globe after a road traffic accident. He later contracted tetanus for which he was given human tetanus immunoglobulin. Although it is rare, tetanus is life-threatening and a thorough immunisation history should be obtained before treatment of tetanus-prone injuries.

4682. Russell, D. J., et al. (2013). "Evaluation and management of 2 ferocactus spines in the orbit." Ophthalmic plastic and reconstructive surgery **29**(5): e120-123.

A 49-year-old woman, who had fallen face first in a cactus 1 week earlier, presented with a small, mobile, noninflamed subcutaneous nodule at the rim of her right lateral orbit with no other functional deficits. A CT scan was obtained, which revealed a 4-cm intraorbital tubular-shaped foreign body resembling a large cactus spine. A second preoperative CT scan, obtained for an intraoperative guidance system, demonstrated a second cactus spine, which was initially not seen on the first CT scan. Both spines were removed surgically without complication. The authors discuss factors that can cause diagnosis delay, review the radiographic features of cactus spines, and discuss the often times benign clinical course of retained cactus spine foreign bodies. To the authors' knowledge, this is the first case report of cactus spines in the orbit. Health-care professionals should have a low threshold for imaging in cases of traumatic injuries involving cactus spines.

4683. Russell, M. E., et al. (2013). "Rehabilitation of an eighteen-year-old male with a severe traumatic brain injury complicated by sinking skin flap syndrome: A case report." PM and R **5**(9): S281.

Case Description: The patient is an 18-year-old male who presented to an outside hospital after a self-inflicted gunshot wound to the head for which the patient underwent emergent hemicraniectomy and decompression. Patient had ventriculoperitoneal shunt placement for hydrocephalus on hospital day 22. He presented to our inpatient rehabilitation hospital 28 days after injury. Patient was making great strides during his rehabilitation course and progressed from total assistance to minimal assistance with ADLs and transfers. However, six weeks into his rehabilitation stay, patient became extremely limited by pain from positional headaches. Multiple medications for pain, including norco, gabapentin and topiramate were started for headaches presumed to be secondary to an overdraining shunt. The shunt was adjusted and headaches improved slightly. Patient began to digress with therapies and was noted to have increasing lethargy, decreased responsiveness, increased spasticity and irretractable nausea and vomiting. Head CT done during week seven of inpatient rehabilitation showed an increase in the sunken in appearance of the brain with increased left to right subfalcine herniation. Patient was transferred to an acute care hospital to expedite cranioplasty given neurologic deterioration from sinking skin flap syndrome. Program Description: 18-year-old male with severe neurological deficits secondary to a gunshot wound to the head. Setting: Rehabilitation hospital. Results or Clinical Course: Three months after injury, patient had shown significant improvement before neurologic deterioration secondary to sinking skin flap syndrome. It is uncertain what deficits may remain after cranioplasty. Patient was discharged to a post-acute brain injury rehabilitation program. Further developments will be discussed. Discussion: Sinking skin flap syndrome is a serious and unusual complication of hemicraniectomy after traumatic brain injury and should be considered given neurologic deterioration in the setting of subfalcine herniation in a patient with hydrocephalus managed with a ventriculoperitoneal shunt. Conclusions: Sinking skin flap syndrome is an unusual neurological complication of hemicraniectomy in the traumatic brain injury population.

4685. Rustia, A., et al. (1999). "Head injury in a military setting: Clinical experience from January 1993 to August 1998." Rivista Medica **5**(3): 131-137.

We analyse the principal causes of head injury in a military setting in 2233 treated patients with a uniform age and sex distribution. We define the pathophysiological mechanisms and significant prognostic factors of open and closed

head trauma including lesions caused by firearms and explosions. We also set out a diagnostic protocol for cases of minor head injury.

4686. Rutherford, G. W. and R. C. Wlodarczyk (2009). "Distant sequelae of traumatic brain injury: premature mortality and intracranial neoplasms." The Journal of head trauma rehabilitation **24**(6): 468-474.

OBJECTIVE: Determine the relationship between traumatic brain injury (TBI) and premature mortality and intracranial neoplasms occurring 6 months or more after TBI., PARTICIPANTS: Not applicable., DESIGN: Systematic review of the published, peer-reviewed literature., PRIMARY MEASURES: Not applicable., RESULTS: We identified 23 studies that examined premature mortality following TBI and 16 that addressed intracranial neoplasms. There was clear evidence of an association between penetrating brain injury and premature mortality among patients surviving at least 6 months; and similarly compelling evidence of an association between moderate or severe TBI and premature mortality among patients injured severely enough to require acute rehabilitation. There was inadequate evidence to reach a conclusion about whether other closed head injuries were associated with premature mortality. For intracranial neoplasms, there was an apparent association between TBI and intracranial neoplasms diagnosed within 1 year following TBI; however, these tumors were likely incidentally found during evaluation for the TBI. For tumors diagnosed more than 1 year post injury, the evidence was inadequate to conclude that there was an association, although at least 1 very large registry-based study found a borderline association., CONCLUSION: More severe TBI (ie, penetrating and moderate and severe TBI requiring rehabilitation) is associated with premature mortality among patients surviving at least 6 months. There is no clear evidence for an association between TBI and intracranial neoplasms presenting more than 1 year following TBI.

4687. Ryu, B., et al. (2021). "Treatment of Mandibular Non-union Using Patient Specific Crib Cage Plates and Cellular Bone Allograft: A Case Report." Craniomaxillofacial Trauma and Reconstruction Open **6**.

A gunshot wound to the mandible frequently creates a comminuted fracture that can be debilitating for the patient and challenging for the surgeon. In some instances, immediate open reduction and rigid fixation is not possible, and closed reduction with intermaxillary fixation is employed. This may lead to non-union or mal-union of the segments. This case report describes the management of mal-union of bilateral comminuted mandibular angle fractures secondary to a gunshot wound injury. The mandibular fractures were repaired using virtually planned patient specific reconstruction plates that included a specially designed crib cage to contain a bone graft. A cellular bone allograft—Vivigen (DePuy Synthes, Warsaw, IN)—was chosen as the bone grafting material. The patient was followed up for 7 months with normal functional status and mouth opening and without pain or signs of infection. This report demonstrates that using a virtually planned crib cage plate with cellular bone allograft can optimize surgical repair and bony healing of comminuted mandible fractures.

4688. Rzaev, D. A., et al. (2017). "[Penetrating orbitocranial injury: a review of the literature and a case report of injury by a watercolor brush in a 3-year-old child]." Pronikaiushchaia orbitokranial'naia travma: obzor literatury s opisaniem klinicheskogo sluchaia raneniia akvarel'noi kistochkoi u rebenka 3 let. **81**(2): 77-87.

We present a rare case of orbitocranial penetrating injury by a watercolor brush in a 3-year-old child. Injuries of this localization can affect important orbital structures (eyeball, blood vessels, nerves, muscles) and cause severe intracranial damages. In some cases, diagnosis of these injuries in children may be difficult due to the lack of marked clinical manifestations. The presented clinical case illustrates the approaches for choosing methods for diagnosis of injury in childhood and subsequent treatment options.

4689. Saad, A., et al. (2013). "Virtual surgical planning in complex composite maxillofacial reconstruction." Plastic and reconstructive surgery **132**(3): 626-633.

BACKGROUND: Complex osteocutaneous maxillofacial reconstruction requiring multiple free flaps and with an extensive zone of injury can be fraught with complications and difficulty. Often, the remnants of native mandible are malpositioned and the skeletal structure of the upper face is distorted. The authors seek to extend the use of virtual planning to complex maxillofacial reconstruction by presenting their early experience in these difficult patients., METHODS: A retrospective chart review of 10 consecutive patients who underwent complex maxillofacial reconstruction

using virtual surgical planning was undertaken. The authors define complex maxillofacial reconstruction as that requiring an osteocutaneous flap in which multiple osteotomies were required in addition to at least one of the following: need for multiple free flaps, history of osteoradionecrosis, and ballistic injury. Synthes Proplan CMF surgical planning was performed using computed tomographic scanning of the maxillofacial area and the donor site. Jigs and cutting guides were created and plates were prebent. The flap was harvested and osteotomized using the jigs and inset. Postoperative computed tomographic scanning was performed to evaluate the reconstruction., RESULTS: Ten consecutive patients who met the criteria underwent review. There were no intraoperative complications. Postoperative computed tomographic scans showed excellent contour of the osseous flaps. All patients had functional mandibular range of motion., CONCLUSIONS: Use of virtual surgical planning allows for complex maxillofacial reconstruction with multiple simultaneous free flaps to be performed reliably and successfully. The use of prefabricated jigs and precontoured plates eases osteocutaneous flap molding and inset, allowing for a more complex procedure to be successful.

4690. Saar, I., et al. (1991). "Recurrent corneal oedema following late migration of intraocular glass." The British journal of ophthalmology **75**(3): 188-189.

This is a report of very late complications following intraocular penetration of numerous fragments of glass as a result of a test tube explosion. Fifteen years after the initial injury glass splinters began to migrate from the vitreous into the anterior chamber, causing acute episodes of corneal oedema. Four such episodes occurred over the past nine years, the corneal oedema each time disappearing within a few days following surgical extraction of the glass splinters. The literature on intraocular glass and its movement within the eye is reviewed.

4691. Sabaci, G., et al. (2002). "Endophthalmitis after deadly-weapon-related open-globe injuries: risk factors, value of prophylactic antibiotics, and visual outcomes." American journal of ophthalmology **133**(1): 62-69.

PURPOSE: To identify clinical and microbiologic factors influencing the prevalence and visual outcomes in endophthalmitis after deadly-weapon-related open-globe injuries., METHODS: In a retrospective study of 228 eyes of 212 patients with deadly-weapon-related open-globe injuries, clinical and microbiologic factors influencing the prevalence and visual outcome in endophthalmitis were analyzed in detail., RESULTS: Twenty-nine eyes enucleated for irreparable damages at presentation were excluded. Nineteen eyes (18 patients) of 199 (186 patients) were associated with culture-proven endophthalmitis. Presence of grade 4 injury, a variable of Ocular Trauma Classification System, and lens disruption at presentation were the significant risk factors for development of endophthalmitis (P =.001; odds ratio = 15.9 [2.0 to 122.1]), and ([P <.001; odds ratio = 17.7 [2.3 to 136.3]), respectively. Favorable outcome (visual acuity of 5/200 or better) was achieved in only four eyes (21%). Five eyes (26.3%) were phthisical, and five eyes (26.3%) were enucleated or eviscerated. All eyes were under the coverage of prophylactic intravenous antibiotics when culture positivity was obtained. Except two eyes with Acinetobactersp., all were infected by gram-positive micro-organisms (89.5%), the most common of which (42%) was Staphylococcus epidermidis. None of the clinical characteristics and treatment modalities affected final visual outcome. Favorable outcome was associated with infection by the less virulent micro-organism S. epidermidis (P =.018; odds ratio = 0.50 [0.25 to 1.00])., CONCLUSIONS: Endophthalmitis after deadly-weapon-related open-globe injuries has a dismal visual prognosis. Severity of injury and lens disruption are significant risk factors for development of endophthalmitis. Infection with a less virulent microbe is the only factor associated with favorable outcome.

4692. Sabel, M., et al. (1999). "Glioblastoma multiforme at the site of metal splinter injury: a coincidence? Case report." Journal of neurosurgery **91**(6): 1041-1044.

The authors report the case of a man who had suffered a penetrating metal splinter injury to the left frontal lobe at 18 years of age. Thirty-seven years later the patient developed a left-sided frontal tumor at the precise site of the meningocerebral scar and posttraumatic defect. Histological examination confirmed a glioblastoma multiforme adjacent to the dural scar and metal splinters. In addition, a chronic abscess from which Propionibacterium acnes was isolated was found within the glioma tissue. The temporal and local association of metal splinter injury with chronic abscess, scar formation, and malignant glioma is highly suggestive of a causal relationship between trauma and the development of a malignant brain tumor.

4693. Sabetay, S., et al. (2014). "Cerebrovascular occlusive disease vertebral artery revascularization in vertebrobasilar ischemia cases the hillel yaffe medical center experience." International Journal of Stroke **9**: 141-142.

Introduction: Symptoms of vertebrobasilar ischemia (VBI) can be caused both by flow limiting lesions and embolic phenomena of the vertebral arteries. VBI is often under-diagnosed and under-treated since the optimal management of vertebral artery (VA) stenosis untill now received limited attention with controversial results. Methods: We present a retrospective review of our medical center's experience in VA reconstruction. Between February 2006 and November 2013, 9 patients underwent 12 VA reconstructions, including transposition of external carotid artery to VA (V3) at the C1-2 level (n = 7), bypass from common carotid artery to VA (V3) with great saphenous vein (n = 3), and relocation of VA origin (n = 2). The presenting symptoms were attributed to flow limiting lesions in 8 cases (66%), embolization in 2 cases (17%), and ischemia after penetrating trauma in 2 cases (17%). Results: All the procedures were performed under general anesthesia with no intraoperative complications. One patient required re-exploration for bleeding. There were no perioperative death or strokes and no cranial nerve injuries. During follow up, two bypass procedures required endovascular treatment of stenosis in the distal anastomosis and return of VBI symptoms. The symptoms resolved in all patients but one (92%) with no late strokes. Conclusions: Although our experience includes a small number of patients, our results are in line with the reported in the literature and suggest that VA reconstruction provides good symptomatic relief with acceptable risk in selected patients. Based on the above elements we developed a comprehensive protocol for decision-making in patients with suspected VBI.

4694. Sackheim, A., et al. (2020). "Disruption of inside-out signaling between capillaries and upstream arterioles after traumatic brain injury is due to a pervasive endothelial in ward rectifier potassium channelopathy." Shock **53**: 113.

Introduction: Traumatic brain injury (TBI) impairs functional hyperemia, the process of cerebral blood flow regulation that delivers blood when demanded by metabolically active neurons (neurovascular coupling); however, the pathophysiologic mechanisms of this impairment are not fully understood. Functional hyperemia depends upon capillary endothelial cells (cECs) responding to neuronal activity through inward-rectifier potassium channels (KIR2). These vascular ion channels conduct a regenerative, hyperpolarizing electrical signal that propagates from the capillaries along the vascular wall to dilate the upstream arteriole. We hypothesized that signaling from capillaries to penetrating arterioles (inside- out signaling) is disrupted following TBI. Methods: Mice were randomized to either fluid percussion brain injury (FPI) or control groups. TBI mice were euthanized after 3-7 days. A craniotomy-based approach utilizing fluorescence of intravascular FITC-dextran was used to measure cerebral blood flow by multiphoton microscopy. Vascular responses were elicited by picospritzing 10 mM potassium (K+) directly on to the capillary bed and measuring diameter and blood flow through the penetrating arterioles. Posterior cerebral arteries (PCAs) were excised from the brain and used for pressure myography experiments. Patch clamp electrophysiology was performed in the conventional whole-cell configuration on freshly isolated cECs from control and TBI animals. All mice were subjected to a battery of behavioral and sensorimotor tests to assess neurological outcomes following both treatments. Results: We obtained real time, in vivo measurements of K+-induced hyperemia in TBI and control animals. In controls, capillary stimulation with 10 mM K+ caused vasodilation of the upstream arteriole and an increase in local blood flow. This K+-induced hyperemia response was impaired in TBI animals. Myogenic tone, measured as the difference in arteriolar diameter between baseline and calcium free conditions, was decreased after TBI. Dilatory responses to 10 mM K+ in pressurized PCAs and capillary KIR2 currents in cECs from TBI animals were also significantly impaired. Three-dimensional renderings of cortical capillaries revealed no changes in the vascular architecture following TBI, suggesting a pathophysiological mechanism of dysfunction. TBI animals exhibited significantly higher behavioral and sensorimotor deficits when compared to controls. Conclusions: In vivo cerebral hemodynamics are altered after TBI. We observed increased myogenic tone in the penetrating arterioles, and an impaired K+ induced hyperemia in response to stimulation of the downstream capillary bed. A pervasive KIR2 channelopathy persists throughout the vasculature of the brain which provides a novel mechanism to explain altered neurovascular coupling after brain injury.

4695. Sacks, D., et al. (2013). "The role of the endonasal endoscope in the operative management of brain abscess: a case report." Journal of neurological surgery. Part A, Central European neurosurgery **74 Suppl 1**: e54-57.

BACKGROUND: The endonasal endoscope has become widely integrated into the operative practice of skull-base surgeons. Although it is not the current standard of practice for the drainage of intracranial abscesses, transnasal neuroendoscopy has the potential for benefit over both stereotaxy and open craniotomy because it is minimally invasive and provides a visual confirmation of debridement. We present two recent cases in which patients with intradural

abscesses adjacent to the anterior skull base were successfully drained and irrigated using an endoscopic approach., CASE: Two patients with post-traumatic intradural brain abscess underwent transnasal neuroendoscopic drainage in a 1-year period. In both cases, the abscesses were drained and irrigated without complication under direct visualization. The patients' outcomes were felt to be positive given their initial insults., CONCLUSION: Transnasal endoscopic drainage of brain abscesses appears to be safe and has particular advantages in specific cases over the current operative standard, which are likely to prove beneficial for patients and cement it as a feasible alternative to stereotactic aspiration and craniotomy. Copyright Georg Thieme Verlag KG Stuttgart . New York.

4697. Sacks, T. (1988). "Prophylactic antibiotics in traumatic wounds." The Journal of hospital infection **11 Suppl A**: 251-258.

There is well-documented evidence justifying, perhaps demanding, the obligatory use of early, anticipatory treatment in open fractures and in penetrating abdominal wounds, and equally convincing evidence that they are not indicated in fractures of the base of the skull with CSF leaks, in thermal injuries, or in simple lacerations. As far as penetrating chest wounds, and bites are concerned, the evidence is perhaps as yet inconclusive, but antibiotics are probably not indicated in these situations.

4698. Sadar, E. S., et al. (1973). "Traumatic aneurysms of the intracranial circulation." Surgery, gynecology & obstetrics **137**(1): 59-67.

4699. Sadeghi, N., et al. (2019). "Patterns of maxillofacial fractures: A systematic review." Trauma Monthly **24**(4).

Context: The face is the most exposed part of the body; therefore, the maxillofacial region is vulnerable to trauma. The evaluation of the incidence and etiology of maxillofacial traumas is necessary to disclose the pattern of fractures. Objectives: The study aimed to evaluate the pattern of maxillofacial fractures (MFs) and associated injuries by a literature review. Data Sources: Original papers investigating the pattern of MFs and associated injuries published before November 2018 were examined. Online sources including PubMed, Scopus, Medline, Wiley, ISI Web of Knowledge, and EMBASE were searched for these papers. The extracted data included study characteristics, participants' characteristics, MFs causes, and distribution of various MFs. Results: In total, 17,055 patients (men: 83.61%; women: 16.38%) were examined. The age range was 21 - 30 years in 40.89% of the patients with MFs. The most common risk factor of fractures was road traffic accidents (45.33%). Mandibular fractures were more frequent than other injuries. Condyle was the most common mandibular fracture (25.89%). Le Fort II was the most common site in the middle-third fractures (30.29%). Conclusions: The results showed that maxillofacial fractures were more frequent in men, in the age of 21 to 30 years, in the site of the mandible, and mainly caused by road traffic accidents.

4700. Sadeghi Tari, A., et al. (2005). "Post-traumatic fatal Nattrassia mangiferae orbital infection." International ophthalmology **26**(6): 247-250.

Nattrassia mangiferae orbital infection is a very rare disease that is usually curable. We report the first case of a fatal N. mangiferae orbital infection following a thorn penetration injury in a patient who also had diabetes mellitus, heart failure, and cirrhosis.

4701. Sadeghian, H. and R. Motiei-Langroudi (2016). "Does distracting pain justify performing brain computed tomography in multiple traumas with mild head injury?" Emergency radiology **23**(3): 241-244.

Traumatic brain injury (TBI) is a significant health concern classified as mild, moderate, and severe. Although the indications to perform brain computed tomography (CT) are clear in moderate and severe cases, there still exists controversy in mild TBI (mTBI). We designed the study to evaluate the significance of distracting pain in patients with mTBI. The study population included patients with mild traumatic brain injury (GCS >=13). Moderate and high risk

factors including age <18 months or >=60 years, moderate to severe or progressive headache, >=2 episodes of vomiting, loss of consciousness (LOC), post-traumatic amnesia, seizure or prior antiepileptic use, alcohol intoxication, previous neurosurgical procedures, uncontrolled hypertension, anticoagulant use, presence of focal neurologic deficits, deformities in craniofacial region, and penetrating injuries were excluded. The patients were then grouped based on presence (DP+) or absence (DP-) of another organ fracture with severe pain (based on VAS). The primary outcome was any abnormal findings on brain CT scans; 330 patients were enrolled (184 DP+ and 146 DP-). Overall, two DP+ and one DP- patients had mild cerebral edema in brain CT ($p > 0.99$). No patients had any neurologic symptoms or signs in follow-up. Our results show that in the absence of any other risk factors, distracting pain from other organs (limbs, pelvis, and non-cervical spine) cannot be regarded as a brain CT indication in patients with mild TBI, as it is never associated with significant intracranial lesions.

4702. Sadiq, S. A. and G. Thurairajan (1995). "A case of transorbital intracranial damage underlying a seemingly innocuous injury." Injury **26**(4): 279-280.

4703. Sadove, R. C. and L. A. Powell (1993). "Simultaneous maxillary and mandibular reconstruction with one free osteocutaneous flap." Plastic and reconstructive surgery **92**(1): 141-146.

The concept of immediate reconstruction of massive facial injury with rigid internal fixation and free-tissue transfer continues to evolve. This case is unique in that it is the first report of the following: (1) simultaneous combined maxillary and mandibular reconstruction with one vascularized bone graft and (2) immediate total maxillary reconstruction with vascularized fibular bone. The nasopharynx was closed with a tubed radial forearm flap. Reconstruction was staged over several days, with dissection/banking of flaps, grafts, recipient sites, and debridement as a preliminary stage.

4704. Saeed, A., et al. (2008). "Plain X-ray and computed tomography of the orbit in cases and suspected cases of intraocular foreign body." Eye (London, England) **22**(11): 1373-1377.

AIM: To evaluate the roles of plain X-ray and computed tomography (CT) orbital imaging in cases and suspected cases of intraocular foreign body (IOFB)., METHODS: Retrospective review of clinical and radiological data relating to 204 consecutive cases and suspected cases of IOFB. Setting Royal Victoria Eye and Ear Hospital, Dublin, Ireland., RESULTS: Plain X-rays were performed in the absence of clinically evident ocular penetration in 177 (87%) cases, and no IOFB was demonstrated in any of these radiographs. Twenty-seven (13%) plain X-ray radiographs were obtained in the presence of clinically evident ocular penetration, and an IOFB was clinically visible in 19 (70%) of these cases. CT scans were undertaken in 21 (10%) of the 204 patients. Of these CT images, 9 (43%) and 12 (57%) were undertaken in the absence and presence of clinically evident ocular penetration, respectively. None (0%) and all (100%) of the CT scans obtained in the absence and presence of clinically evident ocular penetration demonstrated an IOFB, respectively., CONCLUSION: Plain X-ray and CT orbital imaging are non-contributory in the absence of clinically evident ocular penetration. In the presence of clinically evident ocular penetration, and where an IOFB is clinically visible, plain X-ray orbital radiography may have a role in excluding multiple IOFBs. In the presence of clinically evident ocular penetration, but where an IOFB is not clinically visible, CT orbital imaging remains the investigation of choice, and the role of pre-CT plain X-ray orbital radiography, as recommended by the guidelines of the Royal College of Radiologists, merits re-evaluation.

4706. Sahan, M., et al. (2014). "[Fracture of the glenoid fossa without mandibular condylar dislocation or fracture: two case reports]." Mandibuler kondil cikigi ve kirigi olmaksizin glenoid fossa kirigi: Iki olgu sunumu. **24**(5): 295-298.

The mandibular condyle region which protects the middle cranial fossa from facial and jaw traumas has an excellent osteomuscular structure. Condylar structures reduce or limit the force of trauma. Most importantly, the condylar neck is the weakest part of the mandible and is easily fractured without dislocation. Generally, this mechanism prevents condylar penetration into the middle cranial fossa; however, there are condylar penetration into the middle

cranial fossa can be rarely. Glenoid fossa fractures without mandibular condylar fracture and dislocation can be made. In this article, we present two cases to assess the isolated glenoid fossa fractures of the temporal bone.

4707. Sahebjam, S., et al. (2015). "A phase 1 study of TPI 287 concurrent with fractionated stereotactic radiotherapy (FSRT) in treatment of brain metastases from advanced breast and non-small cell lung (NSCL) cancer." Neuro-Oncology **17**: v15.

BACKGROUND: TPI 287, a member of taxanes diterpenoid (taxoid) family, is a microtubule-stabilizer with significant cytotoxic activity. In vivo studies have demonstrated that TPI 287 penetrates the blood brain barrier and significantly reduces the formation of large brain metastases in models of human breast cancer brain metastasis. The radiosensitizing effect of taxanes has been well established. METHODS: This phase I study (3 + 3 design) explores the safety, recommended phase II dose (RP2D), pharmacokinetics (PK), and antitumor activity (local control rate, distant intra-cranial control rate, progression-free survival) of TPI 287 administered concurrently with FSRT (NCT02187822). Patients with up to 3 untreated brain metastases (maximum diameter of each brain lesion ≤ 5 cm, maximum tumor volume ≤ 120 cc) from breast cancer or NSCLC are eligible. Eligible patients are treated with FSRT to target brain metastases (25 Gy in 5 daily fractions). TPI 287 is administered intravenously once per week, for total of 3 doses. The first dose of TPI 287 is given concurrently with the first fraction of FSRT. Once the RP2D is determined, an additional 10 patients will be enrolled in an expansion safety cohort, for a planned total enrollment of 36 patients. Effect of treatment on quality of life measures will be evaluated. RESULTS: As of June 2015, a total of 4 patients have been enrolled in the first two dose escalation cohorts (14 and 28 mg/m2). No treatment-related grade 3/4 adverse events (AEs) have been observed. No dose limiting toxicity has been reported, and maximal tolerated dose has not been reached. TPI 287 dose escalation continues. CONCLUSIONS: Preliminary data to date indicate that administration of TPI 287 concurrent with FSRT is well tolerated. Updated safety and efficacy results will be presented.

4708. Sahin, S., et al. (2018). "Gunshot bullet embolisation in the middle cerebral artery." Journal of the Royal Army Medical Corps **164**(2): 120-121.

Bullet embolism (BE) is a rare phenomenon following a gunshot wound. A middle cerebral artery BE was detected in a 36-year-old male patient following a perforating left thoracic gunshot wound without obvious cranial injury. This paper discusses a case of BE in the cranial circulation in conjunction with a review of the relevant literature.

4709. Sahoo, D., et al. (2016). "Head injury assessment of non-lethal projectile impacts: A combined experimental/computational method." Injury **47**(11): 2424-2441.

The main objective of this study is to develop a methodology to assess this risk based on experimental tests versus numerical predictive head injury simulations. A total of 16 non-lethal projectiles (NLP) impacts were conducted with rigid force plate at three different ranges of impact velocity (120, 72 and 55m/s) and the force/deformation-time data were used for the validation of finite element (FE) NLP. A good accordance between experimental and simulation data were obtained during validation of FE NLP with high correlation value (>0.98) and peak force discrepancy of less than 3%. A state-of-the art finite element head model with enhanced brain and skull material laws and specific head injury criteria was used for numerical computation of NLP impacts. Frontal and lateral FE NLP impacts to the head model at different velocities were performed under LS-DYNA. It is the very first time that the lethality of NLP is assessed by axonal strain computation to predict diffuse axonal injury (DAI) in NLP impacts to head. In case of temporo-parietal impact the min-max risk of DAI is 0-86%. With a velocity above 99.2m/s there is greater than 50% risk of DAI for temporo-parietal impacts. All the medium- and high-velocity impacts are susceptible to skull fracture, with a percentage risk higher than 90%. This study provides tool for a realistic injury (DAI and skull fracture) assessment during NLP impacts to the human head.

4710. Sahuquillo, J. and J. A. Dennis "Decompressive craniectomy for the treatment of high intracranial pressure in closed traumatic brain injury." (12).

Background, High intracranial pressure (ICP) is the most frequent cause of death and disability after severe traumatic brain injury (TBI). It is usually treated with general maneuvers (normothermia, sedation, etc.) and a set of first-line therapeutic measures (moderate hypocapnia, mannitol, etc.). When these measures fail, second-line therapies are initiated, which include: barbiturates, hyperventilation, moderate hypothermia, or removal of a variable amount of skull bone (secondary decompressive craniectomy)., Objectives, To assess the effects of secondary decompressive craniectomy (DC) on outcomes of patients with severe TBI in whom conventional medical therapeutic measures have failed to control raised ICP., Search methods, The most recent search was run on 8 December 2019. We searched the Cochrane Injuries Group's Specialised Register, CENTRAL (Cochrane Library), Ovid MEDLINE(R), Ovid MEDLINE(R) In-Process & Other Non-Indexed Citations, Ovid MEDLINE(R) Daily and Ovid OLDMEDLINE(R), Embase Classic + Embase (OvidSP) and ISI Web of Science (SCI-EXPANDED & CPCI-S). We also searched trials registries and contacted experts., Selection criteria, We included randomized studies assessing patients over the age of 12 months with severe TBI who either underwent DC to control ICP refractory to conventional medical treatments or received standard care., Data collection and analysis, We selected potentially relevant studies from the search results, and obtained study reports. Two review authors independently extracted data from included studies and assessed risk of bias. We used a random-effects model for meta-analysis. We rated the quality of the evidence according to the GRADE approach., Main results, We included three trials (590 participants). One single-site trial included 27 children; another multicenter trial (three countries) recruited 155 adults, the third trial was conducted in 24 countries, and recruited 408 adolescents and adults. Each study compared DC combined with standard care (this could include induced barbiturate coma or cooling of the brain, or both). All trials measured outcomes up to six months after injury; one also measured outcomes at 12 and 24 months (the latter data remain unpublished). All trials were at a high risk of bias for the criterion of performance bias, as neither participants nor personnel could be blinded to these interventions. The pediatric trial was at a high risk of selection bias and stopped early; another trial was at risk of bias because of atypical inclusion criteria and a change to the primary outcome after it had started., Mortality: pooled results for three studies provided moderate quality evidence that risk of death at six months was slightly reduced with DC (RR 0.66, 95% CI 0.43 to 1.01; 3 studies, 571 participants; I(superscript 2) = 38%; moderate-quality evidence), and one study also showed a clear reduction in risk of death at 12 months (RR 0.59, 95% CI 0.45 to 0.76; 1 study, 373 participants; high-quality evidence)., Neurological outcome: conscious of controversy around the traditional dichotomization of the Glasgow Outcome Scale (GOS) scale, we chose to present results in three ways, in order to contextualize factors relevant to clinical/patient decision-making., First, we present results of death in combination with vegetative status, versus other outcomes. Two studies reported results at six months for 544 participants. One employed a lower ICP threshold than the other studies, and showed an increase in the risk of death/vegetative state for the DC group. The other study used a more conventional ICP threshold, and results favoured the DC group (15.7% absolute risk reduction (ARR) (95% CI 6% to 25%). The number needed to treat for one beneficial outcome (NNTB) (i.e. to avoid death or vegetative status) was seven. The pooled result for DC compared with standard care showed no clear benefit for either group (RR 0.99, 95% CI 0.46 to 2.13; 2 studies, 544 participants; I(superscript 2) = 86%; low-quality evidence). One study reported data for this outcome at 12 months, whe the risk for death or vegetative state was clearly reduced by DC compared with medical treatment (RR 0.68, 95% CI 0.54 to 0.86; 1 study, 373 participants; high-quality evidence)., Second, we assessed the risk of an 'unfavorable outcome' evaluated on a non-traditional dichotomized GOS-Extended scale (GOS-E), that is, grouping the category 'upper severe disability' into the 'good outcome' grouping. Data were available for two studies (n = 571). Pooling indicated little difference between DC and standard care regarding the risk of an unfavorable outcome at six months following injury (RR 1.06, 95% CI 0.69 to 1.63; 544 participants); heterogeneity was high, with an I(superscript 2) value of 82%. One trial reported data at 12 months and indicated a clear benefit of DC (RR 0.81, 95% CI 0.69 to 0.95; 373 participants)., Third, we assessed the risk of an 'unfavorable outcome' using the (traditional) dichotomized GOS/GOS-E cutoff into 'favorable' versus 'unfavorable' results. There was little difference between DC and standard care at six months (RR 1.00, 95% CI 0.71 to 1.40; 3 studies, 571 participants; low-quality evidence), and heterogeneity was high (I(superscript 2) = 78%). At 12 months one trial suggested a similar finding (RR 0.95, 95% CI 0.83 to 1.09; 1 study, 373 participants; high-quality evidence)., With regard to ICP reduction, pooled results for two studies provided moderate quality evidence that DC was superior to standard care for reducing ICP within 48 hours (MD -4.66 mmHg, 95% CI -6.86 to -2.45; 2 studies, 182 participants; I(superscript 2) = 0%). Data from the third study were consistent with these, but could not be pooled., Data on adverse events are difficult to interpret, as mortality and complications are high, and it can be difficult to distinguish between treatment-related adverse events and the natural evolution of the condition. In general, there was low-quality evidence that surgical patients experienced a higher risk of adverse events., Authors' conclusions, Decompressive craniectomy holds promise of reduced mortality, but the effects of long-term neurological outcome remain controversial, and involve an examination of the priorities of participants and their families. Future research should

focus on identifying clinical and neuroimaging characteristics to identify those patients who would survive with an acceptable quality of life; the best timing for DC; the most appropriate surgical techniques; and whether some synergistic treatments used with DC might improve patient outcomes.

4711. Sahuquillo, J., et al. (1993). "Early ischaemia after severe head injury. Preliminary results in patients with diffuse brain injuries." Acta neurochirurgica **122**(3-4): 204-214.

Ischaemic brain lesions still have a high prevalence in fatally head injured patients and are the single most important cause of secondary brain damage. The present study was undertaken to explore the acute phase of severely head injured patients in order to detect early ischaemia using Robertson's approach of estimating cerebral blood flow (CBF) from calculated arterio-jugular differences of oxygen (AVDO2), lactates (AVDL), and the lactate-oxygen index (LOI). Twenty-eight cases with severe head injury were included (Glasgow Coma Scale Score below or equal to 8). All patients but one had a non-missile head injury. All the patients had a diffuse brain injury according to the admission CT scan. ICP measured at the time of admission was below 20 mmHg in 17 cases (61%). All patients were evaluated with the ischaemia score (IS) devised in our center to evaluate risk factors for developing ischaemia. Mean time from injury to the first AVDO2/AVDL study was 23.9 +/- 9.9 hours. According to Robertson's criteria, 13 patients (46%) had a calculated LOI (-AVDL/AVDO2) value above or equal to 0.08 and therefore an ischaemia/infarction pattern in the first 24 hours after the accident. Of the 15 patients without the ischaemia/infarction pattern, in three cases the CBF was below the metabolic demands and therefore in a situation of compensated hypoperfusion. No patient in our series had hyperaemia. Comparing different variables in ischaemic and non-ischaemic patients, only arterial haemoglobin and ischaemia score (IS) was significantly different in both groups. The ischaemia score had mean of 4.3 +/- 1.7 in the ischaemic group and 2.7 +/- 1.4 in non-ischaemic patients ($p = 0.01$). It is concluded that ischaemia is highly prevalent in the early period after severe head injury. Factors potentially responsible of early ischaemia are discussed.

4712. Saidi, R. F., et al. (2010). "Changing pattern of organ donation at a single center: are potential brain dead donors being lost to donation after cardiac death?" American journal of transplantation : official journal of the American Society of Transplantation and the American Society of Transplant Surgeons **10**(11): 2536-2540.

Donation after cardiac death (DCD) has proven effective at increasing the availability of organs for transplantation. We performed a retrospective examination of Massachusetts General Hospital (MGH) records of all 201 donors from 1/1/98 to the 11/2008, including 54 DCD, 115 DBD and 32 DCD candidates that did not progress to donation (DCD-dnp). Comparing three time periods, era 1 (01/98-12/02), era 2 (01/03-12/05) and era 3 (01/06-11/08), DCD's comprised 14.8,48.4% and 60% of donors, respectively ($p = 0.002$). A significant increase in the incidence of cardiovascular/cerebrovascular as cause of death was evident in era 3 versus eras 1 and 2; 74% versus 57.1% ($p<0.001$),as was a corresponding decrease in the incidence of traumatic death. Interestingly, we noted an increase in utilization of aggressive neurological management over time, especially in the DCD group. We detected significant changes in the make-up of the donor pool over the past decade. That the changes in diagnosis over time did not differ between DCD and DBD groups suggests this difference is not responsible for the increase in DCD rates. Instead, we suggest that changes in clinical practice, especially in management of patients with severe brain injury may account for the increased proportion of DCD.

4713. Saigal, R., et al. (2014). "Induced hypertension does not improve outcomes in penetrating spinal cord injury." Journal of neurotrauma **31**(12): A76.

Many trauma centers treat traumatic spinal cord injured-patients with MAP goals greater than 85-90 mm Hg. However, there is a lack of high grade evidence to support this practice or to identify the best target blood pressure. There is even less evidence to weigh towards specific BP goals for penetrating spinal cord injuries (SCI). We studied our own experience in using pressors to maintain a MAP goal greater than 85-90 in patients with penetrating SCI. We retrospectively reviewed penetrating spinal cord injuries treated at a single academic medical center (San Francisco General Hospital) from 2005-2011. For inclusion, we required an ASIA grade on admission and discharge. Exclusion criteria included inadequate clinical documentation and non-penetrating injury. Nineteen cases met inclusion criteria. 1 case was excluded for inadequate documentation of the ASIA grade. In the remaining 19 cases, mean age was 40.1 (range 18-93). Mean injury severity score was 28.8 (range 9-75). Mean hospital stay was 20.6 days (range 1-151). Six patients had concomitant TBI. Initial American Spinal Injury Association (ASIA) grade was A for 13 patients, C for 1

patient, and D for 5 patients. 18 patients received pressors in order to maintain MAP goals. 17 ASIA grades were unchanged at the time of discharge. Two patients improved: one from ASIA A to B and the second from C to D. One patient worsened from ASIA C to B. There was no obvious benefit to blood pressure augmentation in a retrospective, single-center study of penetrating, traumatic SCI. Two patients improved by one ASIA grade and another worsened by one ASIA grades. Further study is needed to assess whether there is a role for blood pressure augmentation in patients with penetrating SCI.

A case is reported in which an intracerebral bullet track was demonstrated by brain imaging, The possible advantages of technetium-99-m localization and the role of brain imaging in gunshot injuries of the head are discussed.

_____

4715. Saint-Martin, P., et al. (2008). "An unusual death by transcranial stab wound: homicide or suicide?" The American journal of forensic medicine and pathology **29**(3): 268-270.

Penetrating stab wounds of the brain are uncommonly seen in modern times and occur almost exclusively in homicides. We report an unusual death by self-stabbing. A 24-year-old man was found dead at home, the handle of a kitchen knife protruding from his forehead. Data such as the psychiatric history of the victim, the multiplicity and site of wounds, the implement used, the presence of hesitation, and defense wounds were studied to elucidate the manner of death, and the suicidal nature of the event was established after police investigation. Atypical injuries require a careful forensic investigation, and medico-legal aspects of the differentiation between homicide and suicide are discussed in this particular case. A review of the literature revealed few cases of suicidal transcranial stab wounds.

4716. Saito, N., et al. (2014). "Imaging of penetrating injuries of the head and neck:current practice at a level I trauma center in the United States." The Keio journal of medicine **63**(2): 23-33.

Penetrating neck injuries are commonly related to stab wounds and gunshot wounds in the United States. The injuries are classified by penetration site in terms of the three anatomical zones of the neck. Based on this zonal classification system, penetrating injuries to the head and neck have traditionally been evaluated by conventional angiography and/or surgical exploration. In recent years, multidetector-row computed tomography (CT) angiography has significantly improved detectability of vascular injuries and extravascular injuries in the setting of penetrating injuries. CT angiography is a fast and minimally invasive imaging modality to evaluate penetrating injuries of the head and neck for stable patients. The spectrum of penetrating neck injuries includes vascular injury (extravasation, pseudoaneurysm, dissection, occlusion, and arteriovenous fistula), aerodigestive injury (esophageal and tracheal injuries), salivary gland injury, neurologic injury (spinal canal and cerebral injuries), and osseous injury, all of which can be evaluated using CT angiography. Familiarity with the complications and imaging characteristics of penetrating injuries of the head and neck is essential for accurate diagnosis and optimal treatment.

4717. Sakles, J., et al. (2014). "Incidence of hypoxemia during rapid sequence intubation of head injured patients in the emergency department." European Journal of Emergency Medicine **21**(2): 161.

Background: Previous literature has demonstrated that a single event of hypoxemia in a head injured patient substantially increases morbidity. During intubation in the emergency department (ED), patients with head injuries are at great risk of oxygen desaturation. Objectives: To determine the incidence of hypoxemia during rapid sequence intubation (RSI) of head injured patients in the emergency department setting. Methods: Data was collected prospectively through a continuous quality improvement (CQI) database on all patients undergoing RSI in an academic emergency department over a 5 year period (2008-2012). Following each intubation, the operator completed a standardized data form, including the patient's demographic information, trauma diagnosis, highest and lowest pulse oximetry reading during the intubation, and number of intubation attempts. Patients who sustained blunt or penetrating trauma with the following written diagnoses were included in the study: closed head injury, traumatic brain injury, intracranial hemorrhage, subdural hematoma, subarachnoid hemorrhage, epidural hematoma, gunshot wound to the head. This subset of patients was categorized into 3 groups based on percent decrease in saturation during intubation: mild (10-19%), moderate (20-29%), and severe (>29%). Within these groups, we determined how many intubations were

completed on the first attempt. Results: There were 435 trauma patients with a diagnosis of head injury that underwent RSI in the five year period. Of these, 350 had oxygen saturations documented. 320 of these cases were a result of blunt trauma, while 30 were a result of penetrating trauma. 20% of patients (n=69) were found to have experienced desaturation of 10% or more. 8.6% had mild desaturation, 4.9% had moderate desaturation, and 6.3% had severe desaturation. 30 out of these 69 patients were intubated on the first attempt. Conclusion: In this study we found an alarmingly high rate of hypoxemic events during the intubation of head injured patients. Steps to avoid hypoxemia in this patient population are warranted, such as adequate pre-oxygenation prior to intubation, apneic oxygenation during intubation, and the avoidance of prolonged intubation attempts.

4718. Sakles, J. C., et al. (2013). "Incidence of hypoxemia during rapid sequence intubation of head-injured patients in the emergency department." Annals of emergency medicine **62**(4): S147.

Study Objectives: Previous literature has demonstrated that a single event of hypoxemia in a head-injured patient substantially increases morbidity. During intubation in the emergency department (ED), patients with head injuries are at great risk of oxygen desaturation. The purpose of this study is to determine the incidence of hypoxemia during rapid sequence intubation (RSI) of head-injured patients in the ED. Methods: Data was collected prospectively through a continuous quality improvement (CQI) database on all patients undergoing RSI in an academic emergency department over a 5-year period (2008-2012). Following each intubation, the operator completed a standardized data form, including the patient's demographic information, trauma diagnosis, highest and lowest pulse oximetry reading during the intubation, and number of intubation attempts. Patients who sustained blunt or penetrating trauma with the following written diagnoses were included in the study: closed head injury, traumatic brain injury, intracranial hemorrhage, subdural hematoma, subarachnoid hemorrhage, epidural hematoma, gunshot wound to the head. This subset of patients was categorized into 3 groups based on percent decrease in saturation during intubation: mild (10-19%), moderate (20-29%), and severe (>29%). Results: There were 435 trauma patients with a diagnosis of head injury that underwent RSI in the five-year period. Of these, 350 had oxygen saturations documented. 320 of these cases were a result of blunt trauma, while 30 were a result of penetrating trauma. A total of 19.7% of patients (n=69) were found to have experienced desaturation of 10% or more. Thirty out of these 69 patients were intubated on the first attempt (Table). Conclusions: In this study we found an alarmingly high rate of hypoxemic events during the intubation of head-injured patients. Steps to avoid hypoxemia in this patient population are warranted, such as adequate pre-oxygenation prior to intubation, apneic oxygenation during intubation, and the avoidance of prolonged intubation attempts. (Table Presented).

4719. Sakr, S., et al. (2016). "Surgical management of penetrating intracranial bullet injuries." Neurosurgery Quarterly **26**(1): 37-41.

Objectives: This study aimed to determine the outcome after gunshot wounds (GSWs) to the head and to evaluate the impact of prognostic factors mentioned in the literature on the outcome. Methods: This prospective study included 30 patients; 24 males and 6 females with a mean age of 31 years. All with penetrating GSWs to the head admitted to the emergency department of Cairo University Hospitals from January 2008 till June 2011. Shotgun was the most common injury in this study, whereas bullet injury was in only 3 patients (10%). Preoperatively, patients were categorized according to their Glasgow Coma Scale (GCS) into mild, moderate, and severe penetrating head injury. Upon admission, all patients underwent a complete physical and neurological examination together with a computed tomography of the brain without contrast. Initial management included a variety of the following according to indications; resuscitation, prophylactic antiepileptics, antibiotics, control active bleeding from wounds, and measures to decrease intracranial pressure. Surgical intervention ranged from simple debridement to hematoma evacuation and/or bullet extraction. Outcome was assessed after surgical interference using GCS and Glasgow Outcome Scale. Results: Fifteen (50%) patients had mild penetrating head injury (GCS 13 to 15), 12 patients (40%) were severely injured (GCS 3 to 8), and only 3 patients (10%) were moderately injured (GCS 9 to 12). Eighteen patients (60%) were found to have isolated intracranial injury, whereas 40% had other associated injuries. Twelve patients (40%) had an associated intracranial hematoma on their initial computed tomography scan. The average follow-up period was 16 months. The most common systemic complications were urinary tract infection (12 patients) and chest infection (12 patients), whereas the most common local complications were wound infection (10 patients), cerebrospinal fluid fistula (8 patients), and hydrocephalus (5 patients). At the follow up, The GCS of 10 patients (33.3%) was (13 to 15), 6 patients (20%) were (9 to 12), 5 patients (16.7%) showed persistent vegetative state (<3), and 9 patients (30%) died.

Postoperative outcome was significantly correlated with the preoperative one (P<0.001). According to Glasgow Outcome Scale, 33.3% of patients had good recovery and 30% of the patients died. The others suffered from various degrees of disability. Conclusions: The prevalence of GSWs to the head is increasing dramatically as private ownership of weapons and gang-related urban violence increases. Most of the irreversible brain damage from a GSW is sustained at impact and can be understood in terms of a missile's trajectory and the pattern of energy transfer to brain tissue. Treatment is aimed at preventing subsequent brain injury that might further limit recovery. One third of patients obtain a good recovery.

4720. Salam, A. A., et al. (1990). "Penetrating brain stem injury from crossbow bolt: a case report and review of the literature." Archives of emergency medicine **7**(3): 224-227.

Because injury to the brain stem is usually associated with diffuse brain damage, recovery is rare and mortality high. A non-fatal penetrating injury involving the brain stem is described from a crossbow bolt. The diagnosis and management of such injuries are discussed.

4721. Salama, A. and M. Jesin (2011). "Racial disparities in craniomaxillofacial trauma." International journal of oral and maxillofacial surgery **40**(10): 1111.

Racial disparities have been shown to exist in several arenas of health care. The institutional trauma registry at Boston Medical Center was queried to investigate racial injury patterns and outcomes in craniomaxillofacial trauma from 2001 to 2010. 2357 complete records were reviewed that met inclusion criteria based on ICD-9 codes. Multivariate/bivariate logistic regression was used to analyze data. There were distinct differences in injury mechanism based on race. Less than 1% of White patients were admitted for ballistic injuries compared to 13.1% of Blacks and 5.8% of Asians. The male:female ratio amongst Blacks, Hispanics and Whites was 6:1, 4:1 and 2.5:1 respectively. Death following ICU admission was related to age, shock, GCS, ISS, but not race ($p < 0.0001$). The risk of mortality was greater in patients with gun shot wounds (OR 14.3, $p < 0.0001$) and with admission systolic blood pressure < 90mmHg (OR 12.3, $p < 0.0001$) Length of stay among non-ICU patients was strongly related to ISS, a diagnosis of shock on admission, increasing numbers of surgical procedures; OR 0.28, 0.98, 1.09, $p < 0.001$. Relationships between race, length of stay or insurance status did not reach statistical significance. This study illustrates distinct differences in injury patterns according to race, however there were no statistically relevant relationships between race, gender and cause specific mortality. Shock, decreased GCS and increased ISS were the most powerful predictors of outcome. The data strongly suggest that while racial disparities exist in the mechanism of injury, patient outcomes were similar irrespective of race.

4722. Salama, K., et al. (2021). "A rare case of a penetrating cranio-facial foreign body stuck in the skull base." International journal of surgery case reports **81**.

Introduction: Penetrating craniofacial wounds due to foreign bodies, specifically sharp white blades, represent an eventual life threatening condition and a rare case of emergency facial surgery requiring a complex medical care. We report an original case of a penetrating craniofacial wound by a knife with a review of the literature concerning the tendencies, the complications and the specific medical care needed for these particular cranio-facial lesions. Presentation of case: A 35 year old man admitted to our ENT emergency room with a penetrating craniofacial wound caused by a knife stuck in the cranio-orbital-nasal junction. A craniofacial profile x-ray showed the presence of the metallic foreign body, a knife, penetrating deeply to the base of the skull. Computed tomography showed that the transcranial metallic foreign body arrived in the right sellar region after passing through the nasal cavity and the right sphenoid sinus with hemosinus and suprentorial pneumocephaly. the management consisted of multidisciplinary management, and the extraction was performed successfully under 3D endoscopic control. Conclusion: The majority of penetrating craniofacial wounds secondary to foreign bodies, regardless of their size, are rarely associated with major neurological symptoms and their management must be adapted to their potential severity.

4723. Salar, G., et al. (2004). "Multiple craniocerebral injuries from penetrating nails. Case illustration." Journal of neurosurgery **100**(5): 963.

4724. Salazar, A. M. and J. Grafman (2015). "Post-traumatic epilepsy: clinical clues to pathogenesis and paths to prevention." Handbook of clinical neurology **128**: 525-538.

Post-traumatic epilepsy (PTE) remains one of the most intractable consequences of traumatic brain injury (TBI) and its incidence and characteristics have remained relatively constant through the past century, in spite of significant advances in medical management. Survivors of military penetrating head injury (PHI) suffer by far the highest incidence of (PTE), ranging from 32% to 55%, and they are a particularly valuable group in which to study this complication. Clues to the high incidence of PTE in PHI survivors are likely related to dural penetration with free intracerebral blood, and perhaps to retained ferric metal fragments. The failure of well-reasoned and well-conducted trials evaluating conventional anticonvulsants for prevention of PTE also offers important clues and has forced us to reconsider our approach to management. Here we briefly review the clinical characteristics of PHI patients with PTE, with an emphasis on clues to pathogenesis that can generalize to other types of head injury; followed by a discussion of the pathogenetic mechanisms common to epilepsy, PHI, and TBI in general, with an eye to future neuroprotection and PTE prophylaxis. Future studies that more directly target the basic pathogenesis of TBI, including neuroinflammation and lipid peroxidation with their consequent excitotoxic mechanisms and aberrant regeneration, may ultimately prove to be more fruitful in the struggle to understand and control this especially stubborn complication of head injury.

4725. Salazar, A. M., et al. (1986). "Consciousness and amnesia after penetrating head injury: neurology and anatomy." Neurology **36**(2): 178-187.

Among 342 men who survived severe penetrating brain wounds, only 15% had prolonged unconsciousness and 53% had no or momentary unconsciousness after injury, emphasizing the focal nature of these wounds. The left (or language-dominant) hemisphere was dominant for the "wakefulness" component of consciousness. The areas most associated with unconsciousness included the posterior limb of the left internal capsule, left basal forebrain, midbrain, and hypothalamus. Left dominance was not seen for posttraumatic amnesia after elimination of the wakefulness variable, suggesting that wakefulness may be linked to the role of the left hemisphere in verbal memory.

4726. Salazar, A. M., et al. (1985). "Epilepsy after penetrating head injury. I. Clinical correlates: a report of the Vietnam Head Injury Study." Neurology **35**(10): 1406-1414.

Of 421 veterans who had penetrating brain wounds in Vietnam 15 years ago, 53% had posttraumatic epilepsy, and one-half of those still had seizures 15 years after injury. The relative risk of developing epilepsy dropped from about 580 times higher than the general age-matched population in the first year to 25 times higher after 10 years. Patients with focal neurologic signs or large lesions had increased risk of epilepsy, and site of the lesion may have been more important than size in determining occurrence. Family history of epilepsy or preinjury intelligence had no effect on seizure occurrence. Seizure frequency in the first year predicted future severity of seizures. Phenytoin therapy in the first year after injury did not prevent later seizures.

4727. Saldana Rodrigue, M., et al. (2011). "Outcome for traumatic optic neuropathy: treatment versus no treatment." International journal of oral and maxillofacial surgery **40**(10): 1109.

Background: Traumatic optic neuropathy (TON) is an important cause of severe visual loss following blunt or penetrating head trauma. Following the initial injury, optic nerve swelling within the optic nerve canal can result in secondary retinal ganglion cell loss. Optic nerve decompression with steroids or surgical interventions or both have therefore been advocated as a means of improving visual prognosis in TON. Objectives: The aim of this review was to examine the effectiveness and safety of surgical interventions, using steroids and observation in the management of TON. Method:We included only randomised controlled trials of TON in which any form of surgical intervention either on its own or in combination with steroidswas compared to any steroid regime alone or no treatment. Conclusions: There is a relatively high rate of spontaneous visual recovery in TON. There is no convincing data that steroids provide any additional visual benefit over observation alone. Recent evidence also suggests a possible detrimental effect of steroids in TON. Each case therefore needs to be assessed on an individual basis and proper informed consent is paramount. Neither there is evidence that surgical decompression of the optic nerve provides any additional benefit. On the other hand, surgery carries a definite risk of complications such as postoperative cerebrospinal fluid leak and meningitis. The decision to proceed with surgery in TON remains controversial and each case needs to be assessed on its own merits.

4728. Saleem, S. N. and Z. Hawass (2021). "Computed Tomography Study of the Mummy of King Seqenenre Taa II: New Insights Into His Violent Death." Frontiers in medicine **8**.

Seqenenre-Taa-II, The Brave, (c.1558–1553 BC) ruled Southern Egypt during the occupation of Egypt by the Hyksos. The mummy was physically examined and X-rayed in the 1960s, which showed severe head wounds that have prompted various theories about the circumstances of his death. We postulated that Computed Tomography (CT) study of Seqenenre-Taa-II's mummy would give insights into the circumstances of his death. We examined Seqenenre's mummy using CT and compared the findings with the archaeological literature as well as with five Asian weapons found in Tell-el-Dabaa. CT findings indicate that Seqenenre died in his forties. The mummies deformed hands suggest that the King was likely imprisoned with his hands tied. CT images provided detailed analysis of Seqenenre's previously reported injuries to the forehead, right supra-orbital, nose-right orbit, left chick, and skull base. This study revealed additional craniofacial fractures in the right lateral side of the skull that had been concealed by the embalmers beneath layers of material. Analysis of the morphology of the injuries enabled a better understanding of the mechanism of trauma, possible number of the attackers, and their relative position to the King. The size and shape of the fractures correlated well with the studied Hyksos weapons. The lethal attack was aimed at the King's face, likely in an attempt to disgrace him. Mummification of Seqenenre's body was limited to evisceration without brain removal. The desiccated brain is shifted to the left side of the skull. This may indicate that the King's dead body stayed on its left side for some time—long enough for decomposition start before the mummification began. This suggests that the King likely died at a location distant from the funeral place, possibly on a battlefield. The embalmers attempted to conceal the King's injuries; the methods used suggest that the mummification took place in a royal mummification workshop rather than in a poorly equipped location. CT findings of Seqenenre's mummy helped us to better understand the circumstances of his violent death. His death motivated his successors to continue the fight to unify Egypt and start The New Kingdom.

4729. Salehpoor, F., et al. (2016). "Prognostic serum factors in patients with traumatic brain injury: A systematic review." Neurosurgery Quarterly **26**(1): 19-36.

Objective: The aim of the study was to systematically review which factor of serum, assessed in traumatic brain injury (TBI), predicts patient's outcome. Materials and Methods: Databases were searched for relevant publications between 2005 and January 2013, and those fulfilling the following selection criteria were included: (1) studies conducted from 2005 until February 2013; (2) studies in which factors affecting the outcome after TBI were evaluated; (3) studies that defined TBI as "acute changes in brain function resulting in a strong external force to the head"; (4) studies in which the result was measured by the Glasgow Outcome Score (GCS) or by means of a comparable measure describing the activity limitation and neurological state; (5) studies in which the correlation between the measured factors in the first month after injury and prognosis was addressed; and (6) studies involving patients with moderate and/or severe TBI (GCS<13). All of the papers shortlisted were checked and approved by a specialist and expert in that field. A systematic review and analysis was performed for the prognostic factors assessed in the studies. Results: A total of 71 studies were included, 58 of which were of high quality. Most studies used the GCS at 6 months after injury as the outcome measure, sometimes in combination with other outcome measures. Strong evidence for predicting outcome was found for serum concentration of S100 protein, NSE, MBP, NF-H, GFAP, UCH-L1, blood glucose levels, serum levels of LDH, sodium level, prothrombin time, partial thromboplastin time, platelet count, D-dimer, HSP 70, serum levels of IL-8, number of circulating endothelial progenitor cells (EPCs), and DNA levels in serum. Moderate evidence for predicting outcome was found for high serum MMP9. Strong evidence of no association was found for WBC count and serum cortisol levels, and moderate evidence of no association was found for serum total cholesterol. For other determinants, inconclusive or no evidence or limited evidence was found. Conclusions: S100 protein, NSE, MBP, NF-H, GFAP, UCH-L1, blood glucose levels, serum levels of LDH, sodium level, prothrombin time, partial thromboplastin time, platelet count, Ddimer, HSP 70, serum levels of IL-8, number of circulating EPCs, and DNA levels in serum predicted outcome after TBI. WBC count, serum cortisol levels, total cholesterol, and MMP9 did not have predictive values.

4730. Salerian, A. J. (2010). "President Kennedy's death: a poison arrow-assisted homicide." Medical hypotheses **75**(4): 372-377.

"President John F. Kennedy's death was a neurotoxin-assisted homicide" is the hypothesis of this study. A review of medical evidence demonstrates evidence of a neurotoxin-assisted homicide. The convergence of three independent

actions, or the signature traits of a neurotoxin-assisted homicide- the emergence of neurological signs consistent with a neurotoxin-induced paralysis, the induction of a small neck wound consistent with a flechette-transported neurotoxin entry wound, and the execution of a coverup to eliminate neurotoxin evidence, supports this hypothesis. This review suggests, JFK's death had all the signature traits of a neurotoxin-assisted homicide. Copyright 2010 Elsevier Ltd. All rights reserved.

4731. Salhia, B., et al. (2000). "Expression of vascular endothelial growth factor by reactive astrocytes and associated neoangiogenesis." Brain research **883**(1): 87-97.

Injury to the central nervous system (CNS) invokes a reparative response known as astrogliosis, characterized largely by hypertrophy, proliferation and increased expression of glial fibrillary acidic protein (GFAP), resulting in reactive astrocytosis. Based on our prior observation that peritumoral reactive astrocytes express Vascular Endothelial Growth Factor (VEGF), a highly potent and specific angiogenic growth factor, we have hypothesized that reactive astrocytosis also contributes to the neovascularization associated with astrogliosis. To evaluate this hypothesis we evaluated human surgical/autopsy specimens from a variety of CNS disorders that induce astrogliosis and an experimental CNS needle injury model in wild type and GFAP:Green Fluorescent Protein (GFP) transgenic mice. Using computer image semi-quantitative analysis we evaluated the number of GFAP-positive reactive astrocytes, degree of VEGF expression by these astrocytes, associated Factor VIII-positive microvascular density (MVD) and Ki-67 proliferating endothelial cells. The degree of reactive astrocytosis correlated to levels of VEGF immunoreactivity and MVD in the neuropathological specimens. The mouse-needle-stick brain injury model demonstrated this correlation was temporally and spatially related and maximal after 1 week. These results, involving both human pathology specimens augmented by experimental animal data, supports our hypothesis that the neoangiogenesis associated with reactive astrogliosis is correlated to increased reactive astrocytosis and associated VEGF expression.

4732. Salibi, B. S. (1963). "AN UNUSUAL BULLET WOUND OF THE CRANIUM: RECOVERY FROM A PRE-EXISTING LONG-STANDING HIGH-TONE DEAFNESS ON THE SAME SIDE." Archives of neurology **9**: 313-318.

4733. Salim, A., et al. (2008). "Intracranial pressure monitoring in severe isolated pediatric blunt head trauma." The American surgeon **74**(11): 1088-1093.

Very little research regarding standard treatments for pediatric traumatic brain injury (PTBI) exists. The objective of this study was to examine the use of intracranial pressure (ICP) monitoring devices in PTBI and to determine if its use was associated with any outcome benefit. Data were collected from the Trauma Registry over an 11-year period (1996-2006) on all blunt trauma pediatric patients (age < 14 years) with an initial Glasgow Coma Scale score 3 vs. 55%, P = 0.01) than patients without monitors. However, there was no difference in mortality (28% vs. 35%, P = 0.52), discharge location (P = 0.10), and discharge capacity (P = 0.84). After multivariable analysis to adjust for the differences between the two study groups, the use of ICP monitor provided no survival benefit (adjusted odds ratio: 1.1; 95% confidence interval [CI]: 0.3-4.1; adjusted P value = 0.85). The use of ICP monitor was, however, independently associated with a higher risk of developing extracranial complications (adjusted odds ratio: 4.3; 95% CI: 1.2-16.4; adjusted P value = 0.025). In conclusion, the use of ICP monitors in pediatric patients with severe isolated head injury provided no survival benefit and was associated with an increased risk of complications.

4734. Sal'kov, N. N. and D. V. Ovcharenko (2014). "[Case report of spine and spinal cord injury]." Zhurnal voprosy neirokhirurgii imeni N. N. Burdenko **78**(3): 49-52.

We present a case report of spine and spinal cord injury caused by wound to the face by a foreign body followed by its penetration to cervical soft tissues and lateral compression of the spinal canal by the foreign body causing a neurological deficit. A significant regression of neurological disorders was observed after the dislocation of the vertebra had been eliminated.

4736. Saltz, S., et al. (2015). "The complications associated with treating depression and traumatic brain injury: A case report of a suicide attempt in a 26 year old male." Neuropsychopharmacology **40**: S307.

Background: Traumatic brain injury (TBI) is a debilitating illness that often causes comorbid depression. Treating depression is often difficult with only 30%-40% of patients responding to their first antidepressant. Medical comorbidities exacerbate the struggle of determining optimal pharmacotherapy for a patient. Psychiatrists, in particular, may be exposed to patients with traumatic brain injury (TBI) secondary to the mental illness and substance abuse that may accompany TBI4. While first line pharmacotherapies for depression remain selective serotonin reuptake inhibitors (SSRIs), patients with TBI cannot necessarily be treated with these medications. It is well documented in the literature that both SSRIs and SNRIs may cause hyponatremia. Likewise, traumatic brain injury is often complicated by SIADH or cerebral salt wasting syndrome (CSWS). Methods: We present a case of a 26 year old male status post suicide attempt via gunshot wound resulting in traumatic brain injury. Results: CT brain scan was done and significant for a penetrating ballistic injury to the face, brain, and calvarium with a trajectory extending from the left inferior face, through the left maxillary sinus, ethmoids, posterior right orbit, right frontal region, and through the right frontal calvarium. Hospitalization was complicated by diabetes insipidus, CSF leak, increased pneumocephalus, and hyponatremia. Conclusions: One needs to consider electrolyte abnormalities, seizure propensity, fall risk, potential weight loss, and confusion in TBI patients when choosing psychotherapeutic agents. This case report highlights the difficulties accompanying choosing safe and effective treatment modalities for depression as many psychotherapeutics have side effects that limit their use in patients with traumatic brain injury.

4737. Salvadori, A., et al. (2013). "Pediatric wartime: First learning of 63 pediatric intensive care unit admissions in the French military hospital of Kabul." Intensive care medicine **39**: S26-S27.

Objectives: Children management during wartime is a challenge for non-specialized medical teams in pediatric trauma. The purpose of this study is to describe the features of pediatric wartime admissions in intensive care unit at the French military hospital of Kabul. Methods: A retrospective study of all intensive care unit pediatric admissions between June 2011 and August 2012 was conducted. Results: 261 patients were analyzed. Pediatric patients represented 24 % of all admissions (63 patients). Mean age was 8.9 ± 4.1 years old and mean ISS was 25 ± 13. Traumatic diagnoses were responsible for 92 % of all pediatric admissions. The primary mechanism was explosion (43 %) followed by gunshot wound (22 %) and motor vehicle crash (13 %). Twenty-four patients (38 %) sustained abdominal injuries with more than a half was penetrating. 23/63 (37 %) had thoracic injuries among which 11 (48 %) was penetrating. 21/63 (33 %) sustained head injuries, 20/63 (32 %) had traumatic brain injury and 17/63 (27 %) was had multiple penetrating injuries. Twenty-six patients were mechanically ventilated with a mean duration of mechanical ventilation of 3 ± 4 days. 89 % required surgery, 87 % a body scan and 43 %were transfused. The mean length of stay was 3 ± 2.5 days. 3 patients died during the study period. Conclusion: Our study confirms a significant number of pediatric wartime admissions (24 %). The primary mechanism encountered in the field was explosion and gunshot wound.

4738. Salvati, M., et al. (1997). "Spontaneous movement of metallic foreign bodies. Case report." Journal of neurosurgical sciences **41**(4): 423-425.

We report a case of missile injury to the brain with an unusual complication. The bullet migrated by its mere weight to a distant location through the brain parenchyma after initially lodged in a superficial site. Movement of the bullet was first detected on CT scan and the significance and treatment of this finding is emphasized.

4739. Salzano, A., et al. (1999). "[The role of computed tomography in gunshot lesions of the chest. The authors' personal experience]." Ruolo della Tomografia Computerizzata nelle lesioni da arma da fuoco del torace. Esperienza personale. **98**(5): 356-360.

PURPOSE: CT is a valuable tool in assessing thoracic gunshot wounds. CT is also the method of choice in emergency, because it permits rapid depiction of bullet damage to the chest and to other body districts. This in turn

permits correct assessment of the main thoracic injuries, plus adequate and prompt planning of surgical treatment or support intensive care. We report on the role of CT in diagnosing the complex pleuropulmonary, cardiovascular and thoracic wall injuries caused by gunshot wounds, with their specific and acute signs which differ greatly from those of other types of chest trauma., MATERIAL AND METHODS: In the last 4 years, we observed 76 cases of gunshot injury, twenty-six of them involved the chest. The patients, 25 men and 1 woman (mean age: 32 years, range: 17-48), were all submitted to emergency CT with i.v. contrast agent injection and the CT-angiography technique. The reanimator was always present to monitor the patients' vital functions and shock state. CT of the chest was integrated with CT of the abdomen and pelvis in 4 cases and with CT of the skull in 3 cases, to detect associated bullet wounds if any., RESULTS: The most frequent CT finding was lung parenchyma tear and bruise (25 cases), followed by hemothorax (18 cases) and subcutaneous chest wall emphysema (9 cases). Pneumothorax was seen in 5 cases, associated with hemothorax in 6; rib injuries were found in 7 cases; pneumomediastinum was found in 4 cases and areas of pulmonary atelectasis in 3; the diaphragm was ruptured in 4 cases. CT showed spinal involvement in 11 patients, with injury of D3 and D5 in 4 and 3 cases, respectively; signs of interrupted spinal marrow were found in 7 cases. Damage from gunshot wounds was detected in the liver, spleen, skull and limbs in 3, 2, 3 and 10 cases, respectively., DISCUSSION AND CONCLUSIONS: Chest radiography shows major gunshot wound damage to the chest and lungs, except for heart injuries and minimal pneumothorax. When abdominal and skull injuries are associated, CT should be the method of choice because it permits prompt and panoramic assessment of the severity of pulmonary and extrathoracic damage. This results in prompt and targeted treatment, avoiding unnecessary delays which may damage the patient further.

4740. Salzano, A., et al. (1999). "[The topicality and use of the radiological exam in gunshot wounds of the limbs. An assessment of 132 cases]." Attualita e impiego dell'esame radiologico nelle ferite da arma da fuoco degli arti. Valutazione di 132 casi. **98**(6): 468-471.

INTRODUCTION: Gunshot wounds of limbs are frequent injuries especially in Western countries. They can be single or associated with other penetrating gunshot wounds, for instance to the chest, abdomen and skull., PURPOSE: We investigated the current role and usefulness of conventional radiography in the assessment of gunshot injuries to limbs because, despite major advances in diagnostic imaging, this method remains the examination of choice in this condition. We stress the valuable contribution of conventional radiography to detection of bone blow-out fractures, multifocal traumatic bone changes, bone and joint injuries, bullet retention, and finally subcutaneous emphysema., MATERIAL AND METHODS: We retrospectively reviewed 132 cases of firearm injuries of limbs submitted to radiography March 1996 to July 1999. All the patients were men ranging in age 17-66 years (mean: 35). Radiography followed a preliminary physical examination, and follow-ups were carried out in the following days after orthopedic reduction of bone fractures or surgery with metal osteosynthesis. Emergency CT was performed first when chest, abdomen, or skull were involved., RESULTS: The lower limbs were involved three times as much as the upper ones; the leg was most frequently involved (61%), followed by thigh (61%), forearm and hands (24%), and feet (15%). The right lower limb was wounded in 65% of cases, especially tibia (55 cases) and femur (46 cases). Spiral injuries to bone diaphysis were the most frequent ones, followed by mixed fractures caused by cortical bone sinking from bullet impact. Bullets were retained in 60% of cases; subcutaneous emphysema was found in 78% of cases and vascular injuries in 25 cases in relation to disarranged fractures. We observed 4 arteriovenous fistulas during 3 years' follow-up., DISCUSSION AND CONCLUSIONS: Gunshot wounds to the limbs need a different clinical, diagnostic and therapeutic approach than thoracoabdominal and skull injuries, which require immediate and quick diagnosis and emergency treatment. The cases with injury to a primary artery from open and splintered fractures require emergency surgical reconstruction with vascular anastomosis and reduction of compound fractures, to prevent necrosis and amputation. Conventional radiography does depict the bullet and its site, subcutaneous emphysema, blow-out fractures, and the location of bone splinters. This permits adequate emergency surgery and an efficacious orthopedic approach, as well as selection of the cases to be submitted to clinical monitoring.

4741. Salzano, A., et al. (1999). "[Gunshot wounds of the abdomen studied by computed tomography. The authors' personal experience in 30 cases]." Ferite da arma da fuoco dell'addome studiate con Tomografia Computerizzata. Esperienza personale in 30 casi. **98**(3): 168-172.

INTRODUCTION: CT plays an important role in depicting gunshot wounds in parenchymal and hollow organs in the abdomen. Relative to other techniques and to emergency laparotomy, CT permits good assessment of abdominal content, major injuries and changes in other districts, such as chest, pelvis and skull. We investigated the yield and role

of CT in diagnosing abdominal gunshot wounds, with their rich and varied radiological signs and associated injuries., MATERIAL AND METHODS: We retrospectively reviewed the findings of 30 patients with abdominal gunshot wounds examined in 4 years at Loreto-Mare Hospital, Naples. All patients were men, age ranging 19-54 years (mean: 35); 6 of them were not from the European Union. Examinations were carried out from diaphragm to pubis with i.v. contrast injection and the CT angiography technique. CT was integrated with chest studies in 6 cases and with skull studies in 5. Subsequent CT follow-ups were necessary in 12 cases submitted to conservative treatment., RESULTS: Liver was the most damaged parenchyma, with hemorrhage and lacerocontusion in 7 cases and mashed in 1 case; spleen was involved in 4 cases; hemoperitoneum was found in 18 cases. Diaphragm was involved in 5 cases and pancreas in 2; gallbladder, stomach and duodenum were involved in 1 case each and jejunum-ileum and colon in 3 and 6 cases, respectively. CT showed renal injury in 3 cases and bladder injury in 2. Eight patients had vertebral gunshot damage. Pneumothorax, hemothorax and lacerocontusion were found in 7 cases; brain was injured in 4 cases and limbs in 16., DISCUSSION AND CONCLUSIONS: Tissue damage extent depends on the speed and kinetic energy the bullet carries into the abdomen. Abdominal radiography shows the bullet and its site, pneumoperitoneum from gastrointestinal perforation, crash bone injuries, vertebral trauma and subcutaneous emphysema. Instead, CT depicts early parenchymal damage and vascular injury and thus becomes a complete and necessary tool for imaging gunshot wounds. CT provides early diagnostic information which help plan emergency treatment and thus decrease mortality. As for angiography and US, we suggest they be used subsequently because in emergency they may delay the diagnosis. Moreover, vessel rupture and active intraabdominal bleeding are easily detected with spiral CT, which appears the best tool for prompt assessment of the injuries associated with gunshot wounds in other districts such as, the skull. To conclude, CT permits adequate planning of emergency surgery and helps select the cases for follow-up, intensive care and conservative treatment.

4742. Salzano, A., et al. (2000). "[Gunshot wounds of the cranium studied with computerized tomography. Personal experience in 23 cases]." Ferite da arma da fuoco del cranio osservate con Tomografia Computerizzata. Esperienza personale in 23 casi. **99**(1-2): 26-30.

INTRODUCTION: Gunshot wounds to the head are usually mortal injuries. Their frequency has been increasing in the last years because of increasing crime rates. Gunshot wounds to the head require close clinical and diagnostic cooperation of the neurosurgeon and radiologist, detailed assessment of skull and brain damage, and finally prompt treatment. Emergency Computed Tomography (CT) makes a useful tool for depicting bullet course and brain damage, and thus helps plan treatment. We investigated the CT signs of subdural hematoma, lacerocontusive focus, subarachnoid hemorrhage, hemoencephalus, skull bone fracture and thecal hollow and report them as an aid to the neurosurgeon and the radiologist, for best treatment planning, and in an attempt to establish useful prognostic criteria., MATERIAL AND METHODS: We retrospectively reviewed 23 cases of gunshot injuries to the head studied with CT at the Emergency Unit of Loreto Mare Hospital in Naples, Italy. Twenty patients were men and 3 women; their mean age was 31 years (range: 18-49). Three women and 2 men had been injured accidentally by wandering bullets, and one case was an attempted suicide; all the other cases resulted from shootings. CT slices were 10 mm thick, with 8 mm gap (5 mm in complex injuries and when posterior cranial fossa was involved); all scans were unenhanced., RESULTS: We found 22 penetrating gunshot wounds: 13 of them with thecal entry hole and intracranial bullet retention and 9 with an entry and an exit hole. One case was a superficial wound. Crash skull fractures were seen in 22 cases and they were fragmented in 12, with overlapping thecal fragments in 4, and with deep fragments in 2 cases. There were scattered bone splinters in 3 cases and the bullet was retained in the mastoid bone in one case. Lacerocontusive foci were assessed in 22 cases, brain swelling in 20, subarachnoid hemorrhage in 19, brain hematoma in 15, blood in the ventricular system in 9, pneumoencephalus in 7, air bubbles along the bullet course in 7, impression on ventricula and linear structures in 7, interhemispheric blood in 5, and finally blood effusion in Sylvian scissure in 4 cases., DISCUSSION AND CONCLUSIONS: Gunshot wounds to the head are complex and severe traumas with high mortality rates because of both early and late effects and complications. CT provides the neurosurgeon with abundant findings for diagnosis and surgical planning, which may result in improved survival rates. In these patients emergency CT plays a fundamental diagnostic role in depicting brain damage and thus remains the method of choice for thorough, rapid and accurate brain and skull studies, as well as to detect possible injury to the chest and abdomen.

4743. Salzano, A., et al. (2000). "[Craniocerebral trauma from bullets: the correlation between computed tomography, the clinical picture, neurosurgical treatment and the long-term sequelae]." Traumi cranio-encefalici da proiettile: correlazione tra Tomografia Computerizzata, clinica, trattamento neurochirurgico e sequele a distanza. **99**(3): 156-160.

PURPOSE: To demonstrate the usefulness of CT findings in the planning of brain neurosurgery in gunshot victims, for prompt and successful treatment., MATERIAL AND METHODS: Thirty patients with brain gunshot wounds were examined with CT over 5 years. The patients were 27 men and 3 women whose mean age was 33 years (range: 17-56). Brain CT was carried out with thin (5-mm) slices and 10-mm gap; dynamic scanning (3-mm interscan time) was used especially in case of posterior fossa involvement and diffuse brain damage. The examination was integrated with cervical scout views to detect bullets in the neck and cervical dislocation. CT follow-up was carried out in 20 patients 24 hours postoperatively and every 6 hours in 9 patients in a severe postoperative coma., RESULTS: Twelve intracranial hematomas and 9 subdural hematomas, 3 of them bilateral, were treated and hemorrhage was resolved in 8 lacerocontusive foci. Skull plastic surgery was carried out in 5 cases. Surgical maneuvers were most difficult in the 5 crash bone injuries with wedged splinters; postoperative subarachnoid hemorrhage followed in 3 cases. Blood effusion in ventricles was drained in 6 cases; in 2 of them with permanent catheters. Eleven patients died: 4 right after surgery and 7 an average 15 days postoperatively., DISCUSSION AND CONCLUSIONS: In our series the mortality rate of firearm wounds of the skull base was 34% higher than that of the hemisphere; this is due to carotid hemorrhage and midbrain damage. Such traumas require emergency radiological diagnosis and neurosurgical treatment because of their severity and early irreversible complications. Complex operations and skilled surgeons may prevent disabling postoperative sequels. CT findings are indispensable and must be correctly interpreted. The radiologist and the neurosurgeon must collaborate closely and both must consider several diagnostic and prognostic factors affecting surgical planning.

4744. Samaha, M., et al. (2000). "Sino-orbital foreign body in a child." International journal of pediatric otorhinolaryngology **52**(2): 189-192.

Foreign bodies of the sinuses are uncommon. Few reports exist in the English literature. Among these, the frontal and maxillary sinuses are most often involved. Ethmoid and sphenoid foreign bodies are rare and tend to present with chronic symptoms due to delayed diagnosis. We present a case of an acute presentation of a foreign body involving the orbit and ethmoid sinus in a 12-year-old male.

4746. Sammani, A., et al. (2017). "Thirty years of heart transplantation at the university medical centre Utrecht." Netherlands Heart Journal **25**(9): 516-523.

Purpose To analyse patient demographics, indications, survival and donor characteristics for heart transplantation (HTx) during the past 30 years at the University Medical Centre Utrecht (UMCU). Methods Data have been prospectively collected for all patients who underwent HTx at the UMCU from 1985 until 2015. Patients who were included underwent ortho-topic HTx at an age >14 years. Results In total, 489 hearts have been transplanted since 1985; 120 patients (25%) had left ventricular assist device (LVAD) implantation prior to HTx. A shift from ischaemic heart disease to dilated cardiomyopathy has been seen as the leading indication for HTx since the year 2000. Median age at HTx was 49 years (range 16–68). Median waiting time and donor age have also increased from 40 to 513 days and from 27 to 44 years respectively (range 11–65). Donor cause of death is now primarily stroke, in contrast to head and brain injury in earlier years. Estimated median survival is 15.4 years (95% confidence interval 14.2–16.6) There is better survival throughout these years. Conclusion Over the past 30 years, patient and donor demographics and underlying diseases have shifted substantially. Furthermore, the increase in waiting time due to lack of available donor hearts has led to a rise in the use of LVADs as bridge to transplant. Importantly, an improvement in survival rates is found over time which could be explained by better immunosuppressive therapy and improvements in follow-up care.

4748. Samuelson, M. B., et al. (2017). "Sinonasal metallic foreign body penetration of the anterior cranial fossa." Otolaryngology Case Reports **2**: 10-12.

Introduction: Intracranial foreign bodies have the potential to cause several devastating complications including CSF leak, meningitis, hydrocephalus, nerve or vessel injury, and even death [1,3,5]. These risks must be weighed against

the risks associated with potential management options and techniques for removal. With the advent of endonasal anterior skull base techniques, safe and efficient options for surgical retrieval and skull base repair have become available [1,2,4]. Methods: In the present report, we present three cases involving metallic foreign bodies penetrating anterior cranial fossa via the sinonasal tract, and the management approaches employed. Results: The three cases involved [1] a migrated K-wire from nasal reconstruction in the remote past [2], an acute nail-gun injury, and [3] an impaled car antenna. A combined endoscopic and transcranial approach was performed in the former two cases, while in the latter, an EVD was placed due to elevated ICP after the foreign body had been withdrawn. Conclusion: Intracranial metallic foreign bodies may have significant potential morbidity. Recent advances in endonasal techniques for anterior skull base access may enhance outcomes through reduced morbidity and mortality, improved speed and precision, shorter hospital stays, and lower post-operative pain [1,2,4]. Technical nuances of these approaches and medical decision-making in the context of various neurosurgical considerations are discussed.

4749. Samuthrat, T., et al. (2017). "Transoral Intracranial Injury via Middle Skull Base by a Blunt Chopstick in a Child." World neurosurgery **103**: 952.e911-952.e917.

BACKGROUND: Transoral penetrating injury from a blunt-tipped chopstick is unusual and should be promptly dealt with because it is associated with high morbidity and mortality., CASE DESCRIPTION: We report a case of a 2-year-old girl who sustained a transoral penetrating brain injury after falling onto a bamboo chopstick, which penetrated through the hard palate and eventually led to middle skull base fracture as well as temporal lobe laceration and contusion. The chopstick was successfully extracted via a transoral approach followed by administration of empirical antibiotics and anticonvulsants. The postoperative course was uneventful, and a 2-year follow-up evaluation revealed a favorable outcome., CONCLUSIONS: Preoperative and postoperative imaging and extensive monitoring of the patient's condition are mandatory for evaluation of possible development of complications. An optimal result can be obtained by a tailored management and treatment approach for each specific patient.

4752. Sances, A., Jr., et al. (2002). "Biomedical engineering analysis of glass impact injuries." Critical reviews in biomedical engineering **30**(4-6): 345-377.

This article outlines the history, development, and safety aspects of glass and its use in motor vehicles. It traces the manufacture and describes the characteristics of laminated and tempered glass. It further compares the differences in injuries caused by impact with laminated and tempered glass. The development, use, and results of high penetration resistance (HPR) laminated glass for windshields are examined. Head and neck injuries from impact with glass and glazing structures are delineated. Results of studies with laminated and tempered glass are presented. The probability and severity of injuries occurring secondary to partial or full ejection of vehicle occupants are discussed, and the differences between the performance of laminated and tempered glass are highlighted. Current research to quantify head and neck injury parameters caused by glass impact during rollover is described. The biomechanics of head and neck injury assessment and the development of injury prediction parameters and reference values, respectively, are reviewed.

4753. Sanchez, G. M. and A. L. Burridge (2007). "Decision making in head injury management in the Edwin Smith Papyrus." Neurosurgical focus **23**(1): E5.

The Edwin Smith Papyrus (circa 1650-1550 BC) is a didactic trauma treatise of major interest to neurosurgery, as it deals primarily with cranial and spine injuries. Information regarding the patient's condition is conveyed in the papyrus with sufficient clarity to allow a clinical assessment of each injury. The ancient Egyptian physician/teacher lists the key

diagnostic elements in each case, and then pronounces his opinion of the treatment potential in one of three verdicts: 1) "a medical condition I can treat;" 2) "a medical condition I can contend with;" or 3) "a medical condition you will not be able to treat." The structural organization of the text according to regional injuries of increasing severity permits analysis of sequential cases, and makes it possible to determine which clinical features led the ancient Egyptian physician to give the first or second verdict in the less severe injuries, but the third in the worst cases. Interestingly, the ancient physicians were not deterred from contending with injuries in the presence of basilar skull fractures, traumatic meningismus, skull perforation without overt neurological deficit, drowsiness, limited facial fractures, or closed head injuries without depressed fragments. Factors identified as determinant for the third verdict in head injuries are depressed skull fragments, dura laceration with exposed brain, infected cranial wounds/tetanus, major craniofacial fractures, deep skull-penetrating stab wounds, and aphasia. This study describes three case sequences of head injuries.

4754. Sánchez-Vázquez, M. A., et al. (2001). "Incidental wound shot in a child." Archivos de Neurociencias **6**(3): 153-158.

Incidental wound by stray bullet in a 9 years old child is presented, which was follow up with X-ray, showing bullet shifting downwards, requiring a posterior fossa craniotomy to remove it, evolving without neurological deficit. Literature of the subject is review. Analyses of the circumstances of the injury revealed that the wound was make by the falling bullet, which penetrate the bone, crossing the left brain parenchyma by the speed of weight and gravity, leaving no sequel at all, however it required two surgical procedures. Sequels in this patient were very different of that reported in the literature because of the absence of the hit wave. We recommend in every case remove the bullet by the shorter route. Lesions by stray bullet may be fatal making mandatory federal regulation for freewill shooting in urban areas.

4755. Sancho-Rieger, J. and J. Parra-Martinez (2002). "[Preventive and therapeutic attitude in post-traumatic epileptic seizures]." Actitud preventiva y terapeutica en las crisis epilepticas postraumaticas. **35 Suppl 1**: S39-42.

INTRODUCTION AND DEVELOPMENT: Due to the vast number of different circumstances surrounding them, the frequency with which post traumatic epileptic seizures occur varies greatly from study to study. Immediate and early epileptic seizures, within a week of the traumatism having taken place, are usually of little importance as regards the risk of post traumatic seizures. The most important factors governing the presentation of post traumatic seizures have to do with the seriousness of the injury, the extension of the brain tissue that is affected and the penetrating nature of the brain traumatism., CONCLUSION: Although antiepileptic medication significantly reduces the risk of early seizures from occurring, a review of well designed clinical trials has found no evidence that these drugs reduce the morbidity and mortality associated with head injuries, or the appearance of late seizures.

4756. Sanders, W. R., et al. (2021). "Association of ct-based fronto-temporal contusion volume with the development of post-traumatic epilepsy." Annals of neurology **90**(SUPPL 27): S185-S186.

Post-traumatic epilepsy (PTE) is a common complication of traumatic brain injury (TBI), and TBI is one of the primary causes of acquired epilepsy. Thus far, TBI severity has been the leading risk factor for PTE development. However aside from severity and its related characteristics (penetrating injury, skull fracture, etc.) few etiological risk factors for PTE have been firmly established. Tubi et al (2018) found that lesion location based on MRI is related to both a high incidence of early seizures and longitudinal development of PTE, but lesion volume was not investigated. The CT scan is highly accessible and more common in TBI evaluations and thus evaluation of contusion location and volume could feasibly be used as a screening tool for PTE risk. Thus, in this study we sought to evaluate the effect of both CT-based contusion volume and location on the development of PTE We identified a retrospective cohort of 25 TBI patients admitted to a tertiary care center from 2011-2015 who developed PTE. Patients were matched by age and TBI severity (Glasgow Coma Scale score) with 25 TBI controls who did not develop PTE. Using OSIRIX MD software two blinded raters evaluated contusion volume and location in all 50 patients. Volumes were manually compared and adjudicated by consensus in cases of disagreement >5cc; volume measurements were then averaged. Contusions were classified according to laterality and involvement of the frontal or temporal lobes. Prior research has shown that parietal and occipital contusions exhibit minimal association with the development of PTE, and thus contusions in these lobes were excluded from analysis. Using two-tailed T-tests we compared overall fronto-temporal contusion volume and regional contusion volume (left/right frontal and temporal lobes). We also compared the proportion of subjects with contusions in each anatomic region using Fisher's Exact Test. We found that patients who developed PTE had significantly greater fronto-temporal contusion volume (29.0 vs 4.6 cc, $P < 0.05$). Patients with PTE were more likely to have a left frontal

lobe contusion compared to non-PTE subjects (Fisher's Exact Test, P < .05). We did not find a significant difference in lesion volume for any specific region between PTE and non-PTE patients. These data suggest that greater fronto-temporal contusion volume is associated with development of PTE. These findings also illustrate the possible utility of CT contusion volume measurement as a PTE risk screening tool .

4757. Sandiumenge, A., et al. (2020). "Donor referral from outside the intensive care unit: A multidisciplinary cooperation model using communication apps and redefining refereal criteria." Medicina intensiva **44**(3): 142-149.

OBJECTIVE: We evaluate the impact of a web-based collaborative system on the referral of possible organ donors from outside of the intensive care unit (ICU)., STUDY DESIGN: Cohort prospective study., SETTINGS: University hospital., PATIENTS AND INTERVENTION: In 2015 a virtual collaborative system using a cross-platform instant messaging application replaced the previous 2014 protocol for the referral of patients outside of the ICU with a severe brain injury in whom all treatment options were deemed futile by the attending team to the donor coordination (DC). Once the DC evaluated the medical suitability and likelihood of progression to brain death (BD), the option of intensive care to facilitate organ donation (ICOD) was offered to the patient's relatives. This included admission to the ICU and elective non-therapeutic ventilation (ENTV), where appropriate., RESULTS: A two-fold increase of referrals was noted in 2015 [n=46/74; (62%)] compared to 2014 [n=13/40; (32%)]; p<0.05. Patients were mostly referred from the stroke unit (58.6%) in 2015 and from the emergency department (69.2%) in 2014 (p<0.01). Twenty (2015: 42.5%) and 4 (2014: 30.7%) patients were discarded as donors mostly due to medical unsuitability. Family accepted donation in 16 (2015: 62%) and 6 (2014: 66%) cases, all admitted to the ICU and 10 (2015: 62.5%) and 3 (50%) being subject to ENTV. Ten (2015: 66.6%) and 5 (2014: 83.3%) patients progressed to BD, 60.5+/-20.2 and 44.4+/-12.2h after referral respectively. Nine (2015) and 4 (2014) of these patients became utilized donors, representing 29.0% (2015) and 13.0% (2014) of the BD donors in the hospital during the study period (p<0.05)., CONCLUSION: The implementation of a virtual community doubled the number of patients whose families were presented with the option of donation prior to their death.

4758. Sanford, R., et al. (2018). "Longitudinal trajectory of brain volume and cortical thickness in primary infection." Topics in Antiviral Medicine **26**: 47s-48s.

Background: HIV penetrates the brain early in infection. However, brain volume changes that occur during this period and the effect antiretroviral therapy (ART) has on these changes are unclear. To explore this issue, we used tensor-based morphometry (TBM) and cortical modeling to examine the longitudinal trajectory of regional brain volumes and cortical thickness in treated and untreated primary HIV-infected (PHI) participants. Methods: PHI participants (<1 year after exposure) in the PISCES cohort from San Francisco underwent longitudinal MRI. Several participants commenced ART during follow-up. TBM and cortical modeling estimated regional brain volumes and cortical thickness, respectively. A two-phase mixed-effect model assessed the trajectory of our MRI measures before and after ART. This involved fitting a linear model at time points before ART initiation and a different linear model at time points after ART. Both models were constrained to meet at the time of ART initiation. Additional mixed-effect models assessed correlations of regional MRI measures with CD4+ and CD8+ cell counts, CD4/CD8 ratio, and CSF and blood HIV RNA at time points before ART. Results: 65 male PHI participants enrolled ((mean±SD) age 36.8±9 year, education 15.4±2.3 year, duration of infection 4.2±2.5 month, MRI per participant 2.5±1.5). Prior to ART initiation, we observed that longer duration of infection was correlated with brain volume loss in the thalamus, caudate, temporal lobe and cerebellum as shown by TBM (see Fig 1 for voxel-wise statistics), and with cortical thinning in the frontal and temporal lobes, as well as middle cingulate cortex (p<.05) (Fig 1B). After ART initiation, no further significant brain volume changes were found by TBM (Fig 1A). However, small but statistically significant increases of cortical thickness in the right frontal and temporal lobes correlated with longer ART duration (p<.05) (Fig 1B). Before ART, increased CSF HIV RNA was related with volume reductions in the thalamus (p<0.1) (Fig 1C). CD4+ cell count and CD4/CD8 ratio were positively correlated with cortical thickness in the left frontal lobe (p<.05) (Fig 1D). Conclusion: Regional subcortical volume loss and cortical thinning occur before ART initiation. However, initiating ART can halt further structural deterioration. These findings support the hypothesis that brain injury due to HIV occurs during untreated infection and worsens in the absence of ART. This suggests that early initiation of ART preserves longterm brain health. (Figure Presented).

4759. Sanger, J. R., et al. (1992). "Scalp reconstruction with a prefabricated abdominal flap carried by the radial artery." Plastic and reconstructive surgery **89**(2): 315-319.

Custom prefabrication of free flaps provides an unlimited variety of applications, since flaps can be created with expendable tissues and without restriction to naturally occurring vascular territories. These principles also can be used to customize flaps that could not be completed by conventional means. We report a case of scalp reconstruction using a random-pattern abdominal flap in which a radial artery fascial flap was induced to serve as the vascular carrier. In addition to providing durable scalp coverage, the prefabricated free flap enabled salvage of an abdominal flap that would otherwise have been aborted after intermediate transfer to the forearm.

4760. Sani, S., et al. (2005). "Successful repair of an intracranial nail-gun injury involving the parietal region and the superior sagittal sinus. Case report." Journal of neurosurgery **103**(3): 567-569.

Intracranial nail injuries to the brain are rare. Various techniques for the removal of penetrating nails have been reported, but to date successful nail extraction following an injury involving the superior sagittal sinus (SSS) has not been reported. The authors report the case of a nail-gun injury to the midline parietal region with penetration of the SSS. They describe an original surgical technique involving the use of a graft patch of temporal fascia and muscle to repair the SSS following extraction of the nail. The procedure resulted in preservation of distal flow across the sinus and a good neurological outcome. Technical considerations in the repair of penetrating posterior SSS injuries are discussed. Penetrating nail injuries to the brain involving the SSS can be successfully repaired with maintenance of sinus patency.

4761. Sanjakdar, S., et al. (2016). "Evaluation of acute and chronic caffeine preexposure in the wrair penetrating ballisticlike brain injury model." Journal of neurotrauma **33**: A78-A79.

Caffeine (1, 3, 7-trimethyxanthanine) is one of the most widely used psychoactive drugs to combat fatigue and sleep loss. As a non-specific adenosine receptor antagonist, caffeine has recently been shown to exert neuroprotective effects against brain injury in animal models of Parkinson's disease (PD) and stroke. However, studies of the neuroprotective effects of caffeine on traumatic brain injury (TBI) are limited. This study assessed the potential therapeutic effect of caffeine on neurobehavioral recovery in the WRAIR penetrating ballistic-like brain injury (PBBI) model. Unilateral frontal PBBI was produced in the right hemisphere of anesthetized rats (10% injury severity level). Animals were randomly assigned to pretreatment groups: (1) acute caffeine (25mg/kg CAF) or vehicle (gavage, 1 h prior to PBBI); (2) chronic caffeine (0.25 g/L CAF) or water (water bottle, 3 weeks prior to PBBI). Blood samples (0.7mL) were collected at 1 h, 4 h, 24 h, and the terminal endpoints to measure plasma levels of the glial biomarker GFAP and inflammatory cytokines. Motor function was evaluated on the rotarod (7 and 10 days post) at fixed-speed increments of 10, 15, and 20 rpm. Cognitive performance was evaluated on the Morris water maze (MWM). In pilot studies, cognitive performance in the MWM revealed deficits in all injury groups with the average latency to find the hidden platform (across all testing days) increased by 140% (PBBI) and 130% (25mg/kg CAF) vs. respective sham ($p < .05$). Results of the probe trial indicated that caffeine-treated rats showed reduced thigmotaxic behavior and spent more time in the target annulus zone; however, these results were not statistically significant. The effects of chronic caffeine treatment and plasma GFAP and inflammatory cytokine levels are currently ongoing. Overall, the results of this study indicate that acute caffeine does not promote significant neurofunctional recovery when delivered via oral gavage in the 10% PBBI model. Future studies will evaluate additional doses and injury severity levels.

4762. Sanjakdar, S. S., et al. (2019). "Differential Effects of Caffeine on Motor and Cognitive Outcomes of Penetrating Ballistic-Like Brain Injury." Military medicine **184**(Suppl 1): 291-300.

This study assessed the effect of caffeine on neurobehavioral recovery in the WRAIR penetrating ballistic-like brain injury (PBBI) model. Unilateral frontal PBBI was produced in the right hemisphere of anesthetized rats at moderate (7%-PBBI) or severe (10%-PBBI) injury levels. Animals were randomly assigned to pretreatment groups: acute caffeine (25 mg/kg CAF gavage, 1 h prior to PBBI), or chronic caffeine (0.25 g/L CAF drinking water, 30 days prior to PBBI). Motor function was evaluated on the rotarod at fixed-speed increments of 10, 15, and 20 RPM. Cognitive performance was evaluated on the Morris water maze. Acute caffeine showed no significant treatment effect on motor or cognitive outcome. Acute caffeine exposure prior to 10%-PBBI resulted in a significantly higher thigmotaxic response compared to vehicle-PBBI groups, which may indicate caffeine exacerbates post-injury anxiety/attention decrements. Results of the chronic caffeine study revealed a significant improvement in motor outcome at 7 and 10 days post-injury in the 7%-PBBI

group. However, chronic caffeine exposure significantly increased the latency to locate the platform in the Morris water maze task at all injury levels. Results indicate that chronic caffeine consumption prior to a penetrating TBI may provide moderate beneficial effects to motor recovery, but may worsen the neurocognitive outcome.

4764. Santana-Montero, B. L., et al. (2009). "Cerebellar abscesses caused by dog bite: a case report." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **25**(9): 1137-1141.

INTRODUCTION: Bites by house pets can be lethal or cause a series of catastrophic events with severe sequels, such as the loss of a limb or a systemic infection which may be life-endangering, especially in the case of children being bitten., PRESENTATION: A 2-year-old girl was attacked by a dog, causing lesions at the occipital region. This was treated initially as a superficial wound that became further complicated with two cerebellar abscesses. These abscesses required neurosurgical and antimicrobial treatment, with a satisfactory outcome., CONCLUSION: The precise and diligent evaluation of a lesion caused by an animal bite may prevent further life-endangering complications. To the best of our knowledge, there are no reports about cerebellar abscess caused by a dog bite. When cranial lesions are penetrating, an abscess must to be considered. We insist on the importance of medical evaluation and adequate treatment of such lesions.

4765. Santander, X. A., et al. (2019). "Occult Transorbital Intracranial Injury by Windshield Wiper Handle: Case Report and Review of Literature." World neurosurgery **126**: 530-532.

BACKGROUND: We present the case of a 51-year-old male with an occult transorbital intracranial injury after a car accident. The identified foreign object was a windshield wiper handle. To our knowledge, this is the first case reported., CASE DESCRIPTION: Multidisciplinary treatment with maxillofacial and otorhinolaryngology departments was planned. A bifrontal craniotomy with removal of the foreign object and posterior orbital reconstruction were performed. A review of the literature was done, in order to highlight certain general principles in decision making despite the variability in case presentation., CONCLUSIONS: Occult TII is a rare subtype of penetrating brain injury. Diagnosis requires high suspicion as it can be missed during physical examination. Computed tomography (CT) scan, CT angiogram, and magnetic resonance imaging should be performed in order to design the optimal treatment for each patient. Magnetic resonance imaging should be avoided when metallic density on CT is observed. The use of a broad-spectrum antibiotic regimen is critical.

4766. Santangelo, G., et al. (2018). "Imaging and surgical approach to a pediatric penetrating intradural wooden splinter: case report." Journal of neurosurgery. Pediatrics **21**(4): 409-413.

Penetrating spinal injuries by wood are infrequently reported. They are particularly rare in children. Only 6 cases of wooden fragments causing penetrating intradural spinal injury have been reported. The authors report a case of a 3-year-old girl who suffered a penetrating wound on her lower back after sliding on a wood floor. A portion of the extraspinal part of the wooden splinter was removed prior to presentation; however, a high suspicion for retained foreign body was maintained. Findings on CT were equivocal, but the diagnosis was confirmed on MRI. An incomplete cauda equina syndrome was noted on examination. She was taken to the operating room for removal of the wooden foreign body, repair of a durotomy, and repair of a CSF leak. At 8 months after surgery, the patient had fully recovered without sequelae. The roles of imaging modalities, prophylactic antibiotics, and surgery are discussed.

4767. Santiago, J., et al. (2021). "MALIGNANT HEMISPHERIC INFARCTION AFTER SUBTLE TRACHEAL RUPTURE." Chest **160**(4): A835.

TOPIC: Critical Care TYPE: Medical Student/Resident Case Reports INTRODUCTION: Tracheal rupture after endotracheal intubation is a rare but life-threatening complication with an incidence of approximately 0.005%. Predisposing factor can be a weakness of the membranous trachea secondary to chronic illness or steroid use. Herein

we present a case of a young woman who developed a distal tracheal rupture after emergent endotracheal intubation with devastating consequences. CASE PRESENTATION: A 48-year-old female with a medical history of hypertension, epilepsy, and panhypopituitarism secondary to a respected craniopharyngioma was admitted to the intensive care unit with a diagnostic impression of obstructive uropathy with septic shock and multiorgan failure. Supportive management with aggressive fluids resuscitation, antibiotics, dual vasopressor therapy, and endotracheal intubation was given. Hours later, the patient became hemodynamically unstable requiring increased vasopressor therapy with increased demand in ventilation parameters. Physical examination was positive for massive subcutaneous emphysema from her chest tracking through facial and neck planes. A chest computerized tomography (CT) scan was performed and showed a distal tracheal rupture as the most likely cause of the massive pneumothorax that progressed to tension subcutaneous emphysema. Upon acute neurological deterioration, a head CT scan was performed, revealing a left pan-hemispheric malignant ischemic stroke involving the left anterior, middle, and posterior cerebral arteries suggestive of a left internal carotid artery (ICA) complete occlusion. The patient had a National Institutes of Health Stroke Scale score above 20, a left hemisphere infarction, and a GCS 3/11, conferring a poor clinical outcome. As poor prognosis and poor quality of life were expected, the family members opted to withdraw life support. DISCUSSION: Malignant hemispheric infarction has a mortality rate as high as 80 percent with catastrophic neurologic sequelae. Its incidence is less than ten percent of all ischemic infarcts and it's generally caused by embolic occlusion of the ICA. CONCLUSIONS: To our knowledge, there are no malignant hemorrhagic strokes provoked by traumatic intubation resulted from tracheal rupture documented to this day. We presume the etiology of this event to be subcutaneous air that exerted enough pressure between the fascial and cervical planes to result in significant vascular compression. Tracheal rupture is one of the most feared immediate complications of intubation as it could result in increased morbidity and mortality. There is no established consensus for the treatment yet, but early surgical repair has been the mainstay of treatment. However, conservative management has been chosen in cases of small ruptures with similar outcomes. REFERENCE #1: JOSEPH, M. M., & LEWIS, S. (2002). Stroke after penetrating trauma of the oropharynx. 4768. Santiago, L. A., et al. (2012). "A clinical comparison of penetrating and blunt traumatic brain injuries." Brain injury **26**(2): 107-125.

BACKGROUND: Traumatic brain injury (TBI) is a leading cause of injury death and long-term disability in the USA. It commonly results from blunt (closed) or penetrating trauma. The majority of civilian TBI is caused by falls or motor vehicle collisions, whereas military TBI mainly results from explosions. Although penetrating injuries are less common than closed injuries in the civilian population, they are far more lethal. Unfortunately, the pathophysiologic differences between penetrating and closed TBI remain poorly understood due to the lack of studies on the subject. Many studies on the prognostic factors of mortality and functional outcome after TBI exclude penetrating brain injuries from their series because they are believed to have a different pathophysiology., METHODS: 125 Articles regarding brain injury were reviewed and summarized for this report., RESULTS: Despite the absence of a clear delineation between penetrating and blunt TBI, the current guidelines for penetrating TBI suggest defaulting to management strategies used for closed TBI with limited supportive evidence. Thus, injuries that appear to have different pathophysiologies and outcomes are managed equally and perhaps not optimally., CONCLUSION: In view of the incomplete understanding of the impact of mechanism of injury on TBI outcomes, as demonstrated in the current review, new research studies are required to improve evidence-based TBI guidelines tailored especially for penetrating injuries.

4770. Santoro, R., et al. (2014). "Penetrating foreign body in the nasal floor through nasolacrimal duct." BMJ case reports **2014**.

Clinical otolaryngologists frequently encounter nasal foreign bodies (FBs) particularly among children. The removal of nasal FBs is a common otolaryngological practice. However, occasionally trauma results from FBs being lodged in the nasal cavity especially through the nasolacrimal duct. In this article we present an unusual case of a FB that

from the left medial canthus went inside the nasolacrimal duct, then through the inferior turbinate and stuck in the floor of the nose. We describe the transnasal endoscopic approach used and we recommend that the treatment be done as soon as possible to avoid complications. Copyright 2014 BMJ Publishing Group Ltd.

4771. Santos, C., et al. (2018). "Craniotomy and trans-orbital approach for an e-cigarette removal." Journal of neurosurgical anesthesiology **30**(4): 464-465.

Introduction: Traumatic brain injuries (TBIs) are considered a major cause of death in individuals younger than 45 years old. Male young adults, late teenagers, and elderly people are at the highest risk. TBIs can be blunt or penetrating. Even though blunt injuries occur more often, a penetrating trauma carries worse prognosis. We present a patient with a penetrating TBI who was admitted following a motor vehicle collision with a foreign body extending from the right medial orbit to middle fossa involving the right temporal lobe. Case Report: A 31-year-old male patient with unknown past medical history transferred from an outside hospital following a motor vehicle collision. Admitted due to a transorbital intracranial foreign body. Patient was ETOH intoxicated (147), with urine drug screen positive for amphetamines and cannabis. He was confused and combative, but moving all extremities. The right eye was swollen shut, dilated right pupil, and ophthalmoplegia observed. Unable to determine visual field due to combativeness. CT head showed an elongated metallic/plastic object that entered the right orbit via the medial canthus and penetrated intracranial by fracturing the orbital roof lateral to the optic canal (Fig. 1). CTA showed patent intracranial vessels without severe vascular injury. Neurosurgery indicated a level A dual approach, trans-orbital and craniotomy for a foreign body removal. Patient was transferred to the operating room and had general anesthesia with endotracheal tube and standard ASA monitors. Intraoperative period was unremarkable and patient was transferred to neurosurgical intensive care unit for postoperative care. Reevaluated by Ophthalmology 1 week after discharge, unable to see out of right eye, with intact extraocular movements, and normal intraocular pressure. Conclusions: Hundreds of patients are evaluated at daily basis in the Emergency Departments due to TBI. It is also known that motor vehicle collisions caused by intoxicated drivers are a major social/health problem that needs to be addressed aiming prevention based on education, and exemplary law enforcement/judiciary zero tolerance policies. Penetrating TBIs are less common than blunt traumas; however, they must be treated aggressively to decrease morbidity and mortality.

4772. Santos, G., et al. (2013). "Traumatic middle cerebral artery aneurysm secondary to a gunshot wound." Journal of neuroimaging : official journal of the American Society of Neuroimaging **23**(1): 115-117.

Traumatic intracranial aneurysms are rare lesions, accounting for less than 1% of all intracranial aneurysms. Formation of these lesions after a penetrating missile wound is very unusual, and diagnosis can be difficult due to the presence of associated lesions. In this article, we report a case of a woman who developed a middle cerebral artery aneurysm after a gunshot wound, and discuss potential pitfalls found during diagnostic work-up. 4773. Santos, J. G. R. P. D., et al. (2018). "Effects of transcranial LED therapy on the cognitive rehabilitation for diffuse axonal injury due to severe acute traumatic brain injury: study protocol for a randomized controlled trial." Trials **19**(1): 249.

BACKGROUND: Photobiomodulation describes the use of red or near-infrared light to stimulate or regenerate tissue. It was discovered that near-infrared wavelengths (800-900 nm) and red (600 nm) light-emitting diodes (LED) are able to penetrate through the scalp and skull and have the potential to improve the subnormal cellular activity of compromised brain tissue. Different experimental and clinical studies were performed to test LED therapy for traumatic brain injury (TBI) with promising results. One of the proposals of this present study is to develop different approaches to maximize the positive effects of this therapy and improve the quality of life of TBI patients., METHODS/DESIGN: This is a double-blinded, randomized, controlled trial of patients with diffuse axonal injury (DAI) due to a severe TBI in an acute stage (less than 8 h). Thirty two patients will be randomized to active coil helmet and inactive coil (sham) groups in a 1:1 ratio. The protocol includes 18 sessions of transcranial LED stimulation (627 nm, 70 mW/cm2, 10 J/cm2) at four points of the frontal and parietal regions for 30 s each, totaling 120 s, three times per week for 6 weeks, lasting 30 min. Patients will be evaluated with the Glasgow Outcome Scale Extended (GOSE) before stimulation and 1, 3, and 6 months after the first stimulation. The study hypotheses are as follows: (1) transcranial LED therapy (TCLT) will improve the cognitive function of DAI patients and (2) TCLT will promote beneficial hemodynamic changes in cerebral circulation., DISCUSSION:

This study evaluates early and delayed effects of TCLT on the cognitive rehabilitation for DAI following severe acute TBI. There is a paucity of studies regarding the use of this therapy for cognitive improvement in TBI. There are some experimental studies and case series presenting interesting results for TBI cognitive improvement but no clinical trials., TRIAL REGISTRATION: ClinicalTrials.gov, NCT03281759 . Registered on 13 September 2017.

4774. Santos, M., et al. (2012). "Identification of a periorbital wooden foreign body as the cause of chronic ocular discharge in a horse." Australian veterinary journal **90**(3): 84-87.

The clinical, diagnostic and therapeutic features of a horse with a wooden foreign body embedded in the deep portion of the right masseter muscle adjacent to the right orbit are presented. The purpose of this report is to describe the clinical presentation, magnetic resonance imaging findings and treatment of a penetrating wooden foreign body in a horse that had no history of trauma or evidence of a puncture wound. This report documents the usefulness of magnetic resonance imaging to detect a wooden foreign body embedded in the soft tissues of a horse with a chronic copious ocular discharge. Two surgical procedures were necessary, which is a frequent complication encountered with wooden foreign bodies. Copyright © 2012 The Authors. 4775. Santos, M. A. L., et al. (2018). "A rare case report of penetrating head trauma and internal carotid thrombosis caused by a domestic knife." Brazilian Neurosurgery **37**.

Background: Penetrating non-missile cerebral injuries are about 0,4% of all craniocerebral injuries. Although it is recommended to perform angiographic studies, vascular injuries are uncommon and there are only few cases reported in the literature, making the management of such lesions challenging. Case Description: In this case report, we present a 21-year-old male, victim of physical aggression with a domestic knife which penetrated the skull through the temporal bone and was stucked in his right cavernous sinus. Angiogram showed right internal carotid oclusion. We performed a two-step surgery, occluding the internal carotid at the cervical segment and at the supra-clinoidal segment. Then, we took off the knife under direct visualization. This approach was possible because the right middle cerebral artery had adequate flow from the contra lateral carotid. The patient had favorable outcome. Conclusion: This case report illustrate a rare condition where the surgical approach was the mainstay of treatment.

4776. Santos, T. d. S., et al. (2011). "Impacted foreign bodies in the maxillofacial region-diagnosis and treatment." The Journal of craniofacial surgery **22**(4): 1404-1408.

Foreign bodies are often encountered by oral and maxillofacial surgeons and may present a diagnostic challenge to the trauma surgeon due to many factors such as the size of the object, the difficult access, and a close anatomic relationship of the foreign body to vital structures. They are usually a result of injuries or operations. Fragments of broken instruments can be left behind and entire teeth or their fragments can be displaced during extraction. The approach to this kind of injury should be sequential and multidisciplinary, beginning with the trauma unit that will provide maintenance of the airways, hemodynamic stabilization, and, but only if necessary, neurologic, ophthalmologic, and vascular evaluation. With a view to illustrating and discussing the diagnosis and treatment of this kind of injury, this study reports impacted foreign bodies in oral and maxillofacial region. The following data were collected: age, sex, race, etiology, occurrence of fracture, anatomic location of the fracture, daytime of the traumatic event, type of the object, signal and symptoms, type of imaging examination used, type of anesthesia, approach, transoperative complication, period between surgery and hospital liberation, and the occurrence of death. Foreign body injuries in the maxillofacial region can place the patient's life at risk, so a correct initial treatment performed by a multidisciplinary team increases the survival of this kind of patient.

4777. Sanuki, R., et al. (2019). "Normal aging hyperactivates innate immunity and reduces the medical efficacy of minocycline in brain injury." Brain, behavior, and immunity **80**: 427-438.

Symptoms of many neurodegenerative diseases appear later in human life. However, young animal models for penetrating traumatic brain injury (pTBI) have been used to study neurodegenerative diseases and evaluate the efficacy of neuroprotective medicines. Possibly because of this discordance, effective neuroprotective drugs have still not been developed. For patients suffering from pTBI, aging is known to be a significant prognostic factor of mortality. In this study, we aimed to establish a model of aged pTBI animals using Drosophila melanogaster. We successfully generated

aged pTBI flies as a new pTBI model showing increased neurodegeneration and higher mortality. To elucidate the mechanism of increased vulnerability in aged pTBI animals, we analyzed the GenBank-deposited transcriptome data of young and aged flies, demonstrating the importance of innate immunity genes for higher mortality in aged pTBI models. We found that in the context of pTBI, normal aging strongly activated the expression of antimicrobial peptide genes and upregulated the nuclear factor-kappaB gene in the immune deficiency pathway, but not the Toll pathway. Moreover, we found that minocycline increased the survival of young pTBI flies, but not aged pTBI flies. These results suggested that immune system activation under neurodegenerative conditions was involved in normal aging, thereby inhibiting the medicinal efficacy of neuroprotective drugs effective for young flies in aged flies.

4778. Sanus, G. Z., et al. (2014). "Osteointegration of a bisphenol-a-glycidyl-dimethacrylate composite and its use in anterior skull base defects: an experimental study in an experimental design model of cerebrospinal fluid leak." The Journal of craniofacial surgery **25**(4): 1524-1528.

OBJECT: Promising clinical results were reported in watertight closure of anterior skull base defects (ASBDs) with bisphenol-a-glycidyl-dimethacrylate (bis-GMA)-based materials to prevent the cerebrospinal fluid leaks. However, interrelation of these materials with surrounding bones in histologic level, referred to as the osteointegration, has not been reported in the anterior skull base. In addition, an illustrative case with an ASBD that was repaired using a bis-GMA composite has been presented., METHODS: Twenty New Zealand rabbits were divided into 4 groups: control and sham groups consisted of 2 and 6 rabbits, respectively. The "skull base defect" group (n = 6) underwent a unifrontal craniectomy and an iatrogenic ASBD followed by creating a dural defect to obtain a cerebrospinal fluid leak. Similar bony and dural defects were acquired in the "repair with bis-GMA based allograft" group (n = 6), but the bony defect was closed with bis-GMA-based allograft., RESULTS: All animals in the "skull base defect" group died in 3 weeks after surgery. There were no animal losses in the "repair with bis-GMA based allograft" group at the sixth month. Histologic evaluation revealed complete osteointegration of bis-GMA composite with surrounding bones., CONCLUSIONS: bis-GMA based allograft achieved a watertight repair of the ASBD. Histologic findings of this study showed that bis-GMA composite is a reliable material to be used in the closure of anterior skull base bony defects.

4779. Sanus, G. Z., et al. (2008). "Use of Cortoss as an alternative material in calvarial defects: the first clinical results in cranioplasty." The Journal of craniofacial surgery **19**(1): 88-95.

A clinical series of 13 patients who underwent cranioplasty using a new quick setting material, namely Cortoss, was done over 3-year period. Thus, the primary objective of this study is to evaluate the role of Cortoss in the treatment calvarial defects which were mainly due to trauma (4 patients), tumor or tumor-like lesions (5 patients), middle cerebral infarction (3 patients), and gun shot wound (1 patient). The surgical technique was found to be simple and effective. Long-term follow-up (mean 24.3 months) demonstrated satisfactory results in terms of surgical (functional) and cosmetic outcomes. None of the patients developed complications including infections, foreign body reactions or material leakage. The results led us to suggest that the use of Cortoss in the case of calvarial defects seems to be safe, effective, quick, and a feasible method for cranioplasty. We conclude that the mechanical, immunologic, and technical-grafting properties of Cortoss, together with its superior esthetic and psychological effects, probably will make it the best material for cranioplasty.

4780. Sanz de la Torre, J. C. and M. Perez-Rios (1996). "[Neuropsychological evaluation of a case of organic personality disorder due to penetrating brain injury]." Evaluacion neuropsicologica de un caso de trastorno organico de la personalidad por lesion cerebral penetrante. **24**(130): 643-649.

In this paper, an organic personality disorder case by penetrating brain injury, predominantly localized in the right frontal lobe, is presented. Neuropsychological and neuroimaging (CT scan studies) were performed. We assessed the main cognitive aspect: orientation, attention, memory, intelligence, language, visual-spatial functioning, motor functioning, executive functioning and personality. The results obtained, point out disorders in the patient's behavior and in the executive functions. Likewise, other cognitive functions as: attention, memory, language and visual-spatial functioning, show specific deficits.

4782. Saribeyoglu, K., et al. (2007). "Laparoscopy offers diagnosis and treatment in abdominal stab injuries." Surgical laparoscopy, endoscopy & percutaneous techniques **17**(5): 396-401.

PURPOSE: To assess the role of laparoscopy in the diagnosis and treatment of abdominal stab injuries (ASI)., METHODS: Patients who underwent laparoscopic procedures due to ASI were included in the study. Hemodynamic instability, injuries to the posterior trunk, concomitant severe cranial injuries, and prior abdominal operations were considered as contraindication for laparoscopy., RESULTS: From January 1997 to March 2006, 88 patients underwent laparoscopic management of ASI. In 45 patients (51.1%), there was no intra-abdominal pathology requiring surgical intervention (nontherapeutic laparoscopy) and 5 patients in this group had no peritoneal penetration (negative laparoscopy). In another 25 patients (28.4%), laparoscopic treatment was performed (therapeutic laparoscopy), including bleeding control in liver, colonic, gastric, and diaphragmatic repairs and intra-abdominal bleeding control. Laparotomy was avoided in a total of 70 (79.5%) patients. In 18 patients (20.5%), laparoscopy was converted to laparotomy. There was no mortality, and except one missed small bowel injury nor perioperative morbidity in patients undergoing laparoscopy. In the laparotomy group, major complications were seen in 7 patients., CONCLUSIONS: Laparoscopy is safe and efficient in the management of ASI and should be more frequently considered as a therapeutic tool.

4783. Sarkar, D., et al. (2009). "Expect the unexpected: two cases of penetrating head and neck trauma from Operation Iraqi Freedom." Ear, nose, & throat journal **88**(9): E19-21.

The protocol for treating penetrating head and neck trauma in a war zone differs from the standard protocol. Rather than first securing an airway, as is standard in civilian trauma cases, the primary emphasis is on assessing and controlling hemorrhage because it is the leading cause of morbidity and mortality in a battlefield setting. Once that has been addressed, we shift to standard advanced-trauma life-support protocols. We describe two cases we encountered at our combined medical clinic in Western Baghdad--one involving a 4-year old Iraqi child with an ammunition round lodged in her neck and one involving a 38-year-old female U.S. soldier with a round lodged in her right superolateral orbit. Both cases were transferred to combat support hospitals for further treatment after our initial assessment and treatment, and both had successful outcomes.

4784. Sarkar, K., et al. (2012). "Differences in rotterdam and gcs scores between adult and pediatric traumatic brain injury." Neurology **78**(1).

Objective: Assess if radiographic differences exist between adult and pediatric traumatic brain injury. Background Traumatic brain injury (TBI) represents one of the leading causes of hospitalization and death among pediatric patients. Admission computerized tomography(CT) scans play an important role in classifying and treating TBI,but little is known about the differences between CT findings in adult and pediatric populations. Design/Methods: This was a retrospective analysis of a TBI registry data from 1206 consecutive non-penetrating TBI patients treated at a Level 1 adult and pediatric trauma center from August 2008 to January 2011. Pediatric was defined as younger than 16. Non-accidental trauma and gun shot wounds were excluded. Admission CT scan were evaluated for the presence of skull fractures, different patterns of ICH, midline shift, and compression of basal cisterns. Results: Of 1206 patients in our registry, 349(28%) were pediatric. The distribution of gender, race, and GCS were similar between adult and pediatric populations ($P > 0.05$). The distribution of CT findings, however, was significantly different. Pediatric TBI patients were more likely to experience skull fractures (44% vs 20.71%) and epidural hematoma (17.3% vs 9.8%), and pediatric TBI was less likely to be associated with contusion, subdural hematoma, subarachnoid hemorrhage, or compression of basal cisterns ($p<0.05$). Rotterdam score were significantly less in the pediatric population(2.3 vs 2.6). Conclusions: Despite similarities in demographics and clinical severity between adult and pediatric TBI, there were significant differences in the pattern of CT findings. The Rotterdam CT Score differentiates these two populations more effectively than GCS. These findings may reflect differences between adult and pediatric anatomy, differences in biomechanical forces during injury, or differences in physiology and intracranial compliances. These differences may have a significant impact on clinical trial design and treatment strategies for patients in different age groups.

4785. Sarkar, K. and K. Shahlaie (2011). "Computed tomography characteristics of pediatric traumatic brain injury." Annals of neurology **70**: S46.

Little is known about the differences in CT findings between adult and pediatric TBI populations. A retrospective analysis of 1206 consecutive non-penetrating TBI patients treated at a Level 1 trauma center from August 2008 to January 2011 was performed. Admission CT scan were evaluated for skull fractures, ICH, midline shift, and basal cistern compression. Of 1206 patients in our registry 349(28.5%) were pediatric. Demographics and injury severity distribution were similar between the two populations (p> 0.05). The distribution of CT findings, however, was significantly different. Pediatric TBI patients were more likely to be associated with skull fractures (57.0% vs 23.4%) and EDH (17.2% vs 9.7%), and less likely to be associated with contusion, SDH, SAH, or basal cisterns compression (p<0.05). Despite similarities in demographic characteristics and clinical severity between adult and pediatric TBI, there were significant differences in the pattern of CT findings. These findings may reflect differences in anatomy (skull fractures), biomechanical forces during injury (ICH patterns), or intracranial compliances (mass effect). These differences may have a significant impact on clinical trial design and treatment strategies for patients in different age groups.

4787. Sarkar, K., et al. (2013). "Rotterdam CT score can detect differences between pediatric and adult TBI." Neurology **80**(1).

OBJECTIVE: To determine if radiographic differences can be measured using the Rotterdam CT Score between adult and pediatric traumatic brain injury (TBI). BACKGROUND: Traumatic brain injury (TBI) represents one of the leading causes of hospitalization and death among pediatric patients. Admission computerized tomography(CT) scans play an important role in classifying and treating TBI, but little is known about the differences between CT findings in adult and pediatric populations. DESIGN/METHODS: This is a retrospective analysis of TBI registry data from 1,206 consecutive non-penetrating TBI patients treated at a Level 1 adult and pediatric trauma center from August 2008 to January 2011. RESULTS: The distribution of gender, race, and GCS were not significantly different between adult and pediatric populations. The distribution of CT findings, however, was significantly different. Pediatric TBI patients were more likely to have skull fractures (OR 3.21, p<0.01) and epidural hematomas (OR 1.96, p<0.01). Pediatric TBI was less likely to be associated with contusion, subdural hematoma, subarachnoid hemorrhage, or compression of basal cisterns (p<0.05). Rotterdam CT scores were significantly lower(2.3 versus 2.6, p< 0.001). and distribution significantly different in the pediatric population. CONCLUSIONS: We found significant differences in CT scan findings in pediatric versus adult TBI, despite the fact that both groups were statistically similar with regard to clinical severity of injury as measured by the GCS score. These differences may be due to anatomical characteristics, biomechanics of injury, and/or differences in injury mechanisms between pediatric and adult patients. The unique characteristics of pediatric TBI warrant

consideration when designing clinical trial design, or predicting functional outcome using prognostic models developed from adult TBI data.

4788. Sarnaik, A. P., et al. (1989). "Role of aggressive intracranial pressure control in management of pediatric craniocerebral gunshot wounds with unfavorable features." The Journal of trauma **29**(10): 1434-1437.

During a 6-year period, 14 consecutive children with penetrating craniocerebral gunshot wounds (GSW) were studied. Eleven patients were comatose on admission. Five had an admission Glasgow Coma Scale (GCS) score of 4 or less and developed clinical signs of brain death within 12 hours despite maximum therapeutic efforts. The remaining six patients, all of whom had three or more of the previously described unfavorable prognostic features, were aggressively managed with prophylaxis and treatment of intracranial hypertension. Intracranial pressure (ICP) was controlled with mechanical hyperventilation, mannitol osmotherapy, pentobarbital, and surgical decompression. Substantial intracranial hypertension occurred for up to 10 days after admission. There were four survivors. Neurobehavioral and intellectual functions were evaluated over a period of 1 to 2 years. Although serious cognitive deficits were noted, all survivors had sufficient functional recovery to warrant aggressive cardiopulmonary resuscitation and measures to control ICP in the management of comatose victims of craniocerebral GSW.

4789. Sarron, J.-C., et al. (2004). "Dynamic effects of a 9 mm missile on cadaveric skull protected by aramid, polyethylene or aluminum plate: an experimental study." The Journal of trauma **57**(2): 236-243.

BACKGROUND: Most military helmets are designed to prevent penetration by small firearms using composite materials in their construction. However, the transient deformation of the composite helmet during a non penetrating impact may result in severe head injury., METHOD: Two experimental designs were undertaken to characterize the extend of injuries imparted by composite panels using in protective helmets. In the first series, 21 dry skulls were protected by polyethylene plates, with gaps between the protective plate and skull ranging from 12 to 15 mm. In another design, using 9 cadavers, heads were protected by aluminum, aramid, or polyethylene plates. Specimens were instrumented with pressure gauges to record the impact response. The ammunition used in these experiments was 9 mm caliber and had a velocity of 400 m/s. A macroscopic analysis of the specimens quantified fractures and injuries, which were then related to the measured pressures., RESULTS: Protective plates influenced both the levels of injury and the intracranial pressure. Injuries were accentuated as the plates was changed from aluminum to composite materials and ranged from skin laceration to extensive skull fractures and brain contusion. Fractures were associated with brain parenchymal pressures in excess of 560 kPa and cerebrospinal fluid pressure of 150 kPa. An air gap of a few millimeters between the plate and the head was sufficient to decrease these internal pressures by half, significantly reducing the level of injury., CONCLUSIONS: Ballistic helmets made of composite materials could be optimized to avoid extensive transient deformation and thus reduce the impact and blunt trauma to the head. However, this deformation cannot be completely removed, which is why the gap between the helmet and the head must be maintained at more than 12 mm.

4790. Sasaoka, Y., et al. (1995). "[Penetrating injury of the head, neck and chest by a nail-gun: a case report]." No shinkei geka. Neurological surgery **23**(12): 1099-1104.

A very rare case of directly penetrating injury of the head, neck and chest caused by a nail-gun was reported. A 56-year-old male was admitted to our critical care center due to chest injury. On admission, he showed numbness of the hand & leg, left hemiparesis and hypalgesia. Physical examination disclosed three nails on the left anterior chest, but other wounds or nails were not found. Chest films showed three nails penetrating the lung without reaching the heart, but other nails were found by skull and neck films. One nail had penetrated the cervical canal at the C1 level through the posterolateral cervical region. Two other nails were demonstrated at the right temporal and the left frontal region, Computed tomography revealed no massive cerebral hemorrhage and cerebral angiography showed no extravasation and no passage through main vessels. Emergency surgery was performed uneventfully and the nails in the chest, neck and head were totally removed. He was discharged one month after surgery. Some injuries caused by a nail-gun have been reported in the world literature but in Japan this multiple injury case was the first reported. Since nail-gun injuries can cause multiple damage, systemic X-ray examination was very important.

4791. Sasidharan, G. M. and A. Chauhan (2018). "Penetrating Injury Due to Bicycle Brake Handle Causing Middle Cerebral Artery Infarct." Indian Journal of Neurotrauma **15**(2-3): 67-69.

An 8-year-old boy was brought to the emergency room with history of fall from a bicycle he was riding. On examination, he had a swelling in the left orbit with a small laceration under the medial aspect of the left eyebrow. The Glasgow coma scale was E2M5V2. An emergency computed tomographic (CT) scan showed infarct causing mass effect in the territory of the left middle cerebral artery. CT angiogram showed that a branch of the middle cerebral artery was occluded at the end of track traversed by the bicycle brake handle. The patient underwent decompressive craniectomy. Initial methylmethacrylate cranioplasty had to be removed due to infection. Later, the patient underwent titanium cranioplasty. At last follow-up, he was going to school. Hemiparesis persisted. Children are vulnerable to penetrating injury by the relatively sharp brake handle when they fall from an adult bicycle. Previous reports include fatal injury by similar mechanism. In this case, it caused injury to the middle cerebral artery without causing bleed. Bicycle manufacturers could be advised to make the vehicle safer for children by twisting the end of the brake handle.

4792. Sathish, K., et al. (2018). "Fatal Transorbital Intracranial Penetrating Injury Due to a Bicycle Brake Handle." The American journal of forensic medicine and pathology **39**(3): 253-256.

Transorbital intracranial injuries are uncommon and mostly accidental in nature. These injuries are usually associated with high mortality. The key to preventing this mortality involves an early diagnosis of intracranial injuries and immediate and appropriate management. Any delay can pose a serious risk to the patient's life. A case of a 55-year-old man who had experienced an accidental self-fall while riding a bicycle is presented. Initially, he was treated at a primary health center. He was referred to the tertiary care institute due to unavailability of ancillary investigation at the primary health center. He was declared dead on arrival at the casualty in the tertiary institute. On autopsy, it was observed that the injury above the right side of the upper eyelid was penetrating the right side roof of the orbit and the right cerebral cortex and brainstem. The highlighting feature of the case is that, despite the fatal penetrating brain injury, the eyeball did not sustain any major injury.

4793. Satishchandran, S., et al. (2020). "An Algorithm for Management of Post-Traumatic Maxillofacial Pseudoaneurysms." Journal of oral and maxillofacial surgery **78**(10): e103.

Abstract: Purpose: A pseudoaneurysm (PA) results from the disruption of one or more layers of a blood vessel wall (arterial or venous). This situation leads to a localized collection of blood, which can result in a life-threatening episode of bleeding. The literature regarding post-traumatic maxillofacial PAs is scant; no algorithm or treatment guidelines exist. The purpose of this project is to discuss the treatment algorithm for the management of post-traumatic maxillofacial PAs. Patients and Methods: Patients who presented with post-traumatic maxillofacial PAs were evaluated by history, clinical examination, and imaging studies (computed tomography angiogram [CTA]). Demographics, medical history, injury-related history, radiographic findings, management (observation, interventional radiology [IR] assisted embolization or surgical ligation), and postoperative course are reported. All patients were treated by a collaborative interdisciplinary team consisting of interventional radiologists, oral and maxillofacial surgery (OMS), acute critical care surgery, and otolaryngology. Results: An algorithm for the management of maxillofacial PAs resulting from trauma is presented and exemplified by clinical cases. Case 1 consisted of a 12-year-old male who sustained a gunshot wound to the face, sustained mandible fracture, and immediately developed PA of the facial artery, which was embolized. Case 2 consisted of a 24-year-old male who was involved in an all-terrain vehicle collision with a fence, sustained midface fractures and immediately developed PA of descending palatine artery, which was surgically ligated. Case 3 consisted of a 25-year-old male who was involved in a motor vehicle collision, sustained Le Fort II, bilateral zygomatic complex fractures, and bilateral orbital floor fractures, and a month later, developed PA of the ophthalmic vein, which did not require intervention. Conclusion: PA is a potentially devastating sequela of maxillofacial trauma. It may appear immediately following the injury or at a later time. Although the diagnostic approach is similar, the management of PA varies according to location, vessel involved, size of PA, collateral supply, and the availability of various medical/surgical expertise and institutional resources. In this project, we suggest a treatment algorithm for the management of post-traumatic maxillofacial PAs.

4794. Sato, M., et al. (1994). "A transorbital intracranial foreign body in an infant: A report of three cases." Japanese Journal of Neurosurgery **3**(4): 329-334.

A penetrating injury of the skull is not infrequently encountered in daily practice, although the presence of transorbital intracranial foreign bodies resulting from such injuries have been regarded as extremely rare. In this paper the authors discusse three cases of a transorbital intracranial foreign body found in infants treated at our clinic. These cases are described below. Case 1: This case involves a 1-year-old baby who sustained a stab wound of his left eye with a ball-point pen. Plain skull X-rays and plain computed tomographic (CT) scans reveal the presence of a foreign body in the left orbital and left frontal lobe. Case 2: This case concerns a 10-month-old baby who injured her right eye with a wooden chopstick. Plain CT showed a foreign body at the right superior orbital fissure. Case 3: In this case, a 3-year-old boy sustained a stab wound of his right eye with a wooden chopstick. Plain CT revealed a narrow, straight, low density mass extending from the right orbit via the cavernous sinus to the posterior clinoid process. A right carotid angiogram revealed an occlusion of the extracranial internal carotid artery. All three cases underwent an emergency operation using a subfrontal approach and the foreign body was removed. No complications occurred, such as meningitis and/or CSF rhinorrhea. In 2 of these cases, external occular movement and visual acuity did not return to their normal postoperative levels. In Case 3, however, recanalization of the internal carotid artery was noted. An orbital penetrating wound should be closely inspected, particularly in infants, even wounds that may look superficial and show no signs of intracranial complications during the early stage. In this regard, preoperative angiography is very important in order to confirm the presence of a vascular injury, such as an occluded internal carotid artery.

4795. Satoh, N., et al. (1985). "[Traumatic aneurysms--due to penetrating and nonpenetrating head injuries]." Rinsho hoshasen. Clinical radiography **30**(9): 1005-1008.

4796. Satyarthee, G. D., et al. (2009). "Transorbital penetrating cerebral injury with a ceramic stone: report of an interesting case." Neurology India **57**(3): 331-333.

Penetrating cranial injury is a potentially life-threatening condition. The majority of war injuries are high-velocity penetrating cranial injuries; but in civilian cases, most penetrating cranial wounds are low-velocity type. We report an interesting case of transorbital penetrating cranial injury with a knife-sharpening stone made up of ceramic in a 28-year-old male. The pertinent literature is reviewed and management of such cases is discussed.

4797. Sauaia, A., et al. (1995). "Epidemiology of trauma deaths: a reassessment." The Journal of trauma **38**(2): 185-193.

OBJECTIVE: Recognizing the impact of the 1977 San Francisco study of trauma deaths in trauma care, our purpose was to reassess those findings in a contemporary trauma system., DESIGN: Cross-sectional., MATERIAL AND METHODS: All trauma deaths occurring in Denver City and County during 1992 were reviewed; data were obtained by cross-referencing four databases: paramedic trip reports, trauma registries, coroner autopsy reports and police reports., MEASUREMENTS AND MAIN RESULTS: There were 289 postinjury fatalities; mean age was 36.8 +/- 1.2 years and mean Injury Severity Score (ISS) was 35.7 +/- 1.2. Predominant injury mechanisms were gunshot wounds in 121 (42%), motorvehicle accidents in 75 (38%) and falls in 23 (8%) cases. Seven (2%) individuals sustained lethal burns. Ninety eight (34%) deaths occurred in the pre-hospital setting. The remaining 191 (66%) patients were transported to the hospital. Of these, 154 (81%) died in the first 48 hours (acute), 11 (6%) within three to seven days (early) and 26 (14%) after seven days (late). Central nervous system injuries were the most frequent cause of death (42%), followed by exsanguination (39%) and organ failure (7%). While acute and early deaths were mostly due to the first two causes, organ failure was the most common cause of late death (61%)., CONCLUSIONS: In comparison with the previous report, we observed similar injury mechanisms, demographics and causes of death. However, in our experience, there was an improved access to the medical system, greater proportion of late deaths due to brain injury and lack of the classic trimodal distribution.

4798. Sauer, N. J. and S. S. Dunlap (1985). "The asymmetrical remodelling of two neurosurgical burr holes: a case study." Journal of forensic sciences **30**(3): 953-957.

A human skull identified as that of a 16-year-old female who had been reported missing about 3 years before the discovery of the specimen displayed evidence for the asymmetrical remodelling of bilateral neurosurgical burr holes. While one of the holes retained its original size and shape, gross evidence for the contralateral lesion had virtually disappeared. Initially, the open lesion was mistakenly suspected to be a recent bullet hole.

4799. Sauer, N. J., et al. (1988). "Medicolegal investigation of an eighteenth century homicide." The American journal of forensic medicine and pathology **9**(1): 66-73.

The skeleton of an adult man, recovered from an eighteenth century French fort site in Indiana, exhibited a series of sharp force wounds. The lesions, three cranial and one postcranial, had apparently been made by a heavy metal instrument similar to one of the European ax heads discovered elsewhere at the site. In this paper we describe the wounds, argue that the instrument used to create them was a European ax, and offer the opinion that the manner of death in this case was homicide.

4800. Saunders, S., et al. (2011). "Demonstrating the origin of cardiac air embolism using post-mortem computed tomography; an illustrated case." Legal medicine (Tokyo, Japan) **13**(2): 79-82.

An 83 year old female was found dead in her home. The deceased had been struck repeatedly to the head with at least one weapon, one of which was a hammer. The deceased had suffered both penetrating and non-penetrating blunt trauma to the head as a result of the assault. A multi-detector computed tomography (MDCT) scan was undertaken approximately 12h after death prior to the autopsy examination. This demonstrated the presence of a cardiac air embolus and continuity between the air embolus and the penetrating head injury. Air within the heart is a recognised post-mortem artefact frequently seen on MDCT scans and a common pitfall for inexperienced cadaveric MDCT reporters. This case builds upon a previous report by Kauczor, illustrating how MDCT can be used to demonstrate the origin and route of ingress of a genuine air embolism to the heart.

4801. Sauve, W., et al. (2017). "Neurological and psychiatric comorbidities assessment in the PRISM II study of extromethorphan/quinidine for treatment of pseudobulbar affect." CNS spectrums **22**(1): 104.

Objectives: Pseudobulbar affect (PBA) can occur secondary to certain neurological diseases or brain injury and is characterized by frequent, uncontrollable laughing/crying episodes. While PBA is distinct from mood disorders in which feelings of happiness or sadness can also lead to laughing or crying, persons with PBA may often have psychiatric comorbidities (e.g., depression or anxiety). A recently completed study (PRISM II) evaluated the effectiveness of dextromethorphan/quinidine (DM/Q) for the treatment of PBA in persons with dementia, stroke, and traumatic brain injury (TBI); we assessed the prevalence of comorbid neurological and psychiatric disorders among PRISM II patient cohorts. METHODS: Patients with PBA secondary to either dementia, stroke, or TBI, and a Center for Neurologic Study-Lability Scale (CNS-LS) score ≥ 13 were enrolled and treated with DM/Q 20/10mg BID, open-label for 90 days. Persons with severe dementia, stroke within ≤3 months, penetrating TBI, severe depressive disorders, or psychotic disorders were excluded. Concomitant medications for neuropsychiatric conditions were allowed provided doses were stable, and there were no contraindications to DM/Q use. Baseline assessments included PBA and depression ratings (CNS-LS, episode count, and PHQ-9) concomitant diseases and medications. RESULTS: A total of 367 patients were enrolled (n= 120 TBI, n =113 stroke, n= 134 dementia), 70.8% were receiving.1 psychiatric medication at baseline, most commonly antidepressants (48.5%), antipsychotics (18.0%), and sedatives/anxiolytics/hypnotics (33.8%). A total of 57.5% reported a depression diagnosis at baseline, including 61.7%, 50.4%, and 59.7% of the TBI, stllroke, and dementia populations, respectively; other reported CNS diagnoses included: anxiety disorders, 42.2% (50.0% TBI, 36.3% stroke, and 40.3% dementia, respectively); sleep disorders, 34.1% (40.8%, 29.2%, and 32.1%); cognitive impairment, 28.9% (25.8%, 18.6%, and 40.3%); headache disorder, 20.4% (37.5%, 15.9%, and 9.0%); seizures, 14.7% (17.5%, 16.8%, and 10.4%); post-traumatic stress disorder, 4.6% (13.3%, 0.9%, and 0.0%); Parkinson's disease, 5.2% (0.8%, 4.4%, 9.7%). The baseline mean PHQ-9 score was 13.5 (13.9, 13.4, and 13.2, respectively), suggesting moderate depression. CONCLUSIONS: Persons enrolling in this study of DM/Q for treatment of PBA subsequent to TBI, stroke, or dementia often had other CNS comorbidities, most commonly, depression and anxiety disorders. These findings underscore the importance of considering both neurologic and psychiatric causes in the differential diagnosis of affective symptoms such as uncontrollable laughing and crying. The fact that over 70% of our study population was already being treated for psychiatric comorbidity suggests that specific PBA treatment may still be required.

4802. Savar, A., et al. (2009). "Enucleation for open globe injury." American journal of ophthalmology **147**(4): 595-600.e591.

PURPOSE: To report the experience of enucleation after open globe at an ophthalmic trauma referral center., DESIGN: Retrospective, observational study., METHODS: In an ophthalmic trauma referral center the charts of all patients having suffered an open globe injury between January 1, 2000 and June 30, 2007 were reviewed. Variables assessed were age, gender, type of injury (rupture or laceration [penetrating, intraocular foreign body, or perforating]), ocular trauma score, visual acuity, subsequent enucleation, indication for and timing of enucleation, presence of sympathetic ophthalmia, and length of follow-up., RESULTS: Among 660 open globe injuries, 55 have undergone enucleation (including 4 eviscerations), 11 primarily and 44 secondarily. Eyes with ruptures were significantly more likely to be enucleated than those with injuries attributable to lacerations ($P < .001$). The most common reason for secondary enucleation was a blind, painful eye. Two patients (0.3%) developed sympathetic ophthalmia and have maintained good vision in the sympathizing eye., CONCLUSIONS: The vast majority of open globes can be repaired without requiring primary enucleation. Secondary enucleation is most commonly carried out for pain. Eyes with no light perception can be closely observed if the patient chooses.

4803. Savastio, G., et al. (1991). "[Cranial trauma: the predictability of the presentation symptoms as a screening for radiologic study]." Trauma cranico: predittivita dei sintomi di presentazione come screening per lo studio radiologico. **82**(6): 769-775.

A prospective study was performed on 4,262 consecutive patients who had had skull examinations for recent head trauma. Clinical signs and symptoms and patient history were correlated with skull fractures and intracranial sequelae as identified on CT studies, in order to evaluate the predictive value of each clinical finding and to identify high-yield referral criteria. Ninety-seven skull fractures (3%) and 32 intracranial sequelae (0.7%) were observed. All the intracranial complications were observed in patients with fractures and with altered consciousness of some degrees (Glasgow Coma Scale score less than 13). Most patients were asymptomatic (41%) or showed "low risk" symptoms (29%): among them, neither fractures nor complications were observed. High-risk clinical signs, mainly expressing basilar fractures (as rhinorrhea, otorrhea, focal neurologic signs, retroauricular hematoma) demonstrated high predictive value (100%) for intracranial sequelae. Other "moderate risk" findings for intracranial injury--i.e. loss of consciousness at any time, antegrade or retrograde amnesia, multiple trauma, and possible skull penetration--showed a high correlation with skull fractures and a slightly lower one with intracranial sequelae. The most predictive finding for brain injury was the depressed level of consciousness: brain injuries were never observed in fully conscious patients; in altered consciousness with GCS 15-13 we observed 4% of skull fractures with no sequelae; at GCS values 12-9, 61% of skull fractures and 20% of sequelae were present, whereas at GCS less than 8, 100% of complicated fracture were observed. The finding of skull fracture showed 33% of predictivity for brain damage, which was, however, always associated with "high or moderate risk" clinical signs. Therefore, the authors suggest some guidelines for the management of patients with recent head trauma, including referral criteria for X-rays or CT studies, based on signs and symptoms with high, intermediate and low risk of developing intracranial sequelae.

4804. Savin, I. A., et al. (2006). "[Transcutaneous dilation tracheostomy in the acute period in patients with penetrating craniofacial injury complicated by intracranial hypertension]." Anesteziologiia i reanimatologiia(6): 65-68.

Early tracheotomy is well founded in severe brain injury involving the facial skeleton and skull case. Intracranial hypertension interferes with the safe performance of an operation. The authors developed a procedure for safe paracentetic dilatation tracheostomy (PDT) in the acute phase of severe brain injury. The study covered 15 patients with severe brain craniofacial injury. Surgery was made under intravenous anesthesia (with hypnotics, myorelaxants, narcotic analgesics, and cholinolytic agents). PDT was performed by the combined procedure developed by Sigley and Griegse ("Portex and COOK") under endoscopic guidance (Karl Storz 11001 BN1), by displaying the images. The patient is put to bed, without placing a bolster under the shoulders, the bed head end being elevated at an angle of 30 degrees. Bronchoscopic monitoring was made discretely (20-60 sec) under artificial ventilation through a special connector. There were 3-6 sessions of bronchoscopies. Tracheostomy lasted as long as 24 hours in 5 patients, 48 hours in 12 patients; surgery was made in 7 patients on day 3 after injury. Prior to tracheostomy, a horizontalization test was conducted, which revealed an elevation of intracranial pressure (> or = 20 mm Hg). There were no episodes of intracranial hypertension during tracheostomy. PDT can be safely made in patients with intracranial hypertension when they are put

to bed, without placing a bolster under the shoulder, the bed head end being elevated at an angle of 30 degrees under discrete bronchoscopic guidance.

4805. Savioli, G., et al. (2021). "Major trauma in elderly patients: Worse mortality and outcomes in an Italian trauma center." Journal of Emergencies, Trauma and Shock **14**(2): 98-103.

Introduction: Major trauma is the leading cause of mortality in the world in patients younger than 40 years. However, the proportion of elderly people who suffer trauma has increased significantly. The purpose of this study is to assess the correlation of old age with mortality and other unfavorable outcomes. Methods: We assessed on one hand, anatomical criteria such as ISS values and the number of body regions affected, on the other hand, hemodynamic instability criteria, various shock indices, and Glasgow Coma Scale. Finally, we also evaluated biochemical parameters, such as lactate, BE, and pH values. We conducted a prospective and monocentric observational study of all the patients referred to the Emergency Department of the IRCCS Fondazione Policlinico S. Matteo in Pavia for major trauma in 13 consecutive months: January 1, 2018-January 30, 2019. We compared the elderly population (>75 years) and the younger population (≤75). Results: We included 501 patients, among which 10% were over the age of 75 years. The mortality rate was higher among the older patients than among the younger (4% vs. 1.33%; P = 0.050). Hemodynamic instability was more common in the older patients than in the younger (26% vs. 9%; P < 0.001). More older patients (44%) had an ISS >16, in comparison with 32% of younger patients (P = 0.01). Conclusions: The elderly showed worse outcomes in terms of mortality, hospitalization rate, hemodynamic instability criteria, and anatomical and biochemical parameters.

4806. Savitri, Q. M., et al. (2020). "Localized asymptomatic cerebellar abscess after penetrating brain injury by wooden foreign object with adequate antibiotics administration: A case report." International journal of surgery case reports **72**: 85-90.

INTRODUCTION: Brain abscess is a compilation of pus enclosed in capsule as a result of focal infection in brain parenchyma. It is one of several complications found in patients who suffered penetrating brain injury., CASE PRESENTATION: Thirty-four-year-old man suffered a penetrating brain injury after a 50 cm piece of wood penetrated through his facial skull and ended its tip in his cerebellum, the wood priorly ejected from a moulding machine. As a consequence, he had to undergo a craniotomy procedure to remove the foreign body object and its debris. Following the surgery, adequate antibiotics were administered. Postoperative enhanced head CT revealed a cystic mass formation in the left hemisphere of cerebellum, measured 20x28mm with blood density lesions and a visible ring enhancement. These features suggested a cerebellar abscess. The follow-up enhanced head CT later demonstrated that the size, shape, and location of the abscess were relatively consistent with the previous head CT., DISCUSSION: Penetrating brain injury (PBI) is the most life-threatening head trauma. Although the prevalence number was low compared to other head traumas, its morbidity and mortality number were higher. Brain abscess formation is one of the many PBI complications. Due to direct inoculation of foreign body and its debris, PBI commonly leads an infection process. However, the infection process is supposed to be overcome by administering broad-spectrum antibiotics prophylactically. This case presented an inevitable brain abscess despite of the adequate antibiotics administration., CONCLUSION: Despite adequate antibiotics has been administered, cerebellar abscess after penetrating brain injury is still found challenging to manage. Therefore, holistic-multidisciplinary approaches are needed.

4807. Sawatari, Y. and Y. Alshamrani (2019). "Concurrent hyoid bone fracture associated with multiple facial fractures secondary to assault: Case report and review of literature." Oral and Maxillofacial Surgery Cases **5**(4).

Introduction: Hyoid bone fractures are rarely reported as an isolated entity due to the infrequent occurrence accounting for only 0.002% of all head and neck fractures and 1.15 as the highest incidence. Strangulation remains the most common cause of isolated hyoid bone fractures with an incidence of 27–50%. However, blunt trauma, motor vehicle crash, sport related injuries, falls, assaults, and gunshot wounds are additional documented causes of hyoid bone fractures. Case report: A 23-year-old male who was assaulted to the face. He complained of pain to the face and neck, sore throat, dysphagia and changes in speech. The face and neck CT scans revealed multiple facial fractures along with a hyoid bone fracture. Patient was admitted to for observation and close monitoring for airway protection until the mandible and hyoid bone fractures were treated. ORIF of the mandibular fractures took place; we elected to treat the

hyoid bone fracture conservatively as it was asymptomatic. The patient's hospital course was unremarkable. Result: 56 articles were reviewed from 1949 to 2017, which revealed that isolated hyoid bone fractures and hyoid bone fractures associated with other facial fractures are very rare. Hyoid bone fractures due to direct trauma, road traffic accidents, falls, assault and gunshot wounds are more common in males than females. However, in strangulation and suicidal hanging, the incidence is higher in females than males. Multiple methods can be used to evaluate the hyoid bone fractures. The majority of hyoid bone fractures are treated conservatively

4808. Sawyer, O. and C. P. O'Boyle (2017). "Brain tumour presenting with burns: Case report and discussion." Burns : journal of the International Society for Burn Injuries **43**(3): e31-e32.

Descriptions of burns as the presenting features of underlying neurological pathology are very rare, with only two previously published case reports available. Both of these reports featured meningioma as the pre-existing pathology and both described burn excision and wound healing, prior to surgical tumour ablation. The authors describe the case of a 35-year-old female, who presented with 25% total body surface area burns and recent global neurological deterioration. MRI imaging revealed a large intracranial tumour. Multidisciplinary management included rigorous non-surgical burn wound care and early craniotomy and tumour excision. This proceeded without complication. Burn excision and skin grafting was carried out successfully, two weeks later. This case differs from the previous two reported cases, which both described burn excision, as a pre-requisite to neurosurgery. This case establishes that the presence of a burn wound is not a total contra-indication to intracranial surgery. Copyright © 2016. Published by Elsevier Ltd.

4809. Saydam, F. A., et al. (2014). "Foot ischemia after a free fibula flap harvest: immediate salvage with an interpositional sapheneous vein graft." The Journal of craniofacial surgery **25**(5): 1784-1786.

The most dreaded major donor-site complication of free fibula flap is a foot ischemia, which is fortunately rare. Various authors have discussed the efficacy of the use of preoperative imaging methods including color Doppler, magnetic resonance angiography, and conventional angiography. A 25-year-old man presented with a 10-cm mandibular defect after a facial gunshot injury. Lower extremity color Doppler revealed triphasic peroneal, tibialis anterior, and posterior artery flows. A fibula osteocutaneous flap was harvested, and the mandible was reconstructed. However, the suture sites at the donor site began to demonstrate signs of necrosis, abscess formation, and widespread cellulitis beginning from postoperative day 9. Angiogram of the lower extremity on the 13th day demonstrated no flow in the right posterior tibial artery distal to the popliteal artery, whereas the anterior tibial artery had weak flow with collateral filling distally. An emergency bypass with a saphenous vein graft between the popliteal artery and the distal posterior tibial artery was performed. Repeated debridements, local wound care, and vacuum-assisted closure were applied. A skin graft was placed eventually. The extremity healed without severe functional disability. In conclusion, although the arterial anatomy is completely normal in preoperative evaluation, vascular complications may still ocur at the donor fibula free flap site. In addition, emergency cardiovascular bypass surgery, as we experienced, may be necessary for limb perfusion.

4810. Sayer, N. A., et al. (2008). "Characteristics and rehabilitation outcomes among patients with blast and other injuries sustained during the Global War on Terror." Archives of physical medicine and rehabilitation **89**(1): 163-170.

OBJECTIVE: To describe characteristics and rehabilitation outcomes among patients who received inpatient rehabilitation for blast and other injuries sustained in Iraq and Afghanistan during the Global War on Terror., DESIGN: Observational study based on chart review and Department of Veterans Affairs (VA) administrative data., SETTING: The 4 VA polytrauma rehabilitation centers (PRCs)., PARTICIPANTS: Service members (N=188) admitted to a PRC during the first 4 years of the Global War on Terror for injuries sustained during Operation Iraqi Freedom or Operation Enduring Freedom., INTERVENTION: Multidisciplinary comprehensive rehabilitation program., MAIN OUTCOMES MEASURES: Cognitive and motor FIM instrument gain scores and length of stay (LOS)., RESULTS: Most war-injured patients had traumatic brain injury, injuries to several other body systems and organs, and associated pain. Fifty-six percent had blast-related injuries, and the pattern of injuries was unique among those with injuries secondary to blasts. Soft tissue, eye, oral and maxillofacial, otologic, penetrating brain injuries, symptoms of post-traumatic stress disorder, and auditory impairments were more common in blast-injured patients than in those with war injuries of other etiologies. The mechanism of the injury did not predict functional outcomes. LOS was variable, particularly for those with blast injuries. Patients with low levels of independence at admissions made the most progress but remained more dependent at

discharge compared with other PRC patients. The rate of gain was slower in this low-functioning group., CONCLUSIONS: Blasts produce a unique constellation of injuries but do not make a unique contribution to functional gain scores. Findings underscore the need for assessment and treatment of pain and mental health problems among patients with polytrauma and blast-related injuries. Patients with polytrauma have lifelong needs, and future research should examine needs over time after community re-entry.

4811. Sayhan, M. B., et al. (2011). "Skull base osteomyelitis in the emergency department: A case report." Emergency medicine international **2011**.

Skull base osteomyelitis (SBO) is a rare clinical presentation and usually occurs as a complication of trauma or sinusitis. A 5-year-old child presented to the emergency department with a three-week history of fever associated with drowsiness and left parietal headache, and a week's history of swelling on the left frontoparietal soft tissue. He had suffered a penetrating scalp injury four month ago. On physical examination, there was a tender swelling with purulent stream on the lateral half of his scalp. His vital signs are within normal limits. Plain X-ray of the skull showed a lytic lesion on the left frontoparietal bone. A cranial computed tomography (CT) scan demonstrated a large subgaleal abscess at the left frontoparietal region. SBO possesses a high morbidity and mortality; therefore, prompt diagnosis and appropriate treatment are mandatory to prevent further complications and to reduce morbidity and mortality significantly. © 2011 Mustafa Burak Sayhan et al.

4812. Scanzera, A. C., et al. (2022). "Open globe injuries from projectile impact: Initial presentation and outcomes." Indian journal of ophthalmology **70**(3): 860-864.

PURPOSE: To describe the characteristics and correlates of open globe injuries secondary to projectile injury and outcomes following surgical open globe repair at an urban tertiary referral center., METHODS: Records of all patients with a history of open globe injury secondary to projectile injury and surgical open globe at a tertiary referral hospital between January 1, 2010 and December 31, 2016 were reviewed. Demographics, type of trauma, wound extent, presence of foreign body, and presenting clinical findings are reported. Outcomes for patients with greater than 6 months of follow-up included additional surgeries, final visual acuity, and clinical findings., RESULTS: Of 214 patients who underwent open globe repair, 73 (34.1%) were due to projectile impact. Mean age was 37.9 years and patients were primarily male (n = 66, P < 0.001). Most injuries resulted in globe laceration (68.5%, P < 0.001), and wound extent was zone 1 (45.2%), zone 2 (20.5%), zone 3 (27.4%), or unknown (6.8%). Associated findings included foreign body (35.6%) and orbital fracture (15%). Of 41 patients with at least 6 months of follow-up, 70% had additional surgeries following their initial surgical repair. Laceration injuries tended to be more anterior (P = 0.002) with better visual outcomes (P = 0.045) than those with globe rupture, and concomitant orbital fracture associated with poor visual outcomes. Overall, 58.5% of patients had 20/40 or better final best-corrected visual acuity., CONCLUSION: This is the largest report of open globe injury due to projectile impact. Visual prognosis in this population is very good, with most patients achieving better than 20/40 vision in our study.

4813. Scaparra, E., et al. (2016). "Detection of blood aspiration in deadly head gunshots comparing postmortem computed tomography (PMCT) and autopsy." European journal of medical research **21**(1): 43.

BACKGROUND: The aim of our study was to analyze the reliability of postmortem computed tomography (PMCT) versus autopsy in detecting signs of blood aspiration in a distinct group of patients following deadly head, mouth or floor of mouth gunshot injuries., METHODS: In this study, in 41 cases PMCT was compared to autopsy reports, the gold standard of postmortem exams, regarding detection of blood aspiration. PMCT was evaluated for the presence and level of typical signs of blood aspiration in the major airways and lung using a semi-quantitative scale ranging from level 0 (no aspiration) to 3 (significant aspiration) also taking density values of the described potential aspiratory changes into account., RESULTS: Overall, in 29 (70.7%) of 41 enrolled cases PMCT and autopsy revealed the same level of aspiration. A difference of one level between PMCT and autopsy resulted for 5 (12.2%) of the remaining 12 cases. More than one level difference between both methods resulted for 7 cases (17.2%). Autopsy described no signs of aspiration in 10 cases, compared to 31 cases with reported blood aspiration. In contrast, PMCT revealed no signs of blood aspiration in 15 cases whereas 26 cases were rated as positive for signs of aspiration in the major airways. In 18 of these 26 cases considered positive for blood aspiration by autopsy and PMCT, clear signs of aspiration signs were also described bilaterally by both methods., CONCLUSIONS: The presented study provides evidence for the assumption that PMCT

seems to be helpful in the detection of blood aspiration in cases of deadly head gunshots. In conclusion, it seems reasonable to suggest performing PMCT additionally to traditional postmortem exams in cases of suspected aspiration to rule out false-negative cases and to possibly allow for a more detailed and rather evidence based examination reconnoitering the cause of death. However, the adequate use of PMCT in this context needs further evaluation and the definition of an objective scale for aspiration detection on PMCT needs to be established in future studies.

4814. Scarfo, G. B., et al. (1990). "Oculocerebral perforating trauma by foreign objects: diagnosis and surgery." Journal of neurosurgical sciences **34**(2): 111-116.

Two unusual cases of perforating oculocerebral trauma by foreign bodies treated surgically are reported. Both were caused by industrial accidents. In the first a nail shot from a nail gun ricocheted off the target and crossed the right eyeball and the posterior wall of the orbit, lodging in the homolateral temporal lobe. In the second case a metal fragment expelled by an agricultural machine penetrated the left maxillary sinus, crossed the floor of the orbit, the eyeball and the roof of the orbit and lodged in the homolateral frontal lobe. After accurate neuroradiological examination the patients were operated using simultaneous transcranial and transorbital access. In our opinion this is the only approach which can minimize the risk of infection which is so dangerous in this type of trauma. The functional and aesthetic results, which were very satisfactory in both cases, seem to confirm the correctness of this approach.

4815. Scarpino, M., et al. (2017). "Predictive patterns of sensory evoked potentials in comatose brain injured patients evolving to brain death." Neurophysiologie clinique = Clinical neurophysiology **47**(1): 19-29.

OBJECTIVE: To assess whether Somatosensory Evoked Potentials (SEPs), recorded within 24h after ICU admission, are reliable predictors of brain death (BD) in comatose patients with acquired brain injury of various aetiologies., METHODS: SEPs were classified as absent (A), pathological (P), and normal (N). Considering SEP recordings from both hemispheres, 6 patterns were identified: NN, NP, PP, NA, AP, and AA. The final endpoint was BD., RESULTS: Of the 203 patients included in the study, 70 (34%) evolved toward BD. The survival analysis indicated that the combination of SEP patterns in a two-graded scale (grade 1: NN-NP-PP-NA, and grade 2: AP-AA), allowed for prediction of BD with the best accuracy. This aggregation predicted BD with a sensitivity of 75.7% (CI: 64-84), a specificity of 76.6% (CI: 68-83), a positive predictive value of 64.2% (CI: 53-74) and a negative predictive value of 84.3% (CI: 77-90) in overall patients, and with a sensitivity of 75.0% (CI: 63-84), a specificity of 84.9% (CI: 75-90), a positive predictive value of 77.5% (CI: 63-88) and a negative predictive value of 84.3% (CI: 74-91) when excluding cardiac arrest., CONCLUSION: It is worth including SEPs, in association with other investigations and clinical signs, in prognostic scores of BD. The early identification of patients at high risk of evolving towards BD could help physicians to optimise management.

4819. Schargus, M., et al. (2014). "[Management of suicidal orbital gunshot wounds to the temple]." Management suizidaler orbitaler Schlafen-Schussverletzungen. **111**(10): 965-969.

BACKGROUND: Orbital gunshot wounds are rarely found after suicide. A gunshot fired at point blank range into the temple has devastating effects on all intraorbital and neighboring structures., CASE REPORTS: This article reports on two cases of gunshot wounds to the lateral orbit in attempted suicides with different weapons from 2012 and 2013 and treated at the Ruhr University Eye Hospital in Bochum. In both cases treatment was carried out in cooperation with the department of oral and maxillofacial surgery, Ruhr University Hospital, Bochum. In the first case a 7.65 mm gun was used. The patient presented with a double penetration of both orbits with total destruction of both globes and a reconstruction was not possible. The second patient presented with multiple shots to the head from a small caliber gun (5.6 mm) where one bullet entered the right orbit behind the globe. The bullet could be localized using computed tomography (CT) and surgically removed with preservation of the globe and with a postoperative visual acuity of 20/60., CONCLUSION: The preservation of visual function after orbital gunshot wounds depends on both the projectile channel and the characteristics of the gun and bullet. Close collaboration in surgical management between ophthalmologists, maxillofacial surgeons and neurosurgeons in specialized centers is necessary because patients often present with multiple trauma and prompt interdisciplinary treatment is needed.

4820. Schauer, S. G., et al. (2019). "A descriptive analysis of casualties evacuated from the Africa area of operations." African Journal of Emergency Medicine **9**: S43-S46.

Introduction: The United States (US) military has expanded its area of operations into Africa. This medically immature theater is spread across a large region where prolonged field care (PFC) events are likely to occur. We describe trauma cases reported in the Africa Command (AFRICOM) area of operations to date within the Department of Defense Trauma Registry (DODTR). Methods: We queried the DODTR for all subjects evacuated from the AFRICOM area of operations from January 2002 to June 2017. Results: There were 49 subjects in the registry during our time frame from AFRICOM. Most of the evacuations came from Djibouti (53%). The median age was 29 years, most evacuees being male (92%). Non-battle injuries accounted for most of the injuries (82%), and most were US military (90%). All battle injuries were gunshot wounds (GSW). Composite injury scores were low (median 4, IQR 4–9.5). All subjects survived to hospital discharge. GSWs (22%) and sports injuries (24%) accounted for most evacuations. Serious injuries most frequently involved the extremities (18%) and the thorax (12%). The most frequent major injuries were open fractures (22%) and abdominal injuries (10%). The most frequent facility-based interventions performed were wound debridement (29%) and fracture/joint dislocation reduction (22%). Discussion: Based on this dataset, most of the injuries from AFRICOM were non-battle injuries. All battle injuries were GSWs. Our study highlights the differences in casualty care needs in this region which contrast the primary explosive-based injuries seen within United States Central Command (CENTCOM) operations. The limitations of this dataset highlight the potential value of a Joint Trauma Service (JTS) data collection mandate and resource support for units within this region to facilitate targeted improvements in medical care.

4821. Schauer, S. G., et al. (2015). "Multicenter, prospective study of out-of-hospital administration of analgesia in the combat theater in Afghanistan." Annals of emergency medicine **66**(4): S32-S33.

Study Objective: Early administration of analgesia has been reported to decrease morbidity after combat injuries. Currently limited data exists on analgesia administration practices in the out-of-hospital combat setting. In a previous study we reported the rate and type of analgesia in a out-of-hospital combat setting. However, that study was small, not stratified based on Injury Severity Score (ISS), injury pattern, or Glasgow Coma Scale (GCS), or report 30-day outcomes. In this study our goal was to determine whether these factors influence analgesia administration and 30-day outcomes in a large cohort. Methods: In this IRB-approved study, we collected life-saving interventions (LSIs) performed on patients who arrived to 6 combat hospitals from the field, treated by any provider type, and of any nationality. Military special interest patients were excluded. Trained site investigators evaluated patients on arrival and recorded demographics, vital signs, LSIs performed out-of-hospital, and analgesia administration. The agent, route and dose were documented. ISS of <=15 was mild and greater than 15 severe. For statistical analysis we compared the incidence with chi-square or Fisher's exact tests where appropriate. Shapiro-Wilks tests for normality were used. Wilcoxon and Kruskal-Wallis tests were used for non-parametric continuous variables. Percentages and frequencies are reported. $P < .05$ was significant. Results: Five hundred thirty-two patients were included-average age 27 years, 99% male, 40% US or coalition forces. Most procedures were performed by medics. We found no association between ISS score and administration of

analgesic agents. 71% of patients received analgesic agents (541 total administrations): ketamine 36%, fentanyl 30%, morphine 25%, hydromorphone 4%, acetaminophen 2%, ketorolac 2%, oxycodone <1%, and ibuprofen <1%. Those who received analgesics were more likely to have had a penetrating injury (89% vs 79%, P = .0057) and less likely to have a blast injury (87% vs 80%, P = .0394) or burn injury (84% vs 58%, P = .0372). Fentanyl was more likely to be administered for ISS >15 (P = .016). Ketamine was less likely to be given for suspected brain injury (P = .001). Injuries involving the chest and/or abdomen were more likely to receive an analgesic agent (P = .04). However, there was no association between the analgesic agent given and anatomical location of injuries. Our outcomes through 30 days post-injury were death 4%, receiving on-going treatment 75%, discharged home 17%, and unknown 4%. Those who received analgesics were more likely to be in continued medical care at 30 days post injury (87% vs 72%, P = .03). Conclusions: In our out-of-hospital study in the combat theater, we found no association between injury severity score and administration of analgesia. When injuries were more severe fentanyl was more likely to be given. In addition, those who received analgesics were more likely to have sustained a penetrating injury and require on-going care at 30 days. Ketamine was less likely to be used in patients with brain injury.

4822. Schellenberg, M., et al. (2022). "Penetrating injuries to the vertebral artery: interventions and outcomes from US Trauma Centers." European journal of trauma and emergency surgery : official publication of the European Trauma Society **48**(1): 481-488.

PURPOSE: Penetrating injuries to the vertebral artery are rare and incompletely studied. Operative, angioembolic, and nonoperative strategies are management options, although the association between management strategy and outcomes is unknown. This study endeavored to define the epidemiology, management strategy, and outcomes after penetrating injuries to the vertebral artery presenting to trauma centers nationwide., METHODS: Patients with veterbral artery injuries were identified from the National Trauma Data Bank (NTDB) (2016-2017) using ICD-10-CM codes. Only those with penetrating mechanisms of injury were included in the study. Transferred patients were excluded. Study groups were defined by management strategy (Operative management, OM; angioembolization, AE; and nonoperative management, NOM). Patient demographics, injury characteristics, and outcomes were compared between groups using univariate analysis. Multivariate analysis with logistic regression was used to examine independent risk factors for mortality and stroke., RESULTS: Penetrating injuries to the vertebral artery were rare (n = 476, < 1% of NTDB patient population). Median age was 28 [IQR 21-37] years and 81% (n = 385) of patients were male. Interpersonal violence was the most common injury intent (n = 374, 79%). Most patients were managed with NOM (n = 409, 86%), with AE and OM utilized less frequently (8% and 6%, respectively). Stab wounds were the most frequent mechanism of injury among patients managed with OM (62%), while gunshot wounds were most common among patients managed with NOM (84%) or AE (79%). Multivariate analysis of risk factors for stroke revealed only associated carotid artery injury (OR 4.236, 95% CI 1.284-13.970, p = 0.018) and AE (OR 6.342, 95% CI 1.417-28.399, p = 0.016) were independent predictors. Independent risk factors for mortality were advanced age (OR 1.026, 95% CI 1.001-1.052, p = 0.044); elevated ISS (OR 1.030, 95% CI 1.008-1.052, p = 0.006); and associated traumatic brain injury (OR 3.020, 95% CI 1.333-6.843, p = 0.008). Higher ED GCS was independently associated with reduced mortality (OR 0.788, 95% CI 0.731-0.849, p < 0.001)., CONCLUSIONS: Vertebral artery injuries after penetrating mechanisms are infrequent in the United States. Patients with these injuries tend to be young adult men who were injured by gunshot wounds as a result of interpersonal violence. The majority of these injuries were managed nonoperatively, with operative intervention required most commonly for patients injured by stab wounds. Risk factors for both stroke and mortality were principally due to patient factors and associated injuries. Increased risk of stroke among patients managed with angioembolization will need to be further investigated with future study to determine if this risk is imparted from the management strategy itself or from underlying injury characteristics.

4823. Scherer, L. R., 3rd (1995). "Diagnostic imaging in pediatric trauma." Seminars in pediatric surgery **4**(2): 100-108.

In the management of the critically injured pediatric trauma patient, the diagnostic armamentarium of the clinician includes a number of radiographic procedures to assist in determining the life-threatening and disabling injuries of the young patient. This article reviews the emergent and definitive systems radiographs helpful in diagnosing blunt and penetrating injuries. The clinician is provided a stepwise systematic process of evaluating life-threatening and complicated injuries of the head, thorax, abdomen, pelvis, and extremities.

4824. Schibilsky, D., et al. (2015). "Traumatic tracheobronchial injuries-incidence and outcome among 68.216 trauma patients derived from the traumaregister DGU®." Thoracic and Cardiovascular Surgeon **63**.

Objectives: Acute tracheobronchial injuries (TBI) resulting from blunt or penetrating trauma are rare, but potential life-threatening trauma sequelae. Up to now the incidence and mortality of these injuries are not well described. The aim of this study was to assess the incidence and outcome of traumatic TBI within the last decade. Methods: We performed a retrospective analysis of all trauma patients included in the TraumaRegisterDGU® between 2002 and 2012 who were 16 years or older and had an ISS (Injury Severity Score) ≥9. Results: Among 68.216 analyzed trauma patients, 238 had evidence of tracheobronchial injuries (0,3%). Those Patients were predominately male (73.8%) and had a mean age of 37.1 years and suffered from blunt trauma in 89.3% mainly caused by accidents (77.9%). Mortality rates were 21.4% in patients with an AIS = 2 and 53.3% in patients with an AIS = 5, respectively. Most patients died within the first 24 hours (71.6%), whereas in patients with an AIS = 5 35.5% died already within the first 6 hours after hospital admission. Patients demanding operation within the first 24h showed high mortality rates (AIS4: 46,7%, AIS5: 40%). The overall mortality of patients with TBI was 27.5% and therefore nearly doubled the control group (14% overall mortality rate). Conclusion: The Incidence of TBI in this large cohort of trauma patients is very low. However, the affected young and predominantly male patients showing a high mortality reaching nearly double numbers of the control group. The mortality was associated with higher AIS-Score and the need for operation within the first 24h.

4825. Schick, U. and W. Hassler (2003). "Late hydrocephalus in a case of wandering bullet into the pineal region." Acta neurochirurgica **145**(1): 79-81.

We report a patient in whom a bullet in the brain migrated into the pineal region causing hydrocephalus 3 months later. In patients undergoing surgical removal of intracerebral or intraventricular bullets, it is recommended to obtain an x-ray or CT scan on the day of operation. Late hydrocephalus may occur several months after migration of the bullet due to scar tissue.

4826. Schiffer, D., et al. (1991). "Relationship between glial reaction to a stab wound and tumor development after receiving transplacental ethylnitrosourea in the rat." Acta neuropathologica **83**(1): 30-38.

Fisher 344 rats born from mothers treated with ethylnitrosourea (ENU) 50 mg/kg intravenously were injured at the 1st and 2nd month of extrauterine life by a transcranial stab. The wound affected cerebral cortex, white matter and basal ganglia. The animals were killed 15 and 45 days and 5 months after injury and cell reaction was studied histologically and immunohistochemically. Bromodeoxyuridine (BrdUrd) was administered 1 h before sacrifice and the labeled cells were evaluated. In ENU-treated rats injured at 1 month of age only minor differences were found in comparison with injured controls. In ENU rats injured at 2 months of age and killed 15 days later, a higher number of BrdUrd-labeled cells was found in comparison with controls; 45 days after injury the cell reaction acquired the aspect of a microtumor, however, no microtumor unrelated with the needle track was present. In ENU rats killed 5 months after the injury, there was no difference between injured and not injured ENU-treated rats, as far as the aspect and the number of tumors were concerned. The tumor phenotype was, thus, anticipated by the cell response to trauma in ENU rats. The interpretation is that the additional cell division, in response to trauma, anticipate not only the phenotypic, but also the cell kinetics changes, as indicated by BrdUrd labeling.

4827. Schiffer, J., et al. (1985). "Posttraumatic meningioma." Neurosurgery **17**(1): 84-87.

This report concerns three patients with intracranial meningioma developing at the site of an old head injury with skull fracture. These cases, along with literature reports, suggest a causal relationship between head trauma and the subsequent development of meningioma.

4828. Schindler, C. R., et al. (2021). "Influence of Antibiotic Management on Microbial Selection and Infectious Complications After Trauma." Frontiers in medicine **8**.

Background: The inflammatory response and post-traumatic complications like infections play an important role in the pathophysiology of severe injuries. This study examines the microbiological aspects in anti-infective treatment of trauma patients and their inflammatory response in post-traumatic infections complications. Patients and Methods: A

retrospective analysis of prospectively collected data in trauma patients (ISS ≥ 16) over a 1-year period (01/2018 to 12/2018) is provided. Patient population was stratified into severely injured patients without post-traumatic infection (inf-PT), and severely injured patients who developed an infection (inf+PT). Results: Of 114 trauma patients, 45 suffered from post-traumatic infection during the first 10 days of hospitalization. Severely injured patients with concomitant traumatic brain injury (PT+TBI) showed the highest rate of post-traumatic infection. Pro-inflammatory reaction was tracked by levels of Interleukin (IL-)6 (day 3: inf+T 190.8 ± 359.4 pg/dL > inf-PT 56.2 ± 57.7 pg/mL (mean ± SD); p = 0.008) and C-Reactive-Protein (CRP, day 3: inf+PT 15.3 mg/dL > inf-PT 6.7 mg/dL, p = 0.001) which were significantly higher in trauma patients who develop an infectious complication and showed a significant positive correlation with the occurrence of infection. The leading entity of infection was pneumonia followed by infections of the urinary tract mainly caused by gram-negative Enterobacteriaceae. 67.5% of all trauma patients received single-shot antibiosis during initial care in trauma bay. The development of secondary colonization was not relevant positively correlated with single-shot antibiosis (r = 0.013, p = 0.895) and prophylactically calculated antibiotic administration (r = 0.066, p = 0.500). Conclusion: Severely injured trauma patients have an increased risk for development of infectious complications, which mainly is pneumonia followed by infection of the urinary tract mainly caused by gram-negative Enterobacteriaceae. Based on the data in this study, the one-time antibiotic and prophylactic calculated use of antibiotics, like Cephalosporins must be critically discussed in terms of their role in the development of post-traumatic infections and microbial selection.

4829. Schintu, S., et al. (2014). "Object and space perception - is it a matter of hemisphere?" Cortex; a journal devoted to the study of the nervous system and behavior **57**: 244-253.

In the 1980s, following Newcombe's observations, Ungerleider and Mishkin put forward the functional subdivision of the visual system into a ventral stream dedicated to object perception and a dorsal stream dedicated to space perception. Ten years after this discovery, the perception-action model re-defined the dorsal stream as responsible for non-conscious visual guidance, and most recently a tripartition has been suggested to account for a variety of visuospatial functions. Here, we investigated the neural underpinnings of object and space perception by combining the administration of the Visual Object Space Perception (VOSP) battery with a voxel-based lesion symptom mapping (VLSM) approach in a large sample of patients with penetrating traumatic brain injury (pTBI). First, our results provided new support for the complementary role of both hemispheres in object recognition. The right lateral occipital complex was found to be critical in early perceptual discrimination, whereas more anterior temporal and frontal regions in the left hemisphere were found to be critical in more complex forms of object discrimination and recognition. Second, our findings confirmed that space perception depended on the integrity of the right inferior parietal lobule (IPL) and revealed that a network linking the right IPL with the right premotor cortex was critical for the perception of spatial relationships in both 2D and 3D representations. Taken together, our results supported the functional subdivision of the visual system and shed new light on the specific processes involved along both the dorsal and the ventral streams.

4830. Schlag, H., et al. (2021). "Rupture of the Superior Sagittal Sinus in Penetrating Head Injury-Management of a Rare Trauma Mechanism." Journal of neurological surgery reports **83**(1): E3-E7.

Civilian penetrating head injury caused by foreign objects is rare in Germany (Europe), but can result in complex neurovascular damage. We report on a patient who in suicidal intent inflicted on himself a penetrating brain injury near the vertex with a captive bolt gun. A laceration at the junction of the middle to the posterior third of the superior sinus occurred by bolt and bone fragments leading to critical stenosis and subsequent thrombosis. Upon surgery, the proximal and distal sinus openings were completely thrombosed. The sinus laceration was closed by suture and the intraparenchymal bone fragments were retrieved. Postoperative angiography disclosed persistent occlusion of the superior sagittal sinus. The patient did not develop any symptoms due to venous congestion (edema, hemorrhage), suggesting sufficient collateral venous outflow. The patient completely recovered despite the complexity of the lesion.

4831. Schliamser, S. E., et al. (1988). "Intracranial abscesses in adults: an analysis of 54 consecutive cases." Scandinavian journal of infectious diseases **20**(1): 1-9.

A retrospective analysis was performed of 54 consecutive adult patients with intracranial abscesses hospitalized between 1973 and 1985. Clinical signs and symptoms were varying and no single symptom was found in more than 48%

of the patients. Also the laboratory findings were of limited diagnostic value. The etiology of the infections varied with the sources and could be identified in 42 of the patients. In patients with postoperative abscesses or infections after penetrating head injuries Staphylococcus aureus was the most commonly found causative agent. In patients with abscesses originating from sinus, dental or otogenic infections, anaerobic bacteria dominated and most patients had multiple bacterial isolates. A majority of patients (33/47) with diagnosed abscesses were treated with both surgical drainage and systemic antibiotics. 14 patients received antibiotics only, due to inoperable abscesses or spontaneous regression without surgery. 17 of the patients (31.5%) died from their intracranial infections and only 9 survived without sequelae. Important prognostic factors were missed diagnosis and presence of multiple or ruptured abscesses. One patient died of acute brain stem herniation after lumbar puncture, a procedure which was found to be of limited diagnostic value and which seems to be contraindicated in patients with intracranial abscesses.

4832. Schlosser, R. J. and W. E. Bolger (2002). "Traumatic cerebrospinal fluid rhinorrhea." Operative Techniques in Otolaryngology - Head and Neck Surgery **13**(4): 302-308.

Improved instrumentation and imaging for paranasal sinus and skull base surgery has led to minimally invasive endoscopic extracranial techniques to repair cerebrospinal fluid (CSF) leaks. Endoscopic repair has a higher success rate (approximately 90%) and lower morbidity than do traditional intracranial techniques for most defects and has become the standard of care.1-4 CSF leak can occur from a variety of traumatic causes. Blunt trauma from motor vehicle or industrial accident, gunshot wounds, and surgical trauma can impart a CSF leak. Each confers a typical pattern of injury with special management issues. Trauma is a frequent cause of CSF leak that the general otolaryngologist will encounter in clinical practice. This article will review the pre-, intra-, and postoperative management issues needed to care for patients with CSF leak resulting from trauma.

4833. Schmidt, P., et al. (2002). "[Practical application of the Injury Severity Score (ISS) in expert forensic testimony]." Zur praktischen Anwendung des Injury Severity Scores (ISS) in der forensischen Begutachtung. **210**(5-6): 172-177.

The retrospective analysis of the autopsy records of 50 homicides showed that the Injury Severity Score (ISS), a numerical scoring system initially developed to quantify the severity of injuries sustained in road traffic accidents, can also be useful for objectively describing and ranking the overall severity of trauma with regard to forensic issues. The present case report illustrates to what extent the ISS can help to assess the contribution of each assailant in homicides committed by several perpetrators. In the case presented the court was convinced that one perpetrator had inflicted four deep stab wounds to the victim's face (each with bony lesions), 2 stabs to the chest piercing the right lower pulmonary lobe and causing a haemothorax of 200 ml, an abdominal stab wound without involvement of a parenchymatous organ as well as multiple defence wounds of the arms. Thereafter, a second perpetrator was thought to have inflicted several heavy blows with a full water bottle causing severe contusions on the right side of the forehead, the chin, the left side of the face and a spider's web fracture of the frontal bone. Using the ISS an injury severity score of 24 was assigned to the first complex of injuries and a score of 10 to the second complex. The forensic conclusions with regard to prognosis and lethal outcome are discussed.

4834. Schmidt-Matthiesen, A., et al. (1999). "A prospective, randomised comparison of single- vs. multiple-dose antibiotic prophylaxis in penetrating trauma." Chemotherapy **45**(5): 380.

This study was designed to compare the clinical efficacy of a single dose of ceftriaxone with cefoxitin given 3 times a day for 3 days., METHODS: Patients had to have a penetrating injury to only one part of the body, reach the hospital within 2 h and be operated on within 16 h after the trauma. Patients were excluded if it appeared likely that they would require mechanical ventilation for more than 24 h. The same applies to open or grade II/III craniocerebral trauma. The end point was the occurrence of infections within 10 days. The costs of antibiotic treatment were also calculated., RESULTS: 96% of the ceftriaxone patients (n = 97) and 95% of the cefoxitin group (n = 98) remained infection-free. In neither treatment group was deep infection, abscess, phlegmon or sepsis seen. No additional surgery or intensive care due to infection was required. At $41.83 vs. $172.16, the average total cost of delivering antibiotic treatment was significantly lower in the ceftriaxone group ($p < 0.001$)., CONCLUSION: Prophylaxis in penetrating trauma with a single dose of ceftriaxone is safe and has considerable practical and economic advantages.

4835. Schmidt-Matthiesen, A., et al. (1999). "A prospective, randomised comparison of single- vs. multiple-dose antibiotic prophylaxis in penetrating trauma." Chemotherapy **45**(5): 380-391.

UNLABELLED: This study was designed to compare the clinical efficacy of a single dose of ceftriaxone with cefoxitin given 3 times a day for 3 days., METHODS: Patients had to have a penetrating injury to only one part of the body, reach the hospital within 2 h and be operated on within 16 h after the trauma. Patients were excluded if it appeared likely that they would require mechanical ventilation for more than 24 h. The same applies to open or grade II/III craniocerebral trauma. The end point was the occurrence of infections within 10 days. The costs of antibiotic treatment were also calculated., RESULTS: 96% of the ceftriaxone patients (n = 97) and 95% of the cefoxitin group (n = 98) remained infection-free. In neither treatment group was deep infection, abscess, phlegmon or sepsis seen. No additional surgery or intensive care due to infection was required. At $41.83 vs. $172.16, the average total cost of delivering antibiotic treatment was significantly lower in the ceftriaxone group ($p < 0.001$)., CONCLUSION: Prophylaxis in penetrating trauma with a single dose of ceftriaxone is safe and has considerable practical and economic advantages.

4837. Schmitt, H. P. (1983). "[Trauma and tumor: malignant glioma in the area of a traumatic lesion of the brain with metal scales]." Trauma und Tumor: malignes Gliom nach Stecksplitterverletzung des Gehirns. **51**(6): 227-231.

Report of a 75 year-old male who sustained severe head injury by shell splinters during the second world war. 38 years later he died due to a malignant glioma which was localized exactly in the left and right frontal areas damaged by the shell. Multiple metal scales were still localized within these areas and the glioma. The reasons for the presumption of a causal relation between the trauma and the tumor will be discussed.

4838. Schmutz, B., et al. (2014). "Magnetic resonance imaging: an accurate, radiation-free, alternative to computed tomography for the primary imaging and three-dimensional reconstruction of the bony orbit." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **72**(3): 611-618.

PURPOSE: To determine the extent to which the accuracy of magnetic resonance imaging (MRI) based virtual 3-dimensional (3D) models of the intact orbit can approach that of the gold standard, computed tomography (CT) based models. The goal was to determine whether MRI is a viable alternative to CT scans in patients with isolated orbital fractures and penetrating eye injuries, pediatric patients, and patients requiring multiple scans in whom radiation exposure is ideally limited., MATERIALS AND METHODS: Patients who presented with unilateral orbital fractures to the Royal Brisbane and Women's Hospital from March 2011 to March 2012 were recruited to participate in this cross-sectional study. The primary predictor variable was the imaging technique (MRI vs CT). The outcome measurements were orbital volume (primary outcome) and geometric intraorbital surface deviations (secondary outcome) between the MRI- and CT-based 3D models., RESULTS: Eleven subjects (9 male) were enrolled. The patients' mean age was 30 years. On average, the MRI models underestimated the orbital volume of the CT models by 0.50 +/- 0.19 cm(3). The average intraorbital surface deviation between the MRI and CT models was 0.34 +/- 0.32 mm, with 78 +/- 2.7% of the surface within a tolerance of +/-0.5 mm., CONCLUSIONS: The volumetric differences of the MRI models are comparable to reported results from CT models. The intraorbital MRI surface deviations are smaller than the accepted tolerance for orbital surgical reconstructions. Therefore, the authors believe that MRI is an accurate radiation-free alternative to CT for the primary imaging and 3D reconstruction of the bony orbit.

4839. Schneider, R. A., et al. (2007). "20 years of experience in static intensity-modulated total-body irradiation and lung toxicity. Results in 257 consecutive patients." Strahlentherapie und Onkologie : Organ der Deutschen Rontgengesellschaft ... [et al] **183**(10): 545-551.

PURPOSE: To analyze lung complications after allogeneic or autologous transplantation following total-body irradiation (TBI) with compensators, so-called sIMRT (static intensity-modulated radiotherapy)., PATIENTS AND METHODS: Between 1983 and 1998, 257 patients with different hematologic malignancies underwent TBI in six fractions

to a total dose of 12 Gy within 3 consecutive days (212 with 11 Gy lung dose) prior to allogeneic (n=174) or autologous (n=83) transplantation. 40 patients were <16 years of age. Minimum follow-up time was 5 years. Median follow-up period was 110 months (13-231 months)., RESULTS: 5-year survival rate was 47.9%, 5-year tumor-related mortality 23%, 5-year treatment-related mortality 29.2% (12 Gy lung dose: 53.3%+/-14.6%, 11 Gy: 24.1%+/-5.7%). Interstitial pneumonitis (IP) developed in 28 of 257 patients (10.9% +/- 3.8%). IP incidences in the allogeneic and autologous groups were 14.4% (+/-5.6%) and 3.6% (0-7.6%), respectively. IP incidences with 12/11 Gy lung dose were 22% (+/-12%)/8.5% (+/-3.7%). IP mortality was 9.3% (+/-3.6%). 13 of 28 patients with IP had a cytomegalovirus infection, five an acute graft-versus-host disease grade IV of the lungs. IP incidences with 12/11 Gy lung dose were 25% (9-50%)/4.2% (0.2-19.1%) in patients <16 years, and 20.7% (9.4-37.4%) and 13.3% (+/-6.5%) in older patients after allogeneic transplantation., CONCLUSION: Compensator-generated static intensity-modulated TBI with a total dose of 12 Gy and a lung dose of 11 Gy is a modern and comfortable treatment with moderate lung toxicity, small dose inhomogeneities and little setup failure before transplantation. Especially patients <16 years of age benefit from lung dose reduction.

4840. Schneider, R. C., et al. (1972). "Blood vessel trauma following head and neck injuries." Clinical neurosurgery **19**: 312-354.

4841. Schneider, V. and H. Bratzke (1983). "[Malignant hyperthermia following an old gunshot head injury]." Maligne Hyperthermie nach alter Kopfschussverletzung. **90**(1): 71-80.

A case of symptomatic malignant hyperthermia is reported involving a 35-year-old man who suffered a serious cerebral injury after a gunshot to the head and who died from hyperthermia (41.5 degrees C) and tachycardia 1.5 days after dental treatment under general anesthesia. The sceletal muscles did not show any changes that would indicate a myopathy, the CPL value was normal, there was also no familial factor in this case. It is taken as an opportunity here to point out that such a case must not end fatally since there is a drug on the market in the meantime (Dantrolen) which is to be administered i.v. This medication acts causally on the membrane disturbances (release of calcium ions by appropriate trigger substances) which are the underlying cause of the malignant hyperthermia.

4842. Schnieders, J., et al. (2012). "Factors contributing to chronic fatigue after traumatic brain injury." The Journal of head trauma rehabilitation **27**(6): 404-412.

BACKGROUND: The annual incidence of traumatic brain injury in Europe amounts to 235 per 100 000 persons. About two-thirds will develop posttraumatic brain injury chronic fatigue (pTBI-CF)., AIM: To identify the reversible hormonal and nonhormonal causes of pTBI-CF., PATIENTS AND METHODS: Ninety patients with varying degrees of pTBI-CF underwent endocrine testing and an evaluation of sleep, attention, coping style, daily activity and dependency, physical performance, emotional well-being, and quality of life., RESULTS: Vitamin D deficiency was found in 65%, poor sleep quality in 54%, anxiety disorders in 36%, growth hormone deficiency in 16%, and gonadal hormone deficiencies in 9%. Fatigue severity was correlated with poor sleep ($R = +0.65$, $P < .0001$), serum 25-hydroxy vitamin D levels ($R = -0.50$, $P < .0001$), and anxiety ($R = +0.50$, $P < .0001$) but not with growth hormone deficiency or gonadal hormone deficiencies. The first 3 factors together explained 59% of the fatigue score variance., CONCLUSIONS: Poor sleep, vitamin D deficiency, and anxiety were the most important factors associated with pTBI-CF. Appropriate treatment of these disorders may help to reduce fatigue in these patients.

4843. Schober, M., et al. (2022). "EFFECTS OF DOCOSAHEXAENOIC ACID AND SEX ON EX VIVO PHAGOCYTIC CAPACITY AND OXIDATIVE POTENTIAL OF MICROGLIA AND MACROPHAGES IN RAT PUP BRAIN AFTER CONTROLLED CORTICAL IMPACT." Journal of neurotrauma **39**(11-12): A41.

Inflammation and oxidative stress adversely affect pediatric traumatic brain injury (pTBI). In our rat pup pTBI model using controlled cortical impact (CCI) Docosahexaenoic Acid (DHA) decreased microglial inflammatory markers, oxidative stress and adverse outcomes. Whether DHA affects microglial phagocytic capacity and oxidative potential after TBI in either sex is unknown. We hypothesized that CCI increases ex vivo phagocytosis and oxidative potential of microglia (mμ) and macrophages (MO) at Post Injury Day (PID) 1, 3 and 7, blunted by DHA and female sex. 17 day old male/ female rats received CCI/- SHAM followed by vehicle/ DHA.We sorted rat brain cells into CD11b +/CD45 hi/lo (MO/mμ) and CD11b(-)(NEGS, mainly neurons and astrocytes) after exposure to fluorescent beads or DHR123 to assess

phagocytic capacity and oxidative potential and assayed using Image- Stream® and flow cytometry. At PID1, CCI increased microglial phagocytic capacity relative to control (47±1.4 vs 29±1.4 % positive cells, p < 0.0001). Interestingly, microglia showed greater beads/cell than other CD11b+ cells. CCI increased oxidative potential in MO (25±4.2 vs 2.9±0.6% positive cells p = 0.003) and in an "intermediate" population we unexpectedly found at PID1 (not at 3 nor 7: CD11b+/CD45int) relative to controls (25±3.4 vs 3.4±0.6, p = 0.003). By histology and cytospin, these cells are not neutrophils but MO and monocytes. We report novel, ex vivo, functional assays of inflammation in the developing brain after TBI. We anticipate that DHA and female sex will blunt injury at PID 7 and PID1. We speculate that intermediates are blood monocytes that enter the brain transiently after CCI.

4844. Schoeneberg, C., et al. (2013). "Gender-specific differences in severely injured patients between 2002 and 2011: data analysis with matched-pair analysis." Critical care (London, England) **17**(6): R277.

INTRODUCTION: Previous studies reported divergent results concerning the effect of gender on patient outcome after severe injury. Results suggest that women have better outcomes because they have lower rates of sepsis and multi-organ failure. The objective of this analysis was to study gender differences in a Level 1 trauma center in Germany., METHODS: Patients who were admitted to hospital between 2002 and 2011 with an Injury Severity Score (ISS) >=16 were included. Data were collected from the Trauma Registry of the German Society for Trauma Surgery and from hospital records. The effects of gender on a variety of parameters were investigated. To eliminate the influence of differences in ISS, an analysis of groups with similar ISS was performed. Also, a matched-pair analysis of 422 patients was performed., RESULTS: A total of 962 patients met the inclusion criteria. The mortality rate was lower in male patients (25.4% versus 36.59%). Female patients had more severe head injuries, received less fluid volume and had a lower rate of sepsis. Men were more frequently involved in motorcycle accidents and sustained more penetrating trauma. Women were more frequently involved in pedestrian accidents and sustained more falls from under 3 m. The effects of gender were reduced when the data were analyzed by matching ISS. The mortality rate was significantly different in the ISS 26 to 35 group but in mostly all groups, the mortality rate was higher in women. In the matched-pair analysis, the rate of sepsis and the length of the ICU stay were significantly lower in women and the mortality rate showed no significant difference (28.1% for male patients versus 33.01% for female patients). Women died after an average of 5.22 days, and men died after an average of 9.02 days., CONCLUSIONS: Gender-based differences in patient outcome after severe trauma were observed in this study. Women are more likely to die in the first days after trauma. Upon extended hospital stay, women had a better survival rate because they had a lower rate of sepsis. No significant differences in mortality rate could be found, but there was a trend towards a higher rate in female patients.

4845. Schoenfeld, A. J., et al. (2013). "The nature and extent of war injuries sustained by combat specialty personnel killed and wounded in Afghanistan and Iraq, 2003-2011." The journal of trauma and acute care surgery **75**(2): 287-291.

BACKGROUND: Previous studies regarding combat wounding have a limited translational capacity due to inclusion of soldiers from all military branches and occupational specialties as well as a lack of information regarding soldiers who died in theater., METHODS: A search was performed of the Department of Defense Trauma Registry and Armed Forces Medical Examiner data set for the years 2003 to 2011 to identify all injured personnel with the military specialty 19D (cavalry scout). A manual search was conducted for each record identified, and age, rank, location and manner of injury, mechanism of injury, Injury Severity Score (ISS), and extent of wounding were abstracted. The incidence of injuries by body region and rates for specific types of wounds were determined. Statistically significant associations between rank, location of injury, manner of injury, body region involved, and injury mechanism were assessed using chi2 analysis. Associations between ISS, rank, manner of injury, and survival were evaluated by t test with Satterthwaite correction., RESULTS: A total of 701 casualties were identified with 3,189 distinct injuries. Mean (SD) age of injured personnel was 25.9 (6.0) years. Thirty-five percent of the cohort was composed of soldiers who died in theater. Explosions were the most common mechanism of injury (70%), while 18% of wounds occurred owing to gunshot. Extremity wounds and injuries to the head and neck represented 34% of casualty burden. Thoracic trauma occurred in 16%, and abdominal injuries occurred in 17%. Wounds with a frequency exceeding 5% included skin, extremity, facial, brain, and gastrointestinal injuries. Vascular injury occurred in 4%. Gunshot wounds were a greater cause of injury in Afghanistan (p = 0.001) and resulted in a higher percentage of thoracic injuries (p < 0.001)., CONCLUSION: The nature and extent of trauma sustained by combat-specific personnel seems to be different from that experienced by all soldiers deployed to a war zone.

4846. Schooler, C., et al. (2008). "Brain lesion and memory functioning: short-term memory deficit is independent of lesion location." Psychonomic bulletin & review **15**(3): 521-527.

We analyzed the effects of patterns of brain lesions from penetrating head injuries on memory performance in participants of the Vietnam Head Injury Study (Grafman et al., 1988). Classes of lesion patterns were determined by mixture modeling (L. K. Muthen & B. O. Muthen, 1998-2004). Memory performance was assessed for short-term memory (STM), semantic memory, verbal episodic memory, and visual episodic memory. The striking finding was that large STM deficits were observed in all classes of brain-injured individuals, regardless of lesion location pattern. These effects persist despite frequent concomitant effects of depressive symptomatology and substance dependence. Smaller deficits in semantic memory, verbal episodic memory, and visual episodic memory depended on lesion location, in a manner roughly consistent with the existing neuropsychological literature. The theoretical and clinical implications of the striking, seemingly permanent STM deficits in individuals with penetrating head injuries are discussed.

4847. Schrader, W., et al. (2000). "[Penetrating and perforating eye injuries in 343 patients due to auto accidents before and after compulsory seat belt legislation resulting in fines (1966-1998)]." Penetrierende und perforierende Augenverletzungen bei PKW-Unfallen von 343 Patienten vor und nach Einfuhrung des Bussgeldes fur "Gurtmuffel" (1966-1998). **217**(1): 23-29.

BACKGROUND: Constructional improvements of passengers safety in cars alone did not result in a significant decline of open globe injuries in traffic accidents. Only after compulsory seat belt legislation was introduced in Germany and Great Britain, a 60%-75% reduction in ocular injuries was observed. We examined, how the characteristics of severe eye injuries in car accidents changed during the last 28 years., PATIENTS AND METHODS: The case records of 343 patients, who suffered from open globe injuries during car accidents between 1966 and 1993 and were primarily admitted in the University Eye Hospitals of Freiburg and Wurzburg, have been analyzed retrospectively. Injuries were evaluated for their extent, time of injury (hour and season), age, sex and outcome of visual acuity after surgery., RESULTS: Between 1966 and 1984 wind-screen injuries declined slowly from 25/year to 16/year. Since the introduction of compulsory seat belt legislation in Germany in 1984 we observed a sudden reduction to 4 injuries/year, followed by an additional slow decline to 2.5 injuries/year. Male/female ratio changed from 2.1/1 before to 9/1 after 1984. Due to the seat belt legislation, injuries declined during summer season (april through september) by factor 7.6, during winter season (october through march) by factor 3.8. Injuries during daylight (6 a.m. to 6 p.m.) decreased more rapidly (by factor 14) than during nighttime (6 p.m. to 6 a.m.: factor 4). The decline of eye injuries was most pronounced among those with an age of less than 23 years (by factor 10.8) and those who were 31-50 years old (by factor 6.8), but least among those between 23 and 30 years of age (2.2). Since 1984, open globe injuries combined with mid-facial and cranial fractures increased resulting in a poorer visual outcome: 29% of eyes became blind before 1984 and 40% since then due to the higher survival probability of very severe accidents. A majority of injured persons still had not fastened their seat belt and about 50% were drunk., CONCLUSION: Compulsory seat belt legislation introduced in Germany in 1984 was most effective in preventing eye injuries among female passengers, during daytime or among persons younger than 23 years. However, 23-30 year old male drivers who had not fastened their seat belt, drove in darkness or during winter and had drunk alcohol, were still at highest risk for an open globe injury. The increase of victims with a combination of open globe injuries and midfacial injuries, polytrauma or cerebral trauma may be related to the airbag and other improved safety measures.

4848. Schreckinger, M., et al. (2011). "Transorbital penetrating injury: case series, review of the literature, and proposed management algorithm." Journal of neurosurgery **114**(1): 53-61.

Transorbital penetrating injury (TPI), an uncommon subset of head trauma, requires prompt multidisciplinary surgical intervention. While numerous case reports appear in the literature, there is a lack of discrete recommendations for initial evaluation, surgical intervention, and postoperative care of patients with TPI. A retrospective review of 4 cases of TPI at the University of Michigan Health System was undertaken to assess for diagnosis, treatment, and follow-up. In addition, a PubMed search using the terms "penetrating orbital trauma," "penetrating orbital injury," "transorbital penetration," and "transorbital penetrating injury" were used to search for articles discussing the presentation and management of penetrating orbital trauma. All 4 of the patients at the University of Michigan underwent focused physical examination performed by a multidisciplinary trauma team followed by dedicated maxillofacial and head CT scanning. The patients' treatments varied, depending on the mechanism and extent of the injury. An analysis of the case

series presented here as well as other published cases suggests an algorithm for diagnosis and treatment for patients with TPI, which includes focused evaluation, diagnostic imaging with maxillofacial CT scanning, and management of the injury that focuses on the path of penetration and the presence of the foreign body in situ at the time of presentation. Magnetic resonance imaging is indicated in patients who have indwelling wooden foreign bodies. Angiography should be performed in patients with suspected vascular injury. Treatment decisions should be made by a multidisciplinary team with input from neurosurgery, ophthalmology, otolaryngology, and maxillofacial surgery.

4849. Schreiber, M. A. (2019). "Prehospital tranexamic acid improves survival after traumatic brain injury in patients with intracranial hemorrhage." Shock **51**(6): 26.

Introduction: Tranexamic acid (TXA) has been shown to improve survival after trauma in patients at risk for major hemorrhage. There is also evidence to suggest that TXA may benefit patients with moderate to severe traumatic brain injury (TBI). We hypothesized that prehospital administration of TXA would result in a favorable neurologic outcome as measured by Glasgow Outcome Score-Extended (GOS-E) 6 months after injury in patients with moderate to severe TBI. Methods: We performed a prospective randomized doubleblind trial in 12 regions of North America served by 39 Emergency Medical Services (EMS) systems and 20 trauma centers within the Resuscitation Outcomes Consortium. The trial was approved by the FDA and Health Canada. Blinded kits containing TXA or placebo were stored on EMS units and the participating trauma centers. Patients with a suspected TBI, Glasgow Coma Scale (GCS) of 3-12, and systolic blood pressure ≥ 90 mmHg were eligible for inclusion by exception from informed consent. Patients were randomized to one of three arms: prehospital placebo bolus followed by an 8 hour in-hospital placebo infusion [placebo, (PCB)], 1-gram TXA prehospital bolus followed by an in-hospital 1-gram TXA infusion over 8 hours [bolus-maintenance, (BM)], or 2-gram TXA prehospital bolus followed by 8 hour in-hospital placebo infusion [bolus only, (BO)]. Our primary pre-specified analysis adjusted for regional site and combined the two TXA dosing regimens in order to increase power to detect a difference in unfavorable GOS-E at 6 months due to TXA administration. Additional primary aims included pairwise comparisons among the three groups related to GOS-E, survival, blood product requirements, thrombelastography (TEG) and complications. GOS-E and survival outcomes were compared using logistic regression. GOS-E and survival analyses other than the primary analysis were adjusted for age, gender, mechanism of injury, qualifying GCS, Injury Severity Score, and head Abbreviated Injury Scale score. Multiple imputation of the primary outcome in cases where the 6-month follow-up data were missing was performed based on our pre-specified analysis plan. Pre-specified subgroups analyzed included patients not lost to follow-up, patients meeting all eligibility criteria, patients with no infusion-related protocol deviations, and patients with an intracranial hemorrhage (ICH) on initial CT. Results: 967 patients were randomized and administered study drug; 309 PCB, 312 BM group and 346 BO group. The mean age in years (standard deviation) and incidence of penetrating trauma in the PCB, BM, and BO groups respectively was 40(18), 42(19), 43(19) and 5%, 4% and 1%. The mean GCS was 8 with a standard deviation of 3 in all groups. The incidence of ICH on initial CT was 57% in the PCB group, 58% in in the BM group, and 58% in the BO group. The prehospital dose was completely infused in 94% of patients in the PCB group, 93% in the BM group and 95% in the BO group. The estimated time from injury to start of the prehospital infusion was similar between the groups with a median time of approximately 40 minutes and about 75% of patients received the infusion within 1 hour of injury. The rates of complete infusion of the in-hospital dose were: 69% PCB, 73% BM, and 77% BO. Reasons for incomplete infusion included death, safety concerns such as seizure, withdrawal of consent, patient discharge, protocol non-compliance, and treatment unblinding due to indications for open-label TXA. Open-label TXA was administered to 4% of PCB patients, 2% of BM, and 1% of BO. There was no difference in TEG parameters on admission between groups with mean (SD) LY30 of 1.5(3.1), 1.8(4.9) and 1.5(4.1) in the PCB, BM and BO groups, respectively. Blood products were administered within 24 hours to 23%, 21%, and 16% in the PCB, BM, and BO groups, respectively. Among those receiving blood products within 24 hours, the mean (SD) infusion volume in liters was 2.4 (3.9), 2.1 (2.6), and 1.7 (2.1) in the PCB, BM and BO groups, respectively. The 6-month follow-up rates were 88% (PCB) and 84% for both the BM and BO groups. The rates of unfavorable GOS-E among patients not lost to follow-up were 40% (PCB), 42% (BM), and 39% (BO), and among all patients after multiple imputation were 38% (PCB), 36% (BM), and 34% (BO). GOS-E £ 4 at 6 months did not significantly differ for either the combined TXA group compared to placebo [odds ratio (95% CI) 0.86 (0.64, 1.16)] or for any pairwise comparison [BM vs PCB 0.92 (0.65, 1.30), BO vs PCB 0.82 (0.58, 1.14), BO vs BM 0.89 (0.63, 1.24)]. In the subset of patients with ICH on initial head CT, GOS-E £ 4 was lower in the BO group compared to the BM group: BM vs PCB 1.25 (0.73-2.12), BO vs PCB 0.69 (0.41, 1.17), BO vs BM 0.55 (0.33, 0.93). The 28-day mortality rates in the entire cohort were 17% (PCB), 17% (BM), and 12% (BO). Pairwise odds ratios for 28- day mortality were: BM vs PCB 1.12 (0.65, 1.93), BO vs PCB 0.66 (0.37, 1.17), BO vs BM 0.59 (0.34, 1.03). Among patients with ICH on initial CT, the BO group experienced lower

28-day mortality compared to both the BM and PCB groups: 27% (PCB), 25% (BM), and 17% (BO). Pairwise odds ratios (95% CI) for 28-day mortality were: BM vs PCB 1.02 (0.55, 1.89), BO vs PCB 0.49 (0.26, 0.95), BO vs BM 0.49 (0.25, 0.93). A greater portion of patients in the BO group experienced seizures (5% compared to 2% in both the BM and PCB groups); however, the groups did not differ significantly in seizures considered to be serious (1% PCB, 1% BM, 2% BO). Patients in the BM group experienced fewer thromboembolic events (4%) compared to the BO (9%) and the PCB (10%) groups. Conclusions: A prehospital 2 gram bolus of TXA or a prehospital 1 gram bolus followed by a 1 gram in-hospital infusion did not demonstrate superiority in either 6-month GOS-E or 28-day survival over placebo for all included patients. A prehospital 2 gram bolus of TXA resulted in improved 28-day survival compared to both placebo and a 1 gram prehospital bolus followed by a 1 gram in-hospital infusion in patients with CT confirmed ICH after TBI. A Phase III randomized controlled trial comparing 2 grams of prehospital TXA to placebo in patients with moderate to severe TBI is indicated.

4850. Schreuder, W. H., et al. (2011). "Civilian firearm injuries to the face in an urban hospital: Demographics, injury pattern, management and outcome." Journal of oral and maxillofacial surgery **69**(9): e95-e96.

Statement of the Problem: In an increasing violent civilization, more specialists will be confronted with firearm-related injuries from interpersonal violence and suicides. This study provides a 6-year retrospective view of nonfatal gunshot wounds to the face in an urban level I trauma center, with special emphasis on demographics, acute and late management to final outcome. Materials and Methods: This study was carried out in the Groote Schuur Hospital in Cape Town using different registration sources to trace patients treated for nonfatal gunshot wounds to the face. Clinical notes, operative notes and radiographic studies available in medical records were retrospectively reviewed for demographic information, injury pattern, the use of diagnostic studies, injured structures, resuscitation methods, amount and duration of admissions and the immediate and late management including reconstructive procedures. Methods of Data Analysis: A total of 80 patients were identified in the period from January 1999 until January 2005. Six of these patients were referred by rural centers at least 24 hours after injury for specific management of the maxillofacial injuries or reconstructive procedures. Results of Investigation: Most victims were male (94%) with a mean age of 26.7 years. Fifty-seven patients (71%) had isolated gunshot wounds to the head and neck area. Information on ballistic etiology and range of shot was not available. A total of 87 bullets injured the facial structures, most commonly entering through the midface (51%), after which most bullets lodged (38%) in the maxillofacial tissues. Ten traumatic vessel injuries were diagnosed in 29 patients (39%) receiving an angiogram at the initial trauma care. None needed surgical intervention. For securing the airway 18 patients (24%) underwent endotracheal intubation. In one patient a cricothyroidotomy was performed after intubation failed. A tracheostomy was indicated in 16 patients (22%), of which 4 were performed under local anesthesia. Considering the craniofacial skeleton, most patients suffered from a fracture of the mandible (58%), followed by dentoalveolar fractures (54%) and maxillary/zygomatical fractures (31%). Ocular injury was seen in 4 patients and 16 patients suffered nerve injury. Eighty-nine percent of the patients needed surgical intervention, most often including thorough debridement of the wound (73%), soft tissue repair (61%), extraction of fractured teeth (46%), and surgical removal of the bullet (35%). Patients with facial skeleton fractures were addressed by intermaxillary fixation and closed reduction (33%), archbars (10%) or ORIF (15%). Eight patients received reconstructive procedures, either immediate (4 patients, mean interval of 12 days) or delayed (4 patients, mean interval 68 days). One patient was referred for a reconstructive procedure after 562 days. The mean follow-up was 99 days (range 0-1,061 days). Most patients were discharged during follow-up. However, 24 patients did not return after a mean follow-up of 33 days post injury. In the follow-up period no complications or long-term sequelae were seen in only 24% of the patients. Conclusion: Gunshot wounds to the face are complex soft tissue and skeletal injuries, accompanied by many possible complications and long-term sequelae. Treatment by experienced surgeons is necessary, in order to prevent devastating functional and aesthetic consequences. After resuscitation, the current trend is to pursue early and comprehensive treatment if possible.

4851. Schrieff, L. E., et al. (2013). "Demographic profile of severe traumatic brain injury admissions to Red Cross War Memorial Children's Hospital, 2006 - 2011." South African medical journal = Suid-Afrikaanse tydskrif vir geneeskunde **103**(9): 616-620.

BACKGROUND: Paediatric traumatic brain injury (PTBI) is a major public health problem. However, recent epidemiological data for PTBI in South Africa (SA) are lacking., OBJECTIVES: To establish a demographic profile of severe PTBI admissions to the Red Cross War Memorial Children's Hospital (RCWMCH) over a 5-year period, by investigating

trends in annual admissions, age, sex, language, time and day of injury, and aetiology. Methods. This retrospective, descriptive, quantitative study included children admitted to the RCWMCH with severe traumatic brain injury (TBI) between June 2006 and April 2011, who required intracranial monitoring. We used the Division of Paediatric Neurosurgery's TBI database to identify cases for inclusion in the study and to gather demographic and injury information., RESULTS: Descriptive statistics suggested that: (i) the number of annual admissions did not vary substantially across the study period; (ii) the peak admission age was 6 years; (iii) more boys than girls were admitted; (iv) the major mechanism of injury was pedestrian road traffic accidents; and (v) most injuries occurred on weekends. These results are discussed against the backdrop of international research on PTBI and reflect the extent to which epidemiological findings on TBI in high-income countries compare with those from low- and middle-income countries such as SA., CONCLUSION: The identification of aetiological factors and the description of demographic profiles of children sustaining TBI constitutes a basis for preventative policy administration and intervention strategies in SA.

4852. Schrieff-Elson, L. E., et al. (2015). "Low brain oxygenation and differences in neuropsychological outcomes following severe pediatric TBI." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **31**(12): 2257-2268.

PURPOSE: Traumatic brain injury (TBI) is a leading cause of morbidity and mortality in children. Preventing secondary injury by controlling physiological parameters (e.g. intracranial pressure [ICP], cerebral perfusion pressure [CPP] and brain tissue oxygen [PbtO2]) has a potential to improve outcome. Low PbtO2 is independently associated with poor clinical outcomes in both adults and children. However, no studies have investigated associations between low PbtO2 and neuropsychological and behavioural outcomes following severe pediatric TBI (pTBI)., METHODS: We used a quasi-experimental case-control design to investigate these relationships. A sample of 11 TBI patients with a Glasgow Coma Scale score <=8 who had PbtO2 and ICP monitoring at the Red Cross War Memorial Children's Hospital underwent neuropsychological evaluation >=1 year post-injury. Their performance was compared to that of 11 demographically matched healthy controls. We then assigned each TBI participant into one of two subgroups, (1) children who had experienced at least one episode of PbtO2 <= 10 mmHg or (2) children for whom PbtO2 > 10 mmHg throughout the monitoring period, and compared their results on neuropsychological evaluation., RESULTS: TBI participants performed significantly more poorly than controls in several cognitive domains (IQ, attention, visual memory, executive functions and expressive language) and behavioural (e.g. externalizing behaviour) domains. The PbtO2 <= 10 mmHg group performed significantly worse than the PbtO2 > 10 mmHg group in several cognitive domains (IQ, attention, verbal memory, executive functions and expressive language), but not on behavioural measures., CONCLUSION: Results demonstrate that low PbtO2 may be prognostic of not only mortality but also neuropsychological outcomes.

4853. Schubert, W., et al. (2002). "Incorporation of titanium mesh in orbital and midface reconstruction." Plastic and reconstructive surgery **110**(4): 1022-1022.

Several authors have demonstrated the safety and effectiveness of titanium in orbital reconstruction. One question posed by clinicians is what happens to large pieces of titanium in communication with the paranasal sinuses or nasal-oral-pharyngeal area. This question becomes increasingly relevant as titanium is used to reconstruct extensive defects for which the destruction of bony architecture requires the placement of mesh in proximity to these areas. The objective of this study was to examine the gross and histologic soft-tissue response to large segments of titanium mesh in the setting of orbital and midface reconstruction, particularly when exposed to the nasal-oral-pharyngeal area and paranasal sinuses. In this study, large segments of titanium mesh were used in eight patients to reconstruct orbital and midface defects, with direct communication between the mesh and nasal-oral-pharyngeal area and paranasal sinuses. Four patients had suffered self-inflicted gunshot wounds; as a result, much of their midface was missing, including the inferior and medial orbital floor, maxilla, nose, naso-orbital-ethmoid complex, and hard palate. Extensive sheets of titanium mesh were used to reconstruct their medial and inferior orbital walls, nasal bridge, and maxilla. In the fifth patient, titanium mesh was used to reconstruct the maxilla after resection of a squamous cell carcinoma of the nasolacrimal duct. In the sixth and seventh patients, mesh was used to reconstruct the nasal bridge after severely comminuted nasal fractures resulted in the loss of bone and mucosa. Finally, the eighth patient had titanium mesh used to replace cocaine-induced bone loss involving the left medial orbital floor and wall and part of the maxilla. On gross examination by either endoscopy or direct inspection, all eight patients had rapid soft-tissue incorporation of the titanium mesh. Initial examination typically revealed budding of soft tissue through mesh interstices, followed by progressive incorporation. One patient's mesh was covered in only 15 days. Two patients underwent biopsies of this

newly formed soft tissue. One had biopsies performed at 3, 15, and 31 months after the original operation. Biopsy examination at 3 months revealed incorporation of the titanium with fibrous soft tissue covered by ciliated respiratory epithelium, goblet cells, and squamous epithelium with metaplasia. In addition, the dense, acute inflammation present at 3 months evolved into mild, chronic inflammation at 31 months. The second patient had a single biopsy 4 months after secondary orbital reconstruction for delayed enophthalmos. Biopsy examination revealed a fibrous soft-tissue sheath lined by squamous epithelium with metaplasia. Again, mild chronic inflammation was present within the soft tissue. This study provides evidence of titanium's compatibility with soft tissue. The mesh underwent progressive incorporation with soft tissue that was then resurfaced by indigenous cells, including respiratory epithelia and goblet cells. This phenomenon occurred despite communication with the nasal-oral-pharyngeal area and paranasal sinuses.

4854. Schubiger, O., et al. (1986). "Temporal bone fractures and their complications. Examination with high resolution CT." Neuroradiology **28**(2): 93-99.

A total of 84 patients with 89 fractures of the temporal bone were examined with high resolution CT (HRCT) a few hours to 21 months after the initial trauma. Axial HRCT disclosed 63 longitudinal, 13 transverse, 10 complex and 3 atypical fractures. The diagnosis of a temporal bone fracture was established by axial HRCT in almost every case. However, for the precise topographic analysis of the course of the fracture, additional coronal HRCT proved helpful. The most common, surgically treatable complication of temporal bone fracture is disruption of the ossicular chain. Twenty-three such lesions were demonstrated by combined axial and coronal HRCT; 22 lesions of the facial canal could be demonstrated in 27 patients presenting with facial nerve palsy. The most common site of injury to the facial canal was the region of the geniculate ganglion. The only life-threatening complication of a temporal fracture may be otorhinoliquorrhea. This was present in 9 cases. The most common site of leakage identified was the tegmen tympani. With Metrizamide-HRCT precise localisation of the dural laceration was possible in 7 of these 9 cases.

4855. Schubl, S. D., et al. (2016). "Cervical spine immobilization may be of value following firearm injury to the head and neck." The American journal of emergency medicine **34**(4): 726-729.

BACKGROUND: Penetrating injuries to the head and neck may not be able to cause unstable fractures without concomitant spinal cord injury, rendering prehospital spinal immobilization (PHSI) ineffectual, and possibly harmful. However, this premise is based on reports including predominantly chest and abdominal injuries, which are unlikely to cause cervical spine (CS) injuries., METHODS: We performed a retrospective review of all patients presenting with a penetrating wound to the head or neck over a 4-year period at an urban, level 1 trauma center to determine if there was a benefit of PHSI., RESULTS: One hundred seventy-two patients were identified, of which 16 (9.3%) died prior to CS evaluation. Of 156 surviving patients, mechanism was gunshot wound (GSW) in 36 (28%) and stab wound (SW) in 120 (72%). Fifty-eight patients had PHSI placed (37%), and GSW patients' odds of having PHSI were greater than SW patients (OR 2.3; CI 1.08-4.9). Eight of 156 surviving patients eventually died (5.1%), and the odds of mortality were greater among those that had PHSI than those without (OR 5.54; CI 1.08-28.4). Six (3.8%; 5 GSW, 1 SW) patients had a CS fracture. Two GSW patients (5.6%) had unstable CS fractures with a normal neurological exam at initial evaluation., CONCLUSIONS: Of patients with a GSW to the head or neck that survived to be evaluated, 5.6% had unstable fractures without an initial neurologic deficit. PHSI may be appropriate in this population. Further studies are warranted prior to a determination that PHSI is unnecessary in penetrating head and neck injuries.

Penetrating head trauma in children causes uncommon and potentially life-threatening injuries. We report on a case of penetrating cranial stab wound to the right parietal region of the head to a 29-week fetus. The child was delivered by emergency Caesarian section. Neurosurgical intervention after birth was necessary. The injury caused a posthaemorrhagic hydrocephalus. Real-time ultrasound examination visualises the brain damage and the development of a hydrocephalus e vacuo.

4857. Schultz, R. C. and D. L. de Camara (1984). "Athletic facial injuries." JAMA **252**(24): 3395-3398.

Most facial injuries that occur during athletic activities are of a minor nature, consisting of lacerations, contusions, and abrasions. These are usually treated by a team physician or an emergency department physician. However, minor injuries must be differentiated from the more significant injuries, especially those involving facial bone fractures. Significant facial trauma must be diagnosed accurately and treated with precision to avoid permanent facial deformity. Soft-tissue trauma as well as fractures are included in this review, and evaluation of the injured athlete is emphasized. A systematic approach is developed for diagnosing and treating common facial injuries in athletes.

4858. Schulz, C., et al. (2008). "Image-guided neurosurgery for secondary operative removal of projectiles after missile injury of the brain." Surgical neurology **69**(4): 364-368.

BACKGROUND: The primary treatment of penetrating missile injuries of the brain includes debridement of the scalp, fractured skull, and necrotic brain parenchyma. It is acceptable to remove all bony and metallic fragments that are accessible without additional trauma to nondamaged brain regions. Therefore, bone chips and bullets are often initially retained in the brain and are supposedly responsible for delayed cerebral infections and posttraumatic seizures., METHODS: We successfully operated on 3 patients electively to remove bony and metallic fragments secondarily after penetrating brain trauma. We used an electromagnetic neuronavigation system for preoperative planning and chose a less invasive approach for the exact intraoperative localization of the fragments., RESULTS: All fragments were extracted without any problems. No patients had any additional neurologic deficits, and no signs of cerebral infections or seizures occurred between 4 and 8 weeks after the operative revision., CONCLUSION: We recommend the implementation of neuronavigation techniques into the surgical strategy for secondary removal of retained missile fragments.

4859. Schulz, M. R., et al. (1992). "[Conservative or surgical treatment for foreign body injuries of the brain]." Konservative oder operative Behandlung von Fremdkorperverletzungen des Gehirns. **53**(2): 69-73.

Presenting our patients with cerebral foreign body injuries since 1954 we find that surgical management is not absolutely indispensable. Criteria for conservative management are presented with illustrative cases.

_____

4860. Schumacher, M., et al. (1983). "[Intravital and postmortal CT examinations in cerebral gunshot injuries]." Intravitale und postmortale CT-Untersuchungen bei Hirnschussverletzungen. **139**(1): 58-62.

The value of CT was assessed in 24 patients who died of cerebral gunshot injuries and in two patients with more recent injuries in order to reconstruct the mode of injury and for adding forensic information. The post-mortem and intravital appearances described and are compared with ultrasound rotation compound scans of the isolated brains. CT showed good agreement with pathological findings. Ultrasound produced images with an accuracy between CT and photographs of the brain specimen. Both methods are regarded as valuable additions to the pathological and forensic information concerning gunshot injuries.

4862. Schuster, J. M., et al. (1999). "Acute traumatic posteroinferior cerebellar artery aneurysms: report of three cases." Neurosurgery **45**(6): 1465-1468.

OBJECTIVE AND IMPORTANCE: Posterior fossa subarachnoid hemorrhage secondary to blunt head trauma is rarely associated with traumatic aneurysms of the posterior circulation., CLINICAL PRESENTATION: We present three cases of posterior fossa subarachnoid hemorrhage from ruptured posteroinferior cerebellar artery (PICA) aneurysms after blunt head trauma. In each case, there was no associated penetrating injury or cranial fracture. All three patients presented with acute hydrocephalus requiring ventriculostomy. Two of the three patients had a proximal PICA aneurysm visible on emergent angiography. The remaining patient's aneurysm, although not visible on his initial angiogram, was detected on a subsequent angiogram 72 hours later., INTERVENTION: All patients underwent successful surgical clipping of their aneurysms. Two cases required sacrificing of the parent vessels because of the friable nature of the false aneurysms. In each case, severe symptomatic vasospasm occurred, requiring angioplasty. All three patients also

required a ventriculoperitoneal shunt for persistent hydrocephalus., CONCLUSION: Features of these three cases and similar cases reported in the literature support the theory that vascular ruptures and traumatic aneurysms of the proximal PICA may be related to anatomic variability of the PICA as it transverses the brainstem. This variability predisposes individuals to vascular lesions, which occur in a continuum based on the severity of the injury. Posterior fossa subarachnoid hemorrhage after head injury requires a high index of suspicion and warrants aggressive diagnostic and therapeutic interventions.

4863. Schutzner, J., et al. (2017). "[Ruptures of the diaphragm]." Ruptury branice. **96**(12): 493-497.

INTRODUCTION: The diaphragm is a flat muscle that divides the thoracic and abdominal cavities, and it is one of the most important muscles involved in respiration. Traumas of the diaphragm include its rupture caused by an external force, resulting in blunt or penetrating injuries. Diaphragmatic rupture is associated with the risk of a prolapse (i.e. not a typical hernia) of abdominal organs into the pleural cavity. The rupture may occur due to a blunt injury of the chest or abdomen, or due to penetrating injuries (gunshots, stab wounds, foreign bodies) in the lower part of the chest and epigastrium. Ruptures never heal spontaneously and always require suture of the diaphragmatic defect. Most acute rupture cases are managed using laparotomy; thoracotomy is preferred for lately recognised ruptures to facilitate the removal of adhesions in the thoracic cavity developed between the diaphragmatic defect and a lung. Thirty one patients with diaphragmatic rupture were operated at the 3rd Department of Surgery of the 1st Faculty of Medicine, Charles University and University Hospital Motol between 2006 and 2016. Acute rupture was present in 60% of the cases and chronic in 40%. Right-sided rupture was found in 20% and left-sided in 80%., CONCLUSION: The authors describe surgical treatment of diaphragmatic ruptures. They recommend an early surgical treatment if diaphragmatic rupture is recognized. Generally, the prognosis of the patients depends on availability of professional health care; ideally, these patients should be treated at specialised traumacentres with specialists for abdominal and thoracic surgery. The authors advise against establishing injudicious thoracic drainage in cases where diaphragmatic rupture with herniation of abdominal organs into the thorax may be present.Key words: polytrauma - acute rupture of diaphragm - chronic rupture - suture - patch.

4864. Schuur, P. M., et al. (1997). "Use of random amplification of polymorphic DNA in a case of Pasteurella multocida meningitis that occurred following a cat scratch on the head." Clinical infectious diseases : an official publication of the Infectious Diseases Society of America **24**(5): 1004-1006.

We cultured Pasteurella multocida from the cerebrospinal fluid (CSF) of a 4-month-old infant who presented with meningitis. The patient had been scratched on the head by a cat. Culture of the cat's claws also yielded P. multocida. The isolates had identical biochemical patterns. Analysis of both strains by random amplification of polymorphic DNA and comparison of these strains with P. multocida strains isolated from other cats showed that the two strains were identical and completely different from the unrelated isolates. Our patient's meningitis most likely resulted from direct inoculation of P. multocida into the CSF.

4865. Schwab, K., et al. (1993). "Residual impairments and work status 15 years after penetrating head injury: report from the Vietnam Head Injury Study." Neurology **43**(1): 95-103.

We investigated the relationship of neurologic, neuropsychological, and social interaction impairments to the work status of a large sample of penetrating head-injured patients wounded some 15 years earlier during combat in Vietnam. Extensive standardized testing of neurologic, neuropsychological, and social functioning was done at follow-up on each head-injured patient (N = 520), as well as on a sample of uninjured controls (N = 85). Fifty-six percent of the head-injured patients were working at follow-up compared with 82% of the uninjured controls. Seven systematically defined impairments proved to be most correlated with work status. These were post-traumatic epilepsy, paresis, visual field loss, verbal memory loss, visual memory loss, psychological problems, and violent behavior. These disabilities had a cumulative and nearly equipotent effect upon the likelihood of work. We suggest that a simple summed score of the number of these seven disabilities can yield a residual "disability score" which may prove to be a practical tool for assessing the likelihood of return to work for patients in this population and perhaps in other brain-injured populations. These findings may also help to focus rehabilitation efforts on those disabilities most likely to affect return to work.

4866. Schwabenlander, M., et al. (2016). "Brain, Craniofacial, and Dental Lesions of a Free-ranging Gray Wolf (Canis lupus) Implicated in a Human Attack in Minnesota, USA." Journal of wildlife diseases **52**(1): 131-137.

We describe significant brain, craniofacial, and dental lesions in a free-ranging wolf (Canis lupus) involved in a human attack. On postmortem examination, the wolf presented asymmetric atrophy and bone remodeling affecting the mandible, incisive, maxilla, lacrimal, palatine, frontal, and ethmoid bones. There was an asymmetrical skeletal malocclusion and dental abnormalities including rotated, malpositioned, partially erupted teeth, and an odontogenic cyst associated with an unerupted canine tooth. Brain changes were bilateral loss and atrophy of extensive cortex regions including olfactory bulb, peduncles, and tract, and the frontal lobe. We highlight the relevance of a thorough postmortem examination of wildlife to elucidate disease-based abnormal behavior as the reason for human-animal conflict.

4867. Schwark, T. and N. von Wurmb-Schwark (2016). "Non-fatal impalement of the brain: A case report." Forensic science international **266**: e10-e13.

We present a rare case of a non-fatal impalement injury of the brain. A 13-year-old boy was found in his classroom unconsciously lying on floor. His classmates reported that they had been playing, and throwing building bricks, when suddenly the boy collapsed. The emergency physician did not find significant injuries. Upon admission to a hospital, CT imaging revealed a "blood path" through the brain. After clinical forensic examination, an impalement injury was diagnosed, with the entry wound just below the left eyebrow. Eventually, the police presented a variety of pointers that were suspected to have caused the injury. Forensic trace analysis revealed human blood on one of the pointers, and subsequent STR analysis linked the blood to the injured boy. Confronted with the results of the forensic examination, the classmates admitted that they had been playing "sword fights" using the pointers, and that the boy had been hit during the game. The case illustrates the difficulties of diagnosing impalement injuries, and identifying the exact cause of the injury.

4868. Schwartz, I., et al. (2008). "Cognitive and functional outcomes of terror victims who suffered from traumatic brain injury." Brain injury **22**(3): 255-263.

PRIMARY OBJECTIVE: To describe the outcomes of terror victims suffered from traumatic brain injury (TBI)., RESEARCH DESIGN: Retrospective chart review of 17 terror and 39 non-terror TBI patients treated in a rehabilitation department during the same period., METHODS AND PROCEDURE: Variables include demographic data, Injury Severity Scale (ISS), length of stay (LOS) and imaging results. ADL was measured using the Functional Independence Measurement (FIM), cognitive and memory functions were measured using the Loewenstein Occupational Therapy Cognitive Assessment (LOTCA) battery and the Rivermead Battery Memory Test (RBMT), respectively., MAIN OUTCOME AND RESULTS: Terror TBI patients were significantly younger, had higher ISS score and higher rates of intracerebral haemorrhage (ICH), brain surgery and penetrating brain injuries than the non-terror TBI group. There was no difference in mean LOS, mean FIM values, mean FIM gain and mean cognitive and memory improvement between groups. Terror victims suffered from a higher percentage of post-traumatic epilepsy (35% vs. 10%, p=0.05), whereas the rate of PTSD and the rate of return to previous occupation were similar between groups., CONCLUSIONS: Although TBI terror victims had more severe injury, they gained most of ADL functions and their rehabilitation outcomes were similar to non-terror TBI patients. These favourable results were achieved due to a comprehensive interdisciplinary approach to terror victims and also by national support which allowed an adequate period of treatment and sufficient resources as needed.

4869. Schwartz, J. A., et al. (1987). "Penetrating trauma of the internal carotid artery at the base of the skull." The Journal of cardiovascular surgery **28**(5): 542-545.

A 42-year-old female sustained a partial transection of the internal carotid artery at the base of the skull from a stab wound of the external ear. The clinical presentation and technical aspects of the surgical treatment are presented. The lesion could not be repaired and was successfully treated by ligation. The various techniques of operative exposure of challenging and unusual high carotid injuries which can be employed to eliminate the risk of cerebral embolism, false aneurysm formation, or carotid artery thrombosis associated with conservative management are reviewed.

4870. Schwarz, Y., et al. (2019). "Nasal blowing induces subcutaneous emphysema post penetrating mastoid tip trauma." International journal of pediatric otorhinolaryngology **117**: 48-50.

We describe the case of a child with an isolated penetrating trauma to the mastoid tip. Nasal blowing consequently induced air bubbles coming through the mastoid cutaneous fistula and causing extensive subcutaneous neck emphysema. A computed tomography (CT) demonstrated a right mastoid tip bone fracture with extensive cervical subcutaneous emphysema. The patient was treated conservatively with antibiotics and did not require operative intervention. His subsequent course was uncomplicated. This case emphasizes the importance of taking seriously even what seems to be a minor skin laceration.

4871. Schyma, C. (2012). "Wounding capacity of muzzle-gas pressure." International journal of legal medicine **126**(3): 371-376.

BACKGROUND: Suicidal gunshot wounds that are caused by ammunition fired from a 9-mm Luger pistol, with direct contact between the gun muzzle and the victim's head, present a serious injury pattern even with full metal jacket bullets. Wound ballistic experiments were performed to clarify whether muzzle gases from the firearm have an additional wounding potential., METHODS: Fifteen head models were prepared as follows: an acryl sphere measuring 14 cm in diameter was completely covered with a layer of silicon that was 3 mm thick. These spheres were filled with 10% gelatine. At 4degreeC, these models were fired at with a 9-mm Luger pistol, loaded with Quick Defense 1 expanding bullets. Five shots were fired with direct muzzle contact, one shot was fired from a distance of 10 cm, four shots were fired from a distance of 2 m, and five shots were fired from a distance of 4 m., RESULTS: Each projectile penetrated the model; all but one projectile deformed regularly. Each acryl sphere shattered into comminuted pieces but was held together by the silicon cover. The gelatine filling was then cut into slices 1 cm thick, and each slice was optically scanned. An evaluation was performed following both Fackler's Wound Profile method and the polygon procedure method. The pattern of gelatine disruption did not differ in shots from intermediate ranges, but the amount of gelatine destruction was always more extended in the case of muzzle contact shots. Depending on the section of the bullet path, crack lengths were 31% to 133% longer in contact shots. The first centimetre and the second half of the bullet path showed the greatest increase., CONCLUSION: The experimental findings prove the wounding capacity of muzzle gases.

4872. Schyma, C., et al. (1997). "The MEN frangible: study of a new bullet in gelatin. Metallwerk Elisenhutte Nassau." The American journal of forensic medicine and pathology **18**(4): 325-330.

Experimental gunshots were made with 9 x 19 mm (9-mm Luger) Frangible ammunition using skin, gelatin, and bones as targets. Direct gunshots penetrated 50 cm into gelatin blocks without mushrooming or fragmentation. Skull bone was easily perforated. Head models were penetrated by the bullets, which broke down to myriad fragments within or outside the head. Gunshots through windshields and steel plates led to dangerous bullet fragmentation with a high risk of injury. Gunshots perforating tibias produced comminuted fractures. In all soft tissues, except the direct gunshots into gelatin, high-resolution radiography revealed many metallic fragments along the bullet path. Clinical radiography can show the larger copper fragments, but the explosion-like distribution of metallic foreign bodies in soft tissue is a serious surgical problem.

4873. Schyma, C., et al. (2015). "The 'triple contrast' method in experimental wound ballistics and backspatter analysis." International journal of legal medicine **129**(5): 1027-1033.

In practical forensic casework, backspatter recovered from shooters' hands can be an indicator of self-inflicted gunshot wounds to the head. In such cases, backspatter retrieved from inside the barrel indicates that the weapon found at the death scene was involved in causing the injury to the head. However, systematic research on the aspects conditioning presence, amount and specific patterns of backspatter is lacking so far. Herein, a new concept of backspatter investigation is presented, comprising staining technique, weapon and target medium: the 'triple contrast method' was developed, tested and is introduced for experimental backspatter analysis. First, mixtures of various proportions of acrylic paint for optical detection, barium sulphate for radiocontrast imaging in computed tomography and fresh human blood for PCR-based DNA profiling were generated (triple mixture) and tested for DNA quantification and short tandem repeat (STR) typing success. All tested mixtures yielded sufficient DNA that produced full STR profiles suitable for forensic identification. Then, for backspatter analysis, sealed foil bags containing the triple mixture were attached to plastic bottles filled with 10% ballistic gelatine and covered by a 2-3-mm layer of silicone. To simulate

backspatter, close contact shots were fired at these models. Endoscopy of the barrel inside revealed coloured backspatter containing typable DNA and radiographic imaging showed a contrasted bullet path in the gelatine. Cross sections of the gelatine core exhibited cracks and fissures stained by the acrylic paint facilitating wound ballistic analysis.

4874. Scialpi, M., et al. (1996). "[Computerized tomography in craniocerebral, maxillofacial, cervical, and spinal gunshot wounds. Part II--Clinical contribution and medico- legal aspects]." La Tomografia Computerizzata nelle lesioni da colpi da arma da fuoco cranio-encefaliche, maxillo-facciali, del collo e vertebro-midollari. Parte II--Contributo clinico e aspetti medico-legali. **92**(6): 693-699.

To assess the diagnostic and medicolegal contribution of Computed Tomography (CT) in patients with craniocerebral, maxillofacial, neck and spine gunshot wounds, we submitted to CT 106 patients with gunshot wounds examined over a 7-year period (February, 1988 to December, 1994). Twenty-four of them had craniocerebral injuries (23%), 9 maxillofacial (8%), 8 neck (8%) and 10 vertebral (9%) injuries. Emergency CT demonstrated the mechanism of the injury, the bullet path and site, the site of bone and/or metallic fragments, and damage extent. In all perforating cranioencephalic injuries (n = 7) intracerebral or extrathecal bone fragments were demonstrated adjacent to the bullet entrance and exit holes, respectively. In injury monitoring. CT showed injury evolution, retained fragments and complications, thus enabling damage extent assessment. High Resolution Computed Tomography (HRCT) was useful in locating minute orbitary retrobulbar and intraspinal fragments. Magnetic Resonance (MR) Imaging in postoperative patients proved a valuable tool to assess the extent of spinal cord damage. To conclude, CT is a useful technique to examine the patients with gunshot wounds, which helps plan adequate treatment and solve complex medicolegal problems.

4875. Sclafani, A. P. and S. J. Sclafani (1996). "Angiography and transcatheter arterial embolization of vascular injuries of the face and neck." The Laryngoscope **106**(2 Pt 1): 168-173.

The condition of patients sustaining penetrating neck trauma often appears deceptively stable, even when major structures have been injured. The clinician must identify patients who require treatment and limit invasive procedures in those without significant injuries. Angiography is often used to search for vascular damage following penetration of the neck and face. The charts of 401 hemodynamically stable patients with penetrating cervicofacial wounds who were evaluated by angiography followed, when necessary by either transcatheter arterial embolization and observation or surgery were reviewed. One hundred twelve patients (27.9%) had 131 vascular injuries identified by angiography; 77 (68.8%) of these patients sustained injuries to zone III of the neck or the face. The most commonly injured vessels were the internal carotid artery (ICA), the vertebral artery, and the external carotid artery (ECA) system. Multiple vessel injuries were seen in 17 (15.2%) of 112 patients and were more likely in patients with wounds in zone III or above than in those wounded in zone II or below (20.8% vs. 2.9%, respectively; $P < .025$). Injuries to the internal maxillary artery (IMA) (60%), ECA (53.3%), and the ICA (30.8%) were also significantly more likely to be accompanied by additional vascular injuries ($P < .005$). No clinically significant venous injuries were missed. Complications were noted in only 4 patients, and no deaths occurred as a result of angiography. Angiography is a safe, effective modality in the head and neck trauma setting. Particular scrutiny should be given to patients with zone III or facial wounds, particularly those with documented ICA, IMA, and ECA injuries, since these patients have a higher incidence of multiple vascular injuries.

4876. Sclafani, S. J., et al. (1985). "The management of arterial injuries caused by penetration of zone III of the neck." The Journal of trauma **25**(9): 871-881.

Penetrating trauma of the neck has been divided into three anatomic locations. Zone III, the subject of this paper, is defined as the area between the base of the skull and the lower border of the mandible. Management of these injuries remains problematic. Clinical assessment may be misleading, exploration may damage surrounding neurovascular structures, and injuries may go undetected. This has led us and others to advocate mandatory angiography before any surgical exploration. This report reviews 46 patients with Zone III injuries with respect to types of injuries, therapy and outcome. Angiography was normal in 22 patients who were treated conservatively with no complications. The remaining 24 patients sustained 39 arterial injuries diagnosed by contrast studies. Eighteen internal carotid injuries were identified in 16 patients. At operation ligation was performed in four patients and revascularization in two patients. One of the repairs subsequently thrombosed. Ten patients were managed nonoperatively by observation (seven patients) or angiographic embolization (three patients). Catheter embolization of the external

carotid or its branches was performed to control bleeding (eight vessels) or close arteriovenous fistulas (two patients). Seven nonbleeding external vessels were successfully managed by observation. Two vertebral artery injuries were diagnosed. One required proximal embolization and distal ligation via occipital craniectomy to control a fistula between the vertebral artery and the jugular vein. Overall mortality was 8.6%. Three of the four deaths were in patients with neurologic deficit on admission. Another died of respiratory arrest. An air embolism resulting in hemiparesis was the only complication of the angiographic studies. We conclude that angiography is essential in Zone III neck wounds. It facilitates triage decisions and, combined with transcatheter embolization, enables the majority of these injuries to be managed without surgical exploration.

4877. Sclaroff, A., et al. (2000). "Dental implantation for restoration of posttraumatic deformities: avulsion injuries." Facial plastic surgery : FPS **16**(2): 153-167.

Soft and hard tissue defects of the cranio- and maxillofacial area, especially after an avulsion injury, are challenging to reconstruct. Sophisticated soft and hard tissue transfer techniques have allowed satisfactory reconstruction of the gross anatomic structure. However, these methods do not allow optimal restoration of fine anatomic detail or function. The advent of dental implants and modified dental implants for craniofacial applications has allowed maximization of cosmetic and functional restoration. Prosthodontists are capable of fabricating subunits of the cranio- and maxillofacial area with fine detail, reproducing the coloring, texture, and idiosyncrasies of a patient's native skin. Dental implant technology has allowed these prostheses to be bone anchored, yielding a reproducible and stable attachment. This method of attachment in turn allows flexibility in the design of the prosthesis, to maximize restoration, and imparts an increased sense of confidence to the patient. Illustrated are six examples demonstrating the versatility of dental implants in the reconstruction of avulsion injuries of the cranio- and maxillofacial complex.

4878. Scofield-Kaplan, S. M., et al. (2019). "Orbital wooden foreign body manifesting as hyperdensity on computed tomography." Journal of AAPOS : the official publication of the American Association for Pediatric Ophthalmology and Strabismus **23**(1): 45-47.

Detection of wooden foreign bodies within the orbit can be difficult on imaging, including computed tomography (CT). When visible, wood appears iso- or hypodense and can mimic air or fat. We report the case of a 3-year-old boy with progressive orbital cellulitis following a penetrating wood injury to the right lower lid. CT imaging revealed a linear hyperdensity contiguous with an orbital abscess. He underwent a right anterior orbitotomy with abscess drainage, during which exploration revealed a 2.3 cm retained wooden foreign body. The appearance of wood as hyperdense on imaging is unusual. In the appropriate context, high clinical suspicion for retained wood should be maintained with any irregularity on CT imaging.

4879. Scolozzi, P., et al. (2007). "Complex orbito-fronto-temporal reconstruction using computer-designed PEEK implant." The Journal of craniofacial surgery **18**(1): 224-228.

Cosmetic and functional reconstruction of large and complex calvarial defects remains a challenge for craniofacial surgeons. Computer-designed alloplastic implants have revolutionized the conceptualization and approach to these reconstructions and have become a reliable and irreplaceable part of the surgical armamentarium. We are reporting a case of complex orbito-fronto-temporal reconstruction using a computer-designed PEEK (polyetheretherketones)-Patient Specific Implant (PSI). To the best of our knowledge, no other similar cases regarding the use of these implants in cranial reconstruction have been reported previously.

4880. Scott, J., et al. (2017). "Video-assisted thoracic surgery for the management of pyothorax in dogs: 14 cases." Veterinary surgery : VS **46**(5): 722-730.

OBJECTIVE: To report the perioperative findings and outcome of dogs undergoing video-assisted thoracic surgery (VATS) for the management of pyothorax., DESIGN: Multi-institutional, retrospective study., ANIMALS: Client-owned dogs (n = 14)., METHODS: Medical records of dogs with pyothorax managed via VATS were reviewed for signalment, history, clinical signs, clinicopathological findings, diagnostic imaging results, surgical variables, bacterial culture and sensitivity results, post-operative management and outcome. VATS was performed after placing a

paraxyphoid endoscopic portal and 2-3 intercostal instrument portals. VATS exploration was followed by one or more of the following: mediastinal debridement, tissue sampling, pleural lavage, and placement of a thoracostomy tube., RESULTS: Two dogs (14%) required conversion from VATS to an open thoracotomy to completely resect proliferative mediastinal tissue. These dogs had severe pleural effusion on preoperative thoracic radiographs and one had severely thickened contrast-enhancing mediastinum on preoperative computed tomography (CT). The cause of pyothorax was identified as a penetrating gastric foreign body (n = 2), migrating plant material (n = 2), and idiopathic (n = 10). The median follow-up time was 143 days (range, 14-2402 days). All dogs were discharged from the hospital and their clinical signs resolved. One patient had recurrence of a pyothorax requiring revision surgery 17 months postoperatively., CONCLUSION: VATS allows minimally invasive treatment of uncomplicated canine pyothorax. Preoperative thoracic CT may help identify candidates for VATS among dogs with pyothorax.

4881. Scribano, P. V., et al. (1997). "Pediatric nonpowder firearm injuries: outcomes in an urban pediatric setting." Pediatrics **100**(4): E5.

BACKGROUND: Approximately 32 000 nonpowder firearm injuries are reported annually with more than 60% occurring in the pediatric population. Case reports of serious and fatal injuries have been described; however, no large inclusive series have been published. We reviewed an 11-year experience of an urban pediatric emergency department to evaluate the circumstances, spectrum of injuries, and outcomes attributable to nonpowder firearms., METHODS: A retrospective, descriptive case series of all children 18 years of age or younger evaluated at an urban children's hospital from January 1983 through December 1994 were eligible for study. Patients were identified using a computerized database, the National Electronic Injury Surveillance System, and the trauma registry in the department of surgery. Medical records were reviewed to collect demographic information, circumstances of injury, anatomic site and type of injury, treatment, and outcomes for nonpowder firearm injuries., RESULTS: One hundred eighty patients were identified, and a complete data set was available for 166 (92%). The mean age was 12 +/- 3.7 years, 24% of children were <10 years old, and 71% of the children were male. Three patients returned with a second nonpowder firearm injury during the study period. Forty-nine percent of injuries were intentional and 44% of all injuries occurred during the summer and early fall months. The most common sites of injury were the extremity/buttocks (39%), head and neck (33%), thorax (13%), and eye (8%). Serious injuries included intracranial hemorrhage, cardiac right ventricle laceration, hyphema, and abdominal visceral injury (liver laceration, pancreatic laceration, intestinal perforation). The majority of wounds required local wound care, and the children (74%) were discharged from the emergency department. Of the patients admitted to the hospital (27%), 45% required operative intervention. There were no deaths. Seven percent (12/166) of patients sustained some functional deficit with 42% (5/12) the result of an ocular injury., CONCLUSION: The majority of nonpowder firearm injuries are minor; however, the potential for serious injury should not be underestimated. Minor injuries can be treated with local wound care and tetanus prophylaxis, and patients can be discharged from the emergency department. Education of parents and children to the potential risks associated with these weapons is essential. Stricter regulations regarding ownership of nonpowder firearms and mandatory safety instruction should be considered.

4882. Scuric, I., et al. (2016). "Post-traumatic epilepsy among patients on stationary rehabilitation after traumatic brain injury." Brain injury **30**(5-6): 777.

Objectives: Trauma is one of the most common causes of symptomatic epilepsy, especially after severe traumatic brain injury (TBI). We analysed the incidence, causes and treatment of post-traumatic epilepsy/seizures (PTE) among patients at rehabilitation after TBI. Methods: We collected data for 102 consecutive patients with an average age 42 ± 17 years, of which 84% were men. The average duration of follow-up after TBI was 229 ± 136 days. In the majority (62 patients or 61%) it was a severe TBI and in 21 or 21% a moderate, the mean GCS after the injury was 7 ± 4. Results: Epileptic seizures occurred in 27 (26%) patients, of which 12 during the acute treatment; 12 patients had recurrent attacks during follow-up. Anti-epileptic therapy (AET) at admission was prescribed in 45 patients and in 10 it was introduced during rehabilitation. The most common AET at admission and at discharge was methylphenobarbital (69% at admission and 36% at discharge), followed by carbamazepine (11% vs 13%) and valproate (9%, both at admission and discharge). At discharge there was a higher prevalence of newer AETs (primarily lamotrigine; only 2% at admission, but 25% at discharge, topiramate 4% and levetiracetam 4%; oxcarbazepine was prescribed in 9% of patients at admission and discharge), only four patients required a combination of several drugs. At seven patients AET was discontinued

during rehabilitation and, for 10, more withdrawal was recommended; three patients continued AET drugs for psychiatric diagnoses. Although patients with PTE had higher incidence of cranial fracture with fragments depression, multiple or bilateral brain contusions and Glasgow coma score after trauma 8 or lower, the differences were not statistically significant. The frequency of subdural, epidural or subarachnoid haemorrhage, brain structures midline shift in the acute phase greater than 5 mm, diffuse axonal injury or penetrating injuries was equally common. The only statistically significant difference ($p < 0.001$) was in a higher incidence of severe disorders of consciousness (minimally conscious and persistent vegetative state) in patients with PTE on admission to rehabilitation. Conclusions: PTE has been reported in about a quarter of patients admitted to rehabilitation after TBI, more often in those with prolonged severe disorders of consciousness. Methylphenobarbital is most commonly used in the prevention and treatment of PTE, at the release there is a tendency of introducing newer AET.

4883. Sebag, J., et al. (1986). "Transorbital penetrating injuries to the frontal lobe." Ophthalmic surgery **17**(10): 631-634.

Three cases of transorbital penetrating trauma to the frontal lobe are reported. These cases are remarkable in that minimal ocular trauma was incurred and excellent vision was preserved. These cases underscore the importance of suspecting the possibility of intracranial injury when evaluating penetrating orbital trauma.

4884. Secer, M., et al. (2007). "Transorbital brain injury by a metallic fragment: a case report." Turkish neurosurgery **17**(2): 163-165.

Because of anatomical configuration of the orbit, the brain can be damaged by penetrating transorbital injuries. At first sight, this type of trauma can be thought of as a solitary eye trauma. In this paper, we report a case who suffered from brain injury by a metallic foreign body which passed into the brain through the orbit. He was operated on urgently at two stages and there was no complication after 14 months of follow-up. Any neurological deficit or deterioration of consciousness would be marked. These types of injuries have to be evaluated systemically. Finally, detailed history, neuroradiological investigations, early surgical exploration and multidisciplinary studies are very important to obtain a good outcome.

4885. Secer, M., et al. (2015). "Penetrating shrapnel injuries of the posterior fossa." European journal of trauma and emergency surgery : official publication of the European Trauma Society **41**(2): 157-160.

BACKGROUND: Gunshot injuries of the posterior fossa are rare and may follow a fatal course. In posterior fossa gunshot injuries, cerebellar hematoma, contusion, obstruction of cerebrospinal fluid (CSF) circulation by the shrapnel, and intracranial hypertension caused by autoregulation loss lead to mortality in the early stage., METHODS: In this study, four cases of patients who underwent surgical intervention after penetrating shrapnel injuries of the pure posterior fossa were evaluated., RESULTS: All of the patients were male; their mean age was 26.5 +/- 5 years. The lowest and highest Glasgow Coma Scale scores were 4 and 12, respectively. Neural injury was detected by computed tomography performed after systemic and neurological examination following admission to the emergency service. The shrapnel was found in the cerebellar tissue in three cases and in the fourth ventricle in one case. Following preoperative procedures, surgery was performed with the patient in the prone position. Postoperative monitoring revealed no CSF fistula, meningitis, or hydrocephalus. None of the patients required revision surgery. There were no postoperative mortalities., CONCLUSION: Due to the small volume of the posterior fossa, acute pathologies may lead to rapid neurological deterioration and death. Early surgical intervention and close postoperative follow-up after penetrating shrapnel injuries of the posterior fossa play a significant role in reducing mortality and morbidity.

4886. Sedney, C. L., et al. (2012). "Penetrating injury to the superior sagittal sinus by a nail in a 4-year-old child: a case report." Pediatric emergency care **28**(11): 1220-1223.

Penetrating head injuries are rare in children, with most injuries being accidental as a result of unsupervised use of sharp objects by young children. We present the case of a 4-year-old boy brought to our emergency department with a nail embedded through a wooden board and into his skull. The nail was determined to be entering the superior sagittal sinus through radiographic imaging. Thus, surgical removal of the nail was determined to be necessary. Inspection revealed a likely through-and-through injury to the sinus, and therefore, because sinus reconstruction was not deemed possible, the sinus was occluded with suture ties both in front and behind the nail before nail removal. Postoperatively,

the patient did well and remained neurologically intact. Investigation for possible nonaccidental trauma was conducted. Although most commonly accidental in nature, nonaccidental penetrating traumas have been reported in both pediatric and adult populations. This patient did well after occlusion of his superior sagittal sinus at the coronal suture after penetrating injury by a nail. Penetrating injury in the pediatric population is predominantly thought to be accidental, but a high index of suspicion should be maintained for possible nonaccidental etiology.

4887. Seex, K., et al. (1997). "Trans-orbital penetrating head injury with a door key." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **25**(6): 353-355.

We report a unique case of transorbital penetrating head injury with a door-key. The case highlights the difficulties of preoperative ophthalmological assessment in the presence of a retained object and discusses the management of this and related injuries.

4888. Segal, D. H., et al. (1994). "Neurological recovery after cranioplasty." Neurosurgery **34**(4): 729-731.

A patient who sustained a gunshot wound to the head was successfully treated with acute neurosurgical intervention. Six months after the injury, cranioplasty was used to repair a large skull defect. After cranioplasty, the patient developed significant improvement in motor function in his left upper extremity, which had been plegic after his injury. Although the mechanism of neurological recovery after cranioplasty is controversial, the occurrence of such improvement may be a sufficient indication for cranioplasty in certain patients.

4889. Segal, J. A., et al. (1999). "Aminoglycoside neurotoxicity involves NMDA receptor activation." Brain research **815**(2): 270-277.

Previous studies have led to the hypothesis that the ototoxicity produced by aminoglycoside antibiotics involves the excitotoxic activation of cochlear NMDA receptors. If this hypothesis is correct, then these antibiotics should also injure neurons within the brain. Because aminoglycosides do not readily penetrate the blood brain barrier, we examined the effects of the aminoglycoside neomycin following intrastriatal injection. Neomycin (10-250 nmol) produced dose-dependent striatal damage manifested as an increased gliosis as measured by: (1) [3H]PK-11195 binding, (2) staining for the astrocytic marker glial fibrillary acidic protein (GFAP) and (3) staining for OX-6, an MHC class II antigen expressed by microglia and macrophages. Co-injection of subthreshhold doses of NMDA potentiates the striatal damage produced by neomycin (10 nmol). Moreover, neomycin-induced striatal damage is attenuated by a combination of the NMDA antagonists ifenprodil and 5, 7-dichlorokynurenic acid. Intrastriatal administration of compounds structurally related to neomycin, but devoid of modulatory actions at NMDA receptors (paromamine and 2-deoxystreptamine), fail to produce neuronal damage. These data support the hypothesis that aminoglycoside-induced ototoxicity is, in part, an excitotoxic process involving the activation of NMDA receptors. Moreover, aminoglycosides may damage the central nervous system in individuals with compromised blood brain barriers. Copyright 1999 Published by Elsevier Science B.V.

4890. Segal, S., et al. (2007). "Gaze-evoked amaurosis secondary to an intraorbital foreign body." Canadian journal of ophthalmology. Journal canadien d'ophtalmologie **42**(1): 147-148.

CASE REPORT: Gaze-evoked amaurosis (GEA) is a transient loss of vision upon eccentric gaze. With return to the primary position of gaze, the process promptly resolves., COMMENTS: We present the first reported case of GEA secondary to an intraorbital foreign body that was resolved surgically in the immediate posttraumatic period.

4891. Segura, T., et al. (2002). "[Prolonged clinical pattern of brain death in patients under barbiturate sedation: usefulness of transcranial Doppler]." Patron clinico de muerte cerebral prolongado en paciente bajo sedacion barbiturica: utilidad del Doppler transcraneal. **17**(4): 219-222.

INTRODUCTION: Throughout the world, is fully accepted that a person is dead when brain death exists. In most situations, neurological criteria permit the diagnosis of brain death, but in some instances, as when high-dose barbiturate therapy has been used, confirmatory testing are required by law., CLINICAL CASE: We report the case of a 17 year-old women who suffered high-dose barbiturate therapy due to post traumatic intracranial hypertension. During the period of the barbiturate infusion and until six days after the suppression of this therapy, neurological exploration and

EEG findings seem to confirm brain death, while transcranial Doppler (TCD) study remained normal., CONCLUSIONS: TCD is a fast, simple and accurate confirmatory testing in the determination of brain death and its findings are not affected by high-dose barbiturate therapy. We think that TCD must be present in all hospitals where mechanical ventilation and support of patients are carried out.

4892. Seidel, B. U., et al. (1983). "[Computed tomographic findings and controls in craniocerebral gunshot wounds]." Computertomographische Befunde und Verlaufskontrollen bei Schadel-Hirn-Schussverletzungen. **26**(6): 172-176.

31 patients with craniocerebral gunshot wounds were examined in the acute phase and 14 out of 22 survivors followed up for a period of up to 3 years. The clinical and CT findings as well as treatment measures are explained. The value of CT is convincingly demonstrated with this type of injury, as with others, but its prognostic value including prediction of follow-up results remains limited.

4893. Seidel, G., et al. (1993). "Transcranial color-coded duplex sonography of intracerebral hematomas in adults." Stroke **24**(10): 1519-1527.

BACKGROUND AND PURPOSE: It is well established from pediatric experience and animal experiments that intracerebral blood can be demonstrated by B-mode real-time duplex scanning. This has recently become feasible in adults as well. The present study investigated the changes in the sonographic appearance of intracerebral hematomas over the course of time., METHODS: Starting in May 1991, 23 consecutive patients with intracerebral hematoma confirmed by computed tomography (21 spontaneous and 2 traumatic hematomas) were investigated within 1 year. They were monitored by repeated ultrasound scanning via the transtemporal approach. The sonographic appearance of the hematomas on B-mode scans and the angle-corrected blood flow velocity in the basal cerebral arteries were assessed., RESULTS: There was unequivocal localization of the hematoma in 18 patients (78%). In 3 cases (13%), an adequate acoustic window could not be found. One small intracerebral hemorrhage was overlooked, and one extensive hemorrhage in the basal ganglia was misdiagnosed as a lobar hematoma. There was an alteration of the appearance of the hematoma with time. This was divided into three sonographic stages (initial stage, days 1 to 5; intermediate stage, days 6 to 10; and capsular stage, from day 10). In 14 of the 20 patients with an appropriate acoustic bony echo window, the blood flow velocity in the middle cerebral artery could be measured; in 1 of these patients, the signs of increasing intracranial pressure were apparent from Doppler frequency spectrum. In 5 patients, the intracerebral hematoma could be imaged but not the ipsilateral middle cerebral artery. One female patient showed cerebral circulatory arrest at the time of examination, which took place within 24 hours after the onset of clinical symptoms., CONCLUSIONS: Most intracerebral hematomas in adults can be imaged in B-mode. Their sonographic appearance changes over the course of the disease. The advantages of this noninvasive method are its easy bedside operation and its suitability for follow-up; it is also less stressful than other imaging procedures. It yields a combination of structural and functional diagnostic information. In approximately 13% of the cases, the investigation was not feasible because of inadequate ultrasonic penetration of the intact skull.

4894. Seider, N., et al. (2006). "Delayed presentation of orbito-cerebral abscess caused by pencil-tip injury." Ophthalmic plastic and reconstructive surgery **22**(4): 316-317.

This report describes the clinical and radiologic findings of a child who was stabbed with a pencil tip in his right upper eyelid, in what initially appeared to be an innocuous injury. The child presented again 3 weeks later with a combined orbital and frontal lobe brain abscess. The mechanism of injury is discussed, the orbital and neuro-surgical interventions are detailed, and the medical treatment is presented. Ophthalmologists should have a high index of suspicion for orbital foreign bodies and possible intracranial injury in cases of penetrating eyelid trauma.

4895. Seifert, L. B., et al. (2019). "Transoral Penetrating Knife Injury in the Oral, Maxillofacial Region: A Case Report." Craniomaxillofacial Trauma and Reconstruction Open **3**(1): E51-E55.

Penetrating injuries are a rare yet complex variety of oral and maxillofacial trauma and often require a multidisciplinary approach to treatment. The primary survey is always the first step in trauma management prior to proceeding with further evaluation and treatment. The following case report discusses the clinical strategy for a rare transoral and trans-spinal penetrating injury. A 42-year-old man presented with a penetrating metal injury through the

oral cavity. A computed tomography scan revealed a 12.8-cm-long knife penetrating through the tongue, floor of the mouth, and hypopharynx reaching the spinal cord in close proximity to the right vertebral artery. The patient did not present with any neurological malfunctions. An emergency tracheotomy was performed for airway protection. A balloon catheter was inserted into the right vertebral artery using interventional angiography to prevent massive bleeding prior to extraction. The knife was then surgically removed, and soft tissue reconstruction was performed without major bleeding. Postoperative magnetic resonance imaging angiography showed no bleeding of the right vertebral artery, but there was mild cerebellar infarction. Early isolated paresis of the right arm returned to nearly normal function within 1 week. This case demonstrates that complex penetrating injuries of the oral and maxillofacial region require a structured and multidisciplinary approach to prevent further side effects and obtain an ideal clinical outcome.

4896. Seikaly, H., et al. (1997). "The clavipectoral osteomyocutaneous free flap." Otolaryngology--head and neck surgery : official journal of American Academy of Otolaryngology-Head and Neck Surgery **117**(5): 547-554.

Microvascular free tissue transfer has revolutionized head and neck reconstruction and currently is considered the most successful and reliable method of primary oromandibular reconstruction. This study was designed to assess the feasibility of full thickness free vascularized transfer of the clavicle based on the clavicular branch of the thoracoacromial artery and the soft tissue component associated with the thoracoacromial axis. Forty dissections of the pectoral region were performed on 26 cadavers. The anatomic relations of the region and the thoracoacromial arterial and venous systems were documented in detail. Selective ink injections of the thoracoacromial arterial branches were also performed on fresh cadavers. The clavicle was supplied mainly by the clavicular artery (medial three quarters), with minor contribution from the deltoid artery (lateral quarter). An average of 16.1 cm (range of 12 to 20 cm) was obtained with total clavicular harvest and the clavicle had sufficient width and height to support dental implants. Two soft tissue donor sites were associated with the thoracoacromial artery: the sternocostal head of the pectoralis major muscle, with the overlying skin supplied by the pectoral artery, and the clavicular head of the pectoralis major muscle, with the overlying skin supplied by the deltoid and clavicular arteries. Sensory innervation of the upper chest was supplied through the supraclavicular nerves, whereas the lateral pectoral nerve supplied motor innervation to both heads of the pectoralis major muscle. The anatomy of the clavipectoral donor site and the first case of full thickness free clavicular transfer for mandibular reconstruction in the English literature are presented. The donor site is an excellent source of well vascularized, thin, pliable, hairless, potentially innervated (motor and sensory) soft tissue, along with up to 20 cm of clavicular bone. The surgical anatomy is familiar to the head and neck surgeon. The harvesting does not require repositioning of the patient and is amenable to a two-team, simultaneous approach. The functional and cosmetic donor site morbidity is minimal even with clavicular harvest. The major disadvantage of this flap is the relatively short pedicle. The authors conclude that the thoracoacromial system provides a free flap with osseous and soft tissue components that are well suited for oromandibular reconstruction.

4897. Seikaly, H., et al. (2007). "Clavipectoral osteomyocutaneous free flap in oromandibular reconstruction." The Journal of otolaryngology **36**(3): 186-190.

INTRODUCTION: Mandibular reconstruction continues to challenge most head and neck reconstructive surgeons despite the tremendous advances in surgical and fixation techniques. We recently described the clavipectoral osteocutaneous flap for mandibular reconstruction. This flap encompasses the clavicle and the clavicular head of the pectoralis major with overlying skin., OBJECTIVES: The purpose of this article is to report our prospective clinical experience with the use of clavipectoral osteocutaneous flap in the reconstruction of oromandibular defects., STUDY DESIGN: Prospective case series., METHODS: Five patients with significant mandibular defects underwent reconstruction using the newly described clavipectoral flap. All patients had shoulder range of motion testing preoperatively and at 3 and 6 months postoperatively. Panorex and bone scans were obtained on the seventh postoperative day., RESULTS: All five flaps survived. The transferred clavicles demonstrated good vascularity on the postoperative bone scans. The shoulder morbidity was minimal, with all patients resuming their preoperative level of activity., CONCLUSIONS: The clavipectoral flap has bone and soft tissue components that are especially suited for composite mandibular defects, but it should be used as a second-line flap owing to the short pedicle and the regular need for vein grafts.

4898. Seitelman, E., et al. (2009). "Young man with fishing injury. Intracranial fishing line sinker." Annals of emergency medicine **54**(6): 854-864.

4899. Seitz, I. A., et al. (2014). "Unusual sequela from a pencil stab wound reveals a retained graphite foreign body." Pediatric emergency care **30**(8): 568-570.

Penetrating pencil-tip injuries are common among children and usually resolve without long-term sequelae. However, failure to detect and remove embedded pencil fragments can result in increased morbidity or misdiagnoses of other, more serious, conditions. We report on the case of a 10-year-old boy stabbed with a pencil on his right chin. Initial treatment in the emergency department included irrigation and closure of the laceration. Following suture removal, the patient returned to the emergency department (with bright-purple drainage from the wound site). Radiographic evaluation led to the discovery of an embedded foreign body requiring surgical removal.

4900. Sejpal, K., et al. (2013). "Cultivated limbal epithelial transplantation in children with ocular surface burns." JAMA ophthalmology **131**(6): 731-736.

IMPORTANCE: Although several reports are available on the use of conventional and cultured limbal epithelium using various substrates in the treatment of limbal stem cell deficiency (LSCD), the patient populations studied have been largely adults. Thus, to our knowledge, the outcomes of this procedure exclusively in a pediatric population have not been reported previously., OBJECTIVE: To report the outcomes of autologous ex vivo cultivated limbal epithelial transplantation (CLET) in pediatric patients with LSCD after ocular burns., DESIGN AND SETTING: A retrospective, interventional case series of patients treated at the L. V. Prasad Eye Institute, Hyderabad, India., PARTICIPANTS: Children up to 15 years with LSCD secondary to chemical or thermal injury who underwent CLET from April 1, 2001, through June 31, 2010, with a follow-up of at least 1 year, were included in the study., INTERVENTION: After a limbal biopsy specimen obtained from a healthy area of the limbus, the limbal epithelial cells were cultured on a denuded human amniotic membrane substrate using a xeno-free explant culture technique. A monolayer of cultivated epithelial cells along with the amniotic membrane was transplanted on the patient's affected eye after pannus excision. In cases of failure, the same procedure was repeated., MAIN OUTCOMES AND MEASURES: Ocular surface stability and visual improvement were the primary and secondary outcome measures, respectively. Success was defined as a stable corneal epithelium without conjunctivalization. Eyes with conjunctivalization and persistent epithelial defects were classified as failures., RESULTS: Of the 107 eyes of 107 patients included in this study, 73 eyes (68.2%) underwent 1 and 34 eyes (31.8%) underwent 2 autologous CLET procedures. At a mean follow-up of 3.4 years, 50 eyes (46.7%) achieved completely epithelialized, avascular, and stable ocular surfaces. At the final visit, 58 eyes (54.2%) had improvement in visual acuity of 0.2 or more logMAR units., CONCLUSIONS: Autologous CLET was successful in restoring the ocular surface and improving vision in almost half of the children blinded by ocular burns.

4901. Sekula-Perlman, A., et al. (1998). "Three unusual cases of multiple suicidal gunshot wounds to the head." The American journal of forensic medicine and pathology **19**(1): 23-29.

We describe three unusual cases of suicide involving multiple gunshot wounds, in which all of the victims suffered gunshot wounds to the head, yet none was rendered immediately incapacitated. Injuries were confined to the same area in two of the cases and were located in different areas in the other case. Two of the cases initially appeared to be homicides rather than suicides.

4902. Selden, B. S., et al. (1988). "Outcome of self-inflicted gunshot wounds of the brain." Annals of emergency medicine **17**(3): 247-253.

A consecutive series of 67 patients who had sustained self-inflicted gunshot wounds of the brain was reviewed retrospectively to evaluate factors determining outcome. Weapon caliber, site of bullet entry, degree of brain wounding on computerized tomographic scan, and presenting Glasgow Coma Scale (GCS) score were examined. Overall mortality, degree of disability in survivors, and survival time after injury in fatally wounded patients were assessed. Ninety-eight percent of all patients with an initial GCS score of 8 or less died. When the GCS score was more than 8, 91% of patients survived (P less than .0001). Survival rate was significantly increased in patients with injury limited to one lobe of the brain, compared with patients with brain wounds of greater severity demonstrated on computerized tomographic scan (P less than .05), while a missile crossing both vertical anatomic planes of the brain or coming to rest in the posterior fossa was lethal in 100% of cases. Survivors scored relatively well on the Glasgow Outcome Scale. Almost all (98%) fatally

injured patients maintained vital functions for a time ample for transportation and evaluation at a major referral center. These findings hold important implications for trauma center and critical care resource allocation as well as organ transplantation programs.

4903. Selesnick, S. H. and A. Patwardhan (1994). "Acute facial paralysis: evaluation and early management." American journal of otolaryngology **15**(6): 387-408.

4904. Seleye-Fubara, D. and E. N. Etebu (2012). "Pathology of cause of death from penetrating weapons in the Niger Delta region of Nigeria: an autopsy study of 254 cases." The Nigerian postgraduate medical journal **19**(2): 107-110.

AIMS AND OBJECTIVES: To study the pattern of death caused by penetrating weapons. This is a prospective autopsy study of 254 cases over 8 years (1995 - 2002), SUBJECTS AND METHODS: A retrospective analysis of all the medico-legal autopsies performed by the authors on bodies in which the circumstances of death suggested the use of penetrating weapons over a period of 8 years was carried out by the authors., RESULTS: A total of 254 bodies that died during close combat, communal clashes, militant attacks and armed banditry of penetrating weapons were recorded. The youngest was 2 years old male while the oldest was 75 years old male. The highest death toll occurred between the ages of 20-49 years 197(77.6% cases) with a peak at the age group 20 - 29 years 75(29.5%) cases. There were 218(85.8%) males and 36 (14.2%) females giving a male to female ratio of 6:1. The most common cause of penetrating death was gunshot missiles 136(53.5%), while the most common anatomic site of the wound was the chest wall 85(33.5%). Instant death occurred in 179(70.5%) cases and haemorrhagic shock caused the death of 229(90.2%) cases, while the brain was the most common organ lacerated 61(24.0%)., CONCLUSION: Penetrating wounds were commonly sustained in close combats, during communal clashes, militant and armed robbery attacks, and youth restiveness in the Niger Delta region of Nigeria. Guns which are prohibited by law and other sharp and pointed instruments were freely used. The condition is preventable by enforcing stringent laws, but it resulted into a lot of mortalities.

4905. Selladurai, B. M. (2011). "Epilepsy in head injury." Neurology Asia **16**(SUPPL. 1): 13-15.

Posttraumatic epilepsy accounts for about 20% of symptomatic epilepsy in the general population and about 5% patients referred to epilepsy centers. Mechanisms that can provoke posttraumatic seizures are still not well understood. The extent of focal tissue destruction is one of the key determinants of risk of seizures. Early posttraumatic seizures can worsen ischemic injury and increase intracranial pressure. Adverse sequelae of late posttraumatic seizures include a higher mortality and personality disorders. Whilst anticonvulsant prophylaxis of early seizures is recommended, such therapy is yet to be proven to prevent late posttraumatic seizures.

4906. Sellon, D. C., et al. (2000). "Hepatic abscesses in three horses." Journal of the American Veterinary Medical Association **216**(6): 882-885.

Hepatic abscesses were diagnosed in 3 adult horses. Two were < 4 years old and had evidence of concurrent immune-mediated conditions, including aseptic arthritis, immune-mediated thrombocytopenia, and immune-mediated anemia. Predisposing factors for hepatic abscess formation in these horses included prior abdominal surgery, proximal duodenitis/jejunitis, inflammatory bowel disease, and a penetrating foreign body in the large colon. Serum hepatic enzyme activities were within or slightly greater then reference limits in all 3 horses. The most pronounced and consistent abnormalities on CBC and serum biochemical analyses were hyperproteinemia, hyperglobulinemia, and a decreased albumin-to-globulin concentration ratio. Hepatic ultrasonography identified hepatic abscesses in all 3 horses. A variety of bacteria were isolated from these abscesses, including Staphylococus aureus and Bacteroides fragilis. One horse developed septic tibiotarsal arthritis, presumably as a result of intermittent bacteremia. Despite aggressive medical treatment, all horses were euthanatized because of a worsening condition and poor prognosis.

4907. Selvanathan, S., et al. (2007). "Penetrating craniocerebral injuries from nail-gun use." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **14**(7): 678-683.

Three patients with penetrating craniocerebral nail-gun injuries are described. In the first patient the nail was impinging on the internal carotid artery (ICA) in the carotid canal. On removal of the nail, the patient developed a false

aneurysm at the site. To our knowledge, this is the first reported case of nail-gun injury affecting the ICA and also the first case of penetrating head injury affecting the ICA in the carotid canal. The second patient had seven intracranial nails in the frontal area. Three nails penetrated the left orbit, one of which perforated the globe. One nail damaged the optic nerve resulting in optic neuropathy. In the third patient the nail extended through the squamous temporal bone into the temporal lobe. All three were managed successfully via closed gentle traction without craniotomy and/or endovascular intervention. The literature is reviewed and management options for penetrating head injuries are discussed.

4908. Selvarajah, S., et al. (2014). "The burden of pediatric spinal cord injury in the united states." Neurology **82**(10).

Objective: To update the epidemiology and burden of pediatric traumatic spinal cord injury (TSCI) in the U.S.Background: The burden of acute TSCI among U.S. children was last described between 1997 and 2000 using inpatient data. Improved estimates using current national emergency department (ED) data will inform resource utilization and injury prevention.Design/Methods: We analyzed the prospectively maintained Nationwide Emergency Department Sample (2007-2010). Persons age <18 years with a diagnosis of acute TSCI were identified using ICD-9 diagnosis codes 806.∗and 952.∗(N=6,132), and weighted to produce U.S. national estimates. Outcomes include incidence of pediatric TSCI, mortality, discharge disposition, and inflation-adjusted charges in 2010 USD.Results: The cumulative incidence of pediatric TSCI remained steady between 2007 and 2010, averaging17.5 per million-population. The median age at presentation was 15 years (Interquartile range IQR=12-16) with majority being males (72.5%). C1-C4 injuries were predominant in children <5 years (47.4%), whereas adolescents aged 16-17 years, were more likely to sustain thoracic level injuries (26.6%), P<0.001. Children <5 years presented with higher injury severity scores (22, IQR=13-29), and concurrent brain injury (24%) compared to older children, P<0.001. Children <5 years were more likely to be injured from a RTA (50.9%) compared to older children. Firearms were implicated in 8.3% of injuries, of which 94.7% were in adolescents aged 13-18 years. Of 35 TSCI-related deaths in the ED, 40% were children aged <5 years. Inpatient admission was necessary in 62.4% of patients. Despite stable incidence rates, average ED treatment charges per visit increased significantly from $3,495 in 2007 to $4,889 in 2010 (P<0.008). The overall cumulative pediatric TSCI ED charge was $17.7 million.Conclusions: The average treatment charge per pediatric TSCI ED visit increased by $1,394 (40%) between 2007 and 2010, although incidence held steady. RTA-related TSCI disproportionately affects young children while firearm-related TSCI is most common among adolescents aged 13-18 years. These findings inform TSCI prevention strategies and support efforts at reducing firearm injuries.

4909. Semkin, V. A., et al. (1996). "[The use of titanium plates and endoprostheses for the mandibular condyles in reconstructive surgery of the mandible]." Ispol'zovanie titanovykh plastin i endoprotezov myshchelkovykh otrostkov v rekonstruktivnoi khirurgii nizhnei cheliusti. **75**(3): 27-29.

Potentialities of titanium plates and endoprostheses of the condyle processes in replacement of the postoperative defects of mandibular bone tissue are discussed. A recently developed Russian kit of titanium plates and instruments and specificities of plasty to repair bone defects using this kit are described. The results of surgical repair in 5 patients subjected to resection of the mandible with exarticulation for tumors or osteomyelitis aftereffects were good: the oval of the face and mandibular function were repaired.

4910. Semple, B., et al. (2016). "Sex-dependent social behavior deficits and neuronal morphology after pediatric brain injury." Journal of neurotrauma **33**: A8-A9.

Chronic social behavior problems after pediatric traumatic brain injury (pTBI) significantly contribute to poor quality of life for survivors, however, the mechanisms underlying such deficits have not been elucidated. We hypothesized that interconnected brain regions comprising the 'social brain network' undergo aberrant neuroplasticity changes during development following pTBI, to influence social functioning at adulthood. We therefore asked whether pTBI influences neuronal morphology in the medial prefrontal cortex (mPFC), a region involved in social cognition and behavior, prior to the development of social problems. Littermate male and female C57Bl/6 mice were subjected to a unilateral controlled cortical impact or sham-operation at postnatal day 21, approximating TBI during early childhood. One cohort were euthanized at 3 weeks post-surgery for Golgi-Cox staining (n = 5/group); a second cohort were maintained until 8 weeks post-surgery for the evaluation of psychosocial and neurocognitive function (n = 8-10/group). Morphological analysis of layer III pyramidal neurons in the ipsilateral mPFC revealed a reduction in dendritic complexity at adolescence after pTBI in male mice compared to sham controls, including fewer branch nodes and ends, as well as

reduced basal dendritic length. By adulthood, consistent with previous studies, male pTBI mice showed deficits in social and sociosexual behaviors. In contrast, mPFC neuroanatomy was unaffected by pTBI in female mice, which also showed a more limited profile of social dysfunction. pTBI mice exhibited robust hyperactivity across multiple paradigms, to a greater extent in males compared to females. Together, our findings demonstrate changes in neuronal morphology, remote from the injury site, several weeks after pTBI in male mice, and associated with the subsequent emergence of social behavior deficits. Sex is a determinant of both regional neuroplasticity and social outcomes after pTBI. It remains unclear whether these changes are an indirect, stress-related consequence of pTBI, or a direct result of aberrant connectivity of the social brain network.

4911. Semple, P. L. and Z. Domingo (2001). "Craniocerebral gunshot injuries in South Africa--a suggested management strategy." South African medical journal = Suid-Afrikaanse tydskrif vir geneeskunde **91**(2): 141-145.

OBJECTIVE: To determine the outcome of craniocerebral gunshot injuries, analyse factors that affect prognosis and suggest a management protocol., DESIGN: A retrospective analysis of civilian craniocerebral gunshot injuries treated over a 7-year period., SETTING: Groote Schuur Hospital's neurosurgery and trauma unit service., PATIENTS: One hundred and eighty-one patients with craniocerebral gunshot injuries were admitted to the Department of Neurosurgery, Groote Schuur Hospital, University of Cape Town, over a 7-year period and a retrospective analysis of these patient records with regard to outcome and prognostic factors was carried out., RESULTS: Seventy-six patients sustained non-penetrating injuries, 8 (11%) of whom had underlying cerebral injury on computed tomography (CT) scan. The prognosis was good in the case of non-penetrating injuries. One hundred and five patients sustained penetrating injuries and 57% (62) had a poor outcome. A Glasgow Coma Score (GCS) of 5 or less following resuscitation was associated with a 98% mortality rate. CT scan evidence of transventricular injury was associated with 100% mortality, bihemispheric injury with 90% mortality, and diffuse cerebral swelling with 81% mortality., CONCLUSION: Patients with non-penetrating craniocerebral gunshot injuries should all undergo a CT scan as 10% will have cerebral injury. The prognosis is normally good. In penetrating craniocerebral gunshot injuries a GCS of 5 or less, or a GCS of 8 or less with CT scan findings of transventricular or bihemispheric injury have such a poor outcome that conservative treatment is indicated.

4912. Senel, A., et al. (1998). "Pediatric civilian gunshot wounds of the cranium." Ondokuz Mayis Universitesi Tip Dergisi **15**(3): 227-234.

Pediatric civilian gunshot wounds of the cranium is relatively rare condition in the neurosurgical practice. The medical records of pediatric patients at our Neurosurgery Clinic (Ondokuz Mayis University, Medical Faculty, Department of Neurosurgery) treated for civilian gunshot wounds of the cranium were reviewed to determine the clinical, pathological and radiological features, and the outcome of these lesions. In total, 14 (8 boys and 6 girls) children were cared for between 1990 and 1996. The agressive surgical treatment (urgent craniotomy, meticulous wound debridment and the removal of all accessible bone and bullet fragments, as well as other foreign materials, decompression, and evacuation of the hematoma) were performed all patients exept six patients who in condition of neurological areflexic and respiratuar arrest. 7 (%50) patients died. 3 (21%) patients with no neurological deficite, 2 (14%) patients with hemiplegic, and 2 (14%) patients with persistent vegetative state were discharged. The postoperative complications included scalp wound infection and subcutaneous cerebrospinal fluid leaks (One patient, 7%), intracerebral apse (one patient, 7%), and subdural ampiyem (one patient, 7%). The agressive surgical treatment of the gunshot wounds of the cranium is controversial, particularly the patient was brought deep comatose and unresponsive (areflexic) state. The prognostic factors included that the neurological state on arrival, radiological features, motivation for the shooting, and missile velocity. We have reviewed our experience over a period of 6 years with 14 pediatric patients. Our experience has led us to purpose a agressive operative approach for patients with a Glasgow coma score of 6 to 15 on arrival. The patients having bihemisphere injuries with a Glasgow coma score of 3 to 5 on arrival, and particularly when combined with scattering of bone and metal fragments away from the bullet track, had worse prognose in our series. We believe that operative approach is unnecessary for patients having bihemisphere injuries with a Glasgow Coma Score of 3 to 5 on arrival, exept large defect of the scalp and skull.

4913. Seniow, J., et al. (2003). "The cognitive impairments due to the occipito-parietal brain injury after gunshot. A successful neurorehabiliation case study." Brain injury **17**(8): 701-713.

OBJECTIVE: The presented case study describes the beneficial results of the neuropsychological rehabilitation of a gunshot victim, even with late initialization of the therapy--over 1 year after head trauma., DESIGN: A case study of DE, a victim with bilateral damage of the parietal-occipital regions of the brain due to a gunshot., METHODS: Neuropsychological rehabilitation, first preceded by an initial neuropsychological examination (standard psychological tests: WAIS-R, RAVLT, Rey's CFT, BVRT and clinical experiments tailored to DE's condition), was initiated 1 year after trauma. The rehabilitation programme consisted of computer-based tasks, paper-and-pencil exercises, and occupational therapy. The patient's progress was assessed as improvement in performance in standardized tests and computer-based tasks., RESULTS: DE was diagnosed with complex cognitive deficits syndrome, including visual associative agnosia, apraxia, visuospatial and constructive disorders and linguistic defects. After 1 year of rehabilitation the patient's functioning significantly improved as measured by psychological tests and computer-based tasks ($p<0.05$) as well as the evaluation of the patient's quality of life., CONCLUSIONS: The case study demonstrates beneficial effects of neurorehabilitation even initialized at the so-called 'late stage' after a brain injury.

4914. Senoglu, M., et al. (2018). "Neurological recovery after traumatic Cauda Equina syndrome due to glass fragments: An unusual case." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES **24**(1): 82-84.

Penetrating spinal injuries with foreign bodies are exceedingly rare. To date, pathological problems due to glass fragments in the spinal canal have rarely been reported. In this report, the case presenting with a back laceration, leg pain, and leg weakness was found to have glass frag-ments in the spinal canal at the L2-L3 level by lumbar computed tomography and magnetic resonance imaging. After L2 total laminectomy and retrieval of the glass fragments, the dura was re-paired. The patient was discharged from the hospital after complete neurological recovery. In cases of spinal canal injuries due to foreign bodies, early operative decompression of the neural elements is the treatment of choice. Patients with Cauda Equina syndrome due to glass fragments have a good prognosis for functional recovery.

4915. Senol Guven, G. and S. Uckan (2016). "Alveolar transport distraction osteogenesis and implant placement: A new frontier." Journal of oral and maxillofacial surgery **74**(9): e6.

Vertical Alveolar Distraction Osteogenesis (VADO) has been used successfully to increase the height of the alveolus for 2 decades. In large defects VADO planning is sometimes impossible as the amount of native bone over the anatomic structures may not be enough. Onlay bone grafting to these large defects is mostly unsuccessful due to the limited amount of thin mucosa covering the graft. Alveolar transport distraction osteogenesis (ATDO) is a relatively new method and indications, technique, and complications are not well known. ATDO was performed on 10 patients (4 male, 6 female) with 12 defects (3 cleft lip-palate, 3 benign tumor resection, 1 posttraumatic, 2 gunshot injury, 3 post extraction severe atrophy). The location of the defects was the anterior mandible (1), posterior mandible (4), anterior maxilla (5), and posterior maxilla (2). 12 distractors were inserted (2 of them were bilateral, 10 of them were unilateral). The mean age of the patients was 39.1 years. All of the surgical procedures were performed by the same surgeon, and, average bone length gained was 18.2 mm (10-26). One or two teeth were distracted with the alveolar bone depending on the position of the teeth. Implants inserted following 3 months of consolidation period. Three patients needed additional horizontal bone grafting from symphyseal area and to these patients implants were inserted 5 months after onlay bone grafting. The length and diameter of the implants were 11.5-13 mm long and 3.5-4 mm wide. Final prosthetic rehabilitation was performed 3 months after implant insertion. Radiographic examination (panoramic, cephalometric radiographs, CBCT) was performed before and after implant insertion. Photographs were taken of these patients for visual examination. After a mean follow-up of 45 months (range 6-96 months) the survival rate of the 25 implants was 91.4% (2 implant failure). All failures occurred during the early healing period (within 3 months after distraction). ATDO is an alternative treatment used to obtain sufficient alveolar bone and mucosa. No donor site is needed, the amount of augmentation can be controlled and implant insertion time will be reduced. It can be concluded that ATDO can be an effective and reliable method for reconstructing wide alveolar defects with dental implants.

4916. Senthilkumaran, S., et al. (2010). "Penetrating head injury from angle grinder: A cautionary tale." Journal of neurosciences in rural practice **1**(1): 26-29.

Penetrating cranial injury is a potentially life-threatening condition. Injuries resulting from the use of angle grinders are numerous and cause high-velocity penetrating cranial injuries. We present a series of two penetrating head

injuries associated with improper use of angle grinder, which resulted in shattering of disc into high velocity missiles with reference to management and prevention. One of those hit on the forehead of the operator and the other on the occipital region of the co-worker at a distance of five meters. The pathophysiological consequence of penetrating head injuries depends on the kinetic energy and trajectory of the object. In the nearby healthcare center the impacted broken disc was removed without realising the consequences and the wound was packed. As the conscious level declined in both, they were referred. CT brain revealed fracture in skull and changes in the brain in both. Expeditious removal of the penetrating foreign body and focal debridement of the scalp, skull, dura, and involved parenchyma and Watertight dural closure were carried out. The most important thing is not to remove the impacted foreign body at the site of accident. Craniectomy around the foreign body, debridement and removal of foreign body without zigzag motion are needed. Removal should be done following original direction of projectile injury. The neurological sequelae following the non missile penetrating head injuries are determined by the severity and location of initial injury as well as the rapidity of the exploration and fastidious debridement.

4917. Seo, B.-R., et al. (2009). "An unusual stab wound causing a traumatic pseudomeningocele at the craniocervical junction." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **16**(10): 1365-1367.

A stab wound to the craniocervical junction complicated by a pseudomeningocele has been reported rarely. A 65-year-old man was stabbed with a knife, and the blade penetrated the space between the occipital bone and the atlas. On admission, he presented with quadriparesis; the left arm was predominantly affected. The sensory level was at C2 on the left side. T2-weighted MRI showed a focal area of hyperintensity at the cervicomedullary junction, localized to the left of the spinal cord. The wound was carefully cleaned and closed. Follow-up MRI revealed a large pseudomeningocele along the trajectory, which resorbed completely without intervention. The quadriparesis improved progressively, except for the left arm, which improved only slightly. The asymptomatic insignificant meningocele completely improved spontaneously without surgery.

4919. Seok, H., et al. (2021). "Reconstruction of anterior skull base fracture using autologous fractured fragments: A simple stitching-up technique." Korean journal of neurotrauma **17**(1).

Objective: A displaced fracture in the anterior cranial base may be complicated by cerebrospinal fluid (CSF) rhinorrhea and enophthalmos. This study introduces a reconstruction technique with direct dural repair and reduction and fixation of the autologous fractured fragments. Methods: Displaced fractures in the anterior cranial base were reconstructed using a stitching-up technique: A bicoronal scalp incision and frontal craniotomy was performed and the displaced bone was withdrawn. The lacerated dura was repaired primarily using a graft. Small holes were created in the intact cranial bones and the displaced harvest bone. Black silk was passed through the holes and the displaced bone was repositioned on tying the silk. Lumbar drain was not placed in any of the cases. The feasibility and outcome were evaluated. Results: Five patients with displaced skull fractures of the anterior cranial base were included. All cases were men who had a direct impact on the forehead and/or eye. All the displaced fractures occurred in the orbital roof, and ethmoid bone fractures were present in 4 cases. Dural laceration was involved in 4 cases and repaired by placing artificial dura in 3 cases and a pericranial graft in 1 case. Following surgery, all cases were uneventful, and the anterior cranial fossa was well reconstructed. CSF leakage or enophthalmos did not occur in any of the cases. Conclusion: Direct dural repair and autologous stitching-up reconstruction using the fractured fragment could be an effective method to prevent CSF leakage and enophthalmos in displaced fractures of the anterior cranial base.

4921. Sepehr, A., et al. (2010). "Novel endoscopic management of penetrating intracranial trauma." The Annals of otology, rhinology, and laryngology **119**(11): 786-788.

We report a unique case of minimally invasive endoscopic removal of a penetrating orbitocranial foreign body (POCFB), and present a review of the literature. A 12-year-old boy was impaled in the orbit with a gate latch. Neurosurgical consultation ascertained that removal via bifrontal craniotomy would necessitate extensive brain retraction and result in permanent anosmia. Attempting nasal endoscopic removal was deemed prudent, given this morbidity and a lack of brain parenchymal violation. The patient recovered without a cerebrospinal fluid leak or other neurologic sequelae. To date, craniotomy is the only reported management of POCFBs in the literature. We herein report the first nasal endoscopic removal of a POCFB.

4922. Seroto, P. M., et al. (2021). "The role of tertiary neurosurgical intervention in non-missile penetrating injuries of the spine." European spine journal : official publication of the European Spine Society, the European Spinal Deformity Society, and the European Section of the Cervical Spine Research Society **30**(6): 1397-1401.

PURPOSE: The objective of the study was to determine whether all patients with spinal non-missile penetrating injuries (NMPIs) need to be managed at a tertiary neurosurgical centre., METHODS: A retrospective analysis of clinical, demographic, and imaging records was performed on all NMPI patients referred to the Department of Neurosurgery at Tygerberg Academic Hospital in Cape Town, South Africa, between 1 January 2016 and 31 December 2019., RESULTS: Ninety-six patients were identified (94 males and 2 females) with 35 cervical, 60 thoracic, and 1 lumbar spinal stab. Eighty-six had an incomplete spinal cord injury. Six patients presented with cerebrospinal fluid (CSF) leak, all of which resolved spontaneously. MRI was performed in nine patients. Six patients had retained blades, of which 5 were removed in the emergency room (ER). Surgery was performed in two patients (cervical intramedullary abscess and a retained blade). Two patients developed meningitis, and one an intramedullary abscess. Twenty-two patients had associated injuries (pneumothorax, bowel injury). The average length of stay was 17 days, with 81% being unchanged neurologically. The average time from discharge to leaving the hospital was 11 days., CONCLUSION: Early management of NMPI should include prophylactic antibiotics and wound debridement and X-ray imaging to exclude retained blades. Bowel and lung injury must be managed accordingly. Tertiary neurosurgical referral is not routinely necessary and is only warranted for deteriorating neurology, retained blades not removable in the ER, and respiratory failure secondary to spinal cord injury. Complications include meningitis and persistent CSF leak, which should be referred timeously. Copyright © 2020. Springer-Verlag GmbH Germany, part of Springer Nature.

4923. Serramito-Garcia, R., et al. (2009). "[Epidural haematoma due to an headrest in an adult]." Hematoma epidural secundario al empleo de cabezal autoestatico en un adulto. **20**(6): 567-570.

A head fixation device with pins is commonly used for immobilization of the patients during neurosurgical procedures. Despite its appropriate management, it may be the cause of some serious complications such as skull perforation and intracranial injuries. We report the case of a 19-years-old young admitted for a endoscopic third ventriculostomy who developed an epidural haematoma due to the penetration of the skull by a pin.

4924. Sersar, S. I., et al. (2016). "Impacted thoracic foreign bodies after penetrating chest trauma." Asian cardiovascular & thoracic annals **24**(8): 782-787.

BACKGROUND: Retained foreign bodies in the chest may include shell fragments, bullets, shrapnel, pieces of clothing, bones, and rib fragments. The risks of removal of foreign bodies must be weighed against the complications of leaving them inside the chest., METHODS: We treated 90 cases of retained intrathoracic foreign bodies in patients admitted to 3 tertiary centers in Saudi Arabia between March 2015 and March 2016. Sixty patients were injured by shrapnel, 26 had one or more bullets, 3 had broken rib fragments, and one had a metal screw. The chest wall was site of impaction in 48 cases, the lungs in 24, pleura in 14, and mediastinum in 4., RESULTS: Removal of the retained foreign body was carried out in 12 patients only: bullets in 9 cases, bone fragments in 2, and a metal screw in one. The predictors for removal were bullets, female sex, and mediastinal position with bilateral chest injury, especially with fracture ribs., CONCLUSION: Retained intrathoracic foreign bodies due to penetrating chest trauma are treated mainly conservatively unless there is another indication for chest exploration. 4925. Sertbaş, İ. and M. Karatay (2020). "The effect of the delay between injury and surgery on mortality, morbidity, and complications in craniospinal gunshot wounding." Trauma (United Kingdom) **22**(3): 193-200.

Introduction: The effect of the surgical approach and the duration between the trauma and surgery on the complications, morbidity, and mortality in cranial and spinal penetrating gunshot injuries are investigated. Methods: Evaluation of 63 patients from the Libyan civil war who were referred to the İstanbul Yeni Yüzyıl University Gaziosmanpaşa Hospital neurosurgery clinic for the treatment and surgery between 2015 and 2017. Results: Complications such as meningitis, superficial infection, and abscess developed in 31% of the patients who underwent surgery within the initial 24 h, 58% of the patients who underwent surgery between 24 and 72 h and in all patients who underwent surgery after 72 h. While an improvement was seen in all 14 patients who had preoperative paresis and underwent surgery within 24 h or between 24 and 72 h, only one of the six patients who had paresis and underwent surgery after 72 h improved. One of the patients who underwent surgery within 24 h, three of those who underwent surgery between 24 and 72 h, and four of those who underwent surgery after 72 h died. Conclusion: The complications, morbidity, and mortality increase with a prolonged duration between the injury and surgery after craniospinal gunshot wounding.

4926. Sethi, J. M. and B. Rozdilsky (1978). "Internal carotid artery embolism by shotgun pellet." The Canadian journal of neurological sciences. Le journal canadien des sciences neurologiques **5**(3): 325-326.

Various examples of foreign body embolization of cerebral arteries, usually followed by serious consequences, have been reported (Lindberg et al., 1961; Chason et al., 1963; Steele et al., 1972; Wetli et al., 1972). However, a shotgun pellet entering the left atrium of the heart through a gunshot wound of the chest with subsequent embolic occlusion of one of the carotid arteries appears to be unique. It is the subject of this short communication.

4927. Setkowicz, Z. and K. Janeczko (2003). "Long-term changes in susceptibility to pilocarpine-induced status epilepticus following neocortical injuries in the rat at different developmental stages." Epilepsy research **53**(3): 216-224.

In the brain, injury-induced gliosis and axonal sprouting have been regarded as age-dependent repairing processes with, unfortunately, epileptogenic effects. The present study examines whether brains injured at different developmental stages become more or less susceptible to experimentally-induced status epilepticus. In 6- and 30-day-old Wistar rats (P6s and P30s, respectively), a mechanical injury was performed in the cortex of the left cerebral hemisphere. On postnatal day 60, all the animals and naive controls received single intraperitoneally pilocarpine injections to evoke status epilepticus. During a 6-h period following the injection, the animals were observed continuously and motor manifestations of seizure activity were recorded and rated. Seven days after pilocarpine injection, the animals were perfused and their body and brain weights recorded. When compared to controls, P6s showed neither significant variations in their epileptic behavior nor in brain and body weights. In relation to controls and to P6s, P30s presented an extremely high mortality, a significant loss of body weight and much longer-lasting seizures of much higher intensity. The data provide evidence that the long-term variations in susceptibility to experimentally-induced status epilepticus are determined by differences in the brain response to injury at different stages of postnatal development.

4929. Sezer, C., et al. (2021). "Spontaneous migration of a bullet in the cerebrum." Journal of Surgical Case Reports **2021**(4).

Herein, we report the case of a 32-year-old man who experienced spontaneous migration of a bullet within the brain following a gunshot injury. Emergent computed tomography revealed the bullet located in the posterosuperior side of mesencephalon. During follow-up after 10 days, the neurological status of the patient had worsened. Computed tomography revealed that the bullet had migrated posteriorly and lodged in the occipital lobe. Although a few studies have reported on the spontaneous migration of a bullet within the brain, the present case is unique as the patient examination changed with migration. We recommend serial imaging and surgery in cases of bullet migration in the brain.

4930. Sh, M. E., et al. (2017). "Management of naso-orbito-ethmoid fractures: A 10-year review." Trauma Monthly **22**(3).

Context: The naso-orbito-ethmoid (NOE) area is an intricate structure composed of the nasal, lacrimal, maxillary, frontal, and ethmoid bones. The treatment of NOE fractures is one of the most challenging issues in the management of maxillofacial injuries. The management of these fractures requires a thorough knowledge of midfacial anatomy, surgical techniques, and the available implements in order to obtain optimal aesthetic and functional results. The aim of this study was to review current knowledge (i.e., from the past ten years) concerning NOE fractures and the related surgical techniques. Evidence Acquisition: An extensive electronic literature search was performed via international and national databases, including MEDLINE/PubMed, Cochrane Central Register of Controlled Trials (CENTRAL), DOAJ, Iranian Science Information database (SID), Iranmedex, and Irandoc. Literature published between October 2004 and October 2014 was searched for using specific keywords. The references from each study were also searched. Finally, all articles relevant to the selected keywords and the topic of the study were reviewed. Results: High-energy blunt or penetrating traumas are themostcommoncause of NOEfractures. NOEfractures account forsome5% and 15% of adult and pediatric facial fractures, respectively. These fractures are characterized by three major post-injury symptoms, namely increased intercanthal distance, diminished nasal projection, and impaired nasofrontal and lacrimal drainage. The prompt management of NOE fractures is of the utmost importance in avoiding secondary deformities. Surgical treatment is guided by the pattern and classification of the injury. The surgical approach also varies according to the fracture type and other concomitant facial injuries. If the fractured fragment cannot be reduced satisfactorily by closed reduction, the operation should be converted into an open reduction and internal fixation. The most common method for medial canthopexy is transnasal wiring. Conclusions: Nowadays, advances in radiographic imaging along with the evolution in minimally invasive surgical techniques have led to more conservative treatment modalities thatmayminimize post-injury complications and improve aesthetic outcomes.

4931. Shackford, S. R., et al. (1993). "The epidemiology of traumatic death. A population-based analysis." Archives of surgery (Chicago, Ill. : 1960) **128**(5): 571-575.

Despite the proliferation of trauma systems, there are no population-based data describing the epidemiology of traumatic death. To provide these data, we reviewed all trauma deaths occurring in San Diego (California) County during 1 year. There were 625 traumatic deaths during the study (27.3 deaths per 100,000 population per year). Motor vehicle trauma was the most common cause of injury leading to death (N = 344 [55.2%]; 15.0 annual deaths per 100,000 population). Central nervous system injuries were the most common cause of death (48.5%, or 13.2 deaths per 100,000 population per year). Sepsis was responsible for only 2.5% of the overall mortality. Based on life-table data, traumatic death resulted in an annual loss of 1091 years of life per 100,000 and an annual loss of 492 years of productivity per 100,000. Injury continues to account for an enormous loss of life despite improvements in survival wrought by trauma systems.

We present an unusual case of a penetrating injury, which was an unsuccessful attempt of suicide.

4934. Shadymov, A. B., et al. (2020). "[Actualization of assessment of morphologic features of incisions and chop wounds of 'barrier' tissues of the head]." Aktualizatsiia otsenki morfologicheskikh osobennostei rezanykh i rublenykh povrezhdenii 'bar'ernykh' tkanei golovy. **63**(1): 15-19.

Aim of this study is to determine the influence of the basic conditions of the traumatic interaction of cutting and chopping objects with 'barrier' tissues of the scalp on the formation of morphological signs of damage. It was suggested to perform the comparative analysis of the morphological signs of incised and chopped scalp tissue wounds obtained by changing one given parameter in experimental damage modeling. The influence of the basic conditions of the traumatic interaction of cutting and chopping objects with the 'barrier' tissues of the scalp on the formation of morphological signs of the resulting damage was determined. The effectiveness of the proposed comparative analysis of morphological signs of incised and chopped lesions was confirmed.

4935. Shaffrey, M. E., et al. (1992). "Classification of civilian craniocerebral gunshot wounds: a multivariate analysis predictive of mortality." Journal of neurotrauma **9 Suppl 1**: S279-285.

Management of cerebral gunshot injuries has changed considerably since Cushing's (1916) and Matson's (1948) classification schemes, developed during World War I and World War II, respectively. These military injuries are characterized by either very high mass, low-velocity shrapnel wounds or by high muzzle velocity missiles causing extensive destruction of tissue. The preponderance of low muzzle velocity weapons seen in clinical practice and the availability of computed tomographic (CT) evaluation within minutes after presentation has altered the range of prognostic indicators available to the neurosurgeon and the amount of relative importance placed on each factor. Raimondi and Samuelson (1970) noted this difference in wound ballistics and offered a classification scheme based on initial neurologic assessment. No well-defined classification system for civilian craniocerebral gunshot wounds has been proposed that evaluates and integrates clinical, laboratory, and neuroradiologic data. A retrospective study was performed on all 62 civilians with gunshot wounds to the head admitted to the University of Virginia Hospital between December, 1984, and November, 1990. The patient population consists of 86% males and 14% females, with an age range of 10-72 years; 60% self-inflicted wounds and 32% patients who died en route or immediately upon arrival at the hospital. The overall mortality rate was 55% at 1 week postinjury. Although we have demonstrated an association between some previously defined factors and prognosis in civilian injury, such as admission Glasgow Coma Scale (GCS) (p = 0.001) and initial pupillary response (p less than 0.001), we have also defined other significant predictors of outcome including abnormal coagulation states on admission (p less than 0.001) and the neuroradiologic examination.(ABSTRACT TRUNCATED AT 250 WORDS)

4936. Shagets, F. W., et al. (1986). "Use of temporalis muscle flaps in complicated defects of the head and face." Archives of otolaryngology--head & neck surgery **112**(1): 60-65.

Large defects in the upper two thirds of the face, skull, and skull base pose challenging reconstructive problems. There are a number of applicable reconstructive techniques, all with various advantages and disadvantages, available to otolaryngologists-head and neck surgeons. One method, originally described in the late 1800s, was evaluated by us. Applications of the technique included reconstruction of large defects of the forehead, dura, and anterior skull base, closure of orbital defects, and soft-tissue augmentation of the face. Advantages of this reconstructive technique are the flap's proximity to the defects and its simplicity of execution.

4938. Shah, A., et al. (2020). "Impact of World War I on brain mapping." Journal of neurosurgical sciences **64**(1): 113-116.

Although much tragedy was experienced during World War I (WWI), the nature of the war and the advancements of weaponry led to a change in the quality and quantity of injuries which were conducive for study. This paper discusses how trauma during WWI led to advances in brain mapping from occipital injuries. Gordon Holmes was a British neurologist who was able to create a retinotopic map of the visual cortex from studying more than 400 cases of occipital injuries; his work has contributed immensely to our understanding of visual processing. There have been many extensions from Holmes' work in regard to how we analyze other sensory modalities and in researching how the brain processes complex stimuli such as faces. Aside from the scholastic benefit, brain mapping also has functional use and can be used for neurosurgical planning to preserve important structures. With the advent of more advanced modalities for analyzing the brain, there have been initiatives in total brain mapping which has added significantly to the body of work started by Holmes during WWI. This paper reviews the history during WWI that led to advances in brain mapping, the lasting scholastic and functional impact from these advancements, and future improvements.

4939. Shah, A. D. and C. Decock (2011). "Occult orbito-cranial penetrating injury by pencil: role of beta tracer protein as a marker for cerebrospinal fluid leakage." Indian journal of ophthalmology **59**(6): 505-507.

Orbito-cranial foreign bodies present a treacherous situation that can escape detection. The only evidence of these foreign bodies may be the entry wound in the form of a small lid laceration. A two-year-old boy presented with right upper lid laceration following a fall two hours back. Analysis of the fluid around the wound revealed a beta-tracer protein (beta-TP) value of 33.5 mg/l suggestive of cerebrospinal fluid (CSF). Three-dimensional computed tomography (CT) scan revealed a foreign body measuring 4.2 cm x 0.8 cm passing from the orbital roof to the frontal lobe. The foreign body tract was explored through the eyelid laceration and a broken pencil was removed followed by dural patch graft. The patient developed no ocular or intracranial complications. Beta-TP, a highly specific marker of CSF is routinely used in screening patients of neurosurgery and otolaryngology with CSF leaks, however, its use has never been reported in ophthalmic literature based on an online PubMed search.

4940. Shah, H. Y., et al. (2022). "Endoscopic endonasal retrieval of air gun pellet retained in the frontal sinus: A case report." International journal of surgery case reports **96**.

Introduction and importance: Foreign bodies in paranasal sinuses are rarely encountered and most commonly present in the maxillary sinus. Guidelines for managing paranasal sinus object removal are limited due to its rarity. However, there are three major management options: open surgery, endoscopic sinus surgery, and observation. Case presentation: We report a rare case of an 18-year-old boy who underwent extended frontal sinus surgery to retrieve a retained air gun pellet in the right frontal sinus and repair the skull base defect resulting from the air gun pellet. Clinical discussion: Physicians commonly use endoscopic sinus surgery (ESS) for improving sinus drainage in recurrent chronic and acute infective sinusitis. Extended sinus surgery aims to maximize the communication between the paranasal sinuses and the nasal cavity. This extended communication helps improve access to the sinus, enhance drainage, and improve the delivery of topical medications. In addition, the use of ESS with the modified Lothrop procedure allows for better exposure of the skull base, which can help with the repair of a CSF leak. Conclusion: Based on our experience with this patient and similar literature, ESS should be considered a treatment option for patients with retained foreign objects in the frontal sinus.

4941. Shah, K., et al. (2022). "Frequency and Etiology of Maxillofacial Fractures in Tertiary Care Hospital." Pakistan Journal of Medical and Health Sciences **16**(5): 429-431.

Trauma is a global issue that causes illness and death. Maxillofacial fractures are common following trauma. Aims: To determine the frequency and etiology of maxillofacial fractures in oral and maxillofacial trauma patients. Study Design: Descriptive cross-sectional. Methodology: The entire study population was adult having oral and maxillofacial trauma visiting the outpatient/emergency department at Hayatabad Medical Complex, Peshawar from April to October 2018. Patients (n=205) were enrolled. Detailed history with examination was done. An OPG (orthopantomogram) radiographic confirmation of maxillofacial fracture was performed, PA face (Reverse Towne's view open mouth), occipitomental (OM) view, sub-mentovertex (SMV) view and computerized tomography (CT) scan when needed. All this information was recorded on Performa. Statistical analysis: Data was analyzed using SPSS version 26. Results were

presented as frequency and percentage. Results: Majority of patients (56.1%) suffered from road traffic accidents, 3.4% patients had few of them (3.4%) had sports injuries, 11.7% patients had interpersonal violence or firearm injuries while rest (18.1%) had injures from animals. As per maxillofacial surgeries, 3.9% patients had maxilla fractures, 10.7% patients had mandible fractures, 17.8% patients had zygomatic complex fractures, 13.2% naso-orbital fractures, 13.2% orbit fractures, 16.6% had frontal bone fractures, and 34.6% had nasal bone fractures. Conclusion: The study concluded that the most common supporting maxillofacial trauma is young men with a common etiological condition of road accidents.

4942. Shah, M. U., et al. (2012). "Retained crossbow bolt after penetrating facial trauma." Otolaryngology - Head and Neck Surgery (United States) **147**: P129.

Objective: 1) Describe a challenging case of removal of a retained crossbow bolt from the maxillofacial region. 2) Review the surgical management techniques. 3) Review of the literature on crossbow injuries to the head and neck. Method: Case report is of a unique mechanism of penetrating maxillofacial trauma with retained foreign body threatening airway and neurovascular injury. Pertinent literature is reviewed. Results: A 31-year-old man presented after being shot twice in the head with crossbow bolts. He was stable on clinical evaluation, and CT revealed an 8.5-cm retained crossbow bolt extending from the right infratemporal fossa through the pterygopalatine fossa, traversing the nasopharynx with the tip just medial to the left mandibular ramus. There was no apparent vascular injury on CT angiogram. After awake tracheostomy for airway control, the bolt was removed by mandibular swing approach combined with nasal endoscopic assistance. Postoperative course was uneventful and follow-up showed excellent wound healing without complications. Conclusion: Otolaryngologists often encounter penetrating injuries and retained foreign bodies to the maxillofacial region. The unique shape of a crossbow bolt, along with threat of airway and neurovascular injury, created a management challenge. Herein we discuss various surgical approaches and review the literature on crossbow injuries to the head and neck.

4943. Shah, M. U., et al. (2016). "Retained crossbow bolt after penetrating facial trauma." Ear, nose, & throat journal **95**(1): E1-4.

We present an unusual case of a retained crossbow bolt in the maxillofacial area of a 31-year-old man. While crossbow injuries are rare, this case is of interest because otolaryngologists are often faced with treating retained foreign objects after penetrating facial trauma. These cases are difficult to manage because of the complexity and variety of injuries that can occur during both the initial trauma and the removal. We focus on the management of the bolt's removal and provide a brief discussion of the relevant literature on crossbow injuries to the head and neck.

4944. Shah, R. N., et al. (2009). "Endoscopic pedicled nasoseptal flap reconstruction for pediatric skull base defects." The Laryngoscope **119**(6): 1067-1075.

OBJECTIVES/HYPOTHESIS: A prospective study of endoscopic expanded endonasal approaches (EEA) with nasoseptal flap reconstructions revealed anecdotal evidence of less available relative septal length in pediatric patients. Our goal is to use radioanatomic analysis of computed tomography (CT) scans to determine limitations of the nasoseptal flap in pediatric skull base reconstruction and to describe clinical outcomes after using the nasoseptal flap in six pediatric patients., STUDY DESIGN: Six pediatric patients who underwent EEA with nasoseptal flap reconstruction were prospectively analyzed for flap coverage and postoperative cerebrospinal fluid (CSF) leak. Fifty maxillofacial CTs of individuals <18 years of age and 10 adult images underwent radioanatomic analysis., METHODS: Measurements included potential nasoseptal flap dimensions and dimensions required to reconstruct an anterior skull base defect, a trans-sellar defect, and a transclival defect. Measurements were compared to determine if flap size would be sufficient to cover independent EEA defects within different age groups., RESULTS: Two out of three patients <14 years of age had inadequate flap coverage; one had a postoperative CSF leak. Patients >14 years of age had adequate flap coverage. Average potential flap length is less than average anterior skull base length until age 9 years to 10 years, and less than average trans-sellar defect length until age 6 years to 7 years. Septal growth is most rapid between 10 years and 13 years., CONCLUSIONS: : The pedicled nasoseptal flap may not be a viable option for EEA reconstruction in children <10 years of age. This flap is a reliable option in patients >14 years of age, as their septums are comparable to adults. Patients 10 years to 13 years of age require careful consideration of facial analysis and preoperative radioanatomic evaluation on an individual basis. Laryngoscope, 2009.

4945. Shah, S. A., et al. (2022). "Types of Fractures in Cranial Vault Followed by a Head Injury: A Retrospective Cross Sectional Study." Pakistan Journal of Medical and Health Sciences **16**(1): 761-763.

Aim: To assess the types of fracture of cranial vault followed by head injury. Study Design: Retrospective cross-sectional study Place and duration: This study was conducted at Pakistan Institute of Medical Sciences Islamabad, Pakistan from June 2020 to June 2021. Methodology: A total of 125 patients with head injury were considered in this study. Total 69 (55.2%) patients were from rural areas and 56 (44.8%) were from urban areas. Types of cranial vault fractures, their radiological findings and cause of injury were analyzed. Result: Out of 125 patients, 102 were identified with severe head injuries. 53 (42.4%) had a fracture in the frontal bone. 49 (39.2%) patients had got injured due to violent assault. Conclusion: Most of the patients who had received a head injury and frontal bone fracture were from rural areas. The most commonly fractured bone in these cases is the frontal bone. The commonest cause of injury in the head was a violent assault.

4946. Shah, V. N., et al. (2021). "Chronic sinonasal symptoms due to retained bullet fragments in the skull base." Otolaryngology Case Reports **19**.

Intranasal foreign bodies (FB) are a rare cause of chronic rhinosinusitis in adults. This report describes a unique case of bullet fragments embedded in the sphenoid bone and clivus for 34 years after a gunshot wound (GSW) to the face, leading to chronic rhinosinusitis. Recurrent acute infections were managed with antibiotics; however long-term cure required surgical intervention and removal of the largest bullet fragment. Surgery had been avoided on the patient for decades because of the proximity to critical neurovascular structures in the paracentral skull base, more specifically the sphenoid bone and clivus. Conservative endoscopic sinus surgery with left partial posterior ethmoidectomy and left maxillary antrostomy, followed by drilling of the sphenoid bone and clivus was performed to remove the FB. Bacterial cultures of surgical specimens revealed the presence of Proteus Mirabilis. The patient reported complete resolution of symptoms following surgery, which was maintained at six months follow-up. This case presents a patient with a metallic foreign body in the skull base for greater than 30 years. Removal of the retained metallic fragment addressed the patient's symptoms effectively. Despite the risks of the procedure related to the location of the foreign body, this case highlights the importance of addressing foreign bodies as underlying cause of chronic rhinosinusitis-like symptoms. Endonasal sinus surgery primarily for removal of a foreign body, also allows opening sinus outflow tracts and removing chronically infected bone and soft tissue.

4947. Shah, V. R. (2008). "Aggressive management of multiorgan donor." Transplantation proceedings **40**(4): 1087-1090.

Transplantation of vital human organs is a lifesaving therapy for patients with end-stage organ failure who are medically fit to undergo the surgical procedure. However, deceased donor management remains one of the most neglected areas in transplantation medicine. Brainstem death leads to hemodynamic, metabolic, and immune consequences. Failure to recognize them and provide adequate physiological support accounts for loss of the scarce source of valuable donor organs. Donor optimization leads to increased organ procurement and contributes to improved organ function in the recipient. This article reviews the management advances and controversies of the brainstem-dead donor in an intensive care unit.

4950. Shahzad, M., et al. (2013). "Pattern of mandibular fractures reported at Liaquat University Hospital Hyderabad." Medical Forum Monthly **24**(6): 91-94.

Objective: The study was conducted to analyze the frequency, gender distribution, age groups, mechanism of accident and site involvement of mandibular fractures reported at liaquat university hospital Hyderabad. Study Design:

Retrospective study. Place and Duration of Study: The study was conducted in Department of Oral & Maxillofacial Surgery Liaquat University Hospital Hyderabad from March 2012 to March 2013. Materials and Methods: A data of 228 of patients who had been diagnosed with a mandibular fracture between March 2012 and March 2013 at the Liaquat University Hospital of Hyderabad, Oral & Maxillofacial Surgery Department was retrospectively reviewed. Patients data including gender, age, mechanism of accident, fracture sites were analysed. Results: 166 (72%) male patients and 62(27%) female patients were reported with mandibular fracture. Most common age group was between 30-40 years. Most common mechanism of accident was RTA in 153 (67%)cases followed by fall from height 42(18%) cases. Most common site involved was Parasymphysis in 112(49%) cases followed by angle in 51(22%) cases. Conclusion: The result of this study shows that road traffic accident is most common cause of mandibular fractures in this region.

4951. Shaikh, M. Y., et al. (2018). "Factors predicting poor outcome in gunshot injuries to brain." Medical Forum Monthly **29**(9): 80-83.

Objective: In view of the recent rise in the incidence of gunshot injuries, it is quite mandatory for scientific studies evaluating the prognostic factors contributing to the outcome of such patients. This study aims to identify such factors and evaluate them clinically Study Design: Retrospective study Place and Duration of Study: This study was conducted at the Department of Neurosurgery, Liaquat National Hospital & Medical College, Karachi from July 2012 to July 2017. Materials and Methods: All patients that suffered gunshot injury from July 2012 to July 2017 were included in the study. Exclusion criteria included all patients that were brought dead or expired within two hours of surgery. Duration of stay, CT scan findings and GOS (Glasgow outcome score) were used to evaluate the prognosis of the patients. The prognostic factors evaluated in the study included age, sex, time of presentation and GCS on presentation. Results: This study included a total sample size of 45 patients after inclusion and exclusion based on established criteria. The average age of the patients was 32 years. About 15% of them were female while 85 % were male. Majority of the patients presented more than 24 hours after the incident (71%). Overall mortality was 6 %(3 patients). On further analysis, higher GCS was associated with a better outcome (<0.05). Our study also showed that extensive brain injury was associated with a poor outcome with a statistically significant difference (<0.05) Conclusion: Gunshot injuries to brain represent a high mortality and neurosurgical emergency. Admitting GCS and number of lobes involved were identified to be the most important predictors of poor outcome but if managed aggressively will have favorable outcomes.

4952. Shakir, A., et al. (2003). "A review of nail gun suicides and an atypical case report." Journal of forensic sciences **48**(2): 409-413.

The nail gun was designed as a powerful industrial tool to drive nails into various hard surfaces with ease. Serious injuries associated with the tool are uncommon and deaths are rare. Unintentional injuries normally occur from misuse of the tool or from ricocheting nails. The intentional use of a nail gun to commit suicide is unusual. This paper will review successful and unsuccessful suicide attempts by use of a nail gun. We will present an atypical case of suicide committed with a nail gun by a 46-year-old depressed male investigated by the Allegheny County Coroner's Office in Allegheny County, Pennsylvania in April 2002. This case reports for the first time a unique pathological finding of a ring of bone traveling with the nail, which has not been seen in wounds of the head caused by other types of projectiles.

4953. Shakir, S., et al. (2022). "Anterior Cranial Base Reconstruction in Complex Craniomaxillofacial Trauma: An Algorithmic Approach and Single-Surgeon's Experience." Archives of plastic surgery **49**(2): 174-183.

Management of traumatic skull base fractures and associated complications pose a unique reconstructive challenge. The goals of skull base reconstruction include structural support for the brain and orbit, separation of the central nervous system from the aerodigestive tract, volume to decrease dead space, and restoration of the three-dimensional appearance of the face and cranium with bone and soft tissues. An open bicoronal approach is the most commonly used technique for craniofacial disassembly of the bifrontal region, with evacuation of intracranial hemorrhage and dural repair performed prior to reconstruction. Depending on the defect size and underlying patient and operative factors, reconstruction may involve bony reconstruction using autografts, allografts, or prosthetics in addition to soft tissue reconstruction using vascularized local or distant tissues. The vast majority of traumatic anterior cranial fossa (ACF) injuries resulting in smaller defects of the cranial base itself can be successfully reconstructed using local pedicled pericranial or galeal flaps. Compared with historical nonvascularized ACF reconstructive options,

vascularized reconstruction using pericranial and/or galeal flaps has decreased the rate of cerebrospinal fluid (CSF) leak from 25 to 6.5%. We review the existing literature on this uncommon entity and present our case series of n = 6 patients undergoing traumatic reconstruction of the ACF at an urban Level 1 trauma center from 2016 to 2018. There were no postoperative CSF leaks, mucoceles, episodes of meningitis, or deaths during the study follow-up period. In conclusion, use of pericranial, galeal, and free flaps, as indicated, can provide reliable and durable reconstruction of a wide variety of injuries.

4954. Shaltakova, G. C. and M. A. Mateev (2009). "[Reconstructive operations for post-burn face and neck cicatricial deformities]." Khirurgiia(6): 58-60.

31 patients with post-burn face and neck cicatricial deformities were operated on during the period of 2005-2007. Triangle and trapeziform skin-fascial flap plasty was performed in 24 patients, 7 patients were treated using vascularized tissue flap transplantation. The choice of the method was based on the author's classification of post-burn skin defects. Flap engraftment was observed in 96,8% patients.

4955. Shandra, O. and S. Robel (2020). "Inducing Post-Traumatic Epilepsy in a Mouse Model of Repetitive Diffuse Traumatic Brain Injury." Journal of visualized experiments : JoVE(156).

Traumatic brain injury (TBI) is a leading cause of acquired epilepsy. TBI can result in a focal or diffuse brain injury. Focal injury is a result of direct mechanical forces, sometimes penetrating through the cranium, creating a direct lesion in the brain tissue. These are visible during brain imaging as areas with contusion, laceration, and hemorrhage. Focal lesions induce neuronal death and glial scar formation and are present in 20%-25% of all people who incur a TBI. However, in the majority of TBI cases, injury is caused by acceleration-deceleration forces and subsequent tissue shearing, resulting in nonfocal, diffuse damage. A subpopulation of TBI patients continues to develop post-traumatic epilepsy (PTE) after a latency period of months or years. Currently, it is impossible to predict which patients will develop PTE, and seizures in PTE patients are challenging to control, necessitating further research. Until recently, the field was limited to only two animal/rodent models with validated spontaneous post-traumatic seizures, both presenting with large focal lesions with massive tissue loss in the cortex and sometimes subcortical structures. In contrast to these approaches, it was determined that diffuse TBI induced using a modified weight drop model is sufficient to initiate development of spontaneous convulsive and non-convulsive seizures, even in the absence of focal lesions or tissue loss. Similar to human patients with acquired post-traumatic epilepsy, this model presents with a latency period after injury before seizure onset. In this protocol, the community will be provided with a new model of post-traumatic epilepsy, detailing how to induce diffuse non-lesional TBI followed by continuous long-term video-electroencephalographic animal monitoring over the course of several months. This protocol will detail animal handling, the weight drop procedure, the electrode placement for two acquisition systems, and the frequent challenges encountered during each of the steps of surgery, postoperative monitoring, and data acquisition.

4956. Shang, E. K., et al. (2013). "Endovascular treatment of a symptomatic extracranial vertebral artery aneurysm." Journal of vascular surgery **58**(5): 1391-1393.

Aneurysms of the extracranial vertebral artery are uncommon, with most cases attributed to penetrating head and neck trauma. We report a 29-year-old man with a symptomatic proximal extracranial vertebral artery aneurysm of unclear etiology. This patient's aneurysm was definitively treated after a successful balloon occlusion test of his affected vertebral artery. An endovascular approach was used combining coil embolization of the distal vertebral artery and a covered stent graft in the subclavian. Although aneurysms of this size and location are traditionally repaired with open aneurysmectomy, we show that endovascular approaches can be a safe and effective alternative.

4957. Shankar, S., et al. (2016). "A rare case of Candida brain abscess secondary to metastatic tongue cancer on initial presentation." Chest **150**(4): 448A.

INTRODUCTION: Fungal brain abscesses are rare causes for altered sensorium and they are often resistant to treatment, resulting in high morbidity and mortality. Brain abscesses are commonly caused due to fungal organisms, especially Candida species. CASE PRESENTATION: A 53 year old man with past medical history of diabetes presented to

the emergency department after being found on the floor. The patient was alert and oriented only to place and person. Patient was diagnosed with diabetic ketoacidosis, acute kidney injury, acute pancreatitis for which he was appropriately treated. Computed tomography (CT) abdomen was consistent with left pyelonephritis and prostatic abscess. Initial urine, blood and stool cultures revealed Candida albicans. Intravenous micafungin and fluconazole were instituted based on culture reports. HIV test was negative. Magnetic resonance Imaging (MRI) of brain demonstrated ring enhancing lesions with vasogenic edema and abnormal restricted diffusion (Figure 1A & 1B). Lumbar puncture was noncontributory. Treatment was changed from micafungin to liposomal amphotericin B with fluconazole with which patient demonstrated both clinical and radiological improvement (Figure 2A &2B). Further evaluation showed an enhancing tongue mass with cervical lymphadenopathy. Biopsy proved the presence of Stage IVA squamous cell cancer of the tongue. Early neoplastic markers, Anti-Hu and Anti-Yo antibodies were negative. DISCUSSION: Candida cerebral abscess are mostly diagnosed at autopsy. An autopsy series demonstrated that up to 6% of patients with systemic candidiasis have evidence of undiagnosed CNS involvement as well. Risk factors include penetrating trauma, neurosurgical intervention, IV drug abuse, corticosteroid use, and malignancies. Candida brain abscesses can also be secondary to the infection of the adjacent structures or be secondary to hematogenous spread from endocarditis, intrabdominal or genitourinary tract infections as in our case. Risk factors present in our patient included diabetes mellitus and malignancy. Only 55% of blood cultures and 23% of lumbar puncture are positive for Candida1. CT and MRI are the preferred imaging modalities for diagnosing brain lesions and monitoring response to therapy. A definitive diagnosis can be achieved from stereotactic brain biopsy, although this is rarely reported. Infectious diseases society of America recommends liposomal Amphotericin B with flucytosine for several weeks to manage Candida brain abscess, switching to azole based therapy. CONCLUSIONS: This case demonstrates the need to consider fungal brain abscesses, as differentials for altered mental status and that with the aid of MRI and effective management, patients may improve neurologically as seen in this patient.

4958. Shannon, R. J., et al. (2014). "Monitoring vigabatrin in head injury patients by cerebral microdialysis: obtaining pharmacokinetic measurements in a neurocritical care setting." British journal of clinical pharmacology **78**(5): 981-995.

AIMS: The aims were to determine blood-brain barrier penetration and brain extracellular pharmacokinetics for the anticonvulsant vigabatrin (VGB; gamma-vinyl-gamma-aminobutyric acid) in brain extracellular fluid and plasma from severe traumatic brain injury (TBI) patients, and to measure the response of gamma-aminobutyric acid (GABA) concentration in brain extracellular fluid., METHODS: Severe TBI patients (n = 10) received VGB (0.5 g enterally, every 12 h). Each patient had a cerebral microdialysis catheter; two patients had a second catheter in a different region of the brain. Plasma samples were collected 0.5 h before and 2, 4 and 11.5 h after the first VGB dose. Cerebral microdialysis commenced before the first VGB dose and continued through at least three doses of VGB. Controls were seven severe TBI patients with microdialysis, without VGB., RESULTS: After the first VGB dose, the maximum concentration of VGB (Cmax) was 31.7 (26.9-42.6) mumol l(-1) (median and interquartile range for eight patients) in plasma and 2.41 (2.03-5.94) mumol l(-1) in brain microdialysates (nine patients, 11 catheters), without significant plasma-brain correlation. After three doses, median Cmax in microdialysates increased to 5.22 (4.24-7.14) mumol l(-1) (eight patients, 10 catheters). Microdialysate VGB concentrations were higher close to focal lesions than in distant sites. Microdialysate GABA concentrations increased modestly in some of the patients after VGB administration., CONCLUSIONS: Vigabatrin, given enterally to severe TBI patients, crosses the blood-brain barrier into the brain extracellular fluid, where it accumulates with multiple dosing. Pharmacokinetics suggest delayed uptake from the blood.

4959. Shanti, R. M., et al. (2014). "Application of maxillomandibular fixation for management of traumatic macroglossia: A case report." Craniomaxillofacial Trauma and Reconstruction **8**(4): 352-355.

We present a case of a 14-year-old adolescent boy who has oral cavity after gunshot wound to the tongue presenting with hemorrhage from the tongue requiring coil embolization of the right lingual artery. The patient subsequently developed macroglossia, which was managed with maxillomandibular fixation for a period of 3 weeks with complete resolution of glossal edema.

The trapezius myocutaneous flap of skin and muscle has, as its major blood supply, the superficial branch of the transverse cervical vessels, which is used as a pedicle. The flap may include the scapular spine as a viable bone graft for mandibular defects. Anatomic and surgical experiences have verified the feasibility of using this flap. The intended vascular pedicle arises separately from the subclavian artery in 25% of these cases. Surgical results using the flap have been excellent. Above the level of the mandible, the flap may lack adequate length. It has been used with success to repair the tongue, floor of the mouth, pharyngeal wall, and skin surface. It is particularly impressive as a method of repairing mandibular defects.

4963. Sharif, S., et al. (2000). "Transnasal penetrating brain injury with a ball-pen." British journal of neurosurgery **14**(2): 159-160.

We report a case of a 44-year-old man with 1 day's history of epistaxis. He was an in-patient in a psychiatric ward with a history of depression. He had CSF rhinorrhoea, was confused and had no focal neurological deficits. A full length pencil was removed from his left nostril in the emergency department. CT of the brain revealed a tract, but also suggested another foreign body in the inter-hemispheric space. He had a para-sagittal craniotomy and a 14 cm ball-point pen was found lying between the two cerebral hemispheres. This was removed and the patient made an uneventful recovery. This is the first report of an attempted suicide by transnasal insertion of a ballpoint pen intracranially.

4965. Sharma, A., et al. (2016). "Intoxication of engineered nanoparticles in cold environment exacerbates ischemia and brain pathology following trauma." Journal of cerebral blood flow and metabolism **36**: 266.

Military personnel often engaged in peace keeping or combat operation have to work in very cold environment across the Globe. When these soldiers are inflicted with brain or spinal cord injury, their pathological outcome may be more severe in cold environment as compared to room temperature. In addition, these soldiers also are exposed to a variety of nanoparticles (NPs) emanating from the environment or following missile or gunpowder explosions. Thus, a combination of NPs and cold environment may alter the course of brain pathology and affect therapeutic potentials of drugs. In present investigation we examined the influence of cold environment with or without NPs intoxication on the pathophysiology of blood-brain barrier (BBB), brain edema and cellular injuries in a well-controlled brain trauma model. Male Wistar rats were (age 10-12 weeks) exposed to cold chamber maintained at 4°C for 2 h daily for 8 weeks. Traumatic brain injury similar to piercing object in the brain was produced by a focal incision of the right parietal cerebral cortex (3 mm deep and 5 mm long) after opening a burr hole into the skull in both cold reared and rats placed at controlled room temperature (21°C). In separate group of rats Ag, or Cu NPs (50-60 nm; 50 mg/kg, i.p.) was administered daily for 1 week and exposed either cold environment or kept at room temperature for 8 weeks. These NPs intoxicated animals were also traumatized in identical manner. In these groups of rats, regional cerebral blood flow (rCBF) was measured using microspheres technique. Also, the BBB, brain edema formation and neuronal injuries were examined. To study the drug effects on neuroprotection identical group of rats were treated with cerebrolysin, a multimodal drug either alone or tagged with TiO2 nanowires after 2 and 4 h of brain injury. The animals were allowed to survive 24 or 48 h after trauma. Our observations show that identical trauma to the brain resulted in aggravation of regional ischemia, breakdown of the BBB, edema formation and cell injuries in animals exposed to cold environment as compared to the group placed at room temperature. In addition, NPs intoxicated group showed additional deterioration of cerebrla circulation and brain pathology in combination with cold exposure as compared to animals placed normal

room temperature. These pathological effects were progressive in nature. Treatment with cerebrolysin (2.5 or 5 ml/kg, i.v.) significantly reduced trauma-induced pathology and enhanced cerebral circulation in normal animals kept at room temperature if given after 4 h of insult. On the other hand higher doses of cerebrolysin (7.5 ml or 10 ml/kg) is needed to induce neuroprotection in rats that were exposed to cold environment before injury. In case of NPs exposure in cold environment TiO2 nanowired delivery of cerebrolysin is needed to achieve comparable neuroprotection. These observations are the first to show that cold environment with NPs exposure exacerbates brain pathology after trauma and in such situations, nanodelivery of neuroprotective drugs e.g., cerebrolysin is needed for effective therapy.

4966. Sharma, A., et al. (2017). "Emergent skull-base mesh cranioplasty for large defects using titanium implants in severe head trauma: A case report of difficult cranionasal separation." Journal of Neurological Surgery Part B: Skull Base **78**.

Introduction: Large defects of the anterior/central skull base are a niche pathology that infrequently occurs in the setting of traumatic head injuries, more specifically high impact motor vehicle accidents and self-inflicted gun shout wounds to the head. Case Description: This 37-year-old otherwise healthy male presented to our level-1-trauma-center in 2012 after a self-inflicted gunshot wound to the face and head. He had an entrance wound in the submental region, with extensive comminuted facial fractures (involving the mandible, mid face, and anterior skull base). Initial CT scan demonstrated a severely comminuted mandible, palatal defect with associated comminuted midface fractures, and anterior skull base defect involving frontal sinus, cribriform plate and orbital roof. CT scan of the head showed an 11 cm subdural hematoma with midline shift and uncal herniation, for which he underwent emergent craniotomy and evacuation of subdural hematoma. His ICP drain was removed, but he developed massive CSF rhinorrhea as a result of his cranial base defect. On day 10, he underwent an open-approach anterior skull base reconstruction using titanium mesh cranioplasty. He tolerated the procedure well, but recovery was complicated by development of cerebritis and brain abscess in the frontal lobe. He improved with drainage of the abscess and antibiotic treatment without initial improvement in cognitive function. Repeat CT after 1 month revealed persistent pneumocephalus in communication with the air space of the nasal and oral cavities. Exam under anesthesia demonstrated a 2.5-cm irregular palatal defect leading from the oral cavity to the nasal cavity, a tract leading to the left frontal sinus where exposed mesh titanium plate was visible. A stage 2 reconstruction was performed with composite free graft of cartilage/bone/mucosa. One month after, a flexible nasal endoscopy demonstrated a viable graft in place and a CT scan demonstrated resolution of pneumocephalus. After enduring cranionasal separation was achieved, the otorhinolaryngology team then repaired the extensively comminuted facial fractures based on CT-guided design of reconstruction plates for his midface fractures. In collaboration with oromaxillofacial surgery, nonviable portions of mucosa and underlying dentition, maxilla, and palate were removed. The resulting palatal defect was occluded with a temporary acrylic obturator. A dental prosthesis was fashioned to obdurate the palatal defect and bridge the maxilla. At the time of writing, the patient had experienced sufficient cognitive improvement for minimal assistance living at home. Discussion: Cranioplasty is required in cranial trauma patients with large basal defects, for physiologic restoration of neurovascular structures, cosmesis and prevention of CSF leak. Several materials can be used to reconstruct cranial defects, and choice should be guided by consideration of biocompatibility, MR- and CT-compatibility, malleability and ease of surgical manipulation, optimal structure, weight, and stress-bearing capability, and finally cost. In the setting of acute trauma, however, the choice of material is narrowed by time-sensitive conditions that necessitate efficient decision-making, surgical planning, and operative action. Titanium-mesh is ideal and allows for easy surgical manipulation and contouring to the cranial defect, increasing accuracy of graft reconstruction and reducing surgical morbidity and mortality.

4967. Sharma, B. R. and M. Sharma (2005). "Severe post thermal burn cicatricial ectropion with corneal ulceration: an illustrative case." JNMA; journal of the Nepal Medical Association **44**(159): 102-105.

Management of postburn cicatricial ectroption of the upper lid is always a challenge for the oculoplastic surgeon, as they are often associated with exposure keratitis and ulceration. Traditionally, split thickness grafts have been described for upper lid reconstruction and tarsorrhaphies have been discouraged. We present a case of corneal ulceration associated with postburn cicatricial ectropion presenting 10 years following the initial trauma. The patient underwent full thickness skin grafting and tarsorrhaphy to release the ectropion with resolution of corneal ulceration. We believe that full thickness skin grafts and tarsorrhaphy are effective in correcting upper lid cicatricial ectropion, without functional compromise.

4968. Sharma, G., et al. (2021). "A Rare Case of Transorbital Penetrating Intracranial Injury by a Screw." Indian Journal of Neurotrauma **18**(1): 91-92.

4969. Sharma, H. S., et al. (2013). "Nanoparticles exacerbate brain pathology and sensory motor disturbances following concussive brain injury." Cell Transplantation **22**(5): 915-916.

Concussive brain injury (CBI) as a result of roadside blast or missile explosion is quite common in military personnel engaged in combat operations across the World. CBI is often associated with mild to moderate brain dysfunction and alterations in cognitive and sensory motor functions. However, these CBI symptoms could be further altered by acute or chronic exposure to various nanoparticles present in the environment or due to gunpowder explosion. In the present investigation effects of SiO2 and carbon nanoparticles (CNPs) on CBI induced pathophysiology was examined in a rat model. The CBI was produced in Equithesin anesthetized (3 ml/kg IP) rats by inflicting a blunt head injury on right parietal skull bone using a 114.6 g of cylindrical iron rod tapering towards one end (2 mm2) not pointed enough to pierce the skull from a height of 20 cm. This weight and distance will result in an impact injury of 0.224 N on the right parietal skull surface without breaking it. In a separate group of rats SiO2 (50-60 nm) or CNPs (45-50 nm) were administered daily in a suspension of Tween 80 at a dose of 50 mg/ kg (IP) for 7 days. In these nanoparticle-treated animals, CBI was inflicted on the 8th day. CBI in normal animals resulted in a marked increase in blood-brain barrier (BBB) disruption and brain edema formation that was most marked in the contralateral left half as compared to the injured ipsilateral side. Interestingly SiO2 treatment resulted in the most marked aggravation of BBB leakage and brain edema compared to CNPs intoxication. However, in nanoparticle-treated injured rats, the left hemisphere was also more adversely affected than the right injured hemisphere. These pathological changes increased over time. Thus, pronounced changes were seen after 8 h CBI and increased further at 24 h after CBI. CBI in normal animals did not result in any marked changes in cognitive and sensory motor disturbances up to 5 h. However, behavioral dysfunctions were prominent after 8 and 24 h CBI in a progressive manner. On the other hand nanoparticle-treated rats showed profound behavioral changes at 5 h after CBI that worsen further with the advancement of time. Taken together, our observations show that nanoparticle intoxication exacerbates CBI-induced brain pathology and behavioral disturbances. These pathophysiological changes following CBI largely depend on the nature of nanoparticles intoxication and duration of trauma.

4970. Sharma, M., et al. (2021). "Delayed Cerebral abscess following a retained shrapnel." Medical Journal Armed Forces India.

Retained foreign bodies following penetrating brain injuries continue to pose therapeutic dilemmas. Previously used aggressive approach involving extensive wound debridement and removal of foreign bodies caused additional neurological deficit with higher mortality. Less aggressive approach used more recently involving decompressive craniectomy has lead to higher incidence of retained foreign bodies with potential of infective sequelae. We describe one such case where, in presence of a retained foreign body, an intracranial abscess formed after a gap of 17 yrs. The case has peculiar radiological and morphological findings.

4971. Sharma, M., et al. (2021). "Craniocerebral missile injuries in a combat zone: spectrum of injuries and lessons learnt." Medical Journal Armed Forces India **77**(4): 382-389.

Background: High-velocity missile injuries are commonly encountered in war or war-like situations. Aggressive resuscitation, early evacuation to neurosurgical center, and application of neurosurgical principles remain tenets of success. Methods: The spectrum of injuries and clinical profile of 14 such cases with craniocerebral missile injuries managed at our center in the northern sector were included. Site of injury, GCS at presentation, associated injuries, surgical intervention, duration of hospitalization, and recovery of the patient were analyzed. Results: Five patients had sustained gunshot wounds, and nine patients had sustained shrapnel injuries. Thirteen patients were deeply comatose, and one patient was conscious. The entry wound was in frontal lobe in eight patients, and in four patients, it was in the faciocranial area. Ten patients had Glasgow Coma Scale (GCS) less than 8 at presentation. Surgical intervention was required in 13 patients, including 11 decompressive craniectomies and anterior skull base repair in four patients with faciocranial entry wound. One patient expired during initial resuscitation, and one patient died in the postoperative period. Location of injury was the single most important determinant of outcome. Conclusion: An early decompressive

craniectomy provides a reasonable chance of recovery. Aggressive debridement involving track explorations, lobectomies, or removal of retained shrapnels is not beneficial. Injuries to the skull base and violation of sinus spaces predispose these patients to cerebrospinal fluid leaks and infective sequelae. All these patients require aggressive postoperative intensive care and rehabilitation.

4972. Sharma, P. G. and D. A. Rajderkar (2018). "Forensic Radiology to the Rescue: Prenatal imaging used to solve a case of a newborn with suspected non-accidental trauma." Journal of Forensic Radiology and Imaging **12**: 72-75.

The allegation of child abuse, or non-accidental trauma, is very serious and can have a devastating impact on children and their families. However, the lack of recognition of injuries resulting from abusive incidents can be equally detrimental. When a child presents to the emergency facility with a suspicious injury it is of the utmost importance that a well-documented medical history be obtained. We present a case of a 3-day old infant sent to the pediatric ER after the pediatrician noted bruising over the right shoulder and clavicle. A subsequent skeletal survey performed demonstrated a mildly depressed skull fracture and an overriding displaced right clavicular fracture raising a concern of non-accidental trauma (NAT). Upon further review of the patient's history, it was noted that the mother was involved in a high- speed motor vehicle collision on the day of delivery. Review of the mother's body trauma computed tomography (CT) scan revealed that the injuries were, in fact, sustained in utero and obviating the need for further NAT work up and investigation. This case demonstrates forensic use of radiologic images to establish a diagnosis of an accidental trauma.

4973. Sharma, S., et al. (2018). "Clinical characteristics and visual outcome, prognostic factor, visual acuity and globe survival in posterior segment intraocular foreign body at Tilganga Institute of Ophthalmology." Nepalese journal of ophthalmology : a biannual peer-reviewed academic journal of the Nepal Ophthalmic Society : NEPJOPH **10**(19): 66-72.

PURPOSE: To evaluate clinical characteristics, visual outcomes and globe survival after intraocular foreign body removal from posterior segment via pars plana approach., METHODS: A hospital based retrospective study. All the patients of penetrating eye injury with intraocular foreign body in posterior segment as detected by computed tomography were enrolled from 2012 to 2014., RESULTS: Thirty patients of 30 eyes were included. The mean age was 27.7 years. (2-52). Twenty-four (80%) were male. Out of 30 eyes 19 (63.3%) eyes had injury at Zone 1 and 11 (36.7%) eyes had injury at Zone 2. The mean time spent between primary repair following surgery and intra ocular foreign body removal, was 15.47 days. Retinal detachment and endophthalmitis prior to intraocular foreign body removal was present in 9/30 of eyes. We looked for correlation between post operative Phthisis bulbi with zone of injury and pre operative endophthalmitis and preoperative retinal detachment. However, p value for the above correlation was more than 0.552 and 0.815 respectively, which was statistically not significant., CONCLUSIONS: The eyes with posterior segment intraocular foreign bodies showing clinical features of preoperative endophthalmitis, retinal detachment and the zone of injury also did not have any direct significance with globe survival. Copyright © NEPjOPH.

4974. Sharp, N. and K. Tieves (2015). "Pediatric Head Trauma." Journal of Pediatric Intensive Care **4**(1): 47-54.

Traumatic brain injury (TBI) refers to a spectrum of brain injury that can result in significant morbidity and mortality in pediatric patients. Pediatric head trauma is distinct from adult TBI. The purpose of this review article is to discuss pediatric TBI and current treatment modalities available.

4975. Sharun, K., et al. (2020). "Diagnosis and surgical management of an intraocular foreign body secondary to ballistic wound in a Rhesus macaque (Macaca mulatta)." Iranian Journal of Veterinary Research **21**(3): 234-237.

Background: Intraocular foreign bodies (IOFBs) such as air gun pellet is a rare finding in wild animals like Rhesus macaque (Macaca mulatta). The purpose of the present scientific report is to describe the surgical retrieval of IOFB secondary to ballistic wound in a wild Rhesus macaque. Case description: A juvenile female wild Rhesus macaque was brought with the history of swollen and inflamed right eye for the past several days. Findings/treatment and outcome: Clinical examination revealed presence of partially healed wound over the dorsal eyelid. Radiographic examination revealed the presence of a metallic foreign body inside the right orbit. Inflamed and persistently closed eyelid prevented the further localization of the metallic foreign body. Lateral canthotomy was performed under general anesthesia. Following the failure to recover the metallic foreign body from the ocular adnexa, right eye vitrectomy was performed to retrieve the IOFB. The metallic foreign body was recovered from the posterior chamber of the right eye. Due to the poor

prognosis of the already damaged eye, enucleation of the eye was performed which was followed by tarsorrhaphy. Further examination of the foreign body identified it as a 4.5 mm (.177 Calibre) air gun pellet. Post-operatively animal was treated with antibiotics and anti-inflammatory drugs. The animal recovered uneventfully. Conclusion: Intraocular foreign bodies secondary to gunshot wound should always be considered as a surgical emergency. Enucleation should be performed in cases having poor prognosis to avoid further complications especially in wild animals like Rhesus macaque.

4976. Shashidhar, M. P. and H. K. Thombre (2015). "Prosthetic rehabilitation of a serving soldier with custom made ocular prosthesis." Medical Journal Armed Forces India **71**: S248-S250.

Eyes are the prominent organs of the facial structure and first feature to be noticed during interactions. Loss of an eye can be because of various reasons like congenital defects, traumatic injury, road traffic accidents, gun shot wounds, or malignant tumors.¹ Gun shot wounds or blast injuries are the most common causes for the loss of eyes in armed forces personnel. The disfigurement associated with the loss of an eye can cause significant physical, psychological and emotional problems.² Prosthetic rehabilitation of such patients with ocular prosthesis will improve patient's quality of life and increase their confidence.

4977. Shaw, H. E., Jr. and M. B. Landers, 3rd (1975). "Vitreous hemorrhage after intracranial hemorrhage." American journal of ophthalmology **80**(2): 207-213.

Eight patients, aged 2 months to 55 years, developed vitreous hemorrhages as a result of subarachnoid or subdural bleeding. Subhyaloid hemorrhages were associated with, or preceded, hemorrhage into the vitreous cavity in four cases. Most vitreous hemorrhages cleared spontaneously, several months later, without major visual sequelae. In one patient, intravitreal blood persisted after 28 months. Vitreous hemorrhage can be a serious complication in patients surviving subarachnoid or subdural hemorrhages and, though uncommon, probably occurs with greater frequency than previously acknowledged. While vitrectomy may be a reasonable therapeutic approach in selected cases, in most instances vitreous hemorrhage following intracranial hemorrhage should be treated conservatively.

4978. Shaw, K.-P., et al. (2011). "A method for studying knife tool marks on bone." Journal of forensic sciences **56**(4): 967-971.

The characteristics of knife tool marks retained on hard tissues can be used to outline the shape and angle of a knife. The purpose of this study was to describe such marks on bone tissues that had been chopped with knives. A chopping stage with a gravity accelerator and a fixed bone platform was designed to reconstruct the chopping action. A digital microscope was also used to measure the knife angle (theta) and retained V-shape tool mark angle (psi) in a pig skull. The kappa value (elasticity coefficient; theta/psi) was derived and recorded after the knife angle (theta) and the accompanied velocity were compared with the proportional impulsive force of the knife and psi on the bone. The constant impulsive force revealed a correlation between the V-shape tool mark angle (psi) and the elasticity coefficient (kappa). These results describe the tool marks--crucial in the medicolegal investigation--of a knife on hard tissues.

4979. Shcherbakova, E. I., et al. (1984). "[Radionuclide cisternography in the late period of penetrating cranio-cerebral wounds]." Radionuklidnaia tsisternografiia v otdalennom periode pronikaiushchikh cherepno-mozgovykh ranenii. **29**(4): 27-32.

An analysis of the radiological signs is presented proceeding from the results of examination of the visualization of the CSF tract in 123 patients in whom radionuclide cisternography with 99mTc-DTPA was performed 1,3,6 and 24 h after administration of a radiopharmaceutical. The radiological appearance of pathology of the CSF system in a long-term period after penetrating craniocerebral wound was developed.

4980. Shcherbuk, I. A., et al. (2014). "[Methodological aspects of surgical approach in victims with severe multiple craniofacial trauma in consideration of severity of traumatic injury]." Vestnik khirurgii imeni I. I. Grekova **173**(3): 49-54.

It is important to improve the medical care system and treatment of victims, introduce new methods of treatment and attract the multidisciplinary specialists in the cases of multitrauma. An integrated approach is required for the identification of different character and severity of multiple craniofacial injuries and the development of rational surgical strategy on this base. Different scales such as AIS, CRIS, ISS, PTS, TRISS, TRISSCAN, CRAMS et.al, were created abroad. Another approach to medical strategy was developed in the department of military surgery of Kirov Military Academy in the late nineties. It was based on investigating of possibilities of surgical strategy optimization by application of objective evaluation of the severity of injuries (military surgery--SP, SG, SS). Given treatment strategy of victims with multiple craniofacial trauma resulted in double reduction of quantity of suppurative and septic complications (from 10.5% to 4.1%). It gave the possibility to reduce the lethality from 6.4% to 4.0%. At the same time a hospital stay was shortened and the strategy allowed obtaining satisfactory functional results of treatment and avoiding reinterventions for removal of posttraumatic facial deformations.

4981. Shea, Y. F., et al. (2011). "An unexpected finding in a lucky elderly man." Hong Kong medical journal = Xianggang yi xue za zhi **17**(5): 423-424.

4982. Shear, D. A., et al. (2011). "Acute neuroprotective effects of glial growth factor 2 in a model of penetrating ballistic-like brain injury." Journal of neurotrauma **28**(6): A120.

Glial growth factor 2 (GGF2; ACORDA Therapeutics) is a member of the neuregulin family of growth factors that is best known for its ability to promote the survival and proliferation of oligodendrocytes and stimulate remylenation in preclinical models of multiple sclerosis. More recently, the GGF2 molecule was demonstrated to have a range of other effects in neural protection and repair including providing trophic support and exerting potent anti-inflammatory and antioxidant effects in the brain. In addition, neuregulins have been shown to play a role in synaptic plasticity, which is important for memory. Thus GGF2 shows promise as a potential neuroprotective therapy for the treatment of traumatic brain injury (TBI). The current study was designed to test the potential neuroprotective effects of GGF2 in our model of penetrating ballistic-like brain injury (PBBI). GGF2 (100 or 500 µg/kg) or vehicle was administered via i.v. infusion at 30 min post-PBBI and given once/day until the experimental endpoint. Animals were sacrificed at 24h, 72h, and 7 days post-injury (n=6/grp/time) and the tissue was processed for histopathological analysis. GGF2 (either dose) treatment did not exhibit any significant neuroprotective effects on lesion size, apoptosis (Bax/BCL2), neutrophil infiltration (MPO), or axonal injury (silver) following PBBI. However, GGF2 dose-dependently reduced the extent of GFAP reactivity in the cortex of PBBI rats at 72h post-PBBI. Critically, no toxic side-effects were observed during acute administration of GGF2, even after multiple treatment days. This observation, combined with our current observations of a GGF2-mediated reduction in GFAP reactivity, provide support for a dose-response study that would combine modified dosing regimens with extended treatment duration.

4983. Shear, D. A., et al. (2013). "Operation brain trauma therapy consortium: Dose-response evaluation of cyclosporine a in the wrair penetrating ballistic-like brain injury (PBBI) model." Journal of neurotrauma **30**(15): A170-A171.

Introduction Cyclosporine A (CsA) has shown beneficial effects on several secondary injury mechanisms in traumatic brain injury (TBI), including inhibition of both calcium induced mitochondrial permeability transition pore opening and calcineurin. This study assessed the therapeutic efficacy of CsA on neurobehavioral and neuropathological outcome metrics in the WRAIR PBBI model. Methods Unilateral frontal PBBIwas produced in the right hemisphere of isoflurane anesthetized rats (10% injury severity level). CsA (SandImmune; UPMC Pharmacy; 10mg/2ml/kg or 20mg/4ml/kg) or vehicle (Cremophor EL 4ml/ kg) were delivered as 10m bolus IV infusions at 15m and 24h post-injury. Blood samples (0.7mL whole blood) were collected at 4h, 24h, and the terminal endpoints to measure serum levels of the neuronal biomarker UCHL-1 and the glial biomarker GFAP. Motor function was evaluated on the rotarod (7 and 10 days post) at fixed-speed increments of 10, 15, and 20 rpm. Cognitive performance was evaluated on the Morris water maze (MWM) days 13-17 (4 trials/day). Histopathological analysis included lesion volume and total hemispheric tissue loss. Groups consisted of: (1) Sham (n =10); (2) PBBI + vehicle (PBBI; n = 13), (3) PBBI + 10 mg/kg CsA (n = 15) and (4) PBBI + 20mg/kg CsA (n = 18). Results Motor testing revealed significant deficits in all injury groups with mean rotarod latencies reduced by 53 ± 9% (PBBI), 41 ± 9% (CsA-10mg/kg), and 34 ± 8% (CsA-20mg/kg) vs. sham ($p < .05$). No significant therapeutic effects were detected on the rotarod task. MWM results revealed significant deficits in all injury groupswith the average latency to find the hidden platform (across all testing days) increased by 55 ± 14% (PBBI), 53 ±

12% (CsA-10mg/kg), and 59 ± 14% (CsA-20mg/kg) vs. sham ($p < .05$). No significant therapeutic effects were detected on MWM parameters, mean lesion volume (PBBI = 40-5mm3; CSA-10mg/kg = 41 -6mm3; CsA-20mg/kg = 39- 11mm3), % tissue loss measured in injured vs. non-injured hemispheres (PBBI = 22 ± 1%; CsA-10mg/kg = 23 ± 2%; CsA-1mg/kg = 18 ± 1%) or serum biomarker levels of UCHL-1 or GFAP. Critically, mortality rates were significantly increased in animals treated with the high dose of CSA (29%mortality) as well as rats treated with the corresponding (4ml/kg) volume of vehicle (39%). Conclusions Overall, the current study failed to demonstrate a therapeutic benefit of CsA in the PBBI using this dosing strategy. While CsA did not worsen performance metrics, tissue loss or biomarker response caused by PBBI, there was an increase in mortality and gross adverse effects (ranging from dehydration to “blackened” tails) observed that was at least partly caused by the vehicle (Cremophor EL). It is worth noting that toxicity was maximal in the PBBI model across the OBTT consortium, which may reflect the severity of PBBI or other unique differences between penetrating and non-penetrating head injury.

4984. Shear, D. A., et al. (2016). "Nicotinamide Treatment in Traumatic Brain Injury: Operation Brain Trauma Therapy." Journal of neurotrauma **33**(6): 523-537.

Nicotinamide (vitamin B3) was the first drug selected for cross-model testing by the Operation Brain Trauma Therapy (OBTT) consortium based on a compelling record of positive results in pre-clinical models of traumatic brain injury (TBI). Adult male Sprague-Dawley rats were exposed to either moderate fluid percussion injury (FPI), controlled cortical impact injury (CCI), or penetrating ballistic-like brain injury (PBBI). Nicotinamide (50 or 500 mg/kg) was delivered intravenously at 15 min and 24 h after injury with subsequent behavioral, biomarker, and histopathological outcome assessments. There was an intermediate effect on balance beam performance with the high (500 mg/kg) dose in the CCI model, but no significant therapeutic benefit was detected on any other motor task across the OBTT TBI models. There was an intermediate benefit on working memory with the high dose in the FPI model. A negative effect of the low (50 mg/kg) dose, however, was observed on cognitive outcome in the CCI model, and no cognitive improvement was observed in the PBBI model. Lesion volume analysis showed no treatment effects after either FPI or PBBI, but the high dose of nicotinamide resulted in significant tissue sparing in the CCI model. Biomarker assessments included measurements of glial fibrillary acidic protein (GFAP) and ubiquitin carboxyl-terminal hydrolase-1 (UCH-L1) in blood at 4 or 24 h after injury. Negative effects (both doses) were detected on biomarker levels of GFAP after FPI and on biomarker levels of UCH-L1 after PBBI. The high dose of nicotinamide, however, reduced GFAP levels after both PBBI and CCI. Overall, our results showed a surprising lack of benefit from the low dose nicotinamide. In contrast, and partly in keeping with the literature, some benefit was achieved with the high dose. The marginal benefits achieved with nicotinamide, however, which appeared sporadically across the TBI models, has reduced enthusiasm for further investigation by the OBTT Consortium.

4985. Shear, D. A., et al. (2010). "Longitudinal characterization of motor and cognitive deficits in a model of penetrating ballistic-like brain injury." Journal of neurotrauma **27**(10): 1911-1923.

Traumatic brain injury (TBI) produces a wide range of motor and cognitive changes. While some neurological symptoms may respond to therapeutic intervention during the initial recovery period, others may persist for many years after the initial insult, and often have a devastating impact on quality of life for the TBI victim. The aim of the current study was to develop neurobehavioral testing parameters designed to provide a longitudinal assessment of neurofunctional deficits in a rodent model of penetrating ballistic-like brain injury (PBBI). We report here a series of experiments in which unilateral frontal PBBI was induced in rats, and motor/cognitive abilities were assessed using a battery of tests ranging from 30 min to 10 weeks post-injury. The results showed that PBBI produced consistent and significant (1) neurological deficits (neuroscore examination: 30 min to 10 weeks post-PBBI), (2) sensorimotor dysfunction in the contralateral forelimb (forelimb asymmetry task: 7 and 21 days), (3) motor dysfunction (balance beam task: 3-7 days; and fixed-speed rotarod task: 3-28 days), and (4) spatial learning deficits in the Morris water maze (MWM) task out to 10 weeks post-injury. Overall, the results of this study demonstrate that PBBI produces enduring motor and cognitive deficits, and identifies the optimal task and testing parameters for facilitating longitudinal screening of promising therapeutic interventions in this brain injury model.

4986. Shear, D. A., et al. (2011). "Severity profile of penetrating ballistic-like brain injury on neurofunctional outcome, blood-brain barrier permeability, and brain edema formation." Journal of neurotrauma **28**(10): 2185-2195.

This study evaluated the injury severity profile of unilateral, frontal penetrating ballistic-like brain injury (PBBI) on neurofunctional outcome, blood-brain barrier (BBB) permeability, and brain edema formation. The degree of injury severity was determined by the delivery of a water-pressure pulse designed to produce a temporary cavity by rapid (<40 ms) expansion of the probe's elastic balloon calibrated to equal 5%, 10%, 12.5%, or 15% of total rat brain volume (control groups consisted of sham surgery or insertion of the probe only). Neurofunctional assessments revealed motor and cognitive deficits related to the degree of injury severity, with the most clear-cut profile of PBBI injury severity depicted by the Morris water maze (MWM) results. A biphasic pattern of BBB leakage was detected in the injured hemisphere at all injury severity levels at 4 h post-injury, and again at 48-72 h post-injury, which remained evident out to 7 days post-PBBI in the 10% and 12.5% PBBI groups. Likewise, significant brain edema was detected in the injured hemisphere by 4 h post-injury and remained elevated out to 7 days post-injury in the 10% and 12.5% PBBI groups. However, following 5% PBBI, significant levels of edema were only detected from 24 h to 48h post-injury. These results identify an injury severity profile of BBB permeability, brain edema, and neurofunctional impairment that provides sensitive and clinically relevant outcome metrics for studying potential therapeutics.

4987. Shear, D. A., et al. (2012). "Operation brain trauma therapy consortium: Dose-response evaluation of nicotinamide in the wrair model of penetrating ballistic-like brain injury." Journal of neurotrauma **29**(10): A72-A73.

Introduction Operation Brain Trauma Therapy (OBTT) is a multi-center consortium evaluating promising therapies across traumatic brain injury (TBI) models.The WRAIR penetrating ballistic-like brain injury (PBBI) model has been well-characterized and produces reliable and reproducible neurobehavioral and neuropathological profiles. This study assessed the therapeutic efficacy of nicotinamide in the PBBI model. Methods Unilateral frontal PBBI was produced in the right hemisphere of isoflurane anesthetized rats (10% injury severity level).Rats were randomized into 4 groups: PBBI + vehicle (PBBI; n = 14), PBBI + 50 mg/kg nicotinamide (NIC-50 mg/kg; n = 15), PBBI + 500 mg/kg nicotinamide (NIC-500mg/kg; n = 16) and sham (n = 9).Nicotinamide was delivered intravenously (IV) at 15m and 24h after injury. Blood samples (0.7mL whole blood) were obtained via the IV catheter at 4h, 24h, and at sacrifice from each rat to measure serum levels of the neuronal biomarker UCHL-1 and the glial biomarker GFAP.Motor function was evaluated on the rotarod (7 and 10 days post) at fixedspeed increments of 10, 15, and 20 rpm.Cognitive performance (acquisition and probe trial) was evaluated on the Morris water maze (MWM) days 13-17 (4 trials/day).Histopathological analysis included lesion volume and total hemispheric tissue loss; both expressed as a % of the contralateral hemisphere. Results Motor testing revealed significant deficits in all injury groups with mean rotarod latencies reduced by 60 -8% (PBBI), 60 - 8% (NIC-50mg/kg), and 48 - 9% (NIC-500mg/kg) vs. sham ($p < .05$).PBBI rats treated with the high dose (500 mg/kg) of nicotinamide showed modest, albeit not significant, improvement on the rotarod task ($p > .05$).MWM results revealed significant deficits in all injury groups with the average latency to find the hidden platform (across all testing days) increased by 121 - 13% (PBBI), 115 - 12% (NIC-50mg/kg), and 132 - 13% (NIC-500mg/kg) vs. sham ($p < .05$).No significant therapeutic effect was detected in nicotinamide- treated rats on MWM parameters.Nicotinamide did not affect PBBI-induced lesion volume measured at 22 days post-injury (% contralateral hemisphere): PBBI = 15 - 2%, NIC-50mg/kg = 15 - 2% and NIC-500 mg/kg = 13 - 1%.Likewise, nicotinamide treatments failed to reduce PBBI-induced hemispheric volume loss: PBBI = 25 - 3%, NIC-50mg/kg = 24 - 4% and NIC-500 mg/kg = 24 - 1%.The high dose nicotinamide (500 mg/kg) significantly reduced post-injury (24h) increases in GFAP serum biomarker levels ($p < 0.05$), but not UCHL-1 levels. Conclusions The acute (24h) beneficial effects of nicotinamide observed on PBBI biomarker (GFAP) data are supportive of research demonstrating neuroprotective efficacy on acute histopathology in other TBI animal models. However, in the absence of any corresponding neuroprotective profiles on the neurobehavioral and neuropathological outcome metrics, nicotinamide is not likely to be selected as a lead candidate for advanced OBTT studies in the PBBI model.

4988. Shear, D. A., et al. (2013). "Operation brain trauma therapy consortium: Dose-response evaluation of erythropoietin in the wrair penetrating ballistic-like brain injury (PBBI) model." Journal of neurotrauma **30**(15): A171.

Introduction Erythropoietin (EPO) is a pleiotropic cytokine that has demonstrated potent anti-apoptotic effects in animal models of stroke and TBI. This study assessed the therapeutic efficacy of EPO on neurobehavioral and neuropathological outcome metrics in the WRAIR PBBI model. Methods Unilateral frontal PBBI was produced in the right hemisphere of isoflurane anesthetized rats (10% injury severity level). EPO (PROCRIT, 10,000IU/mL vial; UPMC Pharmacy) was dosed at 5000 IU/kg (0.50mL/kg) or 10,000 IU/kg (1.0mL/kg) and was administered as a single bolus injection at 15m post-injury via indwelling jugular vein catheters. Blood samples (0.7mL whole blood) were collected at

4h, 24h, and the terminal endpoints to measure serum levels of the neuronal biomarker UCHL-1 and the glial biomarker GFAP. Motor function was evaluated on the rotarod (7 and 10 days post) at fixed-speed increments of 10, 15, and 20 rpm. Cognitive performance was evaluated on the Morris water maze (MWM) days 13-17 (4 trials/day). Histopathological analysis included lesion volume and total hemispheric tissue loss. Groups consisted of: (1) Sham (n = 10); (2) PBBI + vehicle (PBBI; n = 14), (3) PBBI + 5,000 IU/kg EPO (EPO-0.50mL/kg; n = 15) and (4) PBBI + 10,000 IU/kg EPO (EPO-1.0mL/kg; n = 16). Results Motor testing revealed significant deficits in all injury groups with mean rotarod latencies reduced by 51 ± 7% (PBBI), 38 ± 7% (EPO-0.50mL/ kg), and 46 ± 8% (EPO-1.0mL/kg) vs. sham ($p < .05$). Although PBBI rats treated with the low dose of EPO showed a positive (45% ± 13%) trend towards improved performance at 10 days post-injury on the rotarod task, this effect was not significant ($p = .217$ vs. PBBI). MWM results revealed significant deficits in all injury groups with the average latency to find the hidden platform (across all testing days) increased by 147 ± 13% (PBBI), 124 ± 15% (EPO-0.50mL/kg), and 115 ± 11% (EPO-1.0mL/kg) vs. sham ($p < .05$). No significant therapeutic effects were detected on any MWM parameters. Critically, the low dose of EPO resulted in significant increases in mean lesion volume (PBBI = 32-4mm3; ∼EPO-0.50mL/kg = 67- 14mm3; EPO-1.0mL/kg = 42- 7 mm3; $*p < .05$ vs. PBBI) but not in % tissue loss measured in injured vs. non-injured hemispheres (PBBI = 24 ± 1%; EPO-0.50mL/kg = 32 ± 4%; EPO-1.0mL/kg = 25 ± 2%). No therapeutic effects were detected on serum biomarker levels of UCHL-1 or GFAP. Conclusions Overall, while the observations of some positive trends of EPO on motor and cognitive outcome are encouraging, the results of the current study indicate that a single post-injury infusion of EPO is not sufficient to confer significant therapeutic benefit in the PBBI model. However, results demonstrating worsened neuropathology in EPOtreated rats are cause for concern, particularly with regards to clinical treatment for severe penetrating TBI where acute intracranial hemorrhage may present complications.

4989. Shear, D. A., et al. (2009). "Neuroprotective profile of dextromethorphan in an experimental model of penetrating ballistic-like brain injury." Pharmacology, biochemistry, and behavior **94**(1): 56-62.

Dextromethorphan (DM) has been well-characterized as a neuroprotective agent in experimental models of CNS injury. The goal of this study was to determine the neuroprotective profile of DM in a military-relevant model of penetrating ballistic-like brain injury (PBBI). In an acute (3 day) dose-response study, anesthetized male Sprague-Dawley rats were exposed to a unilateral frontal PBBI with DM (0.156-10 mg/kg) or vehicle delivered as an i.v. bolus from 30 min to 48 h post-injury. In a follow-up (7 day) experiment, the 10-mg/kg bolus injections of DM were administered in conjunction with a 6-h infusion (5 mg/kg/h). DM bolus injections alone produced a dose-dependent improvement in motor recovery on a balance beam task at 3 days post-injury. However, more rapid recovery (24 h) was observed on this task when the bolus injections were combined with the 6-h infusion. Moreover, the DM bolus/infusion treatment regimen resulted in a significant (76%) improvement in cognitive performance in a novel object recognition (NOR) task at 7 days post-injury. Although post-injury administration of DM (all doses) failed to reduce core lesion size, the maximum dose of DM (10 mg/kg) was effective in reducing silver-stained axonal fiber degeneration in the cortical regions adjacent to the injury.

4990. Shehu, B. B. and I. Hassan (2006). "Delayed presentation of penetrating craniocerebral injury caused by a nail." Brain injury **20**(13-14): 1455-1458.

A 38-year-old woman presented after 2 weeks with penetrating craniocerebral injury from a six inch nail. She had aphasia and right hemiplegia. Brain CT scan showed no significant cerebral injury. The nail track was infected. Craniectomy and extraction of the nail along with broad spectrum antibiotics was effective. She had no residual neurologic deficit.

4991. Shehu, B. B., et al. (2010). "Fetal head injury from intentional penetrating abdominal trauma in pregnancy." Annals of tropical paediatrics **30**(1): 69-72.

A male fetus was extruded from the uterus following multiple lower abdominal stab wounds to the mother. He was brought to the emergency room at 8 hours of age. He had sustained a compound skull fracture with brain contusion. There was no neurological deficit. Debridement and primary wound closure were undertaken. His mother had multiple lacerations to the uterus and a laceration of the fundus of the bladder. Following resuscitation, she had repair of the uterus and bladder and made an uneventful recovery. At 3 years of age, the boy is developing normally.

4992. Sheikh, N. A., et al. (2022). "Fatal transorbital-intracranial penetrating injury- A case report." Journal of forensic and legal medicine **85**: 102288.

Transorbital injuries are rare and may lead to fatal craniocerebral damage. Ocular penetrating injuries account for 24% of all penetrating head injuries in adults, while this percentage goes up to 45% in children. Any penetrating injury through the eyes may enter the intracranial cavity and might prove fatal to the victim owing to cerebral tissue damage and complex management. The dead bodies of three victims were found by the side of the river with multiple injuries to their eyes. Further examination revealed that they had sustained multiple transorbital-intracranial injuries. In such cases, identifying injury patterns is vital so that cause and manner of death can be determined precisely. A thorough postmortem examination can help identify the alleged weapon involved in the act and may clear the doubts concerned with the manner of death.

4993. Shelsta, H. N., et al. (2010). "Wooden intraorbital foreign body injuries: clinical characteristics and outcomes of 23 patients." Ophthalmic plastic and reconstructive surgery **26**(4): 238-244.

PURPOSE: To describe the clinical characteristics, interventions, and visual outcomes of orbital injuries associated with wooden foreign bodies., METHODS: A retrospective case review of orbital injuries managed at Wills Eye Institute and Massachusetts Eye and Ear Infirmary was conducted between 1992 and 2006., RESULTS: The clinical course and management for a total of 23 intraorbital wooden foreign body injuries were reviewed. The distribution of wood included pencil (39%), tree branch/plant matter (35%), and other treated wood (26%). About half of the subjects (52%) presented with preoperative vision between 20/20 and 20/40. Almost all [corrected] of the subjects with preoperative vision between 20/20 to 20/40 retained vision in that range postoperatively (92%). [corrected] Time from injury to presentation was highly variable, ranging from 24 hours to 17 months (mean, 62 days; median, 3 days). Forty-three percent of subjects presented within 24 hours of injury. The site of foreign body found within the orbit was superior (26%; n = 6), medial 30% (n = 7), inferior (26%, n = 6), posterior (9%; n = 2), and lateral (4%; n = 1). Preliminary radiographic interpretation for foreign body was definite in 61% (n = 14), possible in 22% (n = 5), and absent in 13% (n = 3)., CONCLUSIONS: Young men are at particularly high risk for wood intraorbital foreign body. There was a relatively equal distribution of wood type. The time from injury to presentation was variable, ranging from <1 day to over a year. Almost half of the subjects presented within 24 hours of injury. In patients with a known site of penetration, almost half occurred in the conjunctiva, notably without presence of eyelid laceration, emphasizing the need to check the conjunctiva and fornices closely. Preliminary radiographic readings often miss or are inconclusive in detecting the foreign body. The shape, location, serial examinations, and particularly the use of quantitative CT are extremely helpful in distinguishing retained wood foreign body from other low-density signals of air or fat.

4995. Shemie, S. D., et al. (2006). "Severe brain injury to neurological determination of death: Canadian forum recommendations." CMAJ : Canadian Medical Association journal = journal de l'Association medicale canadienne **174**(6): S1-13.

4996. Shen, W., et al. (2020). "EO1001: A First-in-Class Irreversible Pan-ErbB Inhibitor with Excellent Brain Penetration." Journal of Thoracic Oncology **15**(2): S26.

Background: ErbB receptor tyrosine kinases EGFR (ErbB1), HER2 (ErbB2, neu), HER3 (ErbB3), and HER4 (ErbB4) are part of a complex network activating signaling pathways involved in cell growth and survival. Mutations causing errant ErbB activation are an oncodriver in many cancers including NSCLC. Inhibitors targeting ErbB mutations have transformed outcomes for patients; however, resistance to treatment develops rapidly. The various ErbB receptors have overlapping roles in oncogenesis and crosstalk between ErbB family members is associated with acquired resistance and metastases. For example, amplification of HER2 is a well-established mechanism of acquired resistance to EGFR-TKIs.

The development of next-generation agents targeting multiple ErbB receptors has shown promise but has been limited by toxicity and poor brain penetration. Up to 80% of NSCLC patients will experience a brain lesion associated with their disease; treatment-resistant phenotypes metastasizing to the brain have become an important driver of morbidity and mortality and patients have limited therapeutic options. New agents are needed to address this important and growing unmet medical need. EO1001 is a first-in-class, oral, brain-penetrating, irreversible pan-ErbB inhibitor targeting ErbB1, ErbB2, and ErbB4 that is positioned for near-term entry into clinical development. Methods: In vitro testing: EO1001 exhibits excellent and balanced equipotent activity against all three important ErbB receptors including EGFR, HER2, and HER4 with low nM activity (0.4 to 7.4 nM), with high specificity vs. off-target receptors. In vivo studies: Following oral administration, EO1001 treatment resulted in a statistically significant improvement in outcomes compared to positive and negative controls in erbB-positive mouse orthotopopic models including N87 (Her2+), H1975 (EGFR/T790M), GBM12 (EGFR+), GBM39 (EGVRvIII+). EO1001 rapidly enters the CNS at high concentrations relative to plasma and inhibits signaling downstream of mutant ErbB receptors in tumor tissue. Treatment with EO1001 was generally well tolerated with no gastrointestinal side effects observed at efficacious doses in mouse xenograft models. PK and Toxicity Results: Preclinical pharmacokinetic and toxicology studies have been completed. EO-1001 exhibits a half-life of 16-20 hours in rodent models. Toxicities typical of the ErbB inhibitor class, including gastrointestinal effects, weight loss, and decreased activity, were observed at higher dose groups in both rodent and non-rodent species. Extrapolation to human dosing suggests an attractive therapeutic window in comparison to other agents in the class. Conclusion and Next Steps: EO1001 has the potential to be a best-in-class CNS-penetrating pan-ErbB inhibitor amenable for use as a single agent and in combination regimens. First-in-man clinical testing with EO1001 is planned. Continued characterization of EO1001 activity against specific ErbB mutations will be undertaken in parallel.

4997. Shenoy, S. N. and A. Raja (2003). "Unusual self-inflicted penetrating craniocerebral injury by a nail." Neurology India **51**(3): 411-413.

Penetrating injuries of the brain caused by a nail are rare. An interesting case of a patient with schizophrenia who attempted suicide by a self-inflicted penetrating intracranial injury using a nail is reported here. The literature related to this unusual case is reviewed.

4998. Sheridan, R. L., et al. (1999). "Solid organ procurement from burned children." The Journal of trauma **47**(6): 1060-1062.

BACKGROUND: Burns have constituted a traditional contraindication to solid organ procurement because of concerns that such organs may be damaged by burn shock associated splanchnic ischemia and contaminated by burn wound manipulation associated bacteremia., METHODS: Over a 5-year period, we attempted solid organ procurement from five burned children who had suffered concurrent anoxic brain injury., RESULTS: These four boys and one girl had an average age of 8.1 years (range, 2.5-12 years) and burn size of 29% (range, 4-70%). All were injured in house fires and four of five (80%) required prehospital external cardiac compressions. Brain death was declared an average of 35 hours (range, 2.75-77 hours) after injury. Solid organs procured and successfully transplanted from this group were 4 livers, 10 kidneys, and 2 hearts. Two of the livers and one heart were placed into pediatric recipients. Procured tissues included three sets of cardiac valves, and two corneas. All solid organs transplanted were functional at 6 months, although longer follow-up is not available., CONCLUSION: Early identification and diagnosis of brain death during resuscitation of burn patients with anoxic brain injury, combined with careful resuscitation and support of the brain dead potential organ donor, can result in the recovery of suitable solid organs and tissues for transplantation.

4999. Sherman, H. F., et al. (2001). "Should Level I trauma centers be rated NC-17?" The Journal of trauma **50**(5): 784-791.

BACKGROUND: Previous studies have reached contradictory conclusions regarding where injured children are best treated. Our hypothesis was that no differences in survival outcome exist among trauma centers caring for pediatric patients., METHODS: For 16,108 injured children, we created a dependant variable, As-Ps (actual survival--predicted survival), which represents variation from TRISS-predicted outcome for each individual. We then used that variable to compare trauma centers' survival results overall and results for liver, spleen, and head injuries, statistically adjusting for age and injury severity., RESULTS: When adjusted for age and injury severity, centers with added qualifications in pediatrics and Level I centers had improved survival performance overall and in the subcategory of head injured

children. No differences existed in other organ-specific injury categories., CONCLUSION: The improved unexpected outcome results at Level I centers and centers with Added Qualifications in Pediatrics suggest that a team of qualified professionals working in an institution willing to commit the required resources can sufficiently offer injured children the survival advantage expected of a trauma center.

5000. Sherman, S. and M. R. Levine (1987). "Gunshot wounds of the orbit." Advances in ophthalmic plastic and reconstructive surgery **7**: 181-192.

Five cases of ocular firearm injuries are presented. A physical analysis of the gunshot wound characteristics, with representative examples, is highlighted. The important early and late complications are completely discussed. Appropriate management sequence, including complete evaluation, diagnostic testing, and surgical intervention, is outlined and discussed.

5001. Sherman, W. D., et al. (1980). "Gunshot wounds to the brain--a civilian experience." The Western journal of medicine **132**(2): 99-105.

A study involving 79 patients who were considered for surgical treatment for craniocerebral gunshot injuries between 1972 and 1978 was carried out to develop criteria for radiographic assessment and surgical operation, as well as to improve operative techniques and preoperative planning. The study focused on differences between military and civilian injuries, as well as criteria for gross prediction of outcome. Of note in the overall perspective of the series were (1) the predominance of low-velocity missiles, (2) the high rate of self-inflicted injuries (34 percent), (3) the overall mortality of 23 percent with the rate for persons older than 60 being approximately 70 percent, (4) the correlation between preoperative patient assessment and mortality, (5) complications predominated by cerebrospinal fluid fistulas (10 percent), (6) the value of computerized axial tomographic (CAT) scanning in patient assessment and operative strategy and (7) the ultimate employability rate in survivors (78 percent). An historical review of the development of management principles based on operative experience in the military sector as well as other recent civilian literature also deserves consideration.

5003. Shetty, V., et al. (2001). "Clinician variability in characterizing mandible fractures." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **59**(3): 254-252.

PURPOSE: This study evaluated variability in the clinical parameters commonly used to characterize mandible fractures., PATIENTS AND METHODS: Inter-rater reliability of 18 oral and maxillofacial surgeons was assessed using radiographs of 22 cases of mandible fractures. Raters were asked to evaluate each case based on several parameters including number, location, and displacement of the individual fractures and severity of the composite injury. To evaluate intra-rater reliability, selected cases were reviewed at a second session by a subgroup of these surgeons. Tests of concordance used to quantify measurement reliability included the interclass correlation coefficient and multiple-rater kappa statistics., RESULTS: Inter-rater agreement on the number of constituent fractures ranged from excellent for simpler fractures to poor for complex gunshot injuries. Even within raters, the range of interclass correlation for complex injuries was only 0.33 to 0.42 between the 2 assessments. Clinicians appeared to be better at delineating coronoid, condyle, ramus, and angle fractures; symphyseal and canine region fractures had lower inter- and intrarater agreement. Tests of concordance showed moderate to excellent reliability when fracture displacements were expressed in millimeters, but only fair reliability when displacements were expressed as categories. Even when the clinicians concurred on displacement measurements, a large overlap was observed in their categorization of these displacements. Despite the differences in the assessment of individual parameters, the high intrarater reliability coefficient (0.78) indicated that the individual clinicians had a high internal consistency in their assignment of summary severity scores. Multiple regression analysis revealed the number of constituent fractures, the type of fracture, and amount of fracture displacement (millimeters) to be significant predictors of clinician ratings of injury severity., CONCLUSIONS: The clinician variability underscores the difficulties involved in trauma description and scoring. The study identifies some sources of

clinician variability and emphasizes the need to standardize the characterization of mandible fractures by using explicit guidelines.

5004. Shevach, I., et al. (1992). "Orbital porencephalic cyst following penetrating orbitocranial trauma." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **8**(5): 297-299.

In a 10-year-old boy an orbitocranial penetrating wound produced by an umbrella tip caused an orbital roof bone fragment to penetrate up to the anterior part of the third ventricle behind the left foramen of Monro. Hemorrhages and encephalomalacia developed along the trajectory of the fragment and subsequently a porencephalic cyst was formed at this site. Six months after the trauma, increased pressure developed in the left ventricular system due to obstructive hydrocephalus and consequently the porencephalic cyst herniated into the orbit through the orbital roof fracture, producing intermittent diplopia, left exophthalmos, and palpebral swelling. A ventriculo-peritoneal shunt led to shrinkage of the orbital cyst content and resolution of the symptoms.

5005. Shewell, P. C. and J. D. Nancarrow (1991). "Dogs that bite." BMJ (Clinical research ed.) **303**(6816): 1512-1513.

OBJECTIVE: To study the circumstances of dog bites and identify risk factors., DESIGN: Postal questionnaire survey and case note review of victims of dog bites referred between 1982 and 1989., SETTING: One referral based regional plastic surgery unit., PATIENTS: 146 consecutive patients referred for primary treatment of dog bites, for whom current addresses were available for 133, 107 (81%) of whom returned the questionnaire., RESULTS: The male to female ratio was 74:72; 79 (54%) patients were aged below 15 years. The commonest dogs producing bites were Staffordshire bull terriers (15 cases), Jack Russell terriers (13), medium sized mongrels (10), and Alsatians (nine). 82 of 96 (85%) dogs were male. 29 of 47 (62%) adults were bitten at home and 45 of 60 (75%) children at a friend's, neighbour's, or relative's house. 91 of 107 (85%) bites occurred in the dog's home. Bites occurred during playing with 13 (12%), petting 14 (13%), or waking 16 (15%) dogs. 45 (42%) bites were judged as unprovoked. 32 bites were identified as severe and 11 attacks as sustained., CONCLUSIONS: Most victims are bitten by male dogs which they either own or have had frequent contact with, and the bite occurs in the dog's home.

5007. Shi, J., et al. (2017). "Management of screwdriver-induced penetrating brain injury: a case report." BMC surgery **17**(1): 3.

BACKGROUND: Penetrating brain injury (PBI) can be caused by several objects ranging from knives to chopsticks. However, an assault with long and electric screwdriver is a peculiar accident and is relatively rare. Because of its rarity, the treatments of such injury are complex and nonstandardized., CASE PRESENTATION: We presented a case of a 54-year-old female who was stabbed with a screwdriver in her head and accompanied by loss of consciousness for 1 h. Computer tomography (CT) demonstrated that the screwdriver passed through the right zygomatic bone to posterior cranial fossa. Early foreign body removal and hematoma evacuation were performed and the patient had a good postoperative recovery., CONCLUSIONS: In this study, we discussed the clinical presentation and successful management of such a unique injury caused by a screwdriver. Our goal is to demonstrate certain general management principles which can improve patient outcomes.

5008. Shi, L., et al. (2019). "Diagnosis and treatment of a penetrating brain injury caused by a welding electrode: A case report." Medicine **98**(10): e14528.

RATIONALE: Penetrating brain injury caused by a welding electrode is a rare occurrence. This type of injury requires careful preoperative assessment and timely treatment measures to avoid secondary damage., PATIENT CONCERNS: A 55-year-old male patient fell from a height of approximately 5 m during when a welding electrode in his left hand was inadvertently inserted into his brain. The patient had a GCS score of 15 and complaints of dizziness and headache. CT showed an object of metallic density penetrating the skull and entering the brain parenchyma in the frontotemporal region., DIAGNOSIS: According to the clinical findings and preoperative imaging examination, the

diagnosis was open craniocerebral injury with intracranial foreign body and left orbital wall fracture., INTERVENTION: After definite diagnosis and sufficient preoperative preparation, active surgical treatment was carried out to remove intracranial foreign body. Anti-infection and other symptomatic treatment were given after operation. The signs of infection and changes of vital signs were closely observed., OUTCOMES: After treatment, no obvious adverse reactions were found and the patient was discharged. No complications such as infection occurred during the follow-up period of 6 months., LESSONS: In treating patient with a welding electrode penetrating the brain, assessments need to be made preoperatively, the welding electrode needs to be removed in a timely manner, complete hemostasis needs to be achieved during surgery with total repair of the damaged area, and anti-inflammatory treatment needs to be administered postoperatively to achieve good results.

5009. Shi, W., et al. (2008). "Clinical features of immune rejection after corneoscleral transplantation." American journal of ophthalmology **146**(5): 707-713.

PURPOSE: To summarize the clinical features of immune rejection after corneoscleral transplantation., DESIGN: A retrospective, noncomparative, observational case series., METHODS: Patients who received corneoscleral transplantation because of whole corneal ulcer or corneal perforation at Shandong Eye Institute from July 1, 2003 through July 31, 2005 were included. Fourteen patients (14 eyes) with immune rejection but not recurrence or other complications were reviewed, including ocular vision, rejection onset time, symptoms, and characteristics., RESULTS: The average rejection time in the 14 eyes was 35 days. The rejection arose rapidly, and the mean best-corrected visual acuity decreased to counting fingers or hand movements. Circular limbal congestion and edema developed with circuitous and dilatational vessels. Whole graft edema and Descemet membrane folds were present, but no epithelial rejection line, endothelial rejection line, or keratic precipitate were observed. The average intraocular pressure (IOP) dropped from 13.6 mm Hg to 7.4 mm Hg. Seven eyes had shallow anterior chambers (AC). Retinal and choroidal edema was observed in five eyes., CONCLUSIONS: The clinical features of immune rejection after corneoscleral transplantation include rapid onset of rejection, vision decrease, circular limbal congestion and edema with circuitous and dilatational vessels, whole graft edema and shallow AC, low IOP, and no rejection line or keratic precipitate.

5010. Shibuya, T., et al. (1993). "[A case of penetrating head injury caused by nail-gun]." No shinkei geka. Neurological surgery **21**(4): 373-377.

A rare case of penetrating head injury caused by a nail-gun was described. A 24-year-old male was admitted to our hospital due to head injury. He had handled a nail-gun at a construction site. On admission the patient was fully conscious with no neurological defects. A small wound was observed at the left front-temporal region. Skull films showed a large nail embedded in the skull cavity. A computed tomographic (CT) scan, changing level of window, demonstrated intracerebral hematoma, fragment of skull bone and nail. Cerebral angiography (CAG) showed extravasation at the left frontal region. Emergency operation was performed and his recovery was uneventful. Twenty-two craniocerebral injuries caused by nail-guns have been reported in world medical literature but this was the first report in Japan. The characteristics of craniocerebral nail-gun injuries were less damage and better prognosis compared with gunshot injuries. However intracranial infection and vascular injury were possible lethal complications. In this case, preoperative examination, such as CT scan and CAG was valuable and the early operation for the sake of safety was very effective.

5011. Shields, L. B. E., et al. (2003). "Nonterrorist suicidal deaths involving explosives." The American journal of forensic medicine and pathology **24**(2): 107-113.

Suicidal deaths involving explosives unconnected to terrorism are rare. The investigation of deaths from explosive devices requires a multidisciplinary collaborative effort, as demonstrated in this study. Reported are 2 cases of nonterrorist suicidal explosive-related deaths with massive craniocerebral destruction. The first case involves a 20-year-old man who was discovered in the basement apartment of his father's home seconds after an explosion. At the scene investigators recovered illegal improvised power-technique explosive devices, specifically M-100s, together with the victim's handwritten suicide note. The victim exhibited extensive craniofacial injuries, which medicolegal officials attributed to the decedent's intentionally placing one of these devices in his mouth. The second case involves a 46-year-old man who was found by his wife at his home. In the victim's facial wound, investigators recovered portions of a detonator blasting cap attached to electrical lead wires extending to his right hand. A suicide note was discovered at the

scene. The appropriate collection of physical evidence at the scene of the explosion and a detailed examination of the victim's history is as important as documentation of injury patterns and recovery of trace evidence at autopsy. A basic understanding of the variety of explosive devices is also necessary. This investigatory approach greatly enhances the medicolegal death investigator's ability to reconstruct the fatal event as a means of separating accidental and homicidal explosive-related deaths from this uncommon form of suicide.

5012. Shields, L. B. E., et al. (2008). "Russian roulette and risk-taking behavior: a medical examiner study." The American journal of forensic medicine and pathology **29**(1): 32-39.

Fatal Russian roulette refers to death following an act of extreme bravado in which the individual spins the cylinder of a revolver loaded with at least one cartridge, aims the muzzle at the head, and pulls the trigger. The majority of victims are men younger than 30 years who, in the presence of others, are under the influence of ethanol or other drugs. This is a 10-year (1993-2002) retrospective review of self-inflicted gunshot wounds of the head, among which we culled and paid special attention to cases of Russian roulette, at the Medical Examiners' Offices in Kentucky. Of the 24 incidents of Russian roulette, the majority of victims were white (79.2%), and all were men between 14 and 47 years with a mean age of 24.8 years. Compared with other cephalic firearm suicides, the subjects engaging in Russian roulette were significantly more likely to have elevated blood levels (> or = 0.1%) of ethanol along with various drugs detected in urine. Although the presumed intent of the risky act is to survive, Russian roulette is deemed to be suicide, which is based on a comprehensive understanding of the inherently deliberate, volitional actions of the decedent.

5013. Shih, T.-Y. and Y.-L. Kuo (2002). "Development of intracranial complications following transoral stab wounds in children. Report of two cases." Pediatric neurosurgery **37**(1): 35-37.

Sharp penetrating trauma to the skull and brain is uncommon in children. The related pediatric literature consists mainly of cases involving penetrating stab wounds to the face or scalp resulting from assaults or accidents. Herein, we present two cases of perioral intracranial penetration. The first case was a 2-year-old boy who presented with septic complications and developed a brain abscess. The second case was a 2-year-old girl who presented with a subarachnoid hemorrhage and developed a traumatic pericallosal artery aneurysm. After craniotomy and clipping, both patients made a satisfactory recovery. A high index of suspicion, liberal use of neuroimaging and early operative intervention are important points in the successful management of such cases. Copyright 2002 S. Karger AG, Basel

5014. Shimamura, A. P. and L. R. Squire (1987). "A neuropsychological study of fact memory and source amnesia." Journal of experimental psychology. Learning, memory, and cognition **13**(3): 464-473.

We investigated the ability of amnesic patients to learn new facts (e.g., Angel Falls is located in Venezuela) and also to remember where and when the facts were learned (i.e., source memory). To assess the susceptibility of fact and source memory to retrograde amnesia, patients prescribed electroconvulsive therapy were presented facts prior to the first treatment and were tested after their second treatment. All amnesic patients exhibited marked fact memory impairment. In addition, some amnesic patients exhibited source amnesia (i.e., they recalled a few facts but then could not remember where or when those facts had been learned). Source amnesia was unrelated to the severity of the memory deficit itself, because patients who exhibited source amnesia recalled as many facts as the patients who did not. These results show that the deficit in amnesia includes an impairment in acquiring and retaining new facts. Source amnesia can also occur, but it is dissociable from impaired recall and recognition and appears to reflect difficulty in remembering the specific context in which information is acquired. The findings are discussed in terms of their significance for how memory is organized.

5015. Shimazu, S. and C. H. Shatney (1983). "Outcomes of trauma patients with no vital signs on hospital admission." The Journal of trauma **23**(3): 213-216.

In 5 years, 267 patients with cardiopulmonary arrest after trauma were treated at our institution. The long-term survival rate was 2.6%. Only 1.5% of the 267 patients were functional individuals. Overall, neither the mechanism of injury nor routine emergency thoracotomy influenced the salvage rate. Our results in the management of trauma victims without vital signs indicate that: 1) among blunt trauma patients, those with isolated head injury have the highest survival rate; 2) patients with blunt multisystem injuries involving the chest, abdomen, or truncal orthopedic

structures are unsalvageable; 3) cardiopulmonary arrest with penetrating head or neck wounds is a lethal combination; and 4) with the exception of patients sustaining penetrating chest or heart injuries, emergency thoracotomy does not enhance the survival rate of trauma patients who were formerly declared 'dead on arrival.'

5016. Shimia, M. and S. Sayyahmelli (2009). "Traumatic displacement of the globe into brain." Rawal Medical Journal **34**(2): 234-235.

We report a case where globe was dislocated into the brain following orbital wall fracture. Traumatic dislocation of the eye into the brain is rare and urgent management and surgical repair is indicated. To our knowledge, this is the first case of traumatic displacement of the globe into the brain with satisfactory removal of the globe and orbital wall repair. (Rawal Med J 2009;34: 234-235).

5017. Shimura, T., et al. (1997). "[Clinicopathological studies of craniocerebral gunshot injuries]." No shinkei geka. Neurological surgery **25**(7): 607-612.

UNLABELLED: Gunshot wounds are rare in Japan because of few regulatory laws against the possession of guns. Nevertheless such wounds are increasing in prevalence these days. Reports on the microscopic findings concerning these intracerebral lesions are fewer than those on the macroscopic findings in the scalp, the skull and the intracranial cavity. In this study we evaluated computed tomographical and histopathological findings in craniocerebral gunshot injuries., CASES: Nine patients with gunshot wounds to the head were presented. All were male and the age ranged from 17 to 66 years. Four were suicides and four were attempted murders and the last one was of unknown etiology. Morphological examination was performed on 5 autopsy cases. The distance of the bullet from the cranial cavity was as follows: long distance, 4 cases; close contiguity, 5 cases. The calibers of the weapons were as follows: 38 mm in 6 cases, 45 mm in 1 case and unknown in 2 cases., RESULTS: CT scans were examined in six cases, which revealed a missile track, hemorrhagic contusion, traumatic subarachnoid hemorrhage and marked tension pneumocephalus. In some cases, CT scan also revealed bony and metallic fragments, some deep within the cranial cavity. In the histopathological study, we found marked swollen brain (brain weight over 1500 mg) and hemorrhagic contusion in the vicinity of the missile track and interhemispheric fissure, and widespread traumatic subarachnoid hemorrhage and intraventricular hematoma. We would like to emphasize especially the remote contusion seen in the distant part of the missile track as well as massive exsudation and hemorrhage around the nerve fiber bundles. Remote contusion was observed in the inferior surface of the fronto-temporal lobes, and bilateral hemorrhagic contusion was seen in the vicinity of the superior longitudinal fissure on CT scans and autopsy findings. In one case, the bullet rotated within the intracranial cavity. In conclusion, nine cases of craniocerebral gunshot injuries were examined, while we also reviewed the medical literature concerning the shearing injury produced by gunshot brain wounds. The head injuries were further delineated by the correlation between autopsy and computerized tomography findings.

5018. Shin, T. H., et al. (2012). "Transorbital penetrating intracranial injury by a chopstick." Journal of Korean Neurosurgical Society **52**(4): 414-416.

A 38-year-old man fell from a chair with a chopstick in his hand. The chopstick penetrated his left eye. He noticed pain, swelling, and numbness around his left eye. On physical examination, a linear wound was noted at the medial aspect of the left eyelid. Noncontrast computed tomography (CT) study showed a linear hypodense structure extending from the medial aspect of the left orbit to the occipital bone, suggesting a foreign body. This foreign body was hyperdense relative to normal parenchyma. From a CT scan with 3-dimensional reconstruction, the foreign body was found to be passing through the optic canal into the cranium. The clear plastic chopstick was withdrawn without difficulty. The patient was discharged home 3 weeks after his surgery. A treatment plan for a transorbital penetrating injury should be determined by a multidisciplinary team, with input from neurosurgeons and ophthalmologists.

5020. Shiraishi, S., et al. (2008). "[A case of intralenticular foreign iron body without any symptoms for 20 years]." Nippon Ganka Gakkai zasshi **112**(10): 882-886.

BACKGROUND: After penetrating injury an intralenticular foreign body is usually associated with complications such as traumatic cataracts, uveitis, and glaucoma. Under rare conditions, however, a foreign body may remain in the eye without any complications for many years. There have been few reports of persisting intralenticular foreign bodies in Japan, and no report of an intralenticular body of iron which was retained for more than 6 months. We report a case of intralenticular foreign iron body that stayed without any symptoms for 20 years., CASE REPORT: A 65-year-old male with an episode of ocular pain in his right eye 20 years ago presented with blurred vision in the right eye. Slit lamp examination revealed cataract and a intralenticular foreign body in the right eye. Despite the presence of a black foreign body in the middle of the nucleus, damage to the anterior capsule was minimal. He was successfully treated by surgical removal of the foreign body, phacoemulsification, and intraocular lens implantation. In vitro analysis demonstrated that the foreign body was oxidized Fe., CONCLUSION: A foreign body may remain dormant in the crystalline lens for many years depending on the conditions. We reported a patient with an intralenticular foreign iron body without symptoms for 20 years, who was successfully treated with lens surgery.

5021. Shirley, S., et al. (1994). "Narrowing the organ donation gap: hospital development methods that maximize hospital donation potential." The Journal of heart and lung transplantation : the official publication of the International Society for Heart Transplantation **13**(5): 817-823.

The purpose of this article is to identify and describe this organ procurement organization's hospital development methods that have markedly increased the quantity and quality of organ donor referrals. Procedures used include the establishment of organ donor programs (hospital donor programs) within each donor hospital. The goal for these hospital donor programs is to monitor and maximize organ procurement within each institution. Routine quality assurance or death audits along with referral data from the organ procurement organization's database provide both the organ procurement organization and the hospital donor program with the necessary information to evaluate organ procurement strengths and weaknesses. This data is used in concert with ongoing development activities, which include, but are not limited to, physician and staff education and frequent marketing visits. Early referral to the organ procurement organization of all nonsurvivable head injuries for evaluation as potential organ donors, and a timely request for donation by the organ procurement organization coordinator are emphasized. The results of these efforts have been gratifying. In 1989, 138 referrals and 41 organ donations occurred. In 1990, 174 referrals and 66 organ donations occurred. In 1991, 213 referrals and 71 organ donations occurred. In 1992, 228 referrals and 70 organ donations occurred. In the first 6 months of 1993, 146 referrals and 40 organ donations occurred, for a prorated figure of 292 referrals and 80 organ donations annually. In conclusion, these results appear to validate the benefits of this approach and its significant contribution to narrowing the donation supply and demand gap.

5022. Shlugman, D., et al. (2001). "Abnormal pupillary activity in a brainstem-dead patient." British journal of anaesthesia **86**(5): 717-720.

The pupils in brainstem-dead patients are classically fixed and dilated. We present a case of a brainstem-dead patient whose pupils displayed persistent asynchronous pupillary constriction and dilatation independent of external physical stimuli. Central causes for the phenomenon were excluded leaving an unexplained peripheral cause as the most likely explanation. Early recognition of this phenomenon prevents delay in the diagnosis of brainstem death, lessening to some extent the distress for the family, and facilitating earlier organ donation and allowing the better use of resources.

5023. Shoemaker, W. C., et al. (2006). "Noninvasive hemodynamic monitoring for combat casualties." Military medicine **171**(9): 813-820.

The aims of this study were to develop and to test a noninvasive hemodynamic monitoring system that could be applied to combat casualties to supplement conventional vital signs, to use an advanced information system to predict outcomes, and to evaluate the relative effectiveness of various therapies with instant feedback information during acute emergency conditions. In a university-run inner city public hospital, we evaluated 1,000 consecutively monitored trauma patients in the initial resuscitation period, beginning shortly after admission to the emergency department. In addition to conventional vital signs, we used noninvasive monitoring devices (cardiac index by bioimpedance with blood pressure and heart rate to measure cardiac function, arterial hemoglobin oxygen saturation by pulse oximetry to reflect changes

in pulmonary function, and tissue oxygenation by transcutaneous oxygen tension indexed to fractional inspired oxygen concentration and carbon dioxide tension to evaluate tissue perfusion). The cardiac index, mean arterial pressure, pulse oximetry (arterial hemoglobin oxygen saturation), and transcutaneous oxygen tension/fractional inspired oxygen concentration were significantly higher in survivors, whereas the heart rate and carbon dioxide tension were higher in nonsurvivors. The calculated survival probability was a useful outcome predictor that also served as a measure of severity of illness. The rate of misclassification of survival probability was 13.5% in the series as a whole but only 6% for patients without severe head injuries and brain death. Application of noninvasive hemodynamic monitoring to acute emergency trauma patients in the emergency department is feasible, safe, and inexpensive and provides accurate hemodynamic patterns in continuous, on-line, real-time, graphical displays of the status of cardiac, pulmonary, and tissue perfusion functions. Combined with an information system, this approach provided an early outcome predictor and evaluated, with an objective individualized method, the relative efficacy of alternative therapies for specific patients.

5024. Shore, J. W., et al. (1992). "Repair of telecanthus by anterior fixation of cantilevered miniplates." Ophthalmology **99**(7): 1133-1138.

BACKGROUND: The accepted surgical method for telecanthus repair is transnasal wiring. This procedure requires a stable posterior lacrimal crest on the affected side and surgical manipulation of the wires as they exit the contralateral side. A method for repairing telecanthus that obviates these prerequisites is presented. Indications for use of this technique and comparison to transnasal wiring is discussed., METHODS: A Y-shaped titanium rigid orbital plating system ("miniplate") was used to surgically correct traumatic telecanthus in five patients, two in the acute setting and three in late reconstruction. The miniplate was cantilevered from the lateral aspect of the nose and directed posteriorly into the orbit. This provided a stable fixation point for the medial canthal tendon., RESULTS: Marked resolution of the telecanthus was noted in four patients. No post-operative complications have been encountered to date., CONCLUSIONS: Miniplate fixation was used successfully to repair unilateral traumatic telecanthus. Miniplate fixation of the medial canthal tendon should be considered in unilateral cases of traumatic telecanthus and in cases where poor bony support for transnasal wires is evident.

5025. Shoung, H. M., et al. (1985). "The early prognosis of craniocerebral gunshot wounds in civilian practice as an aid to the choice of treatment. A series of 56 cases studied by the computerized tomography." Acta neurochirurgica **74**(1-2): 27-30.

The authors report a series of 56 cases of craniocerebral lesions secondary to missile injuries studied by means of CT scan. CT scans demonstrate the track of the missile, destruction of deep cerebral parenchyma, dissection of the white matter (intracerebral air) and reactive oedema. The prognostic incidence of CT is discussed. The CT scan helps to choose the best therapeutic management with respect to each particular case.

5026. Shrewsbury, D. W., et al. (1982). "Repair of complicated mandibular defects." Archives of otolaryngology (Chicago, Ill. : 1960) **108**(3): 162-166.

In most instances, the injured mandible can be successfully repaired with arch bars and intermaxillary fixation. However, it is important to identify certain potential problem situations early and apply special techniques for their treatment. Potential management problems, such as the non-compliant patient, the edentulous patient, gunshot wounds, radiated mandibles, tumors, and osteomyelitis, are reviewed. The use of special techniques, eg, the dynamic compression plate, the Morris biphase apparatus, the cobalt-chromium alloy (Vitallium) basket, a suction-irrigation apparatus, and the mandibular reconstruction plate, are described to show how they may be effectively applied to these special situations. With early recognition of these management problems and proper application of these more sophisticated techniques, the quality of care for patients, with mandibular injuries can be enhanced.

5027. Shriver, E. M., et al. (2011). "Trochlear calcification mimicking an orbital foreign body." Ophthalmic plastic and reconstructive surgery **27**(6): e143-144.

A 39-year-old man presented with diplopia 1 day following left orbit trauma. CT scan and ultrasound showed a left trochlear hyperintensity that was interpreted by both the radiologist and echographer as a metallic foreign body.

Surgical exploration failed to identify a foreign body. The patient presumably had preexisting trochlear calcification with a post-traumatic nonconcomitant small-angle vertical deviation and diplopia. Calcification should be considered in the differential diagnosis of trochlear hyperintensity noted on imaging studies.

5030. Shuja, F., et al. (2008). "Role of hypothermia in hemorrhagic shock." Journal of Organ Dysfunction **4**(3): 151-160.

Hemorrhagic shock that leads to cardiovascular collapse does not respond well to conventional methods of cardiopulmonary resuscitation. Even when the source of bleeding can be controlled and the circulation restored, cerebral ischemia lasting for >5 min invariably results in severe brain damage. Often the underlying injuries are reparable but the patient dies of irreversible shock. In this setting, strategies to maintain cerebral and cardiac viability long enough to gain control of hemorrhage and restore intravascular volume could be life-saving. This requires an entirely new approach to the problem, with emphasis on rapid total body preservation, repair of injuries during metabolic arrest, and controlled resuscitation, so-called emergency preservation and resuscitation. Currently, hypothermia is the most effective method for preserving cellular viability during prolonged periods of ischemia. Herein, the authors describe the rationale behind the development of this strategy, its impact on various cellular mechanisms, clinical uses, and the optimal methods for its application.

5031. Shuker, S. (1985). "Spontaneous regeneration of the mandible in a child. A sequel to partial avulsion as a result of a war injury." Journal of maxillofacial surgery **13**(2): 70-73.

A 7-year-old child sustained a severe avulsion injury to the left mandible leaving a 6 cm. gap. A Kirschner wire alone was used for immobilization and stabilization. Radiographs of the mandible 2 1/2 years later showed complete osteogenesis and solid bone formation over the Kirschner wire. The young age of the patient was definitely important in influencing this favourable result. The author's experience in older war injuries patients, using the same procedure, has shown no such bone formation. The source of osteogenesis is believed to be from mesenchymal cells of the soft tissue remaining in the gap. The theories pertaining to the source and mode of osteogenesis in this case are discussed.

5032. Shuker, S. T. (2008). "Management of transcranial orbital penetrating shrapnel/bullet war injuries." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **66**(9): 1927-1931.

5033. Shuker, S. T. (2010). "Base-of-skull/infratemporal fossa shell fragment retrieval." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **68**(11): 2668-2674.

PURPOSE: Shell fragments and bullets are frequently observed to have settled in the skull base and infratemporal fossa (ITF) with the impact resulting in a new surgically complicated trauma. This compact region is one of the most difficult and dangerous locations for lodged objects. When called upon to retrieve these objects, the surgeon faces a complicated challenge. The complexity of the task depends on many factors, such as size, deformation, and surface hooks, as well as identification of the precise anatomic location., MATERIALS AND METHODS: New surgical approaches and successful methods of treatment are presented. The practicability of correctly determining the location of the foreign body is also described. These methods are based on safe and successful practices used in the retrieval of 212 shell fragments from the ITF., RESULTS: In this study, 79% of the ITF fragments and bullets were retrieved by the transoral ITF method. The remaining 21% were removed via the facial path of missile entrance and a transantral approach., CONCLUSION: This article describes feasible, sensible, time-saving practices resulting in lower surgical morbidity in one of the most challenging regions from which to extract lodged missiles. Osseous landmarks are used for

proper localization of trajectories in the ITF by use of posteroanterior and true lateral skull radiographs, which assist in locating metal fragments. The intraoral approach, which is successfully used as a short pathway with minimal tissue damage, may encourage surgeons not to leave fragments unattended.

5034. Shuker, S. T. (2012). "The immediate lifesaving management of maxillofacial, life-threatening haemorrhages due to IED and/or shrapnel injuries: "when hazard is in hesitation, not in the action"." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **40**(6): 534-540.

Maxillofacial/neck vascular injuries caused by improvised explosive devices IEDs or ballistics injuries are life threatening when they cause severe haemorrhage resulting in airway compromise. One should always keep in mind that the best technique used is that which saves the patient's life and not the most expensive and/or technologically advanced. Medical professionals on the scene should have the necessary experience to handle the emergency situations of airway compromise and haemorrhage control. In this instance there is only, "one to a few minutes" to clear airway obstruction and arrest haemorrhage to prevent death. The patients in this study had life-threatening shrapnel injuries of the carotid and/or jugular vessels, and facial primary blast affect implosion of facial middle third air-containing cavities injuries. In a massive casualties arenas, where time=lifesaving, we should need to replace "non-battlefield" civilian techniques with "time driven", combat management for IEDs injuries. In these cases, the immediate and effective compression tamponade using digital, Foley catheter tamponade, packs and/or vessels ligation for severe facial/neck haemorrhage were used successfully.

5035. Shuker, S. T. (2012). "Management of penetrating medial and retro-bulbar orbital shrapnel/bullet injuries." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **40**(8): e261-267.

The presence of shrapnel or a bullet lying in the medial orbital and retrobulbar area is rare. A review of the literature revealed only a few reports. Recently eye/orbital penetrating trauma has increased dramatically, mainly due to IEDs or conventional weaponry in civilian and military casualties. Our experience in the management of these types of injuries prompted this report. Practical techniques for correctly determining the location of retained projectiles in the orbit are described. Surgical techniques for treatment are presented, based on safe and successful practices used in the missile retrievals. Six shrapnel and three bullet injuries, mostly in the medial orbital region, were removed without increasing morbidity and with limited orbital tissue injury.

5036. Shuker, S. T. (2013). "Effect of biomechanism mine explosion on children: craniofacial injuries and management." The Journal of craniofacial surgery **24**(4): 1132-1136.

The significant bodily violence and harm to children from blast injuries continue to be substantially caused by unexploded ordnance and improved explosive devices. Children have many unique anatomic and pathophysiologic attributes that potentially affect their susceptibility to injury. Consequently, this provides a characteristic profile to mine blast effects and projectile injuries. As a result, children's injuries inflicted on craniofacial tissues, airway compromise, hemorrhage, and brain injuries vary significantly from those inflicted on adults. In children more than adults, it is relevant that the simplest, immediate repair of maxillofacial injury is preferable to a major complex surgical approach that is significantly delayed because of availability.Twenty-one cases of mine blast/shrapnel pediatric maxillofacial injuries were selected to represent categorical varieties of a significant but unknown number of casualties treated successfully. The high number of mortality and morbidity caused by mine blast/projectile necessitates a reappraisal of pediatric craniofacial management training. "Losing a single child's life" is especially unacceptable if that loss was found to be due to the medical preparedness being inadequate or the lack of pediatric knowledge.

5037. Shuker, S. T. (2013). "Emergency treatment strategy and the biodynamic effects of massive, "chopped off", mandibular tissue and a prolapsed tongue." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **41**(3): e59-63.

Current weaponry possesses unobserved new, biodynamic wounding effects. For many victims, high velocity, large shell fragments have resulted in massive lower jaw "chopped off" hard and soft tissues injuries accompanied by tongue prolapse. The management challenges begin with lifesaving which is possibly complicated by airway compromise, severe hemorrhage, massive lower jaw loss, and a prolapsed tongue. Consequently, the goal shall be "No patient should die from massive facial tissue injuries alone". That is, if feasible, sensible, lifesaving techniques are applied at the appropriate time. Following general condition stabilization, the surgical management steps of massive lower jaw tissue loss should begin with immediate lost tissue reconstruction. Seventeen cases were selected from an unquantified number patients who had massive mandibular tissue losses in which the tongue, surprisingly, remained intact. In these cases, definitive, early scaffolding stabilization was accomplished by joining the remaining two lower jaw intact segments. The successful procedure consists of using a 2 mm horseshoe shaped Kirschner wire bridging the gap of the mandibular arch which effectively is used as a "scaffold" for rebuilding the soft tissue. Proper, initial, surgical management resulted in protecting lacerated tissue, diminishing subsequent morbidity and disfigurement, preventing a prolapsed tongue and preserving the intact tissues physiological functions. As the spectrum of injuries continues to evolve the clinical characterization of the severity of facial wounds need an expanded classification, appropriate to massive facial injuries. It is suggested it has the following descriptors: blast, penetration, perforation, avulsions and "chopping off" (BPPAC).

5038. Shuker, S. T. (2013). "Interrami intraoral fixation technique for severe mandibular rifle fragmented bullet injury management." The Journal of craniofacial surgery **24**(4): 1168-1174.

Interrami intraoral Kirschner wire fixation technique is presented for the reduction, stabilization, and immobilization of a pulverized and avulsed lower jaw caused by rifle fragmented bullet injuries. This indirect mandibular war injury fixation technique was tolerated by the patients and tissue more than any indirect external fixation. In addition, it is easier than open reduction using large bone plates for disrupted ballistics mandibular injury defects. An interrami intraoral fixation is appropriate for severely disrupted mandibular hard and soft tissues, and has been adapted in cases of mass casualties and limited resources. Benefits of use include limited hospital beds and fewer follow-up visits. Rifle fragmented bullet injuries need more attention for several reasons: not only because of the higher mortality and devastating nature of the injuries, but also because these injuries are responsible for an unreported type of bullet biomechanism wounding in the craniofacial region. In turn, this necessitates specialized victim management. The survival rates depend on immediate proper execution of airway, breathing, and circulation, which become more complicated as it relates to airway compromise and oropharyngeal hemorrhage resuscitation. Survival is predicated on the implementation of feasible, sensible, life-saving techniques that are applied at the appropriate time.

5039. Shuker, S. T. and R. Sadda (2010). "Craniomaxillofacial falling bullet injuries and management." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **68**(7): 1593-1601.

PURPOSE: The purpose of this study was to bring attention to craniocerebral maxillofacial perforating/penetrating injuries due to AK-47 Kalashnikov falling bullets (FBs); these dangerous injuries to both civilians and soldiers are rare. A review of the literature shows no reports on AK-47 FBs leading to double craniocerebral perforation and settling into the maxillofacial region. The number of victims, the AK-47's availability, the associated morbidity and mortality rates, and the rarity of cases prompted this article., MATERIALS AND METHODS: The treatment of injuries to the craniocerebral facial clinical profile due to FBs is challenging, and an understanding of the neurosurgical and maxillofacial management of these low-velocity FB injuries is required., RESULTS: We treated 11 cases due to AK-47 rifle FBs and 1 due to anti-aircraft Dashka 12.7-mm FBs. Craniocerebral facial injuries were treated and lodged bullets removed from different challenging locations in the base of the skull, without increasing morbidity and with avoidance of unnecessary surgical trauma to the affected area by the bullets., CONCLUSION: The required identification of such injuries can be difficult, and the removal of the lodged bullet to prevent secondary complications and reduce the chance of secondary infection can be graver than in other parts of the body. AK-47 FBs are a major public health concern internationally and require serious attention in terms of protection and management for civilians and soldiers in uniform.

5040. Shukla, A., et al. (2017). "Vasopressin Bolus Protocol Compared to Desmopressin (DDAVP) for Managing Acute, Postoperative Central Diabetes Insipidus and Hypovolemic Shock." Case Reports in Endocrinology **2017**.

Introduction. Management of postoperative central diabetes insipidus (DI) can be challenging from changes in volume status and serum sodium levels. We report a case successfully using a dilute vasopressin bolus protocol in managing hypovolemic shock in acute, postoperative, central DI. Case Report. Patient presented after bifrontal decompressive craniotomy for severe traumatic brain injury. He developed increased urine output resulting in hypovolemia and hypernatremia. He was resuscitated with intravenous fluids including a dilute vasopressin bolus protocol. This protocol consisted of 1 unit of vasopressin in 1 liter of 0.45% normal saline. This protocol was given in boluses based on the formula: urine output minus one hundred. Initial serum sodium was 148 mmol/L, and one-hour urine output was 1 liter. After 48 hours, he transitioned to 1-desamino-8-D-arginine vasopressin (DDAVP). Pre-DDAVP serum sodium was 149 mmol/L and one-hour urine output 320 cc. Comparing the bolus protocol to the DDAVP protocol, the average sodium was 143.8 ± 3.2 and 149.6 ± 3.2 mmol/L (p=0.0001), average urine output was 433.2 ± 354.4 and 422.3 ± 276.0 cc/hr (p=0.90), and average specific gravity was 1.019 ± 0.009 and 1.016 ± 0.01 (p=0.42), respectively. Conclusion. A protocol using dilute vasopressin bolus can be an alternative for managing acute, central DI postoperatively, particularly in setting of hypovolemic shock resulting in a consistent control of serum sodium.

5041. Shulman, A. and A. M. Strashun (2009). "Fluid dynamics vascular theory of brain and inner-ear function in traumatic brain injury: a translational hypothesis for diagnosis and treatment." The international tinnitus journal **15**(2): 119-129.

It is hypothesized that in all traumatic brain injury (TBI) patients with a clinical history of closed or penetrating head injury, the initial head trauma is associated with a vibratory sensation and noise exposure, with resultant alteration in vascular supply to the structures and contents of the fluid compartments of brain and ear (i.e., the fluid dynamics vascular theory of brain-inner-ear function [FDVTBE]). The primary etiology-head trauma-results in an initial fluctuation, interference, or interaction in the normal fluid dynamics between brain and labyrinth of the inner ear, with a resultant clinical diversity of complaints varying in time of onset and severity. Normal function of the brain and ear is a reflection of a normal state of homeostasis between the fluid compartments in the brain of cerebrospinal fluid and perilymph-endolymph in the labyrinth of the ear. The normal homeostasis in the structures and contents between the two fluid compartment systems--intracerebral and intralabyrinthine--is controlled by mechanisms involved in the maintenance of normal pressures, water and electrolyte content, and neurotransmitter activities. The initial pathophysiology (a reflection of an alteration in the vascular supply to the brain-ear) is hypothesized to be an initial acute inflammatory response, persistence of which results in ischemia and an irreversible alteration in the involved neural substrates of brain-ear. Clinically, a chronic multisymptom complex becomes manifest. The multisymptom complex, individual for each TBI patient regardless of the diagnostic TBI category (i.e., mild, moderate, or severe), initially reflects processes of inflammation and ischemia which, in brain, result in brain volume loss identified as neurodegeneration and hydrocephalus ex vacuo or an alteration in cerebrospinal fluid production (i.e., pseudotumor cerebri) and, in ear, secondary endolymphatic hydrops with associated cochleovestibular complaints of hearing loss, tinnitus, vertigo, ear blockage, and hyperacusis. The FDVTBE integrates and translates a neurovascular hypothesis for Alzheimer's disease to TBI. This study presents an FDVTBE hypothesis of TBI to explain the clinical association of head trauma (TBI) and central nervous system neurodegeneration with multisensory complaints, highlighted by and focusing on cochleovestibular complaints. A clinical case report, previously published for demonstration of the cerebrovascular medical significance of a particular type of tinnitus, and evidence-based basic science and clinical medicine are cited to provide objective evidence in support and demonstration of the FDVTBE.

5044. Shvyrkov, M. B., et al. (1999). "Non-free osteoplasty of the mandible in maxillofacial gunshot wounds: mandibular reconstruction by compression-osteodistraction." The British journal of oral & maxillofacial surgery **37**(4): 261-267.

We have treated 33 young men with medium to large (3-8 cm) bony and soft tissue defects of the lower third of the face caused by gunshot wounds. After debridement, collapsing the proximal segments for primary approximation of soft and hard tissues and a closed osteotomy of a small fragment of mandible, we used an original compression-distraction device, designed in 1982 and tested during 1983 (analogous devices were absent at that time) to reposition the mandible and cause callus to form (during distraction) between the fragment and to use the remaining stumps of bone to fill in the defect. The soft tissues were repaired at the same time. Twenty-eight of the patients presented within a few hours of injury, and the remaining five had old injuries. The only complications were in the group with old injuries where four patients developed abscesses that required drainage, but these did not interfere with the process of osteogenesis. All 33 patients had good functional and aesthetic results within 3-4.5 months. The method allows a bloodless minimally traumatic procedure which can be carried out in one stage. The results compare very favourably with the classic methods of the treatment of mandibular gunshot injuries.

5045. Shwyrkow, M. B. and A. K. Shamsudinov (1989). "Methods of simultaneous treatment of the mandible defects and the adjacent soft tissues." Acta chirurgiae plasticae **31**(4): 226-235.

Original methods of removing combined defects of the mandibular body and the adjacent soft tissues are described: osteoplasty by local tissues and nonfree osteoplasty. A compression-distraction apparatus of the authors' own construction is used. During the re-arrangement of the bone fragments and the osteotomized portions of the mandible, simultaneous repair of the defect of the bony tissue and the soft tissues takes place without using free bone transplants and soft-tissue flaps. Duration of treatment varies between 2 1/2 and 5 months depending on the size of the defect. A total of 12 persons with traumatic defects of the lower jaw from 2 to 8 cm in length and of the adjacent soft tissues were treated by these methods. Good functional and cosmetic results were obtained.

5046. Siccardi, D., et al. (1991). "Penetrating craniocerebral missile injuries in civilians: a retrospective analysis of 314 cases." Surgical neurology **35**(6): 455-460.

Analysis of 314 cases of penetrating craniocerebral missile injuries in civilians revealed a high rate of early mortality, with 228 victims having died at the scene and a further 38 dead within 3 hours. Surgery was performed in 44 patients who had a preoperative Glasgow Coma Score of at least 4. Out of the 26 survivors, all operated upon, 19 had an adequate recovery (score of 0-3 on the expanded Glasgow Outcome Scale). Vigorous resuscitation and early surgery often resulted in useful survivals and occasionally in spectacular recoveries. However, the high mortality rate on the scene or soon after the injury restricted the possibility of effective management to a minority of cases.

5047. Sichez, J. P., et al. (1982). "[Computed tomography of the head in gunshot wounds. Thirty-three cases (author's transl)]." Le pronostic des plaies craniocerebrales par balle en pratique civile. Serie de trente-trois cas etudies par la tomodensitometrie. **58**(12): 715-717.

The authors report a series of 33 cases of craniocerebral lesions secondary to projectiles injuries studied by means of CT scan. Ct scans demonstrate the path of the missile, destructions of deep cerebral parenchyma, dissections of with matter (intra-cerebral bubble) and reactive oedema. Prognostic incidence of CT is discussed. CT scan helps to choose the best therapeutic approach as regards each particular case.

5048. Siddiqi, S. (2021). "Connectome-targeted neuromodulation across symptoms and disorders." Brain stimulation **14**(6): 1712.

Abstract There is incidental variance in the precise location of different clinical TMS/DBS sites and brain lesions. Each site can be mapped to an underlying circuit using data from a large fMRI connectome database (n=1000), enabling us to retrospectively compare the effects of stimulating different circuits. This session will cover three approaches to connectome-based circuit targeting, each of which was replicated in independent datasets with rigorous permutation-based statistics: 1. Symptom-specific targeting: In two datasets of prefrontal TMS for MDD (n=111), dysphoric symptoms (e.g. sadness, anhedonia) responded best to stimulation of one circuit, while anxious/somatic symptoms responded best to stimulation of a different circuit. These circuits were reproducible across datasets ($p<0.01$) and predicted symptom-

specific improvement in independent cohorts (p<0.0002). 2. Transdiagnostic modulation of depression severity: We analyzed five lesion datasets (n=465), four TMS datasets (n=151), and five DBS datasets (n=101). Diagnoses included stroke (n=269), penetrating brain injury (n=196), MDD (n=195), Parkinson's disease (n=32), and epilepsy (n=25). Similar "depression circuits" were derived from TMS sites that relieve depression, DBS sites that modulate depression, and lesions that cause depression (p<0.005). This "depression circuit" was similar between MDD versus non-MDD patients (p<0.001). 3. Expanding to other disorders: We re-analyzed prior studies of lesions that protect against PTSD or addiction. Penetrating lesions protective against PTSD (n=189) were connected to a common circuit (split-half replication p<0.05). Stroke lesions protective against nicotine use disorder (n=103) were connected to the same circuit as penetrating lesions that reduce alcoholism risk (n=186, p<0.05). We demonstrate that (1) neuromodulation can target different circuits for different symptoms of MDD, (2) antidepressant circuit targets are transdiagnostic, (3) a common circuit can be modulated by TMS, DBS, and brain lesions, and (4) brain lesions can reveal targets for other disorders. These findings provide a robust framework for circuit-based targeting of neuromodulation. Keywords: Connectome, Causal, TMS, DBS

5049. Siddiqi, S. (2022). "Connectome-Targeted Neuromodulation Across Disorders." Biological Psychiatry **91**(9): S58-S59.

Background: There is incidental variance in the precise location of different clinical TMS/DBS sites and brain lesions. Each site can be mapped to an underlying circuit using data from a large fMRI connectome database (n=1000), enabling us to retrospectively compare the effects of stimulating different circuits. Using this approach, we have previously shown that TMS and DBS targets for depression can be identified based on the location of lesions that cause depression. This suggests that lesion connectivity may reveal neuromodulation targets for other disorders. Methods: We analyzed three datasets to identify connectivity of lesions that modify risk of PTSD, addiction, and OCD. 1. Penetrating brain lesions (n=189) in Vietnam Veterans, some of whom developed PTSD (defined by SCID-IV), and all of whom completed an MMPI. 2. Stroke lesions (n=103), some of which led to remission of nicotine use disorder. 3. Published case reports of lesion-induced OCD (n=25). 4. TMS sites associated with change in inhibitory control (n=52). Results: Penetrating lesions protective against PTSD (n=189) were connected to a common circuit (split-half replication p<0.05). Stroke lesions protective against nicotine use disorder (n=103) were connected to the same circuit as penetrating lesions that reduce alcoholism risk (n=186, p<0.05). Published OCD lesions (n=25) were connected to the same circuit as penetrating lesions associated with psychasthenia (n=186, p<0.01) and TMS sites that modify inhibitory control (n=52, p<0.001). Conclusions: Brain lesions may be used to identify new neuromodulation targets for PTSD, addiction, OCD, and potentially other disorders. 5050. Siddiqi, S. H., et al. (2020). "A convergent circuit for depression across brain lesions and brain stimulation." Journal of Neuropsychiatry and Clinical Neurosciences **32**(3): e22.

Background: Lesion locations and neurostimulation sites can reveal causal links between neuroanatomy and behavior. Objective: To determine whether lesions, transcranial magnetic stimulation (TMS), and deep brain stimulation (DBS) converge on a common "depression circuit."Methods: We analyzed five lesion datasets (N5465), four TMS datasets (N5151), and five DBS datasets (N5101), each with incidental variance in the precise lesion or stimulation location. Diagnoses included stroke (N5269), penetrating injury (N5196), major depression (N5195), Parkinson disease (N532), and epilepsy (N525). Each lesion or stimulation site's whole-brain connectivity was estimated using a normative resting-state functional connectivity database (N51000). Connections correlated with depression score (lesion datasets) or change in depression score (stimulation datasets) were identified. Cross-circuit similarity was assessed via permutation testing on mean spatial crosscorrelation. Results: Similar depression circuits were identified across all datasets (p<0.001). Circuits derived from brain lesions, TMS sites, and DBS sites all matched one another (p<0.001), as did circuits derived from patients with or without major depression (p<0.001). The combined circuit was correlated with dorsal attention network and anticorrelated with some parts of the subgenual cingulate. Antidepressant efficacy of individual TMS or DBS sites could be predicted using a depression circuit derived from the other 13 datasets (p<0.0001). This prediction outperformed our existing model based on subgenual connectivity (p<0.05). Conclusion: Lesion locations that cause depression, TMS sites that relieve depression, and DBS sites that modulate depression all converge on a common brain circuit. This transdiagnostic and cross-modal depression circuit may serve as a valuable therapeutic target for improved antidepressant treatment.

5051. Siddiqui, N., et al. (2022). "Proteoglycan alterations after traumatic brain injury." Journal of cerebral blood flow and metabolism **42**(1): 10.

Background: Nearly seventy million people are affected by Traumatic Brain Injury (TBI) annually worldwide resulting in immense societal burden. The glial scar, composed of many activated cell types and extensive extracellular matrix (ECM) alterations, is central to its pathophysiology. While significant attention has been paid to the cellular and general extracellular constituents of this scar, less is known about its glycobiology. Aim:We sought to determine the spatiotemporal dynamics of glycosaminoglycans (GAGs) and proteoglycans at the injury site after TBI. Further, we sought to determine if brain-penetrating GAGs known to be released in diseases associated with systemic inflammation like TBI contribute to ECM changes at the injury site. Method: We performed controlled cortical impact (CCI) or craniotomy-alone (CA) in mice then measured GAGs in brain and plasma at 1 and 7d via mass spectrometry (HPLC MS/MS). We compared transcriptomic profiles of CCI site to contralateral tissue. We confirmed increased expression of proteoglycans identified by transcriptomics via immunohistochemistry. Results/Conclusions: We observed elevations in GAGs at the injury site compared to contralateral tissue after CCI and CA. We did not observe increases in circulating GAGs after CCI when compared to CA. Transcriptomics at the CCI site revealed isolated increases in the proteoglycans glypican3 and decorin. Increased expression of these proteoglycans was verified via immunohistochemistry. Our results suggest that both CCI and CA significantly impact local GAG levels. GAG alterations after TBI may be specifically driven by upregulation of glypican3 and decorin. The precise biologic consequences of these upregulated proteoglycans warrants further investigation.

5052. Siddiqui, S.-U.-D., et al. (2020). "Efficacy of open reduction and internal fixation in achieving bony union of comminuted mandibular fractures caused by civilian gunshot injuries." The surgeon : journal of the Royal Colleges of Surgeons of Edinburgh and Ireland **18**(4): 214-218.

INTRODUCTION: Comminuted fractures of the mandible caused by gunshot injuries were traditionally treated with closed reduction using maxillo-mandibular fixation (MMF). 2,3 Open reduction and internal fixation (ORIF) has become a valuable treatment modality in the management of comminuted mandibular fractures due to low rate of complications and predictable healing 4, 5., OBJECTIVE: To compare the efficacy of ORIF compared with MMF in achieving bony union of comminuted mandibular fractures in gunshot injury patients., METHOD: ology: Randomized controlled trial conducted at the department of Oral & Maxillofacial Surgery, Abbasi Shaheed Hospital for a period of 3 years; total of 40 patients divided equally into two groups. Group A were treated with ORIF and group B were treated with MMF. Callus formation radiographically was confirmed by 8th week post operatively. Data was collected using proforma, entered on a statistical software SPSS version 20. Frequency percentages were computed for age and gender. Chi square and Fisher's exact tests were applied. P value <= 0.05 considered significant., RESULT: A total of 40 patients of gunshot injuries were included in this study. 37 (92.5%) were males and 3 (7.5%) were Females with mean age of 36.35 +/- 12.9 years SD. 19 (47.5%) patients showed callus formation, whereas, 21 (52.5%) did not. Out of 19 patients, 14 (70%) belonged to group A, and 5 (25%) from group B. The final healing considered by 8th week was in 16 (80%) of ORIF group A, and 8 (40%) group B (MMF) after calculating the clinical and radiographic evidences., CONCLUSION: Comparative clinical trials have proven that ORIF is superior to MMF in the management of comminuted mandibular fractures. Early primary repair and internal fixation provides predictable and cost effective results.

5053. Sidlo, J. and H. Sidlova (2018). "Accidental fatal craniocerebral injury caused by broken chain of sawing tool." Forensic science international **289**: e15-e17.

The case of an accidental fatal penetrating craniocerebral injury to a 26-year-old man at work when cutting wood is reported. There was used an angle grinder with an accessory for cutting similar to a chainsaw. The injury was caused by a fragment of the broken chain. The chain fragment broke through the facial part of the head to the left and penetrated the brain in the region of the left parietal bone of the cranial vault. The immediate cause of death was a failure of the central nervous system (brain death). The toxicological analysis of biological materials was negative. The death occurred as a result of a triple violation of safety precautions. The presented case is extremely rare in terms of

fatal injuries caused by power tools for sawing having been published in the forensic literature.

5054. Sidlo, J. and H. Sidlova (2018). "Long-term self-inflicted craniocerebral penetrating injury with a fatal outcome." Forensic science international **293**: e1-e4.

A case of long-term continual self-inflicted penetrating craniocerebral injury to a 59-year-old man with a fatal outcome is reported. The man suffered from paranoid psychosis and alcohol dependence. Over five months, he continually scalped the skin and subcutaneous tissue of his head with a knife until he perforated the skull and dura mater and injured his brain. He eventually sought medical advice, but died after 10 days of hospitalization despite complex conservative treatment. The immediate cause of death was a combination of central nervous system failure and heart failure. The original case presented is sporadic in the forensic literature due to atypical long-term continual self-harm to the head and brain using a sharp object that resulted in perforation of the skull and a fatal outcome. This case also highlights the importance of autopsy to determine the mechanism of injury and cause of death.

5055. Siedler, D. G., et al. (2014). "Diffuse axonal injury in brain trauma: Insights from alterations in neurofilaments." Frontiers in Cellular Neuroscience **8**(DEC).

Traumatic brain injury (TBI) from penetrating or closed forces to the cranium can result in a range of forms of neural damage, which culminate in mortality or impart mild to significant neurological disability. In this regard, diffuse axonal injury (DAI) is a major neuronal pathophenotype of TBI and is associated with a complex set of cytoskeletal changes. The neurofilament triplet proteins are key structural cytoskeletal elements, which may also be important contributors to the tensile strength of axons. This has significant implications with respect to how axons may respond to TBI. It is not known, however, whether neurofilament compaction and the cytoskeletal changes that evolve following axonal injury represent a component of a protective mechanism following damage, or whether they serve to augment degeneration and progression to secondary axotomy. Here we review the structure and role of neurofilament proteins in normal neuronal function. We also discuss the processes that characterize DAI and the resultant alterations in neurofilaments, highlighting potential clues to a possible protective or degenerative influence of specific neurofilament alterations within injured neurons. The potential utility of neurofilament assays as biomarkers for axonal injury is also discussed. Insights into the complex alterations in neurofilaments will contribute to future efforts in developing therapeutic strategies to prevent, ameliorate or reverse neuronal degeneration in the central nervous system (CNS) following traumatic injury.

5056. Siegel, E. B., et al. (1983). "Fatal intracranial extension of an orbital umbrella stab injury." Annals of ophthalmology **15**(1): 99-102.

We examined a patient with an orbital stab injury with fatal intracranial extension in whom the initial emergency examination did not reveal the extent of damage. Ophthalmologic consultation showed an afferent pupillary defect (Marcus-Gunn pupil), which prompted radiologic studies. Orbital tomograms and computerized tomography demonstrated an optic canal fracture and penetration to the contralateral right ventricle. Diabetes insipidus and thermal irregularity developed, and death occurred seven days later.

5057. Sights, W. P. and R. J. Bye (1970). "The fate of retained intracerebral shotgun pellets. An experimental study." Journal of neurosurgery **33**(6): 646-653.

5058. Sikka, S., et al. (2016). "Identification of traumatic brain injury in spinal cord injury across the continuum of care." Archives of physical medicine and rehabilitation **97**(10): e111.

Research Objectives: To explore how TBI is screened among SCI patients across the continuum of care. Design: Retrospective chart review. Setting: Emergency department, trauma, inpatient rehabilitation. Participants: 325 patients with SCI admitted to inpatient rehabilitation facility (IRF) between March 1, 2011 and December 31, 2014 were screened. 49 eligible subjects had a traumatic SCI and received care in the adjoining acute care (AC) hospital.

Interventions: Not applicable. Main Outcome Measure(s): Demographic characteristics and variables that capture diagnosis of TBI/SCI included documentation from ambulance, emergency department, AC, and IRF which included ICD-9 codes, altered mental status, loss of consciousness (LOC), Glasgow Coma Score (GCS), Post Traumatic Amnesia (PTA), neuroimaging, and cognitive assessments. Results: Participants were male (81%), white (55%), privately insured (49%), and aged 39.3 ± 18.0 years with 51% paraplegic and 49% tetraplegic. Mechanisms of injury were gunshot wound (31%), fall (29%), and motor vehicle accident (20%). TBI occurred in 65% of SCI individuals, and documentation of identification of TBI varied in AC H&P (29%), AC discharge note (24%), IRF H&P (29%), AC ICD-9 (37%), and IRF ICD-9 (30%). LOC was recorded in the ER note (22%), EMS report (14%), AC H&P (31%), and IRF H&P (33%). TBI was identified in AC CT imaging (20%). PTA was identified in the AC psychology note (20%). Cognitive assessments were performed on 16% of subjects. Conclusions: Documentation showed variability between AC and IRF and among disciplines. Imaging and GCS were more consistently documented than LOC and PTA. As a result, there is a need to standardize screening processes between AC and IRF to identify those that need specialized intervention. Processes identified to improve care among TBI/SCI individuals include standardizing screening and documentation so the TBI/ SCI treatment protocol can be activated across the continuum.

5059. Sil, K. and S. Chatterjee (2016). "Perforating brain injuries in children-protocol of management from civilian practice." Child's Nervous System **32**(5): 938.

Introduction: Perforating injuries to the brain are caused by a number of blunt and sharp objects in civilian life. This is a report of 15 children with perforating brain injuries which presented to our Centre from 2007 and 2014. Methods: The average age was 5.7 year and 9 were male and 6 female. The etiological agent ranged from spookes of bicycle wheels to idli makers to sharp end of umbrellas. After emergency resuscitation, and a detailed history from witnesses, the radiological investigation useful in all cases was MR scan of brain. Important findings include: entry and exit sites; intracranial fragments; missile track and its relationship to both blood vessels and air-containing skull-base structures; intracranial air; transventricular injury; basal ganglia and brain stem injury; missile track crossing the midline; multi-lobar injury; basal cisterns effacement; brain parenchymal herniation and associated mass effect. In 6 of the cases, the missile tract was suspected to be crossing vascular territory and hence angiography was resorted to. In 3 cases, pseudoaneurysm or arteriovenous fistulae were detected. Although intracranial pressure monitoring was used by us when indicated, in only 1 of the 15 cases did we feel it necessary to measure this parameter. Although debridement is recommended in al cases, we did not intervene in 4 cases where the tract penetrated to deep levels in eloquent areasand where the children arrived very late. In one case the child came with a delayed abscess which required drainage. Results: Bad prognosis in our small series occurred in bilateral hemisphere injuries, in children presenting with low Glassgow Coma scores or with respiratory distress. Conlusions: We would like to propose a algorithm for management of these uncommon injuries in the pediatric age group.

5060. Silva, A., et al. (2021). "Load-bearing ORIF of mandibular fracture caused by firearms projectiles: Case series." International journal of oral and maxillofacial surgery **51**: e12.

Purpose: The main challenge in mandibular fractures caused by firearms is restore the anatomy in the fracture areas, due to the severe destruction of the bone and tooth borne structures. To reestablish these areas, load sharing devices usually lacks support, leading to non-union and infections. Strong systems, with load-bearing pattern are the gold-standard for the treatment of complex mandibular fractures. Methods: A series of patients with mandibular fracture caused by firearms injuries was treated with load-bearing devices and followed to observe the complications and outcomes. Results: A total of 22 patients were enrolled by this study, 19 male and 3 females. All the patients were treated with transcutaneous approach and rigid fixation with a 2.4 mm titanium plate, a total load-bearing device. The complication rate was considered low, with infection of the surgical site (13%) and material fatigue (9%) the most prevalent. Conclusion: Open reduction and internal fixation of mandibular fractures with load-bearing devices is a reliable procedure. The use of these materials in cases of caused by firearms projectiles is fundamental to promote the correct for bone support in long term.

5061. Silva, J. A., et al. (1993). "Misidentification delusions, facial misrecognition, and right brain injury." Canadian journal of psychiatry. Revue canadienne de psychiatrie **38**(4): 239-241.

Individuals suffering from misidentification syndromes may present with right hemispheric pathology and deficits in facial recognition. In addition, misidentification delusions have been associated with aggressive behaviour. The possible linkage between misidentification phenomena, facial recognition, and aggression is discussed, illustrated by the case of a patient suffering from an organic delusional disorder.

5062. Silva, S. F. R., et al. (2014). "Profile of organ donors in Ceara, northeastern Brazil, from 1998 to 2012." Transplantation proceedings **46**(6): 1692-1694.

The use of cadaver donors for transplantation is often the only alternative in the treatment of patients with organ failure. The purpose of this study was to draw a comprehensive profile of solid organ donors in Ceara, northeastern Brazil, from 1998 to 2012. The study was retrospective and based on secondary data regarding sex, age, blood typing, and cause of brain death obtained from the solid organ donor database of the Ceara Transplantation Center covering the period November 1998 to December 2012. During the study period, 976 donors (69% male) were used. Donors were distributed in 4 age groups as follows: 12.9% <18 years, 50.9% 18-40 years, 28.5% 41-60 years, and 7.7% >60 years. The average age was 35 +/- 16 years. On the average, female donors were older than male donors (38.4 +/- 17 y vs 33.5 +/- 16 y; P < .0001). Men were predominant in the age groups 18-40 y (75.3%; P < .0001) and 41-60 y (59.4%; P < .0001). The main causes of brain death were traumatic brain injury (TBI) (56.7%) and stroke (33.1%). The former was more common in men (P < .0001), the latter in women (P < .0001). TBI was caused by traffic accidents (51.4%), of which 50.7% were motorcycle accidents, and urban violence (22.6%), of which 71.2% were associated with firearms. The number of donations increased in the study period (11.2 donors per million population in 1998-2002 to 68.1 in 2008-2012). In Ceara, solid organ donation is on the rise. The predominant donor profile was young men aged 18-40 years with brain death due to TBI caused by traffic accidents and urban violence.

5063. Silvestro, C., et al. (2001). "Delayed effects of a migrated foreign body (sewing needle) in the cervical spine: a case report." Spine **26**(5): 578-579.

STUDY DESIGN: A case report is presented., OBJECTIVE: This report documents one case of intraspinal migration of a metal foreign body., SUMMARY OF BACKGROUND DATA: The migration and penetration of foreign bodies into the spine have been described, but there are only three reports of a needle as the causative object., METHODS: This case report included a chart review, an examination of the patient, and a literature search., RESULTS: The patient successfully underwent surgery, in which the foreign body (a sewing needle) was removed., CONCLUSION: It is important to be aware of the possible delayed penetration of a foreign body into the spine even in patients with few or no symptoms.

5064. Sima, A., et al. (2017). "Predicting long-term global outcome after TBI: Development of a practical prognostic tool." Archives of physical medicine and rehabilitation **98**(10): e94.

Research Objectives: To develop a prognostic tool for informative predictions on long-term functional outcomes after moderate to severe TBI.DesignMultiple Cross-Sectional Analyses at 1, 2, and 5 years post-injury. Setting: Inpatient rehabilitation facilities in multicenter TBI-Model Systems (TBIMS), with follow-up conducted primarily by telephone. Participants: Individuals with non-penetrating TBI and injury date 1997-2017 enrolled in the TBIMS. Interventions: Not applicable. Predictive models were built by a flexible classification tree methodology.Main Outcome Measure(s)Glasgow Outcome Scale. Results: There were 10,125, 8,821, and 6,165 participants in the final analyses for the 1, 2, and 5-year follow-up periods, respectively. PTA duration dominated the branching hierarchy in all model years, with similar cutoffs in each of the follow-up periods. Lower order variables used as prognostication variables included age at injury, premorbid education, occupational category, and productivity, with age at injury being the most proximal predictor when more than one emerged. Generally, patients who spent fewer days in PTA, were younger at injury, employed or productive, and had achieved higher levels of education had better outcomes. Prior TBI, problem alcohol use, illicit drug use, initial motor GCS, focal hemorrhage on CT, cranial surgery, and acute hospital LOS were non-contributory. Predictability in independent test datasets ranged from C-statistic of 0.685 (year-5) to 0.729 (year-2).Conclusion/DiscussionAn easy-to-use prognostic tool for long-term functional outcomes was developed that is based on flexible statistical methodology and a large number of patients. An assessment using an independent dataset showed reasonable predictability, allowing for its use to guide expectations for patients and their families. Findings show that up

to 5 years after moderate to severe TBI, length of PTA, a correlate of injury severity, remains the most critical determinant of functional outcomes.

5065. Siman-Tov, M., et al. (2013). "Reduction in trauma mortality in Israel during the last decade (2000-2010): the impact of changes in the trauma system." Injury **44**(11): 1448-1452.

HYPOTHESIS: Following the introduction of changes to the trauma system there would be a period of time during which the impact on mortality would be minimal. A decrease in mortality rates would be noted as the TS matured and would continue over time., DESIGN: A retrospective cohort study of all severely injured patients (injury severity score >= 16) recorded in the Israeli National Trauma Registry at six level I trauma centres in Israel from 2000 to 2010. Inpatient death rates were examined overall and by sub groups., SETTING: The National Trauma Registry contains hospitalized patients, transfer patients to or from other hospitals and those who died in the emergency department. It excludes patients who were dead on arrival, discharged following treatment in the emergency department, and patients whose injuries by definition are not classified as trauma., MAIN OUTCOME MEASURES: In-hospital mortality, RESULTS: Data included 23,143 severe trauma patients available for analysis. Inpatient mortality rates decreased significantly from 16% in 2000 to 11% in 2010. The odds ratio for mortality in 2010 vs. 2000, adjusted for year, age, sex, mechanism of injury, traumatic brain injury, penetrating injury, and severity of injury (ISS >= 25), was 0.53, confirming a downward trend., CONCLUSIONS: A steady significant reduction in the inpatient mortality rate for severe trauma patients hospitalized at all level I trauma centres in Israel between 2000 and 2010 was observed. Although a single factor that explains the reduction was not identified, evidently the establishment of the trauma system brought about a significant decrease in hospital mortality. Integrated cooperation between components of the national trauma system in Israel over the years may explain the reduction.

5066. Simic, M., et al. (2007). "The characteristics of head wounds inflicted by "humane killer" (captive-bolt gun)--a 15-year study." Journal of forensic sciences **52**(5): 1182-1185.

The "humane killer" or captive-bolt gun, is the tool/weapon widely used in meat industry and private farmer households for slaughtering animal stock. Out of 17,250 autopsies performed at the Institute of Forensic Medicine in Novi Sad during the 15-year period (1991-2005), 29 cases of suicides and two homicides were committed by captive-bolt pistols. Wounds inflicted by captive-bolt guns have specific morphological features, distinctive from wounds made by other kinds of hand firearms. Selected features of the captive-bolt wounds (punched round entrance and a double pattern of smoke soiling) depend on distance and angle of instrument at the time of firing. Autopsy findings were compared with an experimental model consisting of 20 domestic pigs. Obtained results confirmed that the appearance of the entrance hole and soot deposits, along with differences in shape, location, extent, and density of soot blackening, could be useful in identification of weapon, direction of discharge, shooting distance, and angle of the muzzle to the frontal and sagittal planes of the head at the moment of fire.

5067. Simon, G., et al. (2019). "Brain death of an infant caused by a penetrating air gun injury." Legal medicine (Tokyo, Japan) **39**: 41-44.

Air guns are shooting projectiles (pellets) from the expansion of compressed air without involving any chemical reactions. Air guns are often regarded as harmless by the public, but these weapons can produce severe, sometimes lethal injuries, especially in children. A case of a penetrating head injury of an eleven-month-old infant, caused by an ordinary air gun pellet, is presented. The air gun pellet created an exceptionally severe brain injury, and brain death. The factors influencing the severity of air gun injuries - muzzle velocity, muzzle energy, skull thickness - are discussed.

5068. Simon, J. C., et al. (2012). "Penetrating ballistic-like brain injury (PBBI) induces coagulopathy with reduction of platelet-fibrin interaction: A study of thromboelastography in a rat model." Journal of neurotrauma **29**(10): A55.

Introduction Severe coagulopathy often accompanies penetrating brain injury and its incidence isreported to be significantly higher than with closedhead trauma. However the mechanisms underlying coagulopathy in brain injury are poorly understood. The aim of this study is to assess the possible mechanism of using thromboelastography (TEG) in rat PBBI model. Methods Sprague-Dawley rats were allocated to PBBI or sham control groups (n = 7/grp). Experimental

procedures were as follows: PBBI group; a burrhole was made in the frontal skull for PBBI probe insertion and inflation/deflation. Sham control group; received craniotomy only. Arterial blood samples were collected (femoral artery) with a TEG analyzer. The following variables were measured: reaction time (R), coagulation time (K), clot formation rate (a-angle), maximum amplitude (MA), shear elastic modulus (G), coagulation Index (CI), and LY30 (%lysis during 30min after MA) and compared between the PBBI and sham groups. Group differences in each parameter were evaluated and p Values < 0.05 were considered significant. Results CI, which represents the overall coagulation status, was lower in the PBBI vs sham group (Mean - SEM; 3.10 - 0.29 vs 4.34 - 0.58). MA value, which reflects the platelet-fibrin interaction, was significantly smaller in the PBBI vs sham (65.6 - 1.6 vs 73.2 - 3.4, p = 0.0319). Moreover, the G value, which also represents the strength of the fibrin clot, was smaller in the PBBI group vs controls (17590 - 4798 vs 9644 - 615, p = 0.0411). Conclusions These results suggest platelet-fibrin interaction could be reduced in PBBI. The real time“Point of Care”assessment with TEG could help to select more targeted, goal-directed therapy in PBI patients.

Cerebral tissue pulmonary embolus (CTPE) is a rare event following severe blunt or penetrating head trauma and is often complicated by coagulation disturbances and hemorrhage. Donor cerebral tissue pulmonary embolism has been reported to cause lethal, early graft dysfunction in lung transplant recipients. We report a case of donor cerebral tissue pulmonary embolism in a 41-year-old female single lung transplant recipient with excellent post-operative graft function.

5070. Simonit, F., et al. (2020). "A burned body with a gunshot wound in the mouth and a suicide note: A complex or complicated suicide?" Journal of forensic and legal medicine **72**: 101958.

The body of a 53-year-old man was found in a burning car. The ignition key was in start position and the accelerator pedal was held down by his right foot. Autopsy revealed a gunshot entrance wound in the hard palate, a bullet track through the anterior cranial fossa and a projectile lodged in the left frontal lobe. The brain stem was free of lesions and any signs of secondary brain injury, such as brain oedema and intracranial haemorrhage, were not significant. Soot deposits and thermal injury to the mucosa were observed in the airways below the glottis and carboxyhaemoglobin (COHb) saturation was 40%. A single bullet case and a handgun were recovered next to the driver's seat. Fire investigators identified the motor as the beginning of the burning: therefore, the conclusion was that the car had caught fire due to overheating of the engine. Differential diagnosis between complex and complicated suicide was essential. The cause of death was identified as carbon monoxide intoxication, and the injuries to the brain were not felt to be immediately fatal. The case has been classified as a complicated suicide. There are no other published cases of a complicated suicide involving exposure to fire or the use of firearms. Copyright © 2020. Published by Elsevier Ltd.

BACKGROUND: Foreign bodies of the orbit can have a diverse range of clinical presentations, which may be perplexing to the most Ophthalmologists. Wooden foreign bodies can remain quiescent for a long time, before presenting with various complications. We report a case of Post-traumatic chronic non-healing discharging sinus in the left upper lid, which on exploration revealed the presence of the missed wooden foreign body., CASE: A 48-year-old male, presented to Ophthalmic OPD with a complaint of discharge from the left upper eyelid for 18 months. The patient had a history of minor trauma to the left upper eyelid while collecting wood in the forest, 18 months back. The patient was misdiagnosed on previous examinations elsewhere. The diagnosis of retained wooden foreign body was made at our center and surgical exploration was done to remove the same., OBSERVATION: On clinical examination, there was a 2-3mm long sinus in the left upper eyelid with purulent discharge and granulation tissue. Surrounding skin showed hyperpigmentation and excoriation. CT scan orbit was inconclusive. MRI orbit revealed a peripherally enhancing extraconal/conal collection in the left orbit with a central hypo intense structure suggestive of a foreign body. Surgical exploration of the wound was done and a small wooden foreign body measuring 9mm was removed with excision of the sinus tract., CONCLUSION: A history of trauma followed by chronic discharging sinus should evoke suspicion of a retained foreign body. Prompt imaging, followed by surgical exploration should be done to prevent misdiagnosis and inappropriate management. Copyright © NEPjOPH.

5077. Singh, B., et al. (2017). "Traumatic cerrebral fungus: Experience from an institution in North East India." Journal of neurosciences in rural practice **8**(5): 37-43.

Background: Traumatic brain fungus is manifestation of neglected head injury. Although rare it is not uncommon. The patients are usually intact with good Glasgow coma (GCS) score inspite of complex injuries and exposed brain parenchyma but morbidity and mortality is very high with time if no proper and timely management is offered. There is very less study on traumatic brain fungus with no defined management protocols. So an attempt was made to explain in details the surgical strategies and other management techniques in patients with traumatic brain fungus. Aims: To study and evaluate the pattern of causation, clinical presentations, modalities of management of traumatic brain fungus and outcome after treatment. Methods: All patients with fungus cerebri, admitted to our centre from January 2012 to December 2015 were studied prospectively. All the patients were examined clinically and triaged urgently for surgery. CT head was done in all patients to look for any brain parenchymal injury. All patients were managed surgically. Outcome was assessed as per the Glassgow Outcome Score. Results: Total 10 patients were included in the study. 8 were men and 2 women. The patients' ages ranged from 3-48 years (mean 31.6 years). The interval between initial injury and protrusion ranged from 3 days to 6 days (mean 4.1 days). Mean GCS at the time of presentation was 13.2.60% of the patients (n = 6) sustained moderate head injury. (GCS-9-13). Size of the fungus ranged from 5cm×3cm to 8cm×10cm. Conclusion: Early and proper local wound treatment prevents fungus formation. Pre-emptive antibiotics, AEDs and cerebral decongestants are recommended. Loose water-tight duroplasty prevents CSF leak. But mortality and morbidity can be reduced significantly if brain fungus is managed properly by applying basic surgical principles and antibiotic protocols combined with newer surgical modalities.

5078. Singh, B. K., et al. (2015). "Paradigm Shift in Management Strategies of Craniocerebral Missile Injuries Improving Survival Rates and Functional Outcome Score." Indian Journal of Neurotrauma **12**(1): 53-61.

Introduction With development of firearms, civilian violence, ethnic clashes, militancy, terrorist attack, and military operations there is a worldwide increase in incidence of craniocerebral missile injuries. The mortality of patients

with craniocerebral missile injuries is high, and if the victim survives, functional outcome is poor. In spite of high mortality, no proper attention was given in last five decades in improving surgical techniques and resuscitation patterns of patients with craniocerebral missile injuries. Problems Considered The problems are many, but the two problems highlighted are decreased survival because of the inadequate pre-op resuscitation and poor functional outcome due to aggressive surgery. Therefore, the study was performed to evaluate the outcome of early and less aggressive surgical strategy and aggressive preoperative resuscitation in patients with penetrating injuries and also to look for factors prognosticating outcome. Methods A series of 96 patients with craniocerebral missile injuries to head were managed at a single center over a period of 3 years is presented. Aggressive resuscitation was done in all hemodynamically unstable patients and patients with coagulopathy either with blood products, hyperosmolar therapy or ionotropic support on protocols of damage control resuscitation. Blood product therapy consisted of packed red blood corpuscles, fresh frozen plasma (FFP) and platelets. Hypertonic saline was used for hyperosmolar resuscitation, and for ionotropic support dopamine, adrenalin, and vasopressin were used. Minimum debridement of the missile tract was done and maximum cortical tissue was preserved. Results Neurosurgical procedures contemplated on 78 patients. Criteria for craniotomy were—Glasgow Coma Scale (GCS) of < 8 without hypotension and reacting pupils, GCS > 8 with intracranial bone fragments/significant clot, and raised intracranial pressure. Surgical approach were frontotemporal exposure (41%, n ¼ 32/78), frontoparietal exposure (22%, n ¼ 18/78), retrosigmoid exposure (2%, n ¼ 2/78), combined middle and posterior fossa approach (2%, n ¼ 2/78), and decompressive craniectomy (43%, n ¼ 24/78). Procedures done were debridement of devitalized tissue (100%, n ¼ 78/78), extraction of bone fragment (43%, n ¼ 17/39), extraction of metallic pellet (62%, n ¼ 42/67), lax duraplasty (100%, n ¼ 78/789), debridement of missile tract (100%, n ¼ 78/78). Overall, 36 patients were operated within 8 hours and 22 patients were operated within 14 hours. Median age group were 26 years, 81% were male, surgical mortality of 18%, and overall mortality was 33%. Conclusion This study indicates the factors prognosticating outcomes and supports that less aggressive surgery and aggressive preoperative resuscitation has decreased surgical mortality rates and improved functional outcomes.

5079. Singh, D., et al. (2010). "An unusual presentation of head injury: teeth in brain." Turkish neurosurgery **20**(1): 63-65.

Penetrating injuries other than gunshot wounds or low-velocity wounds to the head are extremely rare. We report the case of a 19 year old male who sustained a penetrating craniocerebral trauma following a road traffic accident. Noncontrast CT scan revealed three foreign bodies embedded in left frontal lobe, which on surgery turned out to be human teeth. Mechanism of injury seems to share characteristics of low velocity projectiles. The survey of management pattern of these injuries showed a general agreement about CT scan, antibiotics and anticonvulsants. The prompt management resulted in an excellent outcome. We discuss the management of this unusual case reviewing the current literature on craniocerebral injuries caused by similar objects.

5080. Singh, D. and S. Morley (2008). "Safety of electroconvulsive therapy in a patient with intracranial lead." The Australian and New Zealand journal of psychiatry **42**(12): 1075-1076.

5081. Singh, P. (2003). "Missile injuries of the brain: results of less aggressive surgery." Neurology India **51**(2): 215-219.

Sixty cases of missile injuries (59 males, average age 25 years) were studied over a period of one year. Forty-three patients had suffered splinter injuries, 12 had gunshot wounds and 5 had suffered injuries from improvised explosive devices. The Glasgow coma scale was <5 in 8 patients, 5-8 in 14, 8-12 in 30 and 13-15 in 8 patients. Extensive comminution of skull bones was found in 10 patients. Thirty-five patients had penetration of the skull and the rest had orbito-cranial or facio-cranial wounds. CT scan revealed small hemorrhagic contusion with in-driven bones without mass effect in 15, contusion with mass effect in 36 cases, cortical contusions without in-driven bones (tangential injuries) in 3, distant intracranial contusions in 4, intraventricular hemorrhages in 5, multilobar injuries in 14, and unilobar injury in 40. Fifty-two patients were operated upon at our center, of which 30 were operated within 24 hrs, 10 between 24 to 48 hrs, and 12 between 48 to 72 hrs. Six patients were treated conservatively and 2 underwent only a simple closure of scalp wound. Craniectomy was done in 10 and craniotomy in 42 patients. Two patients developed wound sepsis, one had aspiration pneumonia, one had septicemia and one had deep vein thrombosis while one had post-traumatic hydrocephalus. On follow-up at 6 months, the outcome as per the Glasgow outcome scale was as follows: Good outcome in 42, moderate disability in 7, severe disability in 6 and death of 5 patients. Retained bone fragments were found in 36.3 % on follow-up CT scan but no one had brain abscess.

5082. Singh, P., et al. (2003). "Missile injuries of brain - An experience in northern sector." Medical Journal Armed Forces India **59**(4): 290-297.

During a period of one year, from Jan 99 to Dec 99, 60 cases of missile injuries were treated at our centre. 59 were males and one was a female and their average age was 25 years. 43 patients had suffered splinter injuries, 12 had gunshot wounds and 5 had suffered injuries by improvised explosive devices. Glasgow coma scale was < 5 in 8 patients, 5-8 in 14, 8-12 in 30 and 13-15 in 8 patients. Extensive comminution of skull bones was found in 10 patients. 35 patients had more or less clear penetration of the skull and the rest had orbito-cranial or facio-cranial wounds. CT scan revealed small haemorrhagic contusion with in-driven bones without mass effect in 15, contusion with mass effect in 36 cases, cortical contusions without in driven bones (tangential injuries) in 3, distant intracranial contusions in 4, intraventricular haemorrhages in 5, multilobar injuries in 14, and unilobar injury in 40. 52 patients were operated upon at our centre of which 30 were operated within 24 hours, 10 between 24 to 48 hours, 12 between 48-72 hours. Six patients were treated conservatively and 2 required only simple closure of scalp wound. Craniectomy was done in 10 and craniotomy in 42 patients. Two patients developed wound sepsis, one each developed aspiration pneumonia, septicemia, deep vein thrombosis and post-traumatic hydrocephalus. On follow up at 6 months, outcome as per Glasgow outcome scale was as follows : good outcome - 42, moderate disability in 7, severe disability in 6 and death in 5 patients. Retained bone fragments were found in 40% on follow up CT scan but none had brain abscess.

5083. Singh, T. G., et al. (2015). "Sympathetic ophthalmia in a case of penetrating ocular injury associated with brain injury: A case report." JMS - Journal of Medical Society **29**(2): 116-118.

Sympathetic ophthalmia is a rare bilateral granulomatous inflammation that follows accidental or surgical insult to the uvea of one eye. The diagnosis may be confounded by the associated traumatic brain injury. Here, we report a case of sympathetic opthalmia in a patient who sustained perforating injury of the right eye and traumatic brain injury in the left frontal area following a road traffic accident. Timely diagnosis and surgical intervention was the key to a successful outcome.

5084. Singh, V. and S. R. Channabasappa (2021). "A retrospective study of pattern of cranio-cerebral injuries due to road traffic accident in a tertiary care hospital." Indian Journal of Forensic Medicine and Toxicology **15**(2): 1771-1777.

Head injury is defined as sudden injury due to an external force that affects the functioning of brain. It may be either caused by sudden blow or impact (closed head injury) or by an object penetrating the skull (Penetrating injury). The common causes of head injury include road traffic accidents, fall from height and assault. The mortality from head injury is reported to be between 1-2% of death from all the causes. Not only it is one of the major causes of death in young adults but also may cause permanent disability in survivors. The importance of head injury as a public health problem cannot be overstated. In the studies of Road Traffic accidents provide valuable data for implementing effective emergency services to reduce the trauma related mortality and strengthening legal measures in peak hours of fatal accidents. We aimed to study, pattern of injuries especially cranio-cerebral injuries occurring in vehicular accidents. Patients case records with history of head injury and MLC records of victims of road traffic accident reported to Saveetha hospital, Chennai from 1st Jan 2019 to 31st Dec 2019 period were analysed retrospectively. Out of total 1846 Road Traffic Accidents cases reported to Emergency Medicine department, Saveetha Medical college hospital, Chennai, 10.40% cases had history of head injury. The male/female ratio was 9:1. Commonest age group affected was between 21-40 years involving 126 (65.62%n=192) cases. Fatal traumatic brain injuries were seen in 178 (92.70%, n=192) cases. Amongst 192 head injury cases, scalp injury noted in 167 (86.97%) cases, most common bone fractured was temporal bone 94(48.95%), followed by other bone parts. The commonest variety of intracranial haemorrhage was subdural haemorrhage 173 (n=192, 90.10%) followed by Subarachnoid haemorrhage and Extradural haemorrhage. In 26 (13.54%) patients of head injury, craniotomy surgery was done. The timings between 3PM to 6PM showed the highest number of cases accounting to 61.7% of the cases followed by 26.0% of cases between 6PM to 9PM. The two-wheeler accidents accounted for 69.9% of the head injury cases followed by that due to other vehicles (16.7%).

5085. Singh, V., et al. (2004). "An unusual intraorbital foreign body." Indian journal of ophthalmology **52**(1): 64-65.

A plastic foreign body penetrating the anterior base of skull through the orbit in a 10-year-old male child is reported.

5086. Sinha, P., et al. (2005). "Visualization of bullet track and bullet by radionuclide brain scintigraphy." Clinical nuclear medicine **30**(4): 249-252.

Radionuclide brain scintigraphy is a commonly performed examination for the confirmation of brain death. Although the absence of scintigraphically detectable flow of lipophilic tracers to the brain combined with the lack of uptake in the brain is considered consistent with brain death in the appropriate clinical scenario, the cause of death itself is usually not apparent on the scan. A case of bullet track and bullet visualization during a radionuclide brain death study with Tc-99m hexamethylpropyleneamine oxime (HMPAO) is described.

5087. Sinha, S., et al. (2010). "Survival after a penetrating injury traversing midbrain - case report." British journal of neurosurgery **24**(4): 477-478.

Penetrating civilian shrapnel injuries to brainstem are quite uncommon, but invariably fatal. We report a rare case of a child who survived following shrapnel injury to tectum of midbrain.

5088. Sinha, S., et al. (2021). "Association of plasma biomarkers and blood brain barrier dysfunction in traumatic brain injury using dynamic contrast-enhanced mri." Journal of neurotrauma **38**(14): A4.

Background: Blood-brain barrier (BBB) disruption is a known component of traumatic brain injury (TBI), and has been implicated in TBI-related disability. Here we analyzed the relationship of plasma biomarker levels and dynamic contrast-enhanced (DCE) MRI as a measure of TBI-related BBB dysfunction. Methods: We examined blood-based biomarkers and neuroimaging from eleven adult patients (median age 29 years, 81.8% male) admitted to the hospital following non-penetrating TBI (54.5% motor vehicle accident, 18.2% falls, 27.2% blunt trauma). Blood was collected within 72 hours of injury. 3T DCE MRI was performed 2 weeks post-injury. DCE MRI was analyzed using the Patlak 2-compartment model to calculate total voxel-wise volume across whole brain in which the volume transfer coeffecient (Ktrans) was elevated above the 95th percentile of controls. Multiple linear regression, covarying for age, sex, and Glasgow Coma Scale (GCS) was run for each biomarker to predict Ktrans based on plasma biomarker level. Results: Mean (SD) volume of voxel-wise Ktrans elevation across whole brain for the sample was 960.66mm3 (258.30mm3). Multiple plasma biomarkers demonstrated significant predictive value for Ktrans in the regression model. These included glial fibrillary acidic protein (GFAP) ($F(7,11) = 4.313$, $p = 0.0451$, $R2 = 0.711$), neurofilament light chain (NfL) ($F(7,11) = 9.22$, $p = 0.006$, $R2 = 0.840$), platelet-derived growth factor receptor beta (PDGFRb) ($F(7,11) = 29.22$, $p = 0.000185$, $R2 = 0.911$), and C-reactive protein (CRP) ($F(7,11) = 6.063$, $p = 0.0198$, $R2 = 0.776$). Conclusion: GFAP, NfL, PDGFRb, and CRP were significant predictors of voxel-wise Ktrans elevation after controlling for age, sex, and injury severity, suggesting that these TBI-related plasma biomarkers may serve as biomarkers of TBI-related BBB dysfunction. These findings add further support to BBB dysfunction as an important TBI endophenotype. Future work will examine the relationship of these imaging and blood-based biomarkers with long-term patient outcomes.

5089. Sinnott-Armstrong, W. and F. G. Miller (2013). "What makes killing wrong?" Journal of medical ethics **39**(1): 3-7.

What makes an act of killing morally wrong is not that the act causes loss of life or consciousness but rather that the act causes loss of all remaining abilities. This account implies that it is not even pro tanto morally wrong to kill patients who are universally and irreversibly disabled, because they have no abilities to lose. Applied to vital organ transplantation, this account undermines the dead donor rule and shows how current practices are compatible with morality.

5090. Sipahi, C., et al. (2007). "The prosthodontic restoration of a self-inflicted gunshot maxillofacial defect: a short-term follow-up case report." The International journal of prosthodontics **20**(1): 85-88.

A self-inflicted gunshot maxillofacial defect was restored with dental implants and various attachments. Following mandibular surgical reconstruction, a fixed full-arch implant-supported prosthesis was fabricated. The maxillary defect was restored with an obturator retained with bar-clip and ball attachments. Crowns with an

unfavorable crown-to-root ratio were used to rectify a compromised unilateral interocclusal space. Functional rehabilitation was achieved without any pathologic sequelae and maintained over a 1-year observation period. Provision of a fixed implant-retained mandibular prosthesis opposing a specific design for a maxillary obturator provided short-term and optimistic prognosis in the management of a serious traumatic injury.

5091. Siqueira, F., et al. (2012). "Rehabilitation outcome for the treatment of trauma-induced trismus: A case report." PM and R **4**(10): S221.

Case Description: Patient presented to the outpatient rehabilitation clinic approximately 4 months after a gunshot wound to the face complaining of limited jaw movement, facial pain, and poor nutrition and oral hygiene. A 5-mm jaw opening was observed, and an ultrasound-guided diagnostic block of bilateral temporalis and bilateral masseter muscles was performed. Diagnostic block provided approximately 3 weeks of pain relief and increased jaw opening as reported by patient. Patient subsequently received botulinum toxin A injections followed by intensive joint mobility exercises, manual therapy and modalities such as transcutaneous electrical stimulation and ultrasound to facilitate healing and joint mobility. Program Description: 18-year-old man with history of gunshot trauma to the right side of his face resulting in multiple facial fractures, bilateral visual loss and severe trismus. Setting: Outpatient rehabilitation clinic. Results or Clinical Course: Injection of botulinum toxin A in combination with intensive physical therapy significantly reduced the patient's pain and improved jaw range of motion by at least 50%. Consequently, patient's mood, oral hygiene and nutrition improved, contributing to a better quality of life. Discussion: Trauma-induced trismus can be successfully treated with botulinum toxin A injection in combination with intensive physical therapy. Conclusions: Trauma-induced trismus is uncommonly reported in literature, and further studies are needed to create specific rehabilitation guidelines for this patient population.

5092. Sirko, A., et al. (2018). "Successful surgical treatment of a patient with combined gunshot shrapnel injuries in the heart and brain complicated by middle cerebral artery pseudoaneurysm." Trauma case reports **18**: 17-23.

Successful step-by-step treatment of a combined gunshot shrapnel injury of the brain, damaging the left middle cerebral artery (MCA) branches, and penetrating myocardium injury is discussed. Open brain and heart surgeries were performed. A left MCA pseudoaneurysm was formed postoperatively. Endovascular exclusion of the left MCA pseudoaneurysm was performed using detachable micro coils. Finally, plastic reconstruction of the posttraumatic cranial vault defect was performed using a dynamic titanium plate. Treatment of severe combined gunshot shrapnel brain injury with formation of MCA pseudoaneurysm and a penetrating myocardium injury requires a multimodal approach involving related specialists (neurosurgeon, cardiosurgeon and interventional radiologist).

5093. Sirko, A., et al. (2019). "Successful Surgical Treatment of Severe Perforating Diametric Craniocerebral Gunshot Wound Sustained during Combat: A Case Report." Military medicine **184**(9-10): e575-e580.

Many researchers classify perforating diametric craniocerebral gunshot wounds as fatal because mortality exceeds 96% and the majority of patients with such injuries die before hospitalization. A 23-year-old Ukrainian male soldier was admitted to a regional hospital with a severe perforating craniocerebral wound in a comatose state (Glasgow Coma Scale score, 5). Following brain helical computed tomography, the patient underwent primary treatment of the cerebral wound with primary duraplasty and inflow/outflow drainage. After 18 days of treatment in the intensive care unit, he was transferred to a military hospital for further rehabilitation. This report details our unusual case of successful treatment of a perforating diametric craniocerebral gunshot wound.

5094. Sirko, A., et al. (2020). "Mortality and Functional Outcome Predictors in Combat-Related Penetrating Brain Injury Treatment in a Specialty Civilian Medical Facility." Military medicine **185**(5-6): e774-e780.

INTRODUCTION: The combined use of new types of weapons and new types of personal protective equipment has led to changes in the occurrence, nature, and severity of penetrating brain wounds. The availability of modern equipment, methods of treatment, and trained medical personnel in a civilian hospital, as well as advanced specialty medical care, has improved treatment outcomes. There have been a limited number of publications regarding analysis and predictors of treatment outcomes in patients with combat-related penetrating brain injury in contemporary armed

conflicts. The purpose of this study was to analyze the results of surgical treatment of patients with penetrating brain injury and to identify significant outcome predictors in these patients., MATERIALS AND METHODS: This was a prospective analysis of penetrating brain injury in patients who were admitted to Mechnikov Dnipropetrovsk Regional Clinical Hospital, Ukraine, from May 9, 2014, to December 31, 2017. All wounds were sustained during local armed conflict in Eastern Ukraine. The primary outcomes of interest were mortality rate at 1 month and Glasgow Outcome Scale score at 12 months after the injury., RESULTS: In total, 184 patients were identified with combat-related brain injury; of those, 121 patients with penetrating brain injury were included in our study. All patients were male soldiers with a mean age of 34.1 years (standard deviation [SD], 9.1 years). Mean admission Glasgow Coma Scale score was 10 (SD, 4), and mean admission Injury Severity Score was 27.7 (SD, 7.6). Mortality within 1 month was 20.7%, and intracranial purulent-septic complications were diagnosed in 11.6% of the patients. Overall, 65.3% of the patients had favorable outcome (good recovery or moderate disability) based on Glasgow Outcome Scale score at 12 months after the injury. The following were predictors of mortality or poor functional outcome at 1 year after the injury: low Glasgow Coma Scale score on admission, gunshot wound to the head, dural venous sinuses wound, presence of intracerebral hematomas, intraventricular and subarachnoid hemorrhage accompanied by lateral or axial dislocation, and presence of intracranial purulent-septic complications., CONCLUSIONS: Generally, combat-related penetrating brain injuries had satisfactory treatment outcomes. Treatment outcomes in this study were comparable to those previously reported by other authors in military populations and significantly better than outcomes of peacetime penetrating brain injury treatment.

5095. Sirko, A., et al. (2019). "ANTIBACTERIAL THERAPY FOR PURULENT-SEPTIC COMPLICATIONS IN PATIENTS WITH COMBAT RELATED PENETRATING CRANIOCEREBRAL GUNSHOT WOUNDS." Georgian medical news(294): 10-16.

Aim - to evaluate pathogens and their susceptibility to antibiotic therapy (ABT) in combat-related penetrating craniocerebral gunshot wound (PCGW) patients and develop recommendations for treatment of post-traumatic meningoencephalitis. We conducted a prospective analysis of examination and treatment results of 121 patients who were admitted to the Public Institution, Mechnikov Dnipropetrovsk Regional Clinical Hospital, Dnipro, Ukraine, from 25 May 2014, to 31 December 2017, and were successively enrolled in the study. Intracranial purulent-septic complications were diagnosed in 14 (11.6%) patients including eight cases of isolated meningoencephalitis, three cases of meningoencephalitis combined with ventriculitis, two cases of meningoencephalitis combined with ventriculitis and subdural empyema and one case of multiple brain abscesses. In most cases of combat-related craniocerebral wounds, infections are considered nosocomial and typically related to medical procedures and devices. In most cases, the effectiveness of first-line antibiotics was low, and it was often necessary to prescribe broad-spectrum ABT, including those related to second-line antibiotics and reserve drugs, according to the World Health Organisation classification. The use of initial de-escalation of empiric ABT with the broadest-spectrum drugs, mainly as a part of combination therapy for expected gram-positive and gram-negative aerobic and anaerobic infection pathogens, is recommended.

5096. Sirucek, P., et al. (2017). "Brain death scintigraphy." European Journal of Nuclear Medicine and Molecular Imaging **44**(2): S618.

Introduction: Retrospective analysis of statistical data of brain death scintigraphy from a period of 2003 - 2016 performed on the Department of Nuclear Medicine University Hospital Ostrava. Method: Since 2003 till the end of 2016 (13 years), we examined 220 ventilated patients in a deep coma with areflexia above C1. We performed 229 scintigraphy acquisitions to confirm brain death. Immediately after the intravenous administration of 99mTc-HMPAO there was performed dynamic scintigraphy, followed by static scintigraphy in the front, back and both side projections. Prior to administration of the radiopharmaceutical the radiochemical purity was always checked. All adult patients had during the application of the radiopharmaceutical mean arterial pressure more than 80 mmHg. Most frequent indication for this examination was to include the patient into the transplantation program; exceptionally brain death was diagnosed to stop the intensive care. Results: Majority of the patients were men (151, 69 %), less than a third were women (69, 31%). Patients had a mean age 43 years, the youngest patient was a 10-day newborn, the oldest was 68 years old. This examination was indicated in 25 children. The cause of coma and subsequent cerebral oedema was in 39 % trauma (traffic accidents, falls, suicide - jumping, gunshot wounds of the head), 61% were other causes - AV brain malformation, stroke, complications of epilepsy, complications of anticoagulation therapy, drowning, CO intoxication, brain tumours, abscesses, encephalitis, etc.). Investigations are evaluated qualitatively. Brain death was confirmed, if there was no

accumulation of radiopharmaceuticals supra- and infratentorial. Brain death was detected in 207 patients (94 %), 13 patients at first examination had partially preserved brain perfusion. In the transplant program were enrolled 183 patients (83%), multiorgan harvesting was done in 80 patients (44 %), otherwise kidneys and heart were removed. Conclusion: Brain death scintigraphy is an important diagnostic tool in the process of brain death diagnosis, not only before the removal of organs for transplantation, but also before the termination of anesthesiology and intensive care. It is most often used in patients after cranial trauma and after neurosurgical decompression.

5097. Sise, M. J., et al. (2012). "Withdrawal of care: a 10-year perspective at a Level I trauma center." The journal of trauma and acute care surgery **72**(5): 1186-1193.

BACKGROUND: Withdrawal or limitation of care (WLC) in trauma patients has not been well studied. We reviewed 10 years of deaths at our adult Level I trauma center to identify the patients undergoing WLC and to describe the process of trauma surgeon-managed WLC., METHODS: This is a retrospective review of WLC. Each patient was assigned to one of three modes of WLC: care withdrawn, limited or no resuscitation, or organ harvest. Frequency, timing, and circumstances of WLC, including family involvement, ethics committee consultation, palliative care, and hospice, were reviewed., RESULTS: From 2000 through 2009, 375 patients died with WLC (54% of all deaths; 93% at >= 24 hours). For age >= 65 years, 80% were WLC. Overall, 15% had advance directive documents. Traumatic brain or high cervical spine injury was the cause of death in 63%. Factors associated with WLC included age, comorbidities, injury mechanism and severity, and nontrauma activation status. At time of death, 316 (84%) WLC were under trauma surgeon management. In this group, mode of WLC was care withdrawn in 74%, organ harvest in 20%, and limited or no resuscitation in 6%. Rationale for WLC in non-organ harvest patients was poor neurologic prognosis in 86% and futility in 76%. When family was identified, end-of-life discussions with physicians occurred in 100%. Conflicts over WLC occurred in 6.6% and were not associated with any demographic group. Ethics committee was involved in 2.8%. For care-withdrawn patients, median time to death from first WLC order was 6.6 hours. Palliative care and hospice consults (6% and 9%) increased yearly., CONCLUSIONS: WLC occurred in over 50% of all trauma deaths and exceeded 90% at >= 24 hours. Hospice and palliative care were increasingly important adjuncts to WLC. Guidelines for WLC should be developed to ensure quality end-of-life care for trauma patients in whom further care is futile., LEVEL OF EVIDENCE: III, therapeutic study.

5098. Skarupa, D. J., et al. (2019). "Trends in civilian penetrating brain injury: A review of 26,871 patients." American journal of surgery **218**(2): 255-260.

INTRODUCTION: The aim of our study is to analyze the 5 years' trends, mortality rate, and factors that influence mortality after civilian penetrating traumatic brain injury (pTBI)., METHODS: We performed a 5-year-analysis of all trauma patients diagnosed with pTBI in the TQIP. Our outcome measures were trends of pTBI., RESULTS: A total of 26,871 had penetrating brain injury over the 5-year period. Mean age was 36.2+/-18 years. Overall 55% of the patients had severe TBI and mortality rate was 43.8%. There was an increase in the rate of pTBI from 3042/100,000 (2010) to 7578/100,000 trauma admissions (2014) ($p<0.001$). The mortality rate has increased from 35% (2010) to 48% (2011) ($p<0.001$) followed by a linear decrease in mortality to 40% (2014). Independent predictors of mortality were age, pre-hospital intubation, suicide attempt, and craniotomy/craniectomy., CONCLUSIONS: Incidence and mortality for patients who are brought to hospitals following pTBI have gradually increased over the five-year period. Self-inflicted injury and prehospital intubation were the two most significant predictors of mortality.

5099. Skinker, D. M., et al. (1996). "Chasing the casing: a 38 Special suicide." Journal of forensic sciences **41**(4): 709-712.

Multiple self-inflicted gunshot wounds of the head are uncommon. Detailed history, scene investigation, autopsy findings, consideration of ballistics, and evidentiary proceedings are necessary to determine the manner of death in these cases. This report involves a pattern of atypical, self-inflicted bullet wounds of the head of a 26-year-old male. Investigation confirmed that a single eyewitness and several earwitnesses reported a single discharge of a firearm. The eyewitness testified that the decedent singly discharged a Smith & Wesson revolver, caliber .38 Special, to the right side of his head after interposing several objects between the muzzle and his skin immediately prior to discharge. He was declared brain dead two days later. At necropsy two contiguous atypical entry wounds were present in the right preauricular temple. The inferior wound was interpreted to be a near contact wound. The gray metal slug fragmented,

creating separate tracks to the right maxillary sinus and the mid left posterior cerebrum, respectively. The larger, atypical wound of entry was associated with passage of the projectile through the right temporalis muscle and squamous temporal bone. The projectile, consisting of a slightly distorted empty metallic cartridge case containing a "live" primer, was recovered from its point of final lodgment in the right temporal lobe. The literature addressing paired entry wounds following single discharge of the firearm with interposed targets is relatively sparse. Cases reporting multiple bullet wounds involving suicide are only sporadically reported. This report summarizes the investigative findings supporting the determination of the manner of death and revealing the interesting origin of the "misplaced" casing.

5100. Skoch, J., et al. (2013). "Injury to the temporal lobe via medial transorbital entry of a toothbrush." Journal of neurological surgery reports **74**(1): 23-28.

Objectives?Intracranial penetration by foreign bodies entering via the orbit represent an unusual form of traumatic brain injury. Nevertheless, much is at stake with high risk for cranial nerve and neurovascular injury. We present a case where the bristled end of a toothbrush entered the brain as a projectile via the superior orbital fissure and discuss considerations for surgical management. Setting?A 35-year-old woman suffered a periorbital injury after her husband threw an electric toothbrush at a wall and the head of the toothbrush became a missile that projected through her superior orbital fissure and into her right temporal lobe. She complained of headache and incomplete vision loss in the affected eye. Intervention?After obtaining a cerebrovascular angiogram, we proceeded with emergent orbital decompression and anterograde extraction of the foreign body via a modified frontotemporal orbitozygomatic approach with drilling of the skull base allowing for en bloc removal of the toothbrush. Conclusions?The patient recovered well with improvement in her vision and partial third and sixth nerve palsies. This report illustrates a unique mechanism of injury with a novel intracranial foreign body. We review the neurosurgeon's need for prompt management with an approach customized to the structure of the offending object, the damaged elements, and the surrounding cranial nerves and vascular anatomy. © 2013 Georg Thieme Verlag KG Stuttgart New York.

5101. Skoch, J., et al. (2013). "Injury to the temporal lobe via medial transorbital entry of a toothbrush." Journal of Neurological Surgery, Part B: Skull Base **74**.

Background and Importance: Intracranial penetration by foreign bodies entering via the orbit represents an unusual form of traumatic brain injury. Nevertheless, much is at stake with high risk for cranial nerve and neurovascular injury. We present a case where the bristled end of a toothbrush entered the brain as a projectile via the superior orbital fissure and discuss important considerations for surgical management including modern skull base techniques. Clinical Presentation: A 35-year-old woman suffered a periorbital injury after her husband threw an electric toothbrush at a wall and the head of the toothbrush became a missile that projected through her superior orbital fissure, fracturing her greater sphenoid wing, and into her right temporal lobe. She complained of headache and incomplete vision loss in the affected eye. Intervention: After obtaining a cerebrovascular angiogram, we proceeded with emergent orbital decompression and anterograde extraction of the foreign body via a modified frontotemporal orbitozygomatic approach (two-piece supraorbital modified approach) with drilling of the skull base allowing for en bloc removal of the toothbrush. Conclusion: The patient recovered well with improvement in her vision and with stable partial third and sixth nerve palsies. This case report illustrates a unique mechanism of injury with a novel intracranial foreign body resulting in a superior orbital fissure syndrome. We review the neurosurgeon's need for prompt management with an approach customized to the structure of the offending object, the damaged elements, and the surrounding cranial nerve and vascular anatomy.

5103. Slain, K. N., et al. (2021). "US children of minority race are less likely to be admitted to the pediatric intensive care unit after traumatic injury, a retrospective analysis of a single pediatric trauma center." Injury Epidemiology **8**(1).

Background: The public health impact of pediatric trauma makes identifying opportunities to equalize health related disparities imperative. The influence of a child's race on the likelihood of admission to the pediatric intensive care unit (PICU) is not well described. We hypothesized that traumatically injured children of minority race would have

higher rates of PICU admission, compared to White children. Methods: This was a retrospective review of a single institution's trauma registry including children ≤18 years of age presenting to the emergency department (ED) whose injury necessitated pediatric trauma team activation at a Level 1 Pediatric Trauma Center from July 1, 2011 through June 30, 2016. Demographics, injury characteristics and hospital utilization data were collected. Race was categorized as White or racial minority, which included patients identifying as Black, Hispanic ethnicity, Native American or "other." The primary outcome measure was admission to the PICU. Chi square or Mann Whitney rank sum tests were used, as appropriate, to compare differences in demographics and injury characteristics between those children who were and were not admitted to the PICU setting. Variables associated with PICU admission in univariate analyses were included in a multivariate analysis. Data are presented as median values and interquartile ranges, or numbers and percentages. Results: The median age of the 654 included subjects was 8 [IQR 4–13] years; 55.2% were a racial minority. Nine (1.4%) children died in the ED and 576 (88.1%) were admitted to the hospital. Of the children requiring hospitalization, 195 (33.9%) were admitted to the PICU. Children admitted to the PICU were less likely to be from a racial minority group (26.1% vs 42.5%, $p < 0.001$). After adjusting for age and injury characteristics in a multivariable analysis, racial minority children had a lower odds of PICU admission compared to White children (OR 0.492 [95% C.I. 0.298–0.813, $p = 0.006$]). Conclusions: In this retrospective analysis of traumatically injured children, minority race was associated with lower odds of PICU admission, suggesting that health care disparities based on race persist in pediatric trauma-related care.

5104. Slaus, M., et al. (2007). "Identification and analysis of human remains recovered from wells from the 1991 War in Croatia." Forensic science international **171**(1): 37-43.

From 1996 to the present, the remains of 61 individuals killed during the 1991 War in Croatia were recovered from both dried out and functioning wells. Positive identification was established in 60.7% or 37/61 cases. Remains recovered from the same geographical region but from non-well settings were identified in 77.4% or 1256/1623 cases. The purpose of this paper is to report on the taphonomic, demographic and trauma characteristics of remains recovered from wells and identify factors responsible for the discrepancy in the identification ratios. The age and sex distributions in the well and non-well series were similar, as were the frequencies of recovered personal documents, jewelry and other artifacts. The taphonomic features of the remains were, however, significantly different. Preservation of remains was considerably better in non-well settings (1400/1623 or 86.3% compared to 40/61 or 65.5% in wells). Congruently, commingling of remains was more frequent in wells (26/61 or 42.6% compared to 77/1623 or 4.7% in non-well settings). In bodies recovered from non-well settings the preservation, state and commingling of the remains were strongly correlated with positive identification. None of these features were correlated with the identification of bodies from wells. Instead, identification of remains from wells was significantly affected by the presence or absence of water in the well. As both series have similar frequencies, and identical rankings of identification factors, the reason for the discrepancy in the identification ratios lies in the fact that by themselves, these factors were rarely sufficient for positive identification. In both series the majority of identifications (51.4% in the well, and 58.1% in the non-well series) were established through a combination of biological and non-biological features. The significantly lower identification ratio in the well series resulted from the difficult recovery conditions in wells with significant amounts of water, and the negative effect that water had on the preservation of clothing, personal artifacts and some dental features. Significant differences were also noted in the types and locations of perimortem traumas. There is a significantly higher frequency of entrance gunshot wounds to the back of the head, suggestive of execution style murders, in the well series.

5105. Slewa-Younan, S., et al. (2008). "Do men and women differ in their course following traumatic brain injury? A preliminary prospective investigation of early outcome." Brain injury **22**(2): 183-191.

PRIMARY OBJECTIVE: To examine the effect of a patient's sex on measures of outcome in a matched sample of patients admitted for acute traumatic brain injury (TBI)., RESEARCH DESIGN: A prospective multi-centred group comparison study based in metropolitan Sydney, Australia., METHODS AND PROCEDURES: Data was collected on 25 women admitted for treatment following non-penetrating TBI. Forty-five men were then matched with regards to age and injury severity. All subjects met the study criteria of having a moderate-to-severe TBI and aged 50 years old or younger. Exclusion criteria included history of previous head injury, psychiatric disturbance and significant alcohol and/or substance abuse. Data included injury details and physiological and psychometric measures of outcome., MAIN OUTCOMES AND RESULTS: Women demonstrated better outcomes as indicated by their Glasgow Outcome Scale scores (adjusted for initial injury severity and age at injury odds ratio [OR] 4.2, 95% CI 1.4-12.7) and having shorter Length of Stay (adjusted OR 9.03, 95% CI 3.13-26.08)., CONCLUSIONS: Understanding the presence of sex differences in outcome

following TBI is an emerging area of research. This study indicated that, after matching for initial injury severity and age at injury, women with severe TBI demonstrate a better early outcome than men.

5106. Sloan, M. A., et al. (1991). "Fatal brainstem stroke following internal jugular vein catheterization." Neurology **41**(7): 1092-1095.

Neurologic complications of central venous catheterization are uncommon, and there are no reports of cerebrovascular events. We report a case of massive postoperative vertebrobasilar territory stroke following internal jugular vein cannulation due to inadvertent vertebral artery injury. Autopsy revealed thrombosis at the site of puncture wound in the right vertebral artery, with emboli present in the distal basilar artery.

5107. Slovis, J., et al. (2017). "Long-term outcomes following pediatric traumatic brain injury presentations to the emergency department." Annals of emergency medicine **70**(4): S88.

Study Objectives: To determine prognostic factors of long-term outcome in in pediatric patients who presented to the emergency department with traumatic brain injury (TBI). Methods: A prospective database study was conducted using the Children's Health-Children's Medical Center Dallas (CMCD) Brain and Nerve Injury Center Repository and Database (BNIRD). Patients, ages 0-17 years, were queried from 2001 to 2012. Outcomes and clinical study variables were abstracted from a separate prospective database for patients prior to the formation of the BNIRD in 2005, using a similar protocol. Since the Glasgow Outcome Scale Extended Pediatric (GOSEP) was not available prior to 2005, the Glasgow Outcome Scale (GOS) was used for data collected from 2001-2004. Subjects were admitted to the CMCD Pediatric Intensive Care Unit if TBI was secondary to blunt force trauma from accidental mechanism. Children were excluded if their brain injury was penetrating or abusive, or if they were not expected to survive. Statistical analysis was done using chi-square, Fisher's Exact Test, and logistic regressions in SPSS and the R statistical computing software. Results: 307 patients were included in the study, with an average age of 6.7 years. Of the 307 patients, 67% had severe TBI (GCS 3-8), 15% had moderate TBI (GCS 9-12), and 18% had mild TBI (GCS 13-15). The GOS available in 258 patients and the GOSEP available in 137 patients were assessed at discharge and again on average 16 months after injury. For the GOS group, 47% had improved from poor outcome (GOS 1-3) to good outcome (GOS 4-5) on reassessment, and for the GOSEP group, 24% had improved from poor outcome (GOSEP 5-8) to good outcome (GOSEP 1-4) on reassessment. Of the 8 patients who were discharged in a vegetative state, 7 regained consciousness, with 2 ultimately having good outcome. All patients with a fall mechanism had a good outcome, while those with a motor vehicle collision (MVC) were associated with worse outcomes (RR=0.31 for GOS and RR=0.33 for GOSEP). Favorable predictors included higher GCS in the emergency department (p=0.01) and equal bilateral reactive pupils on arrival (p=0.04). Factors predictive of poor outcomes included intracranial pressure monitor placement (p<0.01), seizures (p=0.01), neurosurgical intervention (p=0.02), asymmetric reactive pupils on arrival (p=0.04), and CPR on scene (p=0.02) or in the ED (p=0.06). Conclusions: Despite poor neurologic status in the emergency department and at hospital discharge, many children who suffered a TBI improved in the long term. As a mechanism of injury, falls were associated with a favorable prognosis, whereas MVC's portended worse outcomes. Poor outcomes were more likely in patients requiring CPR, patients with asymmetric or fixed dilated pupils on arrival, or those requiring intracranial pressure monitor placement.

5108. Smadar, L., et al. (2020). "Demographic, clinical features, and outcomes of pediatric non-penetrating ocular foreign bodies." Graefe's archive for clinical and experimental ophthalmology = Albrecht von Graefes Archiv fur klinische und experimentelle Ophthalmologie **258**(7): 1469-1474.

PURPOSE: Data regarding ocular foreign body (FB) in the pediatric population is sparse. The purpose of this study is to describe the demographic features and the outcomes of pediatric non-penetrating ocular FB., METHODS: The charts of all children with non-penetrating ocular FB who presented at a tertiary medical center between 2011 and 2018 were retrospectively reviewed. Data analyzed included demographics, ocular FB site, the need for general anesthesia, or sedation for FB removal and clinical outcomes., RESULTS: Three hundred and fifty-two children (58.8% boys) with a mean age of 7.7 +/- 3.7 years were included. Two hundred and fifty-one (71.3%) children presented on the same day of injury. Patients with developmental delay presented more often with restlessness than patients without developmental delay (p < 0.0001). One hundred and forty-six (41.5%) of FBs were found on the conjunctiva, 128 (36.4%) under the eyelid, and 62 (17.6%) on the cornea. In 19 (4.5%) cases, general anesthesia or sedation was required for FB removal. A multivariate analysis identified young age (OR 0.976, 95% CI 0.961-0.992, p = 0.003), corneal FB (OR 50.84, 95% CI 10.08-

256.37, p < 0.0001), and developmental delay (OR 18.56, 95% CI 1.22-283.45, p = 0.036), as significant predictors for the need of general anesthesia or sedation. Among patients with corneal FB, in two (3.2%) cases, the corneal FB was complicated by infectious keratitis, resulting in mild corneal scar., CONCLUSION: The rate of general anesthesia for non-penetrating ocular FB removal in children is low. Children presenting with non-penetrating ocular FB have good prognosis without long-term complications.

5109. Small, I. A. (1983). "Reconstructive prosthetic surgery of massive craniofacial injury." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **41**(9): 609-612.

A case has been presented of reconstruction for a patient with massive injuries of the face and jaw. Reconstructive surgery, including bone grafting, skin grafting, and placement of the mandibular staple bone plate, and prosthetic rebuilding of eyes and dentures have made him a reasonably functioning and cosmetically acceptable individual.

5110. Smallfield, A., et al. (2010). "Neck injury at a rural emergency department: perils, pitfalls and management considerations." Canadian journal of rural medicine : the official journal of the Society of Rural Physicians of Canada = Journal canadien de la medecine rurale : le journal officiel de la Societe de medecine rurale du Canada **15**(3): 120-122.

5111. Smathers, R. L. and H. O. Riddervold (1981). "Traumatic intraocular air-fluid level." Journal of the Canadian Association of Radiologists **32**(3): 180.

A patient with direct trauma to the orbit was found to have an ocular air-fluid level, apparently the first such case to be reported.

5112. Smialek, J. E., et al. (1980). "Ethanol in intracerebral clot. Report of two homicidal cases with prolonged survival after injury." The American journal of forensic medicine and pathology **1**(2): 149-150.

Two homicidal cases are reported with prolonged survival after injury. In one case there was a 33-hour survival and the other had a 9-hour survival before death. In both cases there was severe injury to the brain: in one by blunt force and in the other by penetrating injury by firearm. Blood and urine alcohol levels in these cases were low or negative. The blood clot is another potential resource for information in an unnatural death investigation where intoxication is suspected or indicated by the behavior of the victim.

5113. Smilowska, K., et al. (2015). "Penetrating brain injury: a case report." Anaesthesiology intensive therapy **47**(3): 214-218.

BACKGROUND: Gunshot wounds as a result of attempted suicide, criminality or warfare comprise a significant group among penetrating injuries of the brain. A prognosis in such cases is based mainly on an initial score on the Glasgow Coma Scale (GCS). According to the literature, the mortality rate among patients with initial GCS ranging from 3 to 5 points is very high, up to 98.5%. Although there are also many other prognostic factors for high mortality, such as damage to the ventricular system or the involvement of two or more lobes, GCS score seems to be the most important determinant. The treatment in an ICU which is focused on decreasing the risk of secondary brain damage can significantly improve the prognosis and final outcome., CASE REPORT: The authors present the case of a 27-year-old man who suffered a gunshot wound to the right temporal region, self-inflicted from an air-gun. On admission to the intensive care unit he received a score of 3 points on the GCS. There were also other negative prognostic factors - the pellet penetrated two lobes and damaged the third ventricle. Despite the serious prognosis, the appropriate multiprofile treatment and rehabilitation resulted in unexpectedly good recovery. Two years after the trauma the patient was conscious, maintained logical verbal contact, and was able to walk using a walking-aid., CONCLUSION: Rapid transport to a major trauma center is essential for patients with penetrating brain injury. Among all interventions it seems essential to provide the prevention of posttraumatic nervous tissue damage and associated neurological dysfunction.

5114. Smirnov, G. G., et al. (2000). "[Surgical interventions in HIV-infected and patients with AIDS]." Khirurgicheskaia pomoshch' VICh-infitsirovannym bol'nym i bol'nym SPIDom.(7): 46-50.

176 patients with HIV-infection and AIDS were examined. 77 of them underwent various surgical interventions the most frequent of which were: opening of abscess and phlegmons--14 (23%), biopsy of lymphatic nodes--10 (13.1%), appendectomy--5 (6.2%), condyloma excision--21 (27.2%), removal of uterus adnexa--2 (2.5%), pleural puncture--4 (5.9%), cholecyst- and splenectomy--5 (8.2%). Operations for stomach cancer (creation of gastroenteroanastomosis), extrauterine pregnancy, brain tumor (drainage of IV ventricle of the brain), penetrating wound of cornea were performed less often. 43 patients underwent emergency operations without preoperative preparation, 34 patients underwent elective operations. The causes of 6 deaths were secondary diseases (Kaposi's sarcoma, purulent processes, metastases, pulmonary edema). There were no complications and blood changes in postoperative period in infected patients. These patients were discharged in the same terms as non-infected patients. In patients with AIDS, especially in combination with other infections, fever persisted long after the operation. The wound healed by first intention in all the patients, but the sutures were removed on day 10-30. Immunologically, a high ratio T-suppressors/T-helpers existed. An increase in fibrinolytic activity without high tissues hemorrhage was observed.

5115. Smith, A., et al. (2016). "Neurocognitive and psychiatric changes in epilepsy secondary to an occipital gunshot wound." Journal of Neuropsychiatry and Clinical Neurosciences **28**(3): e61.

Background: Epilepsy is associated with neurocognitive and neuropsychiatric changes including increased risk for suicide. Case History: A 52-year-old, right-handed male with epilepsy and visual deficits secondary to an accidental, occipital gunshot wound (GSW) from work and a preceding history of head injuries was referred for pre- and postsurgical neuropsychological testing to assess neurocognitive and neuropsychiatric functioning. He was tested prior to epilepsy surgery in 2013 and then postsurgery in 2015. Initial testing showed largely intact language and verbal memory and impairments in attention, working memory, and verbal fluency. He was also diagnosed with major depressive disorder, severe and posttraumatic stress disorder (PTSD). His fears of having seizures in public leading to social isolation along with his suicidal ideation, substance abuse, gun collection, and marriage separation placed him at high suicidal risk. He was then referred for temporary partial care; however, treatment did not effectively target his neuropsychiatric symptoms. Despite postsurgical improvements in verbal fluency and set-shifting and resolution of substance abuse and seizure-related phobia, he continued to display symptoms of severe depression, PTSD, passive suicidal ideation, and emotional lability. Conclusions: The occipital lobe GSW, subsequent epilepsy, and visual deficits led to functional status changes. Despite improvements in executive functions, resolution of substance abuse and increased social support, clinically elevated neuropsychiatric symptoms were observed at follow-up testing. Other potential comorbid factors for mood symptoms included continued seizures and prior history of head injuries. The persistence of untreated symptoms over time illustrates the need for targeted care in complex neuropsychiatric epilepsy cases.

5116. Smith, C., et al. (2001). "Differential expression of fibroblast growth factor-2 and fibroblast growth factor receptor 1 in a scarring and nonscarring model of CNS injury in the rat." The European journal of neuroscience **13**(3): 443-456.

Injury to the adult brain results in abortive axon regeneration and the deposition of a dense fibrous glial scar. Therapeutic strategies to promote postinjury axon regeneration are likely to require antiscarring strategies. In neonatal brain wounds, scar material is not laid down and axons grow across the lesion site, either by de novo growth or regeneration. To achieve the therapeutic goal of recapitulating the nonscarring neonatal response in the injured adult, an understanding of how ontogenic differences in scarring reflect developmental diversities in the trophic response to injury is required. Fibrobast growth factor-2 (FGF-2) expression is developmentally regulated and has been implicated as a regulator of the wounding response of the adult rat central nervous system. We have investigated the expression of FGF-2 and fibroblast growth factor receptor 1 (FGFR1) after penetrating lesions to the cerebral cortex of 5 days post partum (dpp) (nonscarring) and 16 dpp and adult (scarring) rats. In situ hybridization, immunohistochemistry and Western blotting showed robust and sustained increases in FGF-2 and FGFR1 mRNA and protein in reactive astrocytes around the lesion in scarring rats, a response that was attenuated substantially in the nonscarring neonate. These results demonstrate that changes in astrocyte FGF-2 and FGFR1 expression are coincident with the establishment of a mature pattern of glial scarring after injury in the maturing central nervous system, but it is premature to infer a causal relationship without further experiments.

5117. Smith, E. (1974). "Influence of site of impact on cognitive impairment persisting long after severe closed head injury." Journal of neurology, neurosurgery, and psychiatry **37**(6): 719-726.

The cognitive abilities of right-handed men who had sustained a severe closed head injury between 10 and 20 years earlier were studied. Results showed that a right-sided impact produced greater deficits than a left-sided impact in both verbal and non-verbal skills. The results are interpreted as reflecting left hemisphere damage due to contrecoup injury. Some evidence that a left frontal impact was apt to result in defective visual-spatial functioning is presented. These observations accord with some theories on the mechanics of head injury and with observations on the predictability of sites of cerebral contusion in brain injury uncomplicated by dural penetration, intracranial infection, or cerebral infarction. The roles of the duration of post-traumatic amnesia, the level of neurological responsiveness at the time of admission to hospital, and the age at which the injury was sustained are also discussed.

5118. Smith, E. R., et al. (2019). "Incidence and Cause of Potentially Preventable Death after Civilian Public Mass Shooting in the US." Journal of the American College of Surgeons **229**(3): 244-251.

BACKGROUND: The incidence and severity of civilian public mass shooting (CPMS) events continue to rise. Understanding the wounding pattern and incidence of potentially preventable death (PPD) after CPMS is key to updating prehospital response strategy., METHODS: A retrospective study of autopsy reports after CPMS events identified via the Federal Bureau of Investigation CPMS database from December 1999 to December 31, 2017 was performed. Sites of injury, fatal injury, and incidence of PPD were determined independently by a multidisciplinary panel composed of trauma surgery, emergency medicine, critical care paramedicine, and forensic pathology., RESULTS: Nineteen events including 213 victims were reviewed. Mean number of gunshot wounds per victim was 4.1. Sixty-four percent of gunshots were to the head and torso. The most common cause of death was brain injury (52%). Only 12% (26 victims) were transported to the hospital and the PPD rate was 15% (32 victims). The most commonly injured organs in those with PPD were the lung (59%) and spinal cord (24%). Only 6% of PPD victims had a gunshot to a vascular structure in an extremity., CONCLUSIONS: The PPD rate after CPMS is high and is due mostly to non-hemorrhaging chest wounds. Prehospital care strategy should focus on immediate point of wounding care by both laypersons and medical personnel, as well as rapid extrication of victims to definitive medical care.

5119. Smith, E. R., et al. (2018). "Fatal Wounding Pattern and Causes of Potentially Preventable Death Following the Pulse Night Club Shooting Event." Prehospital emergency care : official journal of the National Association of EMS Physicians and the National Association of State EMS Directors **22**(6): 662-668.

BACKGROUND: Mortality following shooting is related to time to provision of initial and definitive care. An understanding of the wounding pattern, opportunities for rescue, and incidence of possibly preventable death is needed to achieve the goal of zero preventable deaths following trauma., METHODS: A retrospective study of autopsy reports for all victims involved in the Pulse Nightclub Shooting was performed. The site of injury, probable site of fatal injury, and presence of potentially survivable injury (defined as survival if prehospital care is provided within 10 minutes and trauma center care within 60 minutes of injury) was determined independently by each author. Wounds were considered fatal if they involved penetration of the heart, injury to any non-extremity major blood vessel, or bihemispheric, mid-brain, or brainstem injury., RESULTS: There were an average of 6.9 wounds per patient. Ninety percent had a gunshot to an extremity, 78% to the chest, 47% to the abdomen/pelvis, and 39% to the head. Sixteen patients (32%) had potentially survivable wounds, 9 (56%) of whom had torso injuries. Four patients had extremity injuries, 2 involved femoral vessels and 2 involved the axilla. No patients had documented tourniquets or wound packing prior to arrival to the hospital. One patient had an isolated C6 injury and 2 victims had unihemispheric gunshots to the head., CONCLUSIONS: A comprehensive strategy starting with civilian providers to provide care at the point of wounding along with a coordinated public safety approach to rapidly evacuate the wounded may increase survival in future events.

5120. Smith, J. E., et al. (2014). "Outcome of penetrating intracranial injuries in a military setting." Injury **45**(5): 874-878.

BACKGROUND: Penetrating intracranial injuries are common in the deployed military medical environment. Early assessment of prognosis includes initial conscious level. There has been no previous identification of different outcomes depending on mechanism of penetrating injury. The aim of this study was to define outcome from penetrating head injury in our population, and to compare outcome between gunshot wound (GSW) and blast fragment injury, in

order to detect a difference in survival., METHODS: A retrospective database review was undertaken using the UK Joint Theatre Trauma Registry (JTTR) between the dates 2003 and 2011 to identify all cases of penetrating head injury. Data collected included mechanism of injury, first recorded GCS, injury severity score (ISS), abbreviated injury scale (AIS) head score, concomitant extracranial injury, surgical intervention, hospital length of stay, and survival., RESULTS: 813 patients sustained a penetrating head injury, of whom 625 were injured by blast fragmentation and 188 were injured by GSW; overall 336 patients (41.3%) died. There was a significant difference between survival from GSW (41.5%) and blast fragment (63.8%; p<0.001). In addition, the GCS in patients injured by GSW was significantly lower than that in patients injured by blast fragment. 157 cases sustained isolated head injury (79 GSW, 78 blast). The difference in injury severity between these groups was marked; median AIS was higher in the GSW group, survival lower (42% vs. 88%; p<0.001) and distribution of GCS categories less favourable (p<0.001). 338 of 343 patients (98.5%) with a best recorded GCS>5, survived to discharge., CONCLUSION: Most patients who present following penetrating intracranial injury, who have a GCS>5, survive to discharge. There is a significant difference in survival to hospital discharge following penetrating injury caused by blast fragment compared to those caused by GSW, partly attributable to a difference in injury severity. This is the first study to specifically highlight and define this difference.

5121. Smith, M. M., et al. (2003). "Orbital penetration associated with tooth extraction." Journal of veterinary dentistry **20**(1): 8-17.

Three cats and 2 dogs were evaluated for ophthalmologic complications associated with tooth extraction procedures. Orbital penetration leading to ocular and, in one case, brain trauma was secondary to iatrogenic injury from a dental elevator. Outcomes included enucleation of the affected eye in 3 cases, and death from brain abscessation in 1 case. Early treatment or, preferably, referral to a veterinary ophthalmology specialist may prevent such outcomes. Awareness of the anatomical proximity of caudal maxillary tooth roots and the orbit, appropriate interpretation of diagnostic intraoral dental radiographs, and technical proficiency in tooth extraction techniques will minimize these complications in veterinary dental practice.

5122. Smith, M. W., et al. (2013). "Performance of experienced versus less experienced paramedics in managing challenging scenarios: a cognitive task analysis study." Annals of emergency medicine **62**(4): 367-379.

STUDY OBJECTIVE: Out-of-hospital care is becoming more complex, thus placing greater reliance on the cognitive abilities of paramedics to manage difficult situations. In adapting to the challenges in their work, paramedics develop expertise. We study the cognitive strategies used by expert paramedics to contribute to understanding how paramedics and the EMS system can adapt to new challenges., METHODS: We conducted a "staged-world" cognitive task analysis to explore paramedics' handling of cognitive challenges related to sense-making and to resource and task management. A mixed-fidelity simulation was used to present paramedics with 2 challenging scenarios: a pulmonary embolism initially presenting as a myocardial infarction and a 2-person shooting with limited resources available., RESULTS: Participants were 10 paramedics, 6 more experienced and 4 less experienced. Analysis involved comparing the performance of the 2 groups to identify strategies associated with expertise. The more experienced paramedics made more assessments, explored a wider variety of presumptive diagnoses, and identified the pulmonary embolism earlier. They switched attention between the 2 shooting victims more, used their emergency medical technician-basic level partners more, and provided more advanced level care for both patients. Their patients arrived at the emergency department more prepared for specialized emergency care., CONCLUSION: Our findings correspond to general cognitive attributes of expertise: greater cue gathering and inferential reasoning, and more functional and strategic thinking. These results suggest potential areas and methods to facilitate development of expertise, as well as ways to better support use of expertise. Future studies should expand on these findings through larger sample sizes and more complex scenarios.

5123. Smith, O. C., et al. (1987). "Cranial fracture patterns and estimate of direction from low velocity gunshot wounds." Journal of forensic sciences **32**(5): 1416-1421.

Cranial trauma produced by low velocity gunshot wounds is investigated in an autopsy series. In skeletonized remains with postmortem damage, or after surgical debridement, the primary internal or external beveling may become obscured, causing difficulty with the identification of entrance and exit wounds. The morphology of associated

secondary and tertiary fractures based upon the mechanics of their production is discussed as a means of establishing bullet entrance and exit sites.

5124. Smith, S. L. and E. D. Hall (1998). "Tirilazad widens the therapeutic window for riluzole-induced attenuation of progressive cortical degeneration in an infant rat model of the shaken baby syndrome." Journal of neurotrauma **15**(9): 707-719.

Our infant rat model of traumatic subarchnoid hemorrhage combines violent shaking and hypoxia to produce subdural hemorrhaging and progressive cortical degeneration similar to that seen in victims of the shaken baby syndrome. Anesthetized, 6-day-old male rats were subjected to one episode of shaking under hypoxic conditions. Brain histologies revealed moderate-to-severe cortical hemorrhaging at 48 h postinjury and progressive cortical degeneration, as indicated by a 15.3% and 20.2% reduction in cortical wet weight, at 7 and 14 days postinjury, respectively. The purpose of the present study was to assess the effects of two antioxidant lipid peroxidation inhibitors (tirilazad mesylate and PNU-101033E), and the glutamate release inhibitor (riluzole), upon the brain pathology seen in this model. A significant, 54.3-75.3%, reduction in cortical hemorrhaging was observed in rats that were treated with a total of three doses of tirilazad (10 mg/kg, i.p.): 10 min before or 5-30 min after injury, and again at 2 and 24 h postinjury ($p < 0.01$ vs. vehicle). However, treatment with tirilazad or the more potent, brain-penetrating pyrrolopyrimidine, PNU-101033E (10 min before plus 2, 24, 48, and 72 h after), did not attenuate the progressive cortical degeneration typically seen at 14 days postinjury. These results suggest that free radicals play an important role in the pathophysiology of secondary brain hemorrhaging due to shaking + hypoxia, but may not be critical in the mediation of the subsequent neurodegeneration. Rather, glutamate neurotoxicity may be a key factor here. This is suggested by our observation that the glutamate release inhibitor, riluzole, significantly reduced cortical degeneration when it was administered up to 1 h postinjury in the present model. Specifically, the cortical wet weights of rats treated with 8 mg/kg riluzole (i.p.) 10 min before or 1 h after shaking + hypoxia (and again at 24 h postinjury) were 95.3% and 97.4% of noninjured controls, respectively, at 14 days postinjury ($p < 0.02$ vs. vehicle). Riluzole treatment beyond 1 h (e.g., 2 or 4 h postinjury) did not reduce the neurodegeneration. Lastly, we attempted to demonstrate that the therapeutic window for riluzole-induced attenuation of cortical degeneration could be extended beyond 1 h through the use of combination therapy. In this experiment, rat pups were treated with 10 mg/kg tirilazad (i.p.) at 30 min postinjury followed by 8 mg/kg riluzole (i.p.) at 4 and 24 h postinjury. At 14 days postinjury, the cortical wet weights of these rats were 94.5% of noninjured controls, thus demonstrating significant neuroprotection ($p < 0.05$ vs. vehicle) and a widening of the therapeutic window from 1 to 4 h in length. These results suggest that early attenuation of free radical-induced lipid peroxidation may slow down the biochemical cascade of events related to glutamate-induced excitotoxicity and, in doing so, prolong the time during which a glutamate release inhibitor, such as riluzole, is effective.

5126. Smrkolj, V., et al. (1995). "Intracranial injuries by a screwdriver." Forensic science international **76**(3): 211-216.

Two patients with unusual intracranial foreign bodies are presented. Intracranial injuries produced by a piece of screwdriver as a wounding agent have not yet been reported in the literature. In one of our two cases we had to deal with homicide and in another with accidental self-inflicted injury. Both patients died, 5 and 14 days, respectively, after successful removal of the foreign body. In both cases death was due to brain ischaemia and the resulting oedema secondary to arterial injury.

5127. Smutok, M. A., et al. (1989). "Effects of unilateral brain damage on contralateral and ipsilateral upper extremity function in hemiplegia." Physical therapy **69**(3): 195-203.

This article describes the long-term effects of unilateral penetrating hemispheric lesions on contralateral and ipsilateral upper extremity motor performance and functional outcome. Activities-of-daily-living skill and gross motor performance contralateral to the lesions were compared among 32 left-sided and 19 right-sided hemiplegic subjects using analysis of variance and chi-square techniques. Ipsilateral to the damaged hemisphere, fine motor tasks of simple visual motor reaction time, grip and pinch strength, finger tapping, and Purdue Pegboard performance were tested. Analysis of covariance compared each ipsilateral task to performance in the corresponding hand of 70 matched controls.

Results indicate similar long-term functional ADL outcome in right and left hemisphere-damaged subjects, despite more severe contralateral functional motor deficits following lesions of the left hemisphere. Right hemisphere lesions led to ipsilateral decrements in reaction time, and lesions of either hemisphere diminished grip or pinch strength, finger tapping, and pegboard performance ipsilaterally. These results demonstrate that unilateral brain damage involving the motor areas of either hemisphere has detrimental effects on ipsilateral upper extremity motor function. Findings are discussed and related to the concept that the left hemisphere is specialized or has greater neuronal representation for bilateral motor processes. Physical therapists involved in the treatment of patients with hemiplegia should be aware that motor functions of the ipsilateral, nonparetic upper extremity may also be affected adversely by unilateral brain lesions.

5128. Snider, S. B., et al. (2020). "Cortical lesions causing loss of consciousness are anticorrelated with the dorsal brainstem." Human brain mapping **41**(6): 1520-1531.

Brain lesions can provide unique insight into the neuroanatomical substrate of human consciousness. For example, brainstem lesions causing coma map to a specific region of the tegmentum. Whether specific lesion locations outside the brainstem are associated with loss of consciousness (LOC) remains unclear. Here, we investigate the topography of cortical lesions causing prolonged LOC (N = 16), transient LOC (N = 91), or no LOC (N = 64). Using standard voxel lesion symptom mapping, no focus of brain damage was associated with LOC. Next, we computed the network of brain regions functionally connected to each lesion location using a large normative connectome dataset (N = 1,000). This technique, termed lesion network mapping, can test whether lesions causing LOC map to a connected brain circuit rather than one brain region. Connectivity between cortical lesion locations and an a priori coma-specific region of brainstem tegmentum was an independent predictor of LOC (B = 1.2, p = .004). Connectivity to the dorsal brainstem was the only predictor of LOC in a whole-brain voxel-wise analysis. This relationship was driven by anticorrelation (negative correlation) between lesion locations and the dorsal brainstem. The map of regions anticorrelated to the dorsal brainstem thus defines a distributed brain circuit that, when damaged, is most likely to cause LOC. This circuit showed a slight posterior predominance and had peaks in the bilateral claustrum. Our results suggest that cortical lesions causing LOC map to a connected brain circuit, linking cortical lesions that disrupt consciousness to brainstem sites that maintain arousal.

5129. Snyder, H. S. (1998). "Significance of the initial spun hematocrit in trauma patients." The American journal of emergency medicine **16**(2): 150-153.

This study was designed to determine whether the initial spun hematocrit (HCT) value correlated with blood loss requiring operative intervention (OR). A spun HCT was performed on the first available blood sample from 524 admitted patients 12 years of age or older with traumatic injuries (86% blunt, 14% penetrating). Patients in the OR (n = 66) group had a lower mean HCT (35 v 41, P < .001) when compared with the non-OR group. The 81 patients with an HCT of < or = 35 required OR more frequently (41% v 7%, P < .001). An HCT of < or = 35 had a sensitivity of 50%, specificity of 90%, positive predictive value of 41%, and negative predictive value of 93% for identifying the OR group. The effect of hemodilution from intravenous fluid is difficult to assess in a retrospective clinical study.

5130. Snyderman, C. H., et al. (2011). "Avoiding disaster at the skull base: Case studies in 3D." Otolaryngology - Head and Neck Surgery **145**: 16.

Program Description: Disaster awaits unprepared surgeons at the skull base. Multiple routine surgeries in otolaryngology are in close proximity to the skull base. Potential risks of endoscopic sinus surgery include cerebrospinal fluid leak, loss of olfaction, penetrating brain injury, visual loss, hemorrhage from the internal carotid artery, and loss of trigeminal sensory and motor function. Potential risks of temporal bone and lateral approaches include vascular injuries of the sigmoid sinus, jugular bulb, and internal carotid artery; injury to cranial nerves 7-12; cerebrospinal fluid leak, intra- and extradural hemorrhage; and brain trauma. A thorough understanding of skull base anatomy is essential for avoiding such complications during routine surgical procedures. In this miniseminar, case studies will be used to demonstrate potential risks of standard surgical procedures relative to the skull base. Important anatomical landmarks and relationships will be presented in 3D using cadaveric dissections and intraoperative photographs. Strategies to avoid skull base complications will be discussed with an emphasis on everyday surgical procedures. Educational Objectives: 1)

Understand key anatomical relationships at the skull base. 2) Relate skull base anatomy to anterior and lateral skull base approaches. 3) Apply anatomical knowledge to avoid surgical complications.

5131. Sobani, Z. A., et al. (2011). "Cranioplasty after decompressive craniectomy: An institutional audit and analysis of factors related to complications." Surgical neurology international **2**: 123.

BACKGROUND: Although a relatively simple procedure, cranioplasties have been associated with high complication rates. Keeping this in perspective, we aimed to determine the factors associated with immediate and long-term complications of cranioplasties at our institution., METHODS: A retrospective review of patient records was carried out for patients having undergone reconstructive cranioplasties at our institution during the last 10 years (2001-2010). All case notes, records, and investigations were reviewed and the data were recorded in a predesigned questionnaire. Complications were recorded along with existing comorbids and measures taken for their prevention and management. Univariate and multivariate logistic regression analysis was performed to determine possible predictors of complications., RESULTS: A total of 96 patients with a mean age of 33 + 15 years were included in the study. Of the sample, 76% (n = 73) had no comorbids. The leading primary pathology was blunt traumatic brain injuries in 46% (n = 44), followed by cerebrovascular incidents in 24% (n = 23), penetrating traumatic brain injuries in 12% (n = 11), and tumors in 10% (n = 10) of cases, with 41% (n = 39) of patients requiring multiple craniotomies. In a mean follow-up of 386 +/- 615 days, complications were noted in 36.5% (n = 35) of the patients. Twenty six percent of patients (n = 25) had minor complications which included breakthrough seizures (15.6%, n = 15), subgaleal collections (3.1%, n = 3), and superficial wound infections (3.1%, n = 3), whereas major complications (10.4% n = 10) included hydrocephalus (3.1%, n = 3), transient neurological deficits (3.1%, n = 3), and osteomyelitis (2.1%, n = 2). Univariate and multivariate analysis revealed External Ventricular Drain (EVD) placement and parietal flaps to be associated with complications. This could be explained by the fact that the patients requiring EVD usually have relatively severe head injuries, increasing the possibility of hydrocephalus., CONCLUSION: We have found a higher risk of complications of cranioplasty in patients who had EVD placement and removal prior to their constructive surgery. We however did not find any association between risks of complications in any other studied variable. We also did not find any association between intraoperative placement of subgaleal drains and postoperative risk of subgaleal fluid collections. Overall, our results are comparable with other reported series on cranioplasties.

5132. Sobol, S. M., et al. (1982). "Management of inadvertent injury to the carotid artery during head and neck surgery." Head & neck surgery **4**(6): 475-482.

Rare, inadvertent injury to the carotid artery during head and neck surgery may result in disastrous neurologic sequelae or even death. Several cases are presented and used as the stimulus for an analytical discussion of the pathogenesis and management of cerebrovascular complications following head and neck surgery. The major pathogenetic mechanisms are identified as (1) microembolism from an ulcerated plaque; (2) intravascular thrombus with occlusion; (3) unintentional ligation, laceration, or transection; (4) ligation of a dominant external carotid; and (5) transient reduction in cerebrovascular perfusion pressure. Methods for identifying and evaluating the patient at risk for developing cerebrovascular complications are discussed and recommendations are made. The central question in the management of inadvertent arterial injury concerns whether to ligate the vessel or to restore blood flow. The controversies surrounding this issue are discussed in perspective through an analysis of current physiological concepts and of the collective clinical experiences of head and neck, vascular, and neurological surgeons handling extracranial cerebrovascular occlusive disease, penetrating injuries to the carotid artery, and tumor-related carotid catastrophes. Several factors are considered critical in determining appropriate management of any individual case; these include (1) whether recognition of the injury occurs intraoperatively or postoperatively; (2) the presence and severity of neurological deficits; (3) time from the injury to its recognition; (4) a quantitative assessment of collateral circulation; (5) a history of wound contamination or radiation therapy; (6) overall prognosis. These and other considerations are organized into a working framework through which the otolaryngologist and head and neck surgeon can better understand and manage the problem of inadvertent injury to the carotid artery.

5133. Sokobin, A. M. (1998). "Shaken baby syndrome: a comparative study: Anglo-American law and Jewish law--legal, moral, and ethical issues." University of Toledo law review. University of Toledo. College of Law **29**(3): 513-553.

5134. Sola, J. E., et al. (2008). "Pediatric penetrating cardiac injury from abuse: a case report." Pediatric surgery international **24**(4): 495-497.

While cardiac foreign bodies after trauma have been described in the literature, we report the first case of intentional injury in an infant with an intracardiac needle. We review the literature and stress the need for a high degree of vigilance in evaluating children for potential child abuse.

5135. Solarino, B., et al. (2008). "An unusual case of child head injury by coat hanger*." Journal of forensic sciences **53**(5): 1188-1190.

Traumatic brain injury is the leading cause of morbidity and mortality among children suspected of child abuse. Penetrating cranio-facial injuries are generally rare in the pediatric age group and are caused by both accidental and inflicted mechanisms. We report an unusual case of a 2-year-old female who was admitted to a pediatric emergency room with an industrial stainless steel coat hanger impaled in her skull. Pertinent clinical forensic medicine examination, coupled with home inspection and interviews by the local law enforcement, revealed a horrible episode of domestic violence.

5136. Soliman, M. M. and T. A. Macky (2008). "Pattern of ocular trauma in Egypt." Graefe's archive for clinical and experimental ophthalmology = Albrecht von Graefes Archiv fur klinische und experimentelle Ophthalmologie **246**(2): 205-212.

PURPOSE: To review the epidemiology of serious ocular trauma presenting to Kasr El Aini Hospital, Cairo University., METHODS: This is a prospective epidemiological and clinical study of ocular trauma patients admitted to Kasr El Aini hospital during a 6-month period; January-June 2000. Cases were analyzed with respect to: (1) demographics, (2) time, place and nature of trauma, (3) type of injury, (4) time to receive care, and (5) management and visual outcomes following primary repair., RESULTS: One hundred and fifty three eyes of 147 patients (six bilateral injuries) sustaining serious ocular injury requiring hospitalization were included during the study period. Eighty percent of ocular trauma occurred in men ($P < 0.001$ chi-square test) with an average age of 22 years (ranging from 2 months to 76 years). There were 123 (80.4%) open globe injuries and 30 (19.6%) closed globe injuries. Of the open globe injuries, 48 eyes (31.4% of all eyes) were ruptured globes and 75 eyes (49% of all eyes) were lacerated globes (37 intraocular foreign bodies, 35 penetrating injuries and three perforating injuries, that is 24%, 23%, and 2% respectively of all injured eyes). Of the closed globe injuries, 5.9% had hyphema (33% of all patients), 4% lamellar lacerations, and 2.5% vitreous hemorrhage with retinal detachment. Most of the injuries occurred (39.5%) and presented (36.7%) between 12:00-5:59 PM: . Eighteen patients (12%) presented after 24 hours, and nine patients (6%) 1 week after the time of trauma. Presenting visual acuity in 123 patients (123 eyes) was as follows: 98 (80%), ten (8%) and 15 (12%) patients had poor, moderate and good visual acuity respectively. Ten eyes developed posttraumatic endophthalmitis (8% of open globe injuries). On leaving the hospital, 77.1% eyes had a visual acuity of less then 1/60 (poor), 3.9% were between 1/60 and 6/60 (moderate), and 19% were 6/36 and/or better (good). Fifty-two (35%) patients were lost in follow-up: at 1 month, 60%, 7% and 33% of the rest had poor, moderate and good visual acuity respectively., CONCLUSION: The majority of ocular trauma in our population was due to assaultive injuries occurring mainly in males. Open globe injuries were more common than closed globe injuries, and globe lacerations were more common than ruptured globes. Open globe injuries, especially ruptured globes, had the worst visual outcomes. The initial visual acuity correlated well with the final visual acuity. Immediate and comprehensive medical care is mandatory for ocular trauma patients. Educating the public is essential if we wish to prevent eye injuries.

5137. Solmaz, I., et al. (2009). "Traumatic brain injury due to gunshot wounds: a single institution's experience with 442 consecutive patients." Turkish neurosurgery **19**(3): 216-223.

AIM: Traumatic brain injury (TBI) caused by a gunshot wound is a complex injury with a broad spectrum of symptoms and high rates of mortality and morbidity. This study presents an evaluation of TBI caused by gunshot wounds presenting at a single institution and discusses possible predictive factors for the outcome of surgical intervention., MATERIAL AND METHODS: The study sample consisted of 442 patients who underwent surgery for TBI over a 16-year period. All injuries were caused by gunshot wounds, such as bullets and shrapnel. All patients underwent surgical intervention., RESULTS: Almost all patients (99.3%) were male, and the mean patient age was 22.3 years. Wounds were

caused by shrapnel in 68 percent of patients. The Glasgow Coma Scale (GCS) score at admission was below 8 in 116 patients (26.2%) and above 8 in 326 patients (73.8%). In total, 47 patients (10.6%) died despite surgical management, with diffuse brain injury the most common cause of death., CONCLUSION: Low GCS scores, ventricular injuries and bihemispheric injuries are correlated with poor prognosis. Early and less invasive surgery in conjunction with short transportation time to the hospital could decrease mortality rates.

5138. Solmaz, I. A. and B. Tekerekoglu (2015). "Three-Centimeter Bullet in the Orbita of a 2.5-Year-Old Syrian Boy." The Journal of craniofacial surgery **26**(4): 1326-1327.

Aim of this report is to present a patient who has had a retrobulbar bullet in his left orbit after gunshot injury and had full recovery after surgery. A Syrian boy aged 2.5 years was referred to our emergency after a gunshot injury from left temple. First examination showed stable vital functions; the boy was conscious but had marked proptosis and edema on the left eye. Left intraorbital bullet was observed in X-ray and computed tomography. The exact localization of the bullet and the integrity of the left eye cannot be determined because of shining in computed tomography. Under general anesthesia, lateral and inferior orbitotomy was performed and 3-cm long bullet was excised, which was obliquely localized in the retrobulbar, intraconal area. Ten days later, the patient was sent to his homeland with almost full recovery and minimum sequela.

5139. Solomiichuk, V. O., et al. (2013). "Posttraumatic delayed subdural tension pneumocephalus." Surgical neurology international **4**: 37.

BACKGROUND: Pneumocephalus is a complication of head injury in 3.9-9.7% of the cases, it also appears after supratentorial craniotomy in 100% of cases. The accumulation of intracranial air can be acute (<72 hours) or delayed (>=72 hours). When intracranial air causes intracranial hypertension and has a mass-effect with neurological deterioration, it is called tension pneumocephalus., CASE DESCRIPTION: We represent a clinical case of a 75-year-old male patient with open penetrating head injury, complicated by tension pneumocephalus on the fifth day after trauma and underwent urgent surgical correction. Operation performed: Burr-hole placement in the right frontal region, evacuation of tension pneumocephalus., CONCLUSION: Tension pneumocephalus is a life-threatening neurosurgical emergency case, which needs to undergo immediate surgical or conservative treatment.

5140. Solomon, K. D., et al. (1993). "Cranial injury from unsuspected penetrating orbital trauma: a review of five cases." The Journal of trauma **34**(2): 285-289.

Penetrating orbital-cranial injury is potentially life threatening. The history of the trauma and ophthalmologic examination may be misleadingly innocent; serious injury may be overlooked. We present five cases of orbital injury in which the diagnosis of intracranial extension was not obvious at the time of initial examination. A thorough history and physical examination should be performed on all patients, even those with apparently trivial injuries. Intracranial extension should be considered in any case where the injury was caused by an instrument small enough to enter the orbit. The threshold for obtaining a coronal CT scan of the orbits should be lowered, since this is the best way to detect an orbital roof fracture.

5141. Solomon, L. B., et al. (2011). "Weight-bearing-induced displacement and migration over time of fracture fragments following split depression fractures of the lateral tibial plateau: a case series with radiostereometric analysis." The Journal of bone and joint surgery. British volume **93**(6): 817-823.

We investigated the stability of seven Schatzker type II fractures of the lateral tibial plateau treated by subchondral screws and a buttress plate followed by immediate partial weight-bearing. In order to assess the stability of the fracture, weight-bearing inducible displacements of the fracture fragments and their migration over a one-year period were measured by differentially loaded radiostereometric analysis and standard radiostereometric analysis, respectively. The mean inducible craniocaudal fracture fragment displacements measured -0.30 mm (-0.73 to 0.02) at two weeks and 0.00 mm (-0.12 to 0.15) at 52 weeks. All inducible displacements were elastic in nature under all loads at each examination during follow-up. At one year, the mean craniocaudal migration of the fracture fragments was -0.34 mm (-1.64 to 1.51). Using radiostereometric methods, this case series has shown that in the Schatzker type II fractures

investigated, internal fixation with subchondral screws and a buttress plate provided adequate stability to allow immediate post-operative partial weight-bearing, without harmful consequences.

5143. Soltani, S., et al. (2016). "Review of fall injuries and related factors in patients admitted to a trauma referral hospital in Tehran, Iran." International Journal of Medical Toxicology and Forensic Medicine **6**(4): 200-208.

Background: Falls are important causes of mortality and morbidity in urban areas and put a high burden on societies. We investigated patterns of fall traumas and related factors in a referral trauma hospital in Tehran, Iran. Methods: In this routine-data-based study, all documents of fall cases in Hazrate-Rasool hospital, Tehran, Iran, during October 2014-2015 were investigated. Information on demographic factors of patients, fall conditions and outcomes were collected. Data were analyzed by SPSS 11.5. The statistically significant level was considered ≤ 0.05. Results: Of the 307 cases, 70% were male. Median (interquartile range) age was 32 (22-51) years. Of cases, 91% were undergraduates. The mortality rate was 2.6%. Suicide attempts reported in 17 (5.5%) cases and only 2 (12%) of them were successful. Injured body organs in order of frequency were extremities, head and neck, thorax, vertebras, abdomen and pelvis. Outcome (in terms of injured body organs) was related to age and gender of patients alongside with height and reason of the fall. Falls at workplaces, in suicide attempts and among males happened for significantly higher distances. High distance falls and low GCS at admission were related to higher mortality. Majority of falls on a same level happened at home among old women. Conclusion: In our region, fall was a problem of people with low socioeconomic status. Our mortality rate is similar to the highest mortality rates in the world. Personal characteristics along with trauma-related factors are both important in the outcomes of fall cases. Safety equipment at high risk jobs is essential to prevent falls.

5144. Solumsmoen, S. and J. Kelsen (2018). "[Successful treatment and rehabilitation of severe, penetrating brain injury]." Ugeskrift for laeger **180**(33).

Penetrating brain injuries due to gunshots are rare in Denmark. This is a case report of the successful treatment of a 31-year-old man who was shot in the right frontal region of the head. The bullet went through his brain without damaging the large intracranial vessels. On admission he had a GCS of 9. Haematoma removal and bifrontal craniectomy was performed to obtain lowering of the intracranial pressure. One year after the incidence the patient was able return to work. This case report illustrates the importance of early prehospital and neurointensive treatment with lowering of the intracranial pressure and highly specialised rehabilitation.

5145. Solumsmoen, S., et al. (2018). "[Traumatic penetrating brain injury]." Ugeskrift for laeger **180**(51).

Penetrating brain injury is a severe form of traumatic brain injury. It is significantly less prevalent than closed head injury but carries a much worse prognosis. The experience with traumatic penetrating brain injury in Denmark is limited. The most common causes in penetrating brain injury in Denmark are: violence, accidents and suicidal behaviour. The aim of this review is to give a brief update on historical background, mechanisms of disease, recommended medical and surgical treatment, and complications. Clinical examples and a treatment algorithm are discussed.

5146. Sommers, M. S. (1994). "The effects of alcohol intoxication on the initial treatment and hospital course of patients with acute brain injury. (Gurney JG, Rivara FP, Mueller BA, Newell DW, Copass MK, Jorovich GJ. J Trauma 1992;33:709-13.)." Heart and Lung: Journal of Critical Care **23**(1): 95-98.

The purpose of this study was to determine the frequency and degree of alcohol intoxication in individuals with traumatic brain injuries. The study also investigated the association between the degree of intoxication at the time of injury and hospital management and treatment outcome. The study was conducted at a Level I Regional Trauma Center in the Pacific Northwest. During the 16 months of the study, 520 subjects met eligibility criteria, which included: age of 18 years or older; a serum alcohol concentration (SAC) sample drawn in the emergency department (ED) on admission; and an acute brain injury resulting from blunt head trauma (International Classification of Diseases [ICD-9-CM] including at least one head injury code). Subjects with penetrating head injuries or brain injury from hanging, suffocation, drowning or near drowning, burns, electrocutions, hypothermia, hyperthermia, or poisoning were excluded. In addition,

subjects admitted for less than a 1- day admission or admitted and discharged during the same weekend were not included in the study. Data on the subject's severity of injury and medical condition during prehospital care as well as during hospitalization were collected by experienced chart abstractors. SAC was measured from blood drawn in the ED; subjects were then stratified into two groups: intoxicated (SAC ≥ 100 mg/dl; n = 191) and nonintoxicated (SAC < 100 mg/dl; n = 329). When compared with nonintoxicated subjects, intoxicated subjects were more likely to require endotracheal intubation in the field or ED (relative risk [RR] 1.3; 95% confidence interval [CI] 1.1 to 1.5), more likely to require placement of an intracranial pressure bolt (RR 1.4; 95% CI 1.4 to 1.8), more likely to have respiratory distress requiring ventilatory assistance develop (RR 1.8; 95% CI 1.0 to 3.3), and more likely to have pneumonia develop (RR 1.4; 95% CI 0.9 to 2.2). One interesting finding was that intoxicated subjects had a 40% elevation in the relative likelihood of receiving invasive intracranial monitoring as compared with nonintoxicated subjects. This finding may indicate a tendency for intoxicated subjects to have more severe brain injuries than nonintoxicated subjects, or the trend may suggest that clinicians were less willing to rely solely on clinical assessments of cerebral injury in intoxicated subjects than in nonintoxicated, brain- injured subjects. In the study population, therefore, the findings suggested that head-injured, intoxicated subjects were more likely to require diagnostic-management procedures and have more adverse respiratory outcomes than those who were not intoxicated.

5147. Song, S. A., et al. (2017). "The emerging necessity of head and neck expertise in war." Otolaryngology - Head and Neck Surgery (United States) **157**(1): P57.

Objectives: (1) Analyze head and neck trauma from Operation Enduring Freedom (OEF) and Operation Iraqi Freedom (OIF). (2) Describe the impact on mortality for the presence of head and neck surgeons in theater. Methods: This retrospective study used the Department of Defense Trauma Registry, which contains data for patients admitted to US military treatment facilities or at affiliated hospitals in theater in Iraq and Afghanistan from 2002 to 2015. The data were analyzed for differences in anatomic injury patterns, Injury Severity Score (ISS), procedures, injury diagnoses, and mortality. Multivariate logistic regression analysis was performed to determine the independent predictors of mortality. Results: Nearly 18,000 patients suffered head and neck injuries and 13,000 head and neck procedures were performed. The most common injuries included open facial wound (22%), tympanic membrane perforation (8.8%), and closed maxillary fracture (8.6%). Tracheostomy was the most common procedure performed (14%), followed by control of epistaxis (7.6%), eyelid/eyebrow laceration repair (7.5%), and neck exploration (6.6%). The dominant mechanism of injury in non-US military was penetrating (68%) compared with blunt (58%) in US military ($P < .0001$). Elevated ISS (odds ratio [OR] = 39.5, $P < .001$) and penetrating injuries (OR = 2.24, $P < .001$) resulted in higher mortality. The availability of a head and neck surgeon resulted in lower mortality (OR = 0.65, $P < .001$). Conclusions: There has been an increase in head and neck injuries during OIF/OEF when compared with prior conflicts. The availability of head and neck surgeons seem to be associated with a significant decrease in overall mortality.

5148. Sonmez, E., et al. (2012). "An iron rod stuck in the right motor cortex." Turkish neurosurgery **22**(6): 772-774.

Non-missile intracranial injuries caused by foreign bodies are quite uncommon in civilian practice. Nails, knives, screwdrivers and sewing needles are the most commonly reported agents. The authors report a unique case of an adult male patient who suffered a penetrating craniocerebral injury caused by a falling concrete reinforcing iron (rebar) from the fourth floor of a building under construction. The foreign body was safely removed by a right parietal craniectomy as a result of detailed radiological evaluation and preoperative planning. To the best of authors' knowledge, the successful surgical treatment of a penetrating brain injury caused by a rebar has not been reported previously.

5149. Sood, H., et al. (2021). "Acute Bacterial Meningitis Risk Factors in Patients with Craniocerebral Gunshot Injuries." Intensive Care Medicine Experimental **9**(SUPPL 1).

Introduction. Craniocerebral Gunshot Injuries (CGI) can predispose patients to acute bacterial meningitis (ABM) because of the possible spread of bacteria from the skin or contaminated spaces (sinuses, nasopharynx or middle ear) to CNS. Antibiotics are often given prophylactically, although the evidence to support their utility is limited. Objectives. In our study, we sought to determine the incidence of meningitis, use of prophylactic antibiotics, and risk factors for patients who developed ABM after CGI. Methods. A retrospective chart review was performed of all patients who were admitted with a diagnosis of traumatic brain injury to an urban level 1 trauma center from January 1st, 2013 to December 31st, 2019 and patients with CGI were identified. All patients with CGI were screened for ABM within six

weeks following admission, based on cerebrospinal fluid (CSF) analysis and neuroimaging. We also recorded demographic data, medical history, use of prophylactic antibiotics, incidence of skull fractures, CSF leaks, and neurosurgical procedures. Results. Of 4,574 patients presenting with traumatic brain injury, 80 patients (1.75%) had CGI. Of those, 50 patients (62.50%) survived past the first 24 h. 20 out of these 50 patients were given prophylactic antibiotics for meningitis, ranging from 3-10 days (mean = 5.6 days). Of the remaining 30 patients, 7 (23.33%) were diagnosed with ABM, based on neuroimaging in one patient, and CSF findings for the rest. Their age ranged from 17-40 years, and six of the seven patients were male. Skull fractures with CSF leak on presentation were present in 3 out of 7 (42.86%) patients, and all 3 underwent a decompressive craniectomy for refractory intracranial pressure (ICP), within the first week of admission. Moreover, 5 out of the 7 patients had an external ventriculostomy drain (EVD) or ICP monitor placement. 1 out of 7 patients (14.28%) died during the hospital stay whereas all others were discharged to rehab. Amongst the patients who received prophylactic antibiotics, none had a CSF leak and only 2 had an ICP monitor placed. Conclusion. We found that amongst 4574 TBI patients, the incidence of ABM was 23.33% in CGI patients who did not receive antibiotics. Development of ABM was associated with the presence of CSF leaks or undergoing neurosurgical procedures. Patients with a CSF leak had a statistically significant increased odds ratio (OR) of developing ABM compared to patients without a CSF leak (OR 6.50, 95% CI 1.35, 201.29). Similarly, patients undergoing neurosurgical procedures had a higher risk of developing ABM (OR 26.25, 95% CI 2.94, 234.37). Our data suggest that these may be independent risk factors for developing meningitis and that this subset of patients with CGI may need antibiotic prophylaxis. Future prospective studies, especially in CGI patients with CSF leaks and EVD/ICP monitor placements, are needed to confirm our findings.

5150. Soreide, E. and C. D. Deakin (2005). "Pre-hospital fluid therapy in the critically injured patient--a clinical update." Injury **36**(9): 1001-1010.

Venous access and fluid therapy should still be considered to be essential elements of pre-hospital advanced life support (ALS) in the critically injured patient. Initiation of fluid therapy should be based on a clinical assessment, most importantly the presence, or otherwise, of a radial pulse. The goal in penetrating injury is to avoid hypovolaemic cardiac arrest during transport, but at the same time not to delay transport, or increase systolic blood pressure. The goal in blunt injury is to secure safe perfusion of the injured brain through an adequate cerebral perfusion pressure, which generally requires a systolic blood pressure well above 100 mmHg. Patients without severe brain injury tolerate lower blood pressures (hypotensive resuscitation). Importantly, using systolic blood pressure targets to titrate therapy is not as easy as it seems. Automated (oscillometric) blood pressure measurement devices frequently give erroneously high values. The concept of hypotensive resuscitation has not been validated in the few studies done in humans. Hence, the suggested targeted systolic blood pressures should only provide a mental framework for the decision-making. The ideal pre-hospital fluid regimen may be a combination of an initial hypertonic solution given as a 10-20 minutes infusion, followed by crystalloids and, in some cases, artificial colloids. This review is intended to help the clinician to balance the pros and cons of fluid therapy in the individual patient.

5151. Sørensen, D. W., et al. (2015). "Controlled organ donation after circulatory death (cDCD) with use of regional normo termic perfusion (RNP): Case report of two patients in Norway." Acta anaesthesiologica Scandinavica **59**: 37-38.

Introduction: The numbers of patients which progress to a total loss of brain perfusion make up a relatively small fraction of all patients that die in the ICUs. To fulfill the patients wish for organ donation and meet the increased demand for organ transplantation we have established a program for cDCD with the use of RNP for in situ organ preservation. The protocol was approved by the Regional Ethical Committee, Norwegian Directorate of Health and finally the Ministry of Health and Care Services which stated that the cDCD protocol was in accordance with Norwegian Law. The study was presented at Centre for Medical Ethics, acknowledged by local ethical committee and given permission to start by board meeting at Division of Emergencies and Critical Care, Ulleval University Hospital. Objectives: To describe the steps taken to establish the protocol. To present two patient cases. (Figure presented) Results: Two males, one with penetrating brain injury, the other with intracranial hemorrhage, fulfilled the cDCD criteria. Next of kin supported organ donation and in agreement with the medical staff, life-sustaining treatment was withdrawn. Permanent cardiac arrest occurred after 13 and 10 min, respectively. RNP was applied for 54 and 106 min prior to kidney retrieval. Four kidney recipients were successfully transplanted and discharged with normalized creatinine levels. Conclusion: The implementation of cDCD has proven to be a challenge for the medical, ethical and transplant

community. However, excellent transplant results and satisfied next of kin and ICU staff have encouraged us to continue the use of cDCD.

5152. Sorensen, E. J. and C. Kruse-Larsen (1990). "[Practical use of the brain death diagnosis]." Hjernedodsdiagnosen i praktisk anvendelse. **152**(12): 805-806.

A retrospective review of a material spontaneous intracerebral haemorrhages and head injuries from a period of five years revealed that 14% of the patients with these diagnoses eventually are diagnosed as brain dead. In half of the brain dead patients cerebral angiography was carried out and, in all of the cases, this revealed circulatory arrest in the brain. The investigation demonstrates that, on the average, 8.5 hours elapse from the establishing of the diagnosis of brain death until cardiac arrest occurs. In 75 out of 105 cases, relations were asked for permission to remove organs and the reply was affirmative in 52 cases (69.3%). Two patients had already consented to organ donation.

5153. Soria, E. D., et al. (1988). "Traumatic aneurysms of cerebral vessels: a case study and review of the literature." Angiology **39**(7 Pt 1): 609-615.

Traumatic cerebral aneurysms (TCAs) are rare: few more than 100 cases are recorded in the world literature. TCAs are located predominantly in the supratentorial compartment and are classified as either "true" or "false." A true aneurysm is a dilation resulting from partial disruption of the arterial wall. A false aneurysm results from a full-thickness tear, with the scar from the brain tissue or an organized hematoma acting as the aneurysmal wall. The authors present a case of a false traumatic aneurysm of the pericallosal artery, which was discovered in a young patient fourteen months after a self-inflicted gunshot wound to his head. The aneurysm was an incidental finding on a CT scan performed for the investigation of his late posttraumatic seizures. Its presence was confirmed by angiography. The interval between the traumatic episode and the diagnosis of a TCA usually ranges from a few hours to a few weeks, for most are discovered by angiography performed in the acute or subacute stage of a head injury. The long interval between the injury and the diagnosis in our case is exceptional. A previous CT scan done four months after the injury did not reveal the aneurysm, which strongly suggests a protracted growth of the aneurysmal sac long after the trauma.

5154. Soroker, N., et al. (1989). "Practice of prophylactic anticonvulsant treatment in head injury." Brain injury **3**(2): 137-140.

The policy of patient selection for prophylactic anticonvulsant treatment has been evaluated retrospectively in 124 head-injured patients admitted consecutively for rehabilitation after primary neurosurgical treatment. Prophylaxis had been instituted in about 60% (51/83) of high risk patients and in about 30% (12/41) of the patients who did not belong to the high risk categories. The use of existing risk data as guidelines for decisions about anticonvulsant prophylaxis is discussed.

5155. Sosin, D. M., et al. (1989). "Head injury-associated deaths in the United States from 1979 to 1986." JAMA **262**(16): 2251-2255.

Review of US mortality data from 1979 to 1986 identified 315,328 deaths associated with head injury, which represented 2% of all deaths, 26% of injury deaths, and an annualized head injury-associated death rate of 16.9 per 100,000 residents. Motor vehicles (57%), firearms (14%), and falls (12%) were the most frequent causes. Death rates peaked at 15 to 24 years of age and at 75 years or older, with the younger group most affected by motor vehicles (77%) and the older group by falls (43%). Although blacks and whites had similar death rates overall, age- and cause-specific rates varied considerably. The rate of head injury-associated death for males was three times that of females. Rates for head injury-associated death plateaued after declining in the early 1980s. Physicians can play an important role in primary prevention of head injury through careful prescribing of medications, patient counseling, and advocacy of proved interventions such as motor vehicle-occupant restraints. use, we observed 9827 children riding bicycles at sites in high-, middle-, and

5156. Sosin, M., et al. (2016). "Total Face, Eyelids, Ears, Scalp, and Skeletal Subunit Transplant Cadaver Simulation: The Culmination of Aesthetic, Craniofacial, and Microsurgery Principles." Plastic and reconstructive surgery **137**(5): 1569-1581.

BACKGROUND: The application of aesthetic, craniofacial, and microsurgical principles in the execution of face transplantation may improve outcomes. Optimal soft-tissue face transplantation can be achieved by incorporating subunit facial skeletal replacement and subsequent tissue resuspension. The purpose of this study was to establish a reconstructive solution for a full face and scalp burn and to evaluate outcome precision and consistency., METHODS: Seven mock face transplants (14 cadavers) were completed in the span of 1 year. Components of the vascularized composite allograft included the eyelids, nose, lips, facial muscles, oral mucosa, total scalp, and ears; and skeletal subunits of the zygoma, nasal bone, and genial segment. Virtual surgical planning was used for osteotomy selection, and to evaluate postoperative precision of hard- and soft-tissue elements., RESULTS: Each transplant experience decreased each subsequent transplant surgical time. Prefabricated cutting guides facilitated a faster dissection of both donor and recipient tissue, requiring minimal alteration to the allograft for proper fixation of bony segments during inset. Regardless of donor-to-recipient size discrepancy, ample soft tissue was available to achieve tension-free allograft inset. Differences between virtual transplant simulation and posttransplant measurements were minimal or insignificant, supporting replicable and precise outcomes., CONCLUSIONS: This facial transplant model was designed to optimize reconstruction of extensive soft-tissue defects of the craniofacial region representative of electrical, thermal, and chemical burns, by incorporating skeletal subunits within the allograft. The implementation of aesthetic, craniofacial, and microsurgical principles and computer-assisted technology improves surgical precision, decreases operative time, and may optimize function.

5157. Sosiukin, A. E., et al. (2008). "[Pathology of lungs by wounded in the armed conflicts in Northern Caucasus]." Voenno-meditsinskii zhurnal **329**(11): 31-96.

According to 7000 patient histories, wounded in armed conflicts in Northern Caucasus, for the last years, is marked a big part of wounds of mild (45.3%) and medium (31.5%) severity. Heavy and extremely heavy wounds marked conformably in 20.8 and 2.4 percents. An acute respiratory distress-syndrome is marked by 32 wounded with heavy and extremely heavy wounds, including 10--with penetrating wound of brainpan, 9--penetrating wound of bosom and tense hemopneumothorax, 11--penetrating wound of abdomen (with deflection of hollow and parenchymal organs), 2--penetrating wound of lower limbs (with firing breakup of long bones and deflections of great vessel), attended by blood loss and shock. Pneumonia was found during first 3 days after the wound by 47%, on 4-7 day--31%, during second week--13%, latter--9%. In 93% of cases pneumonia was marked in combination with traumatic shock. Radiological examining of radiological plays a conclusive account in diagnostics, and according to meanings--computerized tomography. Estimation of function of exterior breathing is also important.

5158. Soto, E., et al. (2021). "Reconstructive Management of Gunshot Wounds to the Frontal Sinus: An Urban Trauma Center's Perspective." Annals of plastic surgery **86**(6S Suppl 5): S550-S554.

INTRODUCTION: In the last decade, we have seen a steady increase in the incidence of frontal sinus trauma due to gunshot wounds and a decrease in motor vehicle trauma. Penetrating gunshot wounds to the frontal sinus present a unique challenge to the reconstructive surgeon because they require careful consideration of the management principles of plastic surgery. Despite previous reviews on frontal sinus trauma, there are no studies examining the management techniques of frontal sinus fractures due specifically to gunshot wounds. In this study, we aim to retrospectively evaluate the use of a variety of tissue flaps in intervention and associated outcomes., METHODS: A retrospective chart review was completed on all patients with gunshot wound(s) to the frontal sinus from January 2010 to January 2018 at a single institution. The patients were classified based on the fracture pattern (anterior vs posterior table vs both), degree of displacement, presence of nasofrontal outflow tract injury, and evidence of cerebrospinal fluid leak. Patients were then stratified according to the type of reconstruction performed (cranialization, obliteration and need for free flap) and evaluated for major and minor complications after reconstruction., RESULTS: In this study, we present outcome data from 28 cases of frontal sinus trauma due to gunshot wounds. There was a statistically significant difference (P = 0.049) in the type reconstructive strategy employed with each type of flap, with pericranial flaps primarily used in cranialization, temporal grafts were more likely to be used in obliteration, and free flaps were more likely to be used in cranialization. The overall major complication rate was 52% (P = 0.248), with the most common acute major complication was cerebrospinal fluid leak (39%) and major chronic was abscess (23.5%)., CONCLUSIONS: This

report explores the management of frontal sinus trauma and presents short-term outcomes of treatment for penetrating gunshot wounds at a tertiary referral center.

5159. Souter, M. and G. Van Norman (2010). "Ethical controversies at end of life after traumatic brain injury: defining death and organ donation." Critical care medicine **38**(9 Suppl): S502-509.

Death is more than a mere biological occurrence. It has important legal, medical, and social ramifications that make it imperative that those who are responsible for determination of death be accurate and above suspicion. The medical and legal definitions of death have evolved to include consideration of such concepts as loss of integration of the whole organism, loss of autonomy, and loss of personhood. Development of the concept of brain death coincided with advances in medical technology that facilitated artificial ventilation and organ transplantation. More recently, the process of "timed" death with subsequent organ donation (controlled donation after cardiac death transplantation) has raised controversial questions having to do with the limits of treatments that facilitate organ transplant but might hasten death, and the duration of cardiac arrest necessary for declaration of death and the commencement of organ procurement. In this review, we discuss the background and ethical ramifications of the concepts of brain death, and of controversies involved in controlled donation after cardiac death organ transplantation.

5160. Souter, M. J. and M. Kirschen (2020). "Brain death: optimizing support of the traumatic brain injury patient awaiting organ procurement." Current opinion in critical care **26**(2): 155-161.

PURPOSE OF REVIEW: Increasing numbers of deaths on the transplant waiting list is associated with an expanding supply-demand deficit in transplantable organs. There is consequent interest in reviewing both donor eligibility after death from traumatic brain injury, and subsequent management, to minimize perimortem insult to donatable organs., RECENT FINDINGS: Recipient outcomes are not worsened when transplanting organs from donors who were declared dead after traumatic brain injury. Protocolized donor management improves overall organ procurement rates and subsequent organ function. Longer periods of active management (up to 48 h) are associated with improved outcomes in renal, lung, and heart transplantation. Several empirically derived interventions have been shown to be ineffective, but there are increasing numbers of structured trials being performed, offering the possibility of improving transplant numbers and recipient outcomes., SUMMARY: New studies have questioned previous considerations of donor eligibility, demonstrating the ability to use donated organs from a wider pool of possible donors, with less exclusion for associated injury or comorbid conditions. There are identifiable benefits from improved donor resuscitation and bundled treatment approaches, provoking systematic assessments of effect and new clinical trials in previously overlooked areas of clinical intervention.

5161. Sova, M., et al. (2010). "Gunshot wounds of the head and brain." Ceska a Slovenska Neurologie a Neurochirurgie **73**(5): 547-551.

Aim: The authors report the results of treatment to patients with gunshot and captive bolt injury to the brain, all of them undergoing surgery at the Department of Neurosurgery at the Faculty Hospital, Brno in the 2005-2008 period. The article addresses the most important prognostic factors influencing choice of therapeutic procedures. It also includes a classification and pathophysiology of penetrating injuries. The authors present a basic survey of the impact ballistics of gunshot injuries. Patient group and methods: The case histories of 20 patients were subjected to operational review. All of them were male, mean age 59, range 33-80 years. Attempts at suicide accounted for 17 of the them; two arose out of negligent handling of a firearm; and one patient was a victim of violent crime. The clinical status of the patients was retrospectively evaluated by means of the Glasgow Outcome Scale [1], 6 months after the penetrating injury on the part of the survivors. The dependence of GOS on the patient's state of consciousness on admission and the extent of brain involvement according to CT scan were evaluated. Results: The patient's state of consciousness on admission and the extent of brain parenchyma damage on CT scan are the most important prognostic factors dictating approaches to the treatment of these severely injured patients. In our group, the initial Glasgow Coma Scale [2] points totalled 3 in 15 patients (75%), 9 in 1 patient (5%), 14 in 1 patient (5%) and 15 in 3 patients (15%). Initial presenting examination of the brain with computer tomography revealed 9 cases of severe, extensive, multilobar involvement of the brain parenchyma, 11 cases of focal involvement of a single lobe, often in the "eloquent" brain. Mortality in the whole group reached 65%, and 4 cases were classified as donors to the transplantation program. Conclusion: The

specialist literature indicates that the mortality rate of brain gunshot wounds varies between 60% and 90%, and our group suffered a mortality of 65%. This relatively favourable outcome is determined by the fact that 50% of the wounds were inflicted by a slaughterhouse (captive bolt) gun, which lacks the extended penetration of bullet-firing weapons. Despite the fact that serious primary injury to the brain parenchyma occurs, a favourable prognosis may result from emphasis on minimizing further secondary brain damage.

5163. Spallaccia, F., et al. (1996). "[Trauma to the anterior cranial base. Report of a case]." Traumi della base cranica anteriore. Presentazione di un caso clinico. **45**(6): 289-293.

The authors present a case of foreign body retention, following car accident, localized on superior medial corner of the right orbit. The traumatic impact, involving endo-orbital structures, owing to the peculiar direction of the foreign body, caused a fracture in the anterior cranial base and laceration of the dura madre. As the anatomical structures involved did not concern only the MaxilloFacial district, the choice of the protocol to be applied to the patient was taken in accordance with the neurosurgical equipe. An intra cranial surgical approach has allowed to remove, by retrograding the foreign body on its trajectory path, in order not to injure further the already damaged structures involved. Then the tissues have been reconstructed; in particular, the anterior cranial base was restored through the use of pericranial strip. This technique is the elective surgical treatment in lesions of such small entity, as it is able to grant a solid support to the overhanging cerebral parenchyma. Besides, this reconstruction technique provides a complete protecting isolation of the ocular globe from compressive and pulsative phenomena, due to the neurocranial adjacent structures. With this technique, after a 8 month's follow-up. The patient has obtained optimum functional and aesthetic results.

5164. Spanio, S., et al. (2002). "Intracranial dislocation of the mandibular condyle: report of two cases and review of the literature." The British journal of oral & maxillofacial surgery **40**(3): 253-255.

Fractures of the mandibular condylar process are common and account for up to 40% of all mandibular fractures. Penetration of the condylar head into the middle cranial fossa is, however, rare. We have found reports of only 43 cases since 1834. The diagnosis of intracranial condylar dislocation is difficult, there are usually no particular symptoms or neurological signs. As a result, detailed radiological studies are necessary. In the absence of clear radiographic images of the condylar structures, computed tomography (CT) is essential to locate the fragments and to investigate and monitor intracranial lesions. This paper describes the diagnostic and surgical procedures used in two cases of condylar dislocation and discusses them with reference to previous cases. The use of a titanium screw, which was positioned intracranially in the first case, has not, to our knowledge, been described previously. Copyright 2002 The British Association of Oral and Maxillofacial Surgeons.

5165. Spatenkova, V. (2018). "International prospective observational study on intracranial pressure in intensive care (the synapse-ICU study)." European Journal of Neurology **25**: 29.

Background: International prospective observational StudY on iNtrAcranial PreSsurE in intensive care (ICU), the SYNAPSE-ICU was initiated by European Society of Intensive Care Medicine Neuro-Intensive Care Section. The objectives of the study are to explore ICP monitoring variation in practice in order to prioritise uncertainties in the clinical management of critical care patients with acute brain injury and support further collaborative hypotheses based prospective studies. Material and Methods: This study will start in March 2018. It will be conducted in several ICUs in different countries. Inclusion criteria: a) Acute brain injury (ABI) admitted to ICU following: Haemorrhagic stroke, including intracerebral hematoma and subarachnoid haemorrhage, TBI (penetrating and nonpenetrating); age >18 years old; c) worst motor score <6 or requiring intubation and ventilation for neurological reasons/deterioration; d) no eye opening at enrolment. Exclusion criteria: a) acute brain injury (ABI) NOT admitted to ICU; ABI not included in the inclusion criteria; c) age < 18 years old; d) motor score of the Glasgow Coma Scale on admission to ICU = 6. Outcome measures: GOS-Extended at 6 months.

5166. Spatenkova, V., et al. (2020). "Potential brain dead organ donation in neurocritical care mortality." Journal of neurosurgical sciences **64**(3): 247-252.

BACKGROUND: Mortality is a marker of quality in neurocritical care, but it also provides potential for donors after brain death (DBD) following irreversible acute brain damage. The aim of this study was to analyze the neurointensive care unit (NICU) mortality rate and recovery of potential DBD., METHODS: We performed a 10-year prospective observational cohort computer database analysis of 6138 acute neurological and neurosurgical patients (pts, 58.2% male, mean: age 55.9+/-14.7 years, body weight 78.3+/-15.6 kg, body mass index 26.9+/-4.7, NICU stay 3.8+/-5.3 days): 3462 (56.4%) pts with brain disease (mostly stroke 43.2%, tumor 31.1%, trauma 13.6%); 10.3% pts with internal carotid artery (ICA) stenosis; 32.6% pts with spine diseases, and others. Mean Acute Physiology and Chronic Health Evaluation (APACHE) II score on admission was 10.63+/-5.2 and Glasgow Coma Scale on admission was 13.79+/-2.51., RESULTS: There were 159 (2.6%) cases of mortality with a significantly higher mortality rate in pts with brain diseases (95.6% of deceased pts, P<0.001) than in ICA stenosis (0.6%), spine (1.9%) and from others (1.9%). There were 23 (14.5%) pts with clinical signs of brain death, of whom 13 (56.5%) became donors. The main reasons for non-recovery of potential donors were hemodynamic instability (16.7%) and family reluctance (12.5%)., CONCLUSIONS: The study showed that our NICU mortality was 2.6%. There were relatively few clinical signs of brain death and not all potential donors were recovered.

5167. Specht, C. S., et al. (1992). "Orbitocranial wooden foreign body diagnosed by magnetic resonance imaging. Dry wood can be isodense with air and orbital fat by computed tomography." Survey of ophthalmology **36**(5): 341-344.

In computed tomographic (CT) scans, a wooden foreign body can appear as a lucency with nearly the same density as air or fat, and it can be indistinguishable from orbital adipose tissue. Magnetic resonance imaging (MRI) can localize these wooden foreign bodies in the orbit. We studied a case in which a wooden golf tee lodged in the right optic canal of a nine-year-old boy. The head portion lodged in the orbital apex and the tip entered the interpeduncular fossa. Clinical examination revealed a right paranasal laceration; the right eye had no light perception and a peripapillary hemorrhage, but was otherwise normal. Surgical exploration and evaluation by CT failed to locate the foreign body. However, the golf tee was demonstrated by MRI as a low intensity image. Although it was removed by craniotomy with good neurological results, bacterial panophthalmitis led to enucleation of the eye. This case emphasizes the diagnostic value of MRI and the hazards of retained wooden foreign bodies.

5168. Spencer, C. and J. Butler (2010). "Survival after cardiac arrest and severe lactic acidosis (pH 6.61) due to haemorrhage." Emergency medicine journal : EMJ **27**(10): 800-801.

This paper describes a 21-year-old man who presented to the emergency department with a knife wound to his buttock. He had a witnessed cardiac arrest with pulseless electrical activity in hospital as a result of further haemorrhage. His post-resuscitation arterial blood gas revealed a severe lactic acidosis (pH 6.61, lactate 22.0 mmol/l). Despite poor expectations he went on to make a full neurological recovery. To the authors' knowledge, he had the fourth-lowest pH for a cardiac arrest survivor with normal neurology. Severe lactic acidosis occurs post cardiac arrest due to imbalance between cellular oxygen supply and demand. Severe lactic acidosis is associated with hypoxic brain injury but has a low specificity in its prediction. The case illustrates that, especially in younger adults, severe lactic acidosis may be a poor predictor of outcome if it reflects a period of relative hypoperfusion preceding cardiac arrest.

5169. Spennato, P., et al. (2005). "Double concentric craniotomy for a craniocerebral penetrating nail. Case report and technical note." Surgical neurology **64**(4): 368-371.

BACKGROUND: Craniocerebral penetrating injuries from nail-gun accidents are rare and usually are discovered immediately after the trauma. Several surgical procedures have been described to extract a foreign body that is infixed in the skull and has penetrated the surrounding structures; blind extraction, craniectomy, and craniotomy., CASE DESCRIPTION: We report the case of a 25-year-old ex-carpenter who presented with jacksonian seizure at the left limb. Plain radiography of the skull revealed the unexpected presence of a nail hammered in the right parietal bone, penetrating the underlying structures of the frontoparietal area up to a depth of 3 cm. The patient was operated on; a small craniotomy (1 x 1 cm) just around the head of the nail, and a concentric larger frontoparietal bone flap, involving the first craniotomy, were performed. The larger bone flap was elevated first, whereas the small bone flap with the nail infixed was carefully elevated along the axis of the nail, under direct vision of the nail tract., CONCLUSIONS: Double

concentric craniotomy is the only technique that permits the removal of a foreign body that has penetrated both the skull and the brain, under direct vision, without transmitting any undue forces to the underlying structures. With this technique, control of bleeding can also be easily achieved.

5170. Sperry, K. and E. S. Sweeney (1988). "Terminal ballistic characteristics of Hydra-Shok ammunition: a description of three cases." Journal of forensic sciences **33**(1): 42-48.

The Hydra-Shok bullet is characterized by a hollow-point construction, with a distinctive central post in the base of the hollow. These features allow such missiles to be easily identified during the course of an autopsy examination of a gunshot victim. Higher velocity loadings of the Hydra-Shok may fragment along the wound path, occasionally forming a ring-like fragment that suggests this ammunition, but this feature cannot be considered unique. Although radiographic examination is helpful in bullet localization, the characteristic central post may be identified by X-ray only if sufficient expansion results in its exposure. Three cases of shooting deaths involving Hydra-Shok bullets are presented and discussed; in each case, the entrance wounds were indistinguishable from entrances associated with conventional ammunition, and in no instance did the missiles exit from the body (including head, chest, and abdominal wounds). Familiarity with relatively unusual ammunition types such as the Hydra-Shok allows for quick identification by the pathologist at the time of autopsy.

5171. Spiers, A. S. (1994). "Attempted suicide or hitting the nail on the head. Case report." The Journal of the Florida Medical Association **81**(12): 822-823.

A case is reported of attempted suicide by hammering nails through the skull into the brain. This unique attempt at self-destruction was unsuccessful and the treatment, initially by an untrained first-aider and then by a neurosurgeon, was surprisingly simple. There were no long-term sequelae.

5172. Spinella, P., et al. (2009). "Predictors of mortality for penetrating injuries excluding isolated head injury." Shock **31**(1): 91-92.

Introduction: Many clinical trials have used admission systolic blood pressure (SBP) to determine inclusion criteria to identify shock. Inaccurate estimates of mortality in clinical trials have lead to underpowered results. Our hypothesis was that measures of coagulopathy and shock upon admission such as International Normalized Ratio (INR), base deficit (BD), and hemoglobin (Hb) when added to SBP improve prediction of mortality. Methods: Patients with penetrating combat-related injuries who were transfused blood products were included. Patients with isolated severe traumatic brain injury (Head AIS ≥3) and those with any of the variables analyzed missing were excluded. Logistic regression with stepwise elimination was used with receiver operator curve (ROC) analysis for admission SBP, Hb, BD, and INR to determine their ability to predict in-hospital mortality. Results: There were 840 patients included with a median (IQR) age of 24 years (21-28), Injury severity score of 19 (11-29), and mortality of 90/840 (10.7%). The AUC for in hospital mortality increased significantly ($p < 0.05$) as BD, and(Table Presented). INR were included in the prediction model compared to models that did included only SBP and Hb (models 3-5 vs. 1-2). Conclusion: The addition of admission BD and INR as inclusion criteria may improve the ability to select patients with expected mortality for trials in penetrating traumatic injury which exclude isolated severe head injury. Approaches similar to this are needed to improve study design of large clinical trauma trials.

5173. Spiotta, A. M. and S. M. Matoses (2011). "Neurosurgical considerations after bull goring during festivities in Spain and Latin America." Neurosurgery **69**(2): 455-461.

Bullfighting is a highly popular activity during festivities in Spain and Latin America. A scientific society for bullfight injuries, Congreso Internacional de Cirugia Taurina, was founded on November 24, 1974, in recognition of the distinctive pattern of injury that results from bull goring, and a subspecialty of general surgical trauma with emphasis on the acute surgical management of bull-goring injuries has emerged. Injuries to the head and neck are less frequent than genitourinary, inguinal, and abdominal injuries, but are more severe and more likely to result in death. This report reviews the primary venues in which bull goring and associated injuries occur, including the bullfight and the running of the bulls. The biomechanics of the primary and secondary goring injuries are reviewed, with an emphasis on those with the potential to result in neurosurgical injuries. This results in a very unique and devastating pattern of injury that

combines penetrating and blunt mechanisms and results in polytrauma. Neurosurgical expertise should be immediately available on-site in the event of a life-threatening neurological injury.

5174. Spittler, J. F. and H. Langenstein (1991). "[Diagnosis of brain death: limitations of angiography after osteoclastic trepanation]." Diagnose des Hirntodes: Grenzen der Angiographie nach osteoklastischer Trepanation. **116**(48): 1828-1831.

A 50-year-old man sustained severe skull-brain trauma with intracerebral bleeding, cortical contusion foci and fracture of the petrosal bone. He went into coma a few hours after the accident. Three days after surgical removal of an intracerebral bleeding via a frontoparietal osteoclastic trepanation (removal of a 4 x 5 cm piece of bone) there occurred complete brainstem areflexia, respiratory arrest and drop in temperature; the encephalogram was isoelectric. There was thus no clinical-neurological doubt of brain death. But cranial digital subtraction angiography, generally considered to give the most reliable evidence of irreversible loss of cerebral functions, showed contrast medium in the branches of the left cerebral artery. The diagnostic criteria of brain death, as proposed by the Federal German Chamber of Physicians (Bundesarztekammer), were thus not exactly met, and despite the clinically obvious brain death a contemplated removal of organs for transplantation was therefore not undertaken. The patient died 6 hours after the angiography. This case shows that the value of angiography for the diagnosis of brain death may sometimes be limited, at least in those cases in which osteoclastic trepanation has been performed or there are other causes for a skull defect, because they can prevent the rise of intracranial pressure which brings about the cerebral circulatory arrest.

5175. Spitzer, N. and J. K. Singh (2018). "Pediatric ocular trauma caused by recreational drones: two case reports." Journal of AAPOS : the official publication of the American Association for Pediatric Ophthalmology and Strabismus **22**(3): 237-238.

Drones are increasingly being used by children and adults recreationally and commercially. The propeller blades when spinning at high speeds may cause serious harm to the eye and orbital structures. We report 2 cases of injuries to the eye and orbital structures caused by drones.

5176. Splavski, B., et al. (2000). "Intracranial infection as a common complication following war missile skull base injury." Injury **31**(4): 233-237.

The purpose of this paper is to stress the importance of clinical observation, the appropriate antimicrobial therapy, and early surgery in the management of intracranial infection following war missile penetrating skull base injury. There were 21 skull base missile injuries treated surgically in a 4-year period. Careful removal of devitalised brain tissue with dural closure was performed with all patients to prevent the development of intracranial infection. Subsequent clinical and radiological surveillance was performed to detect evidence of infection and abscess formation if fragments were left in place. Broad range antibiotic coverage, and the antioedematous agents were applied in the early postoperative period. Infection about the brain was seen in four cases. We recorded three cases of brain abscess formation, while one patient developed bacterial meningitis. The incidence of infectious complications was relatively high in our series. After the organisms causing infection were known, treatment was modified to be as specific as possible. It was not necessary to reoperate on intracranially retained foreign bodies and fragments since they did not increase the infection rate. However, repeated surgery is necessary for a brain abscess.

5177. Splavski, B., et al. (2006). "[Clinical predictors correlated to outcome of war missile penetrating brain injury]." Klinicki pokazatelji u.spjesnosti lijecenja ratnih penetrirajucih ozljeda mozga. **60**(4): 369-373.

AIM OF THE STUDY: The purpose of this retrospective study was to review and discuss the outcome of surgical management and other clinical predictors influencing the prognosis of war missile penetrating brain injuries., PATIENTS AND METHODS: To determine clinical predictors that influence the prognosis of war missile penetrating brain injury, 126 surgically treated patients who had sustained such an injury during the two-year period of war in Croatia (1991-1993) were retrospectively analyzed. Investigated clinical features were: Glasgow Coma Scale (GCS) score on admission; extent of brain injury; time between injury and hospital admission; presence of intracranially retained foreign bodies or bone fragments; development of postinjury and posttraumatic complications; and Glasgow Outcome Score (GOS) at six-

month follow up. The data were statistically analyzed., RESULTS: Sixty-seven patients survived penetrating missile brain injury, in most of them with GCS score above 8 on admission. The mean time interval to hospital admission in this group of patients was less than two hours. Twelve of 67 patients developed different complications. All patients recovered well according to GOS (GOS 5 and 4) at six-month follow up. Fifty-nine patients died. The wounded who were in moribund state on the hospital admission (n = 11), and those who died during surgery (n = 8) were excluded from the analysis. The remaining 40 patients who did not survive were analyzed. The majority of them had GCS score 3-8 on admission. They mostly sustained bilateral hemispheric lesion, and/or ventricular lesion, and developed brain edema. The mean time interval between injury and hospital admission was over two hours in this group of patients. Postoperative complication developed in 9 of 40 patients., DISCUSSION: The patients with GCS score exceeding 8 had by far more favorable outcome in comparison to those with GCS score less than 8. Considering the extent of injury, patients suffering unihemispheric brain wounds had a more favorable outcome than those with lesions of both hemispheres, and particularly those with transventricular lesions. The time between injury and hospital admission proved to be another important prognostic factor. The majority of patients admitted up to one hour of injury survived, while two thirds of those admitted between one and three hours of injury succumbed. The presence of intracranially retained foreign bodies and bone fragments, and postinjury and postoperative complications implied worse outcome in comparison with their absence., CONCLUSION: The state of consciousness on admission was the most sensitive criterion as far as the prognosis is concerned. The outcome also depended on the extent of brain damage since the wounds associated with a high mortality rate were predominantly bihemispheric. Concerning survival, the time between injury and hospital admission also appeared to be important, as well as intracranially retained foreign bodies and bone fragments, and development of complications. There was no relationship between the presence of retained fragments and development of infection, suggesting that it is not necessary to reoperate for retained fragments. We assume that early surgery is essential for treatment outcome, although it is not necessary to reoperate for retained fragments.

5178. Splavski, B., et al. (1998). "Early surgery and other indicators influencing the outcome of war missile skull base injuries." Surgical neurology **50**(3): 194-199.

BACKGROUND: The aim of this study was to analyze the effect of early surgical management protocol and other important clinical features on the prognosis of patients suffering from war missile skull base injuries., METHODS: Twenty-one patients who suffered from war missile skull base injuries were analyzed in this study. The wounds were mainly caused by shells and/or bullets. Craniotomy represented the standard treatment in all patients. Investigated clinical features included Glasgow Coma Scale score on admission, the mode and the extent of brain injury, time to patient admission to hospital, and the presence of an intracranially retained foreign body. The prognostic importance of complications such as infection, intracranial hemorrhage, cerebrospinal fluid leak, and epileptic seizures was also investigated., RESULTS: The outcome of 21 skull base injuries was as follows: death in seven patients, vegetative state in three, severe disability in two, moderate disability in seven, and good recovery in two patients. The clinical characteristics that implied favorable outcome were: Glasgow Coma Scale score greater than 12, location of injury in the anterior cranial fossa, time to admission shorter than 1 hour, and absence of an intracranially retained foreign body and postoperative complications. The statistical significance of those predictors was at the level of $p < 0.001$ in all cases., CONCLUSIONS: Although the wounds were associated with a high mortality rate, this study showed that there are major differences in prognosis of patients with war missile skull base injuries with respect to certain presenting clinical features.

5179. Spoor, T. C. (1987). "Penetrating orbital injuries." Advances in ophthalmic plastic and reconstructive surgery **7**: 193-216.

Seemingly trivial adnexal injuries may be associated with extensive injuries to the globe, orbit, and brain. A meticulous ophthalmologic examination and orbital and brain computed tomography (CT) scans (axial and coronal views) are essential for complete evaluation of these patients. The ophthalmologist must remain an active participant in the management of these patients to preserve the integrity of the globe.

5180. Springborg, J. B., et al. (2007). "Cranio-cerebral injuries caused by nail guns: report on two cases, review of the literature and treatment algorithm." The Journal of trauma **63**(2): E59-64.

5181. Spurlock, M., et al. (2017). "Perilesional neural stem cell transplantation mitigates lesion volume following penetrating ballistic-like brain injury (PBBI)." Journal of neurotrauma **34**(13): A23.

We previously confirmed engraftment of NSI566 human neural stem cells (hNSC) in PBBI. In this study, we aimed to determine the optimal transplant location relative to PBBI lesion. To do so, we transplanted one million hNSC into each animal one week following injury either in the core of injured tissue (intralesional) or in undamaged tissue immediately surrounding the core (perilesional). We also transplanted the same dose of cells into an uninjured sham group. In a final vehicle group, we transplanted only media with no cells one week following injury. After 12 weeks, we assessed the survival of the transplanted cells and the overall volume of the lesion. Although the survivability of the cells was not significantly different between intra and perilesional groups, there was greater cell survival in the inujred groups compared to non injured control. This suggests that engraftment of cells was not adversely by the PBBI lesion milleu. The injury environment after one week may be conducive to transplanted stem cells in terms of survivability and/or proliferation. PBBI-injured animals that received perilesional hNSC engraftments showed a significant reduction in lesion volume compared to animals that received intralesional hNSC transplants [Unijured + hNSC= 2.64- 0.68mm3; PBBI+ Vehicle = 64.35 - 4.48mm3; PBBI+ Perilesional hNSC= 27.57 - 3.78mm3; PBBI+ Intralesional hNSC= 55.74 - 4.77mm3]. The lesion volume was significantly less in the perilesional transplant group when compared to the vehicle group ($p < .05$ vs. PBBI + Vehicle). Both transplant groups had reduced lesion volume compared to vehicle group.

5182. Spurlock, M., et al. (2013). "Focal neurodegeneration in rat following penetrating ballistic-like brain injury despite acute global metabolic pathophysiology." Journal of neurotrauma **30**(15): A16.

Introduction Penetrating traumatic brain injury (PTBI) is associated with the worst outcomes in TBI. The aim of our study is to document the effects of PBBI on cerebral vascularity, glucose uptake and oxygen consumption (VO2 at 2.5h) and their translation into neuronal degeneration (at 24h). Methods For each experiment, male Sprague-Dawley rats were allocated to control (n = 5) or PBBI groups (n = 6-10) 1) Unilateral PBBI model: A burrhole was made in the right frontal skull, and computed-inflatable probe inserted and inflated (140psi/40ms). 2) 14C-2-deoxy Glucose (2-DG) autoradiography: 2 h post PBBI, radioactive 14C-2-deoxy-D-glucose (50lCi) was administered and serial blood samples taken over 45 minutes and estimated using scintillation counter. Brain sections were exposed to X-ray films. Signals were digitalized and analyzed using densitometry with custom software. 3) Vascular imaging: Fluorescent lectin was perfused from the ascending aorta, at 2.5h, or 24 h after injury, brains were cleared and imaged using Ultramicroscopy. Labeling was quantified by 3D rendered volume reconstructions of cerebral vessels. 4) VO2: 2.5 h after PBBI, animals were perfused with glucose phosphate buffer. Cortex samples were assessed by microrespirometery. 5) FJB Histopathology: Brain sections were stained with Fluoro-Jade B (FJB), a marker for neuronal degeneration, and stereologically assessed. Results Compared to control, at 2 h post PBBI global decrease of glucose utilization and oxygen consumption were observed (1) Global glucose uptake: PBBI; MEAN± SEM; 44.9 ± 0.5µmol/100g/min, Control; 75.2 ± 0.9 µmol/100g/min; $p < 0.05$. A radial gradient of glucose impairment was observed, with the most severe impairment at the lesion core. However, at 24 h post PBBI degenerating neuron incidence caused by primary injury was limited to the focal injury core and peri-injury area: PBBI ipsilateral 128583 ± 27160 cells, PBBI contralateral 3711 ± 1148 cells, $p < 0.001$. Decreased vascular labeling volume was also observed in the ipsilateral hemisphere compared to the contralateral hemisphere: ipsi 2.18E + 10 µm3; contra 6.23E + 10 µm3. An inverse relationship between cerebral metabolism (glucose uptake, oxygen consumption) and FJB labeling along the rostro-caudal axis was observed. Conclusions In PBBI, global 2-DG suppression was consistent with the area of lowered cerebral perfusion pressure (CPP), based on labeling of vasculature with lectin and previous literature on CPP. Thus it could be one possible cause of globally impaired metabolism. The areas with perfect overlap of impaired metabolism and focal FJB labeling appear to be the primary, unsalvagable injury. In contrast, large swathes of brain with acutely impaired metabolism experience significantly less neurodegeneration, appearing to be the salvageable hypoxia/ischemic ''penumbra.'' In the clinic, metabolic preservation via circulatory manipulation may improve PTBI outcomes.

5183. Spurlock, M. S., et al. (2017). "Amelioration of Penetrating Ballistic-Like Brain Injury Induced Cognitive Deficits after Neuronal Differentiation of Transplanted Human Neural Stem Cells." Journal of neurotrauma **34**(11): 1981-1995.

Penetrating traumatic brain injury (PTBI) is one of the major cause of death and disability worldwide. Previous studies with penetrating ballistic-like brain injury (PBBI), a PTBI rat model revealed widespread perilesional neurodegeneration, similar to that seen in humans following gunshot wound to the head, which is unmitigated by any

available therapies to date. Therefore, we evaluated human neural stem cell (hNSC) engraftment to putatively exploit the potential of cell therapy that has been seen in other central nervous system injury models. Toward this objective, green fluorescent protein (GFP) labeled hNSC (400,000 per animal) were transplanted in immunosuppressed Sprague-Dawley (SD), Fisher, and athymic (ATN) PBBI rats 1 week after injury. Tacrolimus (3 mg/kg 2 days prior to transplantation, then 1 mg/kg/day), methylprednisolone (10 mg/kg on the day of transplant, 1 mg/kg/week thereafter), and mycophenolate mofetil (30 mg/kg/day) for 7 days following transplantation were used to confer immunosuppression. Engraftment in SD and ATN was comparable at 8 weeks post-transplantation. Evaluation of hNSC differentiation and distribution revealed increased neuronal differentiation of transplanted cells with time. At 16 weeks post-transplantation, neither cell proliferation nor glial lineage markers were detected. Transplanted cell morphology was similar to that of neighboring host neurons, and there was relatively little migration of cells from the peritransplant site. By 16 weeks, GFP-positive processes extended both rostrocaudally and bilaterally into parenchyma, spreading along host white matter tracts, traversing the internal capsule, and extending ~13 mm caudally from transplantation site reaching into the brainstem. In a Morris water maze test at 8 weeks post-transplantation, animals with transplants had shorter latency to platform than vehicle-treated animals. However, weak injury-induced cognitive deficits in the control group at the delayed time point confounded benefits of durable engraftment and neuronal differentiation. Therefore, these results justify further studies to progress towards clinical translation of hNSC therapy for PTBI.

5184. Spurlock, M. S., et al. (2014). "Multineurotrophin expressing fetal cell transplant in penetrating ballistic brain injury (PBBI)." Journal of neurotrauma **31**(12): A110.

The purpose of this pilot study was to evaluate survival of genetically modified fetal cell transplants in PBBI. FDA approved naïve human fetal spinal cord neural stem cells were transplanted into Sprague Dawley (SD), Fischer344, or Athymic SD rats. Male rats were subjected to PBBI and two weeks later allocated to: Group1: no transplant, Group2: xenogeneic transplant. These groups were immunosuppressed via tacrolimus, mycophenylate, and depo-medrol. In Group 3, SD rat E14 cortical neural precursors lentivirally transduced to express multineurotrophin (MNTS1) were transplanted into PBBI injured SD rats. Group 3 was immunosuppressed with cyclosporine. Cells were microinjected into the peri-lesion region (400,000/rat). The brains were sectioned and assessed for cell specific markers for differentiation and immune response. The human-to-rat transplant rejection at 1 week was comparable to that in Fischer and Athymic at 4 weeks. All xenogeneic transplants were rejected by 8 weeks. In the allogeneic rat-to-rat MNTS-1 expressing transplant group, a robust graft spanning a millimeter square developed. Neurite lengths at week 1 were ~150 micron, and by week 8 extended 3 millimeters from the transplant to engraft the lesion. Varicosities suggestive of synaptic densities on neurites could be seen. Most grafted cells labeled with neural markers while few labeled ambiguously with glial markers. The pilot data indicates that the inflammation response of PBBI and lack of sufficient growth factors mediate rejection of transplanted naive stem cells. However, with appropriate growth factor enhancement, allogeneic fetal transplants can survive and develop in the PBBI model. Transduction of human cells with MNTS1 should allow for their engraftment in athymic rats. These transplants can then be evaluated for safety and therapeutic efficacy.

5185. Spyropoulos, N. D. and S. Anagnostopoulou (1991). "Unusual trajectory of a bullet trapped in the temporal area." Oral surgery, oral medicine, and oral pathology **71**(2): 253-255.

5186. Squire, L. R., et al. (1989). "Description of brain injury in the amnesic patient N.A. based on magnetic resonance imaging." Experimental neurology **105**(1): 23-35.

N.A. has been amnesic since 1960 when at the age of 22 years he sustained a penetrating brain injury with a miniature fencing foil. The amnesia primarily affects verbal material and occurs in the absence of other detectable cognitive deficits. Previous CT scans demonstrated a lucency in the region of the left mediodorsal thalamic nucleus, but no additional damage was revealed. Beginning in 1986 when he was 48 years old, N.A. was evaluated with a series of magnetic resonance imaging (MR) studies. Three major areas of damage were identified. In the left thalamus there is a prominent 3- to 4-mm-wide linear lesion that approximates the position and orientation of the internal medullary lamina. The defect extends for approximately 20 mm anteroposteriorly and likely involves the rostral group of intralaminar nuclei (central medial, paracentral, central lateral, rhomboid, and reuniens nuclei), the caudal group of intralaminar nuclei (centrum medianum and parafascicular nuclei), the ventral aspect of the mediodorsal nucleus, and the ventral lateral and ventral anterior nuclei. It also likely interrupts the trajectories of the mammillothalamic tract and

postcommissural fornix. The posterior hypothalamus is markedly disrupted and the mammillary nuclei appear to be missing bilaterally. Finally, the right anterior temporal lobe is damaged for a distance of about 3.5 cm from the pole to midway through the amygdaloid complex. This damage probably occurred during exploratory neurosurgery done at the time of N.A.'s injury. The hippocampal formation appears intact on both sides. A comparison of these findings with those from other patients with diencephalic amnesia suggests that amnesia can result when several diencephalic structures are damaged conjointly, including the internal medullary lamina, the intralaminar nuclei, the mediodorsal nucleus, and the mammillothalamic tract. Whether amnesia as severe as N.A.'s would result from selective damage to any one of these structures remains to be determined.

_____

5187. Squire, L. R. and R. Y. Moore (1979). "Dorsal thalamic lesion in a noted case of human memory dysfunction." Annals of neurology **6**(6): 503-506.

The extensively studied patient N.A. has had a severe verbal memory deficit since 1960, when he sustained a stab wound to the brain with a miniature fencing foil. His amnesia occurs in the absence of any other known cognitive defect. Recent CT scans have localized a lesion in the left dorsal thalamus of this patient in a position corresponding to the dorsomedial nucleus; there is no radiographic evidence of other damage in the diencephalon or cerebral cortex. The dorsomedial thalamus may be critical in the neuropathology of diencephalic amnesia and, in humans, may be required for normal memory functions.

5188. Sreenivasan, V. and C. O. H. S. Nobleza (2018). "Challenges and ethical issues in the course of palliative care management for people living with advanced neurologic diseases." Annals of palliative medicine **7**(3): 304-319.

In the recent years, there has been an increase in awareness with regards to the role of palliative care (PC) in management of neurologic diseases. In 1996, the need to incorporate PC in the care for patients with neurologic conditions was recognized by the American Academy of Neurology (AAN) Ethics and Humanities Subcommittee. The gaps in research, education and the ability to deliver adequate PC were then acknowledged by the National Academy of Sciences with their publication of "Approaching death: improving care at the end of life" and most recently, continued goals in improving PC was highlighted by another recent publication "Dying in America: improving quality and honoring individual preferences near the end of life". The complexity of managing neurologic patients brings about challenges and ethical issues in this setting. The aim of this review is to discuss and summarize the challenges and ethical issues in the context of PC management of patients with advanced acute, rapidly progressive, slowly-progressive or degenerative neurological conditions that are commonly encountered in practice.

5189. Srienc, A., et al. (2018). "Is Electroconvulsive Therapy a Treatment for Depression Following Traumatic Brain Injury?" Innovations in clinical neuroscience **15**(3-4): 43-46.

Traumatic brain injury (TBI) can be caused by blunt or penetrating injury to the head. The pathophysiological evolution of TBI involves complex biochemical and genetic changes. Common sequelae of TBI include seizures and psychiatric disorders, particularly depression. In considering pharmacologic interventions for treating post-TBI depression, it is important to remember that TBI patients have a higher risk of seizures; therefore, the benefits of prescribing medications that lower the seizure threshold need to be weighed against the risk of seizures. When post-TBI depression is refractory to pharmacotherapy, electroconvulsive therapy (ECT) could provide an alternative therapeutic strategy. Data remain sparse on using ECT in this seizure-prone population, but three case reports demonstrated good outcomes. Currently, not enough evidence exists to provide clinical recommendations for using ECT for treating post-TBI depression, and more research is needed to generate guidelines on how best to treat depression in TBI patients. However, the preliminary data on using ECT in patients with TBI are promising. If proven safe, ECT could be a powerful tool to treat post-TBI depression.

5190. Srihawan, C., et al. (2016). "Clinical Characteristics and Predictors of Adverse Outcome in Adult and Pediatric Patients With Healthcare-Associated Ventriculitis and Meningitis." Open forum infectious diseases **3**(2): ofw077.

Background. Healthcare-associated meningitis or ventriculitis is a serious and life-threatening complication of invasive neurosurgical procedures or penetrating head trauma. Methods. We performed a retrospective study of adults and children with the diagnosis of healthcare-associated meningitis or ventriculitis, as defined by the 2015 Centers of

Disease Control and Prevention case definition, at 2 large tertiary care hospitals in Houston, Texas from July 2003 to November 2014. Patients were identified by infection control practitioners and by screening cerebrospinal fluid samples sent to the central laboratory. We collected data on demographics, clinical presentations, laboratory results, imaging studies, treatments, and outcomes. Results . A total of 215 patients were included (166 adults and 49 children). A positive cerebrospinal fluid culture was seen in 106 (49%) patients, with the majority of the etiologies being Staphylococcus and Gram-negative rods. An adverse clinical outcome was seen in 167 patients (77.7%) and was defined as death in 20 patients (9.3%), persistent vegetative state in 31 patients (14.4%), severe disability in 77 patients (35.8%), or moderate disability in 39 patients (18.1%). On logistic regression analysis, age >45 years (adjusted odds ratio [OR], 6.47; 95% confidence interval [CI], 2.31-18.11; P <= .001), abnormal neurological exam (adjusted OR, 3.04; 95% CI, 1.27-7.29; P = .013), and mechanical ventilation (adjusted OR, 5.34; 95% CI, 1.51-18.92; P = .01) were associated with an adverse outcome. Conclusions . Healthcare-associated meningitis or ventriculitis is associated with significant morbidity and mortality.

5191. Srihawan, C., et al. (2017). "Healthcare-Associated Meningitis or Ventriculitis in Older Adults." Journal of the American Geriatrics Society **65**(12): 2646-2650.

BACKGROUND/OBJECTIVES: Healthcare-associated meningitis or ventriculitis (HCAMV) is a serious and life-threatening complication of invasive neurosurgical procedures or penetrating head trauma. Older adults are at higher risk of adverse outcomes in community-acquired meningitis but studies of HCAMV are lacking. Therefore, we perform the study to define the differences in clinical outcomes between older and younger adults with HCAMV., DESIGN: Retrospective study., SETTING: A large tertiary care hospital in Houston, Texas, from July 2003 to November 2014., PARTICIPANTS: Adults with a diagnosis of HCAMV (N = 160) aged >=65 (n = 35), aged 18-64 (n = 125)., MEASUREMENTS: Demographic characteristics, clinical presentation, laboratory results, treatments, and outcomes (Glasgow Outcome Scale)., RESULTS: Older adults had more comorbidities and CSF abnormalities [pleocytosis, high cerebrospinal fluid (CSF) protein, low CSF glucose) and were more likely to have altered mental status than younger adults (P < .05). An adverse clinical outcome was seen in 142 participants (89%) (death (n = 18, 11%), persistent vegetative state (n = 26, 16%), severe disability (n = 68, 43%), moderate disability (n = 30, 19%). There was no difference in adverse outcomes between older (97%) and younger (86%) adults (P = .13). On logistic regression analysis, abnormal neurological examination (adjusted odds ratio (aOR) = 7.13, 95% confidence interval (CI) = 2.15-23.63, P = .001) and mechanical ventilation (aOR = 11.03, 95% CI = 1.35-90.51, P = .02) were associated with adverse clinical outcomes., CONCLUSION: Older adults with HCAMV have more comorbidities and CSF abnormalities and are more likely to have altered mental status than younger adults but have similar high rates of adverse clinical outcomes.

5193. Sri-Pathmanathan, R. (1990). "The mobile X-ray image intensifier unit in maxillofacial surgery." The British journal of oral & maxillofacial surgery **28**(3): 203-206.

The removal of foreign bodies in the maxillofacial region is often a tedious and time consuming process. The image intensifier, which is a standard piece of hospital equipment, facilitates and expedites this surgical procedure and minimises disfigurement. In addition the image intensifier can be useful in the surgical treatment of maxillofacial trauma. Some applications of such use are illustrated with clinical examples. The use of the image intensifier is presented highlighting the advantages to both patient and clinician in the reduction of radiation exposure, cost effectiveness and saving of time in maxillofacial surgical work.

5194. Srirangam, R., et al. (2012). "Unusual intraorbital foreign body." BMJ case reports **2012**.

A case of a 41-year-old patient presenting late post-trauma with out any major signs or symptoms is presented herewith. On radiological investigation, a peculiar foreign body was identified in the orbital floor. To our surprise the point of entry of the foreign body was not proportionate with the size of it. Moreover, the trajectory and final location of foreign body did not concur with the symptom less presentation of patient. After what was thought to be adequate

investigation, the patient was taken under general anaesthesia to reveal an additional foreign body that put most of the preoperative queries to rest. This case in retrospect emphasises the need for ruling out foreign body in the case of any penetrating injury of orbit with the help of not just radiographs and CT scans but also ultrasonography and MRI.

5195. Srivastava, A. K. and C. S. Cox (2018). Traumatic brain injury. **139:** 1-14.

Traumatic brain injury (TBI) is a common, complex, and costly condition. It is a multidimensional and highly complex condition and an important cause of disability and mortality all around the world. To date, there are no effective treatments available that are able to mitigate subacute injuries and improve long-term functional recovery in TBI. A major reason that several experimental treatments for TBI have failed in the past is the appreciation that TBI is not a single acute event but chronic and progressive tissue damage. Better understanding of the anatomy and pathophysiology of brain injuries, new biomarkers, advanced neuroimaging, and the reorganization of trauma systems have led to a significant reduction in deaths and disability resulting from TBI. In this chapter, we discuss the pathophysiology, classification, clinical presentation, and diagnosis of this condition.

5196. Stack, B. C., Jr. and J. B. Farrior (1995). "Missile injuries to the temporal bone." Southern medical journal **88**(1): 72-78.

Gunshot injuries to the head and neck are frequently seen in patients brought to a level I trauma center. These injuries result in great morbidity and mortality and a significant expenditure of health care dollars. Missile injuries to the temporal bone, though less common, can likewise be devastating. Common sequelae include vertigo, deafness, facial nerve paralysis, and death. A series of missile injuries to the temporal bone treated at Tampa General Hospital during 1993 prompted a review of head and neck missile injuries in our trauma registry over the past 4 years (1989 to 1993). More than 100 patients were shot in the head or neck; 25 of them had injury to the temporal bone. Outcomes included facial nerve injury (8), deafness (9), vertigo (3), and death (13).

5197. Stack, S. and I. Wasserman (2008). "Social and racial correlates of Russian roulette." Suicide & life-threatening behavior **38**(4): 436-441.

The epidemiology of a neglected form of suicidal behavior, Russian roulette, is addressed. Also tested is an explanation of racial differences based on the opportunity theory of deviant behavior related to the availability of revolvers, necessary weapons with which to play Russian roulette. Data refer to 15 cases of Russian roulette found through a search of the medical examiner's suicide files (N = 1,412) and 75 matched controls who suicided by a gunshot to the head. The results support an opportunity perspective: 80% of the Russian roulette victims were African American compared to 30.7% of the controls. Further, among the controls, Blacks were three times more likely than Whites to use revolvers in suicides, a pattern indicating Blacks' greater access to revolvers. Russian roulette victims were entirely male, significantly younger, and less apt to be married than the control group.

5198. Stajcic, Z. and V. Konstantinovic (1997). "Galeal skin island flap in the reconstruction of scalp defects caused by missile injuries." International journal of oral and maxillofacial surgery **26**(5): 331-335.

The use of the galeal skin island flap pedicled either on the superficial temporal or occipital vessels for coverage of scalp defects following neurosurgical treatment of cranial missile injuries, is presented. This technique was applied in seven consecutive patients. The defect was closed in all patients, however, only in three without complications. Indications, advantages and disadvantages of the treatment described are discussed.

5199. Stalder, M. W., et al. (2013). "Versatility of subscapular chimeric free flaps in the secondary reconstruction of composite posttraumatic defects of the upper face." Craniomaxillofacial Trauma and Reconstruction **8**(1): 42-49.

High energy injuries to the upper face present challenging reconstructive problems. In some cases, initial reconstructive efforts result in unfavorable outcomes that require secondary intervention. Chimeric free flaps based on the subscapular system offer the tissue components and volume needed for these complex reconstructions. This is a series of five patients who underwent secondary reconstruction of the middle and upper face following traumatic injury. Mechanism of injury, prior attempts at reconstruction, and characteristics of the tissue defects and the flaps used in

their reconstruction are described. Two patients were female and three were male. Three injuries resulted from gunshot wounds, and two from motor vehicle accidents. All patients had multiple prior failed attempts at reconstruction using local/regional tissue. Defects included symptomatic oronasal or oro-orbital fistulas, enophthalmos, and forehead contour deformities. Two of the flaps used included scapular bone and latissimus muscular components, and three included scapular bone and thoracodorsal artery perforator-based skin paddle components. All free tissue transfers were successful, and no patients suffered significant complications. Chimeric free flaps based on the subscapular system offer a valuable secondary strategy for reconstruction of composite defects of the upper face when other options have been exhausted through previous efforts.

5200. Stallmeyer, M. J. B., et al. (2006). "Imaging of traumatic neurovascular injury." Radiologic clinics of North America **44**(1): 13-vii.

Traumatic injury to the major vessels of the head and neck can result in potentially devastating neurologic sequelae. Until recently, conventional angiography was the primary imaging modality used to evaluate these often challenging patients. Advances in cross-sectional imaging have improved the ability to screen for these lesions, which have been found to be more common than previously thought; however, accepted protocols of imaging evaluation have not yet been fully established. This article presents a general approach to the patient with suspected neurovascular injury. This includes a discussion of the histopathologic spectrum, clinical presentation, mechanisms, radiologic work-up, pertinent issues of the most common lesions, and some of the endovascular techniques used in their management.

5201. Stanbouly, D. and S. K. Chuang (2022). "What Factors Influence the Hospitalization of Self-Inflicted Craniomaxillofacial Gunshot Wounds?" Craniomaxillofacial Trauma and Reconstruction.

Study Design and Objectives: The purpose of this retrospective cohort study is to compare the hospitalization outcomes of managing maxillofacial trauma attempted suicide among handguns, shotguns, and hunting rifles. Materials and Methods: The following retrospective cohort study was competed using data from the Nationwide Inpatient Sample a database from the Healthcare Cost and Utilization Project (HCUP). The primary predictor variable was the type of firearm. The outcome variables were the hospital charges (U.S. dollars) and length of stay (days). We used SPSS version 25 for Mac (IBM Corp., Armonk, NY, USA) to conduct all statistical analyses. Results: A final sample of 223 patients was statistically analyzed. Relative to patients within the Q2 median household income quartile, patients in the Q4 median household income quartile added +$ 172’609 (P <.05) in hospital charges. Relative to patients living in “central” counties of metro areas, patients in micropolitan counties added +13.18 days (P <.05) to the length of stay. Relative to patients in the Q2 median household income quartile, patients in Q3 added +9.54 days (P <.05) while patients in Q4 added +11.49 days (P <.05) to the length of stay. Conclusions: Being within the highest income quartile was associated with increased hospital charges. Patients living in micropolitan counties have prolonged hospitalization relative to patients in metropolitan counties. Relative to the second income quartile, length of stay was higher in the third income quartile and highest in the fourth income quartile. Increase income grants access to deadlier firearms.

5202. Stanec, Z., et al. (1993). "High-energy war wounds: flap reconstruction." Annals of plastic surgery **31**(2): 97-102.

In this article, we emphasize that knowledge of terminal ballistics is essential for understanding the pathophysiology of war wounds. We present our own experiences in treatment of high-energy war wounds in 75 patients treated in the Institute of Plastic and Reconstructive Surgery, Department of Surgery, Clinical Hospital Center in Zagreb. Patients were divided into three groups with regard to the time of definite reconstruction, using local or free microvascular flaps. About 12% of patients underwent flap reconstruction in the acute phase, associated with low complication rate and the shortest hospital stay. Group II was comprised by 18% of the patients and, considering the number of complications, presented the most unfavorable time for reconstruction. Flap reconstruction in the chronic phase resulted in a substantial prolongation of the hospital stay in 82% of patients. Therefore, we advocate proper primary treatment of wounds aimed at early flap closure. This type of management results in a significantly shorter hospitalization and leads to more effective rehabilitation and recovery of patients.

5203. Stanitsas, L., et al. (2016). "If the initial head CT of a trauma patient on antithrombotics is negative, is a second ct necessary?" Critical care medicine. Conference: 46th critical care congress of the society of critical care medicine, SCCM **44**(12 Supplement 1): 466.

Learning Objectives: Studies have indicated delayed intracranial bleeding in patients on chronic oral antithrombotic agents. However, there is a lack of literature addressing aspirin. Few studies have addressed the need for a repeat head computed tomography (CT) after an initial negative head CT in patients on antithrombotics. We hypothesized that patients taking antithrombotics with an initial negative head CT would not have a delayed ICH on a repeated head CT. Methods: Data were retrospectively collected from the trauma registry and electronic medical records at a level 1 trauma center. Patients were included if: seen by Trauma Services 7/1/14-12/31/14, had a blunt mechanism of injury, were taking antithrombotics, and had evidence of cranial/facial injury with a negative initial head CT. Patients were excluded if they were <18 years old or had penetrating head trauma. Results: Seventy-one patients were included. The average age was 77.4 years, ISS 6.7, and GCS 14.6. Mechanism of injury was falls, 80.3%, vehicular 18.3%, and 1.4% other. Twenty-one patients were on warfarin, 10 clopidogrel, 30 aspirin, 3 apixaban, 1 dabigatran, and 6 dual therapy. Seven patients died (1 apixaban, 3 warfarin, 2 aspirin, 1 dual) from other injuries/ co-morbidities. Older patients were more likely to die compared to younger (p=0.009). No patients demonstrated a delayed bleed on a repeat head CT. Conclusions: Patients prescribed antithrombotic agents with evidence of cranial/ facial injury and an initial negative head CT did not demonstrate a delayed bleed on repeated head CT. Discussion will consider implications of this study, but a repeat head CT may not be necessary.

5204. Stanley, R. B., Jr. (1999). "Use of intraoperative computed tomography during repair of orbitozygomatic fractures." Archives of facial plastic surgery **1**(1): 19-24.

OBJECTIVE: To assess the practicality and potential benefits of intraoperative computed tomography using a mobile scanner in the operating room during repair of orbitozygomatic fractures., SETTING: Level I trauma center., DESIGN: Twenty-five patients undergoing open reduction of a unilateral displaced fracture of the zygoma and/or repair of a blow-out fracture of the orbit with cranial bone grafts were placed into a radiolucent head holder and interfaced with the mobile scanner. Spatial vectors were drawn on scans displayed on a computer monitor to allow intraoperative side-to-side comparison of the position of the malar prominences and orbital walls. Corrections of fracture reduction or bone graft position were made as indicated by the comparisons., RESULTS: All scans were accomplished without apparent contamination of the surgical field. Major revisions were performed, based on the scans, in 2 patients whose displaced, comminuted zygoma fractures had been initially reduced with wide exposure of all fracture sites. Minor revisions were performed in 3 patients with displaced but less severely comminuted fractures that had been reduced without exposure of all fracture sites. Bone grafts were repositioned within the orbit in 2 patients with large 2-wall blow-out fractures., CONCLUSIONS: Intraoperative computed tomographic evaluation of the adequacy of repair of orbitozygomatic fractures is feasible with the mobile computed tomographic scanner. The scanner allows correction of discrepancies in position of the malar prominences and orbital walls at the time of acute repair, rather than during costly, more difficult delayed revisions. It may eliminate the need for direct visualization of all fracture sites to ensure adequate reduction in selected cases with displaced, comminuted fractures, thus decreasing operating room time and expense. Further study is required to fully document the cost-effectiveness of this approach to facial fracture management.

5205. Staples, J. A., et al. (2016). "The application of IMPACT prognostic models to elderly adults with traumatic brain injury: A population-based observational cohort study." Brain injury **30**(7): 899-907.

OBJECTIVE: To examine the performance of the International Mission for Prognosis and Clinical Trial Design in Traumatic Brain Injury (IMPACT) prognostic models in older patients., METHODS: Using data from the National Study on Costs and Outcomes of Trauma (NSCOT), this study identified adult patients presenting to US hospitals in 2001 and 2002 with non-penetrating moderate or severe traumatic brain injury (GCS <= 12). IMPACT model calibration and discrimination in the older stratum (65-84 years) was compared to that in the younger stratum (18-64 years)., RESULTS: IMPACT model discrimination did not differ significantly between the older (n = 202; weighted n = 268) and younger strata (n = 613; weighted n = 1632) and was generally adequate (c-statistic for the core-death model = 0.81 [0.77-0.84] vs 0.75 [0.66-0.84], respectively; p = 0.26). IMPACT model calibration was poor for both older and younger strata (Hosmer-Lemeshow p-value for the core-death model = 0.01 vs < 0.0001, respectively). Pre-specified qualitative graphical evaluation suggested substantial under-prediction of mortality in the oldest decades of life, but not among

younger patients., CONCLUSIONS: The examined IMPACT prognostic models demonstrated adequate discrimination and poor calibration in both older and younger patients, yet particular caution may be required when applying these models to the elderly.

5206. Starchenko, A. A., et al. (1994). "[The immune reactions of the cerebrospinal fluid in victims of gunshot wounds of the skull and brain in relation to the treatment procedure and outcome]." Immunnye reaktsii tserebrospinal'noi zhidkosti u postradavshikh s ognestrel'nymi raneniiami cherepa i golovnogo mozga v zavisimosti ot taktiki i iskhoda lecheniia.(1): 23-26.

The paper shows the formation of immunopathological syndromes in the cerebrospinal fluid in the victims with gunshot wounds in relation to the policy and outcome of treatment. Suturing the dura mater during a primary surgical treatment should be regarded as a protective process to limit antigen release, the development of immunological paralysis and autoimmunization. Deaths are caused by the neurogenic immune dysfunction induced by the inadequate functioning of the psychoneuroimmunoendocrine connections of the whole body.

5207. Starnes, B. W. and Z. M. Arthurs (2006). "Endovascular management of vascular trauma." Perspectives in vascular surgery and endovascular therapy **18**(2): 114-129.

Over the past several decades, catheter-based and endovascular techniques have been used with increasing frequency for the management of trauma. This is particularly true for the management of solid organ injury and vascular injuries resulting from pelvic fracture with the use of embolization techniques for successful arrest of active hemorrhage. Likewise, there is a large body of literature regarding the management of acute traumatic vascular injuries involving traditional open surgical techniques. Currently, however, there is sparse literature on the management of vascular trauma with endovascular techniques. The endovascular management of vascular trauma seems particularly appealing in the management of blunt truncal injuries, especially in the setting of severe concomitant brain and lung injury. Extremity and neck injuries are probably best handled by traditional methods of surgical proximal and distal control, the exception to this being base of skull injuries where there is no ability for distal vessel control, and "watershed" areas between the trunk and extremities where proximal vascular control can be quite difficult. This chapter reviews current literature with regard to the endovascular management of traumatic vascular injuries with regions being broadly defined as neck, trunk, and extremity.

5208. Starosta, A. J., et al. (2021). "Scoping Review of Opioid Use After Traumatic Brain Injury." The Journal of head trauma rehabilitation **36**(5): 310-327.

OBJECTIVE: To summarize the current literature to identify what research has been conducted, examine the approaches used, and determine what is presently known about prescription and nonprescription opioid receipts and use among individuals with traumatic brain injury (TBI)., DATA SOURCES: The search strategy included the following: opioid; opiate; analgesics, opioid; opiate alkaloids; or opioid-related disorders; AND brain injury; brain injuries; brain injuries, traumatic; head injury; head injuries; head injuries, closed; head injuries, penetrating; brain concussion; diffuse axonal injury; diffuse axonal injuries; brain trauma/s; head trauma/s; concussion; craniocerebral trauma/s; or TBI. Filters included English and Adults (19+ years). Study Selection: Inclusion: English language, adults with stable TBI, and prescription opioid receipt or use after TBI. Exclusion: Animal models, populations with other acquired brain injury, acute TBI management, and non-peer-reviewed articles, theses, or conference abstracts. Multiple reviewers screened abstracts and full-text articles for eligibility. In total, 771 abstracts were screened, 183 full texts were reviewed, and 21 met eligibility criteria. Data Extraction: Relevant content was independently extracted by multiple observers, including authors, design, sample identification and data source/s, TBI severity, TBI assessment, opioid assessment, study population (demographics, N), military affiliation, comparison groups, date of data collection, and summary of findings., RESULTS: Studies were published between 1987 and 2019; most data were collected prior to 2015. The majority utilized administrative and electronic medical record data from the Department of Veterans Affairs and retrospective cohort designs, and most focused on prescription opioids. There were no studies evaluating interventions to reduce use of opioids in TBI populations. Preliminary findings suggest that prescription opioid receipt is strongly related to psychological symptoms, including comorbid depression, anxiety, and posttraumatic stress disorder., CONCLUSIONS: Despite increased awareness of opioid receipt and use following TBI, there is limited investigation on the examination of

this issue. Future studies should include more varied patient populations as well as evaluate interventions to reduce opioid use following TBI.

5209. Starr, M. R., et al. (2018). "String Technique for Anterior Orbital Fish Hook Removal." Ophthalmic plastic and reconstructive surgery **34**(4): e136-e137.

Removing fish hooks is a common procedure performed by many emergency department providers. There are several techniques that are commonly employed to aid in successful removal. However, when a fish hook becomes embedded within the orbit, there are limited options as to avoid damaging vital surrounding structures. The authors report the removal of a fish hook within the anterior orbit using the string technique in a 25-year-old patient. The procedure was performed under general anesthesia with the aid of size 5 polyglactin suture wrapped around the hook. The procedure itself took less than 10 seconds and was successful in swiftly and safely removing the hook without damaging surrounding orbital structures. The patient recovered well without any permanent sequelae.

5210. Stavrakas, M. and D. Rachovitsas (2017). "Splinting the external auditory canal." Trauma (United Kingdom) **19**(3): 228.

5211. Staworn, D., et al. (1994). "Brain death in pediatric intensive care unit patients: incidence, primary diagnosis, and the clinical occurrence of Turner's triad." Critical care medicine **22**(8): 1301-1305.

OBJECTIVES: To determine the incidence and characteristics of children with brain death in the pediatric intensive care unit (ICU), and to assess the incidence of the clinical triad (Turner's triad) of central diabetes insipidus, low glucose demand, and low CO2 production., DESIGN: Retrospective review of medical records., SETTING: Two multidisciplinary pediatric ICUs., PATIENTS: Medical records of pediatric patients declared brain dead and admitted to two multidisciplinary pediatric ICUs., MEASUREMENTS AND MAIN RESULTS: Patient records were reviewed for demographic data, primary diagnosis, severity of illness (Pediatric Risk of Mortality score and calculated risk of mortality), methods by which brain-death diagnosis was determined, presence of central diabetes insipidus, low glucose demand, low CO2 production in the final 24 hrs before the diagnosis was made, and whether organ donation was accomplished. The incidence of brain death among all patients admitted to the pediatric ICUs was 0.9%, accounting for 11% of patients who died during the same period. The most common presentation leading to brain-death diagnoses was trauma, followed by drowning/near drowning, and meningitis. The majority of brain-death diagnoses were made using both clinical criteria and confirmatory tests (66%). The incidence of clinical signs of Turner's triad was 41% for central diabetes insipidus, 49% for low glucose demand, and 53% for low CO2 production. Two of the three features were present in 38% of patients, and 12% of the patients had all three features., CONCLUSIONS: Our series of brain-dead patients in the pediatric ICU showed a 0.9% incidence of brain death. The most common primary diagnosis was trauma, a finding that is similar to other series. We also demonstrated that the clinical triad (Turner's triad) is present in this patient population, although only 12% of study patients demonstrated all three features.

5212. Steel, B. J., et al. (2022). "A 10-year study of penetrating head and neck injury by assault in the North East of England." Oral and maxillofacial surgery **26**(2): 213-222.

INTRODUCTION: Assaults inflicting penetrating head and neck trauma have potential for serious morbidity or mortality. This paper studies in-depth all cases treated at a level one trauma centre in the North East of England over 10 years., METHODS: All patients assaulted with sharp implements to the head and neck treated from 2010 to 2019 were identified using clinical codes., RESULTS: Retrospective data collection were as follows: 214 patients identified (189 male, 25 female). Average age was 31.5 years (range 3-80). The majority presented between 20:00 and 05:00. Knives were the commonest weapon. Fifty-two had scalp, 137 face and 69 neck injuries. Forty-eight percent had additional non-head and neck injuries. Eighty-six percent required admission, 16.6% to intensive care. Oral and maxillofacial and plastic surgeons provided most treatment. One hundred two required treatment under general and 96 local anaesthetic. Sixteen patients had significant vascular injury, 1 brachial plexus injury, 4 facial nerve injuries (of which 3 repaired) and one required parotid duct repair. Mean length of stay was 3.7 days. No mortality was recorded. Incidence significantly increased from 2010 to 2019., CONCLUSIONS: Head and neck penetrating injuries occur frequently, often with other injuries and mainly in young males. Incidence of significant vascular or nerve injury was low. This study provides

important data for those planning trauma services. Copyright © 2021. The Author(s), under exclusive licence to Springer-Verlag GmbH Germany, part of Springer Nature.

5213. Steen, T., et al. (2015). "Intracranial Injuries from Dog Bites in Children." Pediatric neurosurgery **50**(4): 187-195.

BACKGROUND/AIMS: Infants are especially at risk for intracranial injuries from dog bites due to their small stature and thin skull. Only 21 case reports have been published in the literature. We aim to add knowledge and treatment recommendations based on a more substantial sample., METHODS: Ten pediatric patients with a penetrating skull injury as a result of a dog bite, treated at our institution between 1992 and 2010, were identified and analyzed descriptively. A literature review of the 21 case reports was also conducted., RESULTS AND CONCLUSION: Early diagnosis and treatment can prevent complications from hemorrhage or infections. Based on our results, we recommend obtaining a head CT for all victims sustaining injuries to the head, early use of broad spectrum antibiotics, debridement and irrigation of tissue, and follow-up to identify late infectious complications. Copyright © 2015 S. Karger AG, Basel.

5214. Steenburg, S. D. and C. W. Sliker (2012). "Craniofacial gunshot injuries: an unrecognised risk factor for blunt cervical vascular injuries?" European radiology **22**(9): 1837-1843.

OBJECTIVES: To review our institutional experience with cervical arterial injuries remote from the penetrating tract seen in the setting of craniofacial gunshot injuries., METHODS: Institutional Review Board approval was obtained. Our institutional trauma registry was queried over a 5-year period for patients with cervical arterial injuries due to penetrating craniofacial gunshot wounds who underwent CT angiography. Imaging results and clinical notes were reviewed., RESULTS: A total of 427 patients sustained gunshot wounds to the head, face and/or neck, of whom 222 underwent CT angiography yielding 56 patients with 78 vascular injuries. There were five internal carotid artery injuries remote from the wound tract. The incidence of these "indirect" cervical arterial injuries in our patient population was 1.2%, or 2.8% of patients who underwent CT angiography., CONCLUSIONS: The incidence of "indirect" cervical arterial injuries with craniofacial gunshot wounds is comparable to or slightly higher than those seen in pure blunt trauma. Screening patients with craniofacial gunshot injuries with CT angiography may yield unexpected cervical vascular injuries remote from the penetrating tract. The significance and optimal therapy of these injuries are unknown. Additional experience will be needed to determine the significance of "indirect" cervical arterial injuries in the setting of craniofacial gunshot wounds.

5215. Stein, D. G., et al. (2008). "Does progesterone have neuroprotective properties?" Annals of emergency medicine **51**(2): 164-172.

In this article, we review published preclinical and epidemiologic studies that examine progesterone's role in the central nervous system. Its effects on the reproductive and endocrine systems are well known, but a large and growing body of evidence, including a recently published pilot clinical trial, indicates that the hormone also exerts neuroprotective effects on the central nervous system. We now know that it is produced in the brain, for the brain, by neurons and glial cells in the central and peripheral nervous system of both male and female individuals. Laboratories around the world have reported that administering relatively large doses of progesterone during the first few hours to days after injury significantly limits central nervous system damage, reduces loss of neural tissue, and improves functional recovery. Although the research published to date has focused primarily on progesterone's effects on blunt traumatic brain injury, there is evidence that the hormone affords protection from several forms of acute central nervous system injury, including penetrating brain trauma, stroke, anoxic brain injury, and spinal cord injury. Progesterone appears to exert its protective effects by protecting or rebuilding the blood-brain barrier, decreasing development of cerebral edema, down-regulating the inflammatory cascade, and limiting cellular necrosis and apoptosis. All are plausible mechanisms of neuroprotection.

5216. Stein, K. M., et al. (2000). "Detection of gunshot residues in routine CTs." International journal of legal medicine **114**(1-2): 15-18.

The forensic assessment of non-fatal gunshot wounds often proves to be difficult as wounds have usually been cleaned and protected with a sterile bandage by the time of the examination. The aim of our investigation was to test the possible application of computed tomography (CT) for the forensic assessment. Doing so raised the questions

whether gunshot residues in the soft tissues, detected by means of 3-dimensional CT, can be used as evidence of a close-range shot and whether conclusions can be drawn pertaining to the range of the shot or the type of bullet used based on the distribution of the radiologically detectable material? In this experimental study 39 shots were fired at fresh pig skin and it was possible to distinguish shots fired from distances of more than 10 cm and contact shots independent of the type of bullet. For unjacketed lead bullets, radiopaque material could be seen in the depth of the entrance would for firing distances up to 10 cm. In individual cases, CT data and the 3-D reconstruction could provide valuable information in the forensic assessment of patients with gunshot wounds.

5218. Steiner, M., et al. (1997). "Myositis ossificans traumatica of the masseter muscle: review of the literature and report of two additional cases." Oral surgery, oral medicine, oral pathology, oral radiology, and endodontics **84**(6): 703-707.

Myositis ossificans traumatica of the masseter muscle is uncommon. The condition is benign and results in reactive heterotopic bone formation, usually producing limitation of opening of the jaws. Radiographic and microscopic examination can confirm the diagnosis. Treatment of myositis ossificans traumatica of the masseter muscle is surgical, with other modalities used when occurring in other muscles of the body.

5219. Steinfath, M., et al. (1994). "[Implications of concomitant therapy with psychotropic drugs in emergency care. Discussion of current literature with reference to a case report]." Bedeutung einer bestehenden Therapie mit psychotropen Pharmaka in der Notfallversorgung. Diskussion der aktuellen Literatur anhand eines Fallberichts. **29**(3): 180-183.

This case report deals with an acute psychotic suicidal patient who stabbed two nail-scissors straight into his eyes. The extent of the trauma was unknown primarily during emergency treatment, and an intracranial trauma had to be considered. Furthermore, there was no information on the patient's history including medical therapy or abuse of psychotropic drugs like monoamine oxidase inhibitors, tri- or tetracyclic antidepressants, neuroleptic agents, or lithium salts which could have consequences for subsequent drug administration. The emergency aid management of psychotic patients with the possibility of both an intracranial trauma and an existing psychotropic drug therapy is discussed in this case report.

5221. Stendel, R., et al. (1997). "The relationship between cortical injury and brain tumour. Report of two cases and review of the literature." Acta neurochirurgica **139**(3): 208-214.

We report on two cases of brain tumour and discuss the possible relationship to previous cortical trauma. The first patient, a 67-year-old male patient developed a glioblastoma at the same site of an open shell-splinter injury of the brain after a latency of 48 years. The second patient, a 55-year-old male, had a malignant anaplastic astrocytoma in the right frontal lobe 10 years after clipping of an aneurysm of the anterior communicating artery. Both cases fulfill the criteria of Zulch [52] for the correlation between cortical trauma and tumour. We believe that the development of a brain tumour following a cortical injury is very rare, although possible. Probably the brain must display some form of predisposing genetic alteration for a tumour to develop following a cortical injury.

5223. Stephanov, S. (1999). "Severe craniocerebral injury by an axe with good outcome: case report." Swiss surgery = Schweizer Chirurgie = Chirurgie suisse = Chirurgia svizzera **5**(2): 80-82.

We report a young patient who was operated on for a penetrating slow impact craniocerebral injury in the left frontal region caused by an axe. The patient was admitted comatose, with right hemiplegia. The blade of the axe was embedded deeply into his head. A craniectomy was carried out around the axe blade and it was removed easily. The cerebral wound was 6 cm long in horizontal plane and about 7 cm deep. Significant amount of contused and necrotic brain tissue was aspirated. The patient showed an uneventful recovery.

5224. Stephens, F. L., et al. (2010). "Cranioplasty complications following wartime decompressive craniectomy." Neurosurgical focus **28**(5): E3.

OBJECT: In support of Operation Iraqi Freedom (OIF) and Operation Enduring Freedom-Afghanistan (OEF-A), military neurosurgeons in the combat theater are faced with the daunting task of stabilizing patients in such a way as to prevent irreversible neurological injury from cerebral edema while simultaneously allowing for prolonged transport stateside (5000-7000 miles). It is in this setting that decompressive craniectomy has become a mainstay of far-forward neurosurgical management of traumatic brain injury (TBI). As such, institutional experience with cranioplasty at the Walter Reed Army Medical Center (WRAMC) and the National Naval Medical Center (NNMC) has expanded concomitantly. Battlefield blast explosions create cavitary injury zones that often extend beyond the border of the exposed surface wound, and this situation has created unique reconstruction challenges not often seen in civilian TBI. The loss of both soft-tissue and skull base support along with the need for cranial vault reconstruction requires a multidisciplinary approach involving neurosurgery, plastics, oral-maxillofacial surgery, and ophthalmology. With this situation in mind, the authors of this paper endeavored to review the cranial reconstruction complications encountered in these combat-related injuries., METHODS: A retrospective database review was conducted for all soldiers injured in OIF and OEF-A who had undergone decompressive craniectomy with subsequent cranioplasty between April 2002 and October 2008 at the WRAMC and NNMC. During this time, both facilities received a total of 408 OIF/OEF-A patients with severe head injuries; 188 of these patients underwent decompressive craniectomies in the theater before transfer to the US. Criteria for inclusion in this study consisted of either a closed or a penetrating head injury sustained in combat operations, resulting in the performance of a decompressive craniectomy and subsequent cranioplasty at either the WRAMC or NNMC. Excluded from the study were patients for whom primary demographic data could not be verified. Demographic data, indications for craniectomy, as well as preoperative, intraoperative, and postoperative parameters following cranioplasty, were recorded. Perioperative and postoperative complications were also recorded., RESULTS: One hundred eight patients (male/female ratio 107:1) met the inclusion criteria for this study, 93 with a penetrating head injury and 15 with a closed head injury. Explosive blast injury was the predominant mechanism of injury, occurring in 72 patients (67%). The average time that elapsed between injury and cranioplasty was 190 days (range 7-546 days). An overall complication rate of 24% was identified. The prevalence of perioperative infection (12%), seizure (7.4%), and extraaxial hematoma formation (7.4%) was noted. Twelve patients (11%) required prosthetic removal because of either extraaxial hematoma formation or infection. Eight of the 13 cases of infection involved cranioplasties performed between 90 and 270 days from the date of injury ($p = 0.06$)., CONCLUSIONS: This study represents the largest to date in which cranioplasty and its complications have been evaluated in a trauma population that underwent decompressive craniectomy. The overall complication rate of 24% is consistent with rates reported in the literature (16-34%); however, the perioperative infection rate of 12% is higher than the rates reported in other studies. This difference is likely related to aspects of the initial injury pattern-such as skull base injury, orbitofacial fractures, sinus injuries, persistent fluid collection, and CSF leakage-which can predispose these patients to infection.

5225. Stephens, S., et al. (2019). "Traumatic brain injuries in a paediatric neurosurgical unit: A Queensland experience." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **70**: 27-32.

Traumatic brain injury (TBI) is a leading cause of morbidity and mortality in children with a broad injury spectrum and associated continuum in the level of care required. A dearth of data exists regarding children requiring inpatient neurosurgical admission following TBI. A retrospective study of children 0-16years-old admitted to the neurosurgical unit of a level-1 paediatric trauma hospital in Queensland, Australia following TBI was conducted focusing on the demographics, clinical characteristics, and management of these patients to guide those involved in their management, and identify areas for improvement in injury prevention and trauma system management. Over 48months, 671 patients were identified (62.6% male) with median age 5.0years, the majority transferred from

peripheral centres. Falls (47.2%) and traffic accidents (21.5%) were the most common mechanisms. Non-displaced skull fracture was the most common injury. Moderate or severe TBI (GCS 3-12) was seen in 14.8% of whom were more likely to require surgery, intensive care, or suffer polytrauma. Clinically significant TBI, defined as moderate/severe TBI, polytrauma, death, requiring neurosurgery, intensive care admission, intubation, or admission three or more nights was detected in 57.97% with higher rates in transferred patients (62.9%) versus primary presentations (50.6%). Mechanisms involving low kinetic forces especially low-height falls and children with non-surgical pathology were less likely to meet criteria for clinically significant TBI. Opportunity exists to optimise triage and transfer practices within the trauma network to minimise the economic and social implications of over-triage with many children requiring only brief observation.

5227. Stepien, J., et al. (2004). "[Orbital trauma inflicted by a butcher's knife without any injury of the eyeball]." Uraz oczodolu bez zranienia galki ocznej zadany nozem rzezniczym. **106**(4-5): 664-665.

We present a 25 year old man, who suffered from an apparently serious orbital injury inflicted by a butcher's knife during a fight. The knife perforated the upper lid of the right eye, and than penetrated the orbita along its medial wall into the right maxillary sinus, the ethmoid sinus, finally reaching the left maxillary sinus. The eye bulb, as well as the optic nerve and the muscles remained intact. A major hemorrhage from the nasal cavity, which occurred immediately after the extraction of the knife, was managed successfully by means of anterior and posterior nasal packing. Intranasal synechias developed in the days following the injury, leading to obstruction of the nasal cavities. The synechias were later almost entirely eliminated through appropriate treatment, leaving the patient with practically no complications of this dramatic injury.

5228. Sternbergh, W. C., Jr., et al. (1971). "Bullet within the fourth ventricle. Case report." Journal of neurosurgery **34**(6): 805-807.

5229. Stevens, J. R. and J. Brennan (2016). "Management of Battlefield Injuries to the Skull Base." Journal of Neurological Surgery, Part B: Skull Base **77**(5): 430-438.

High velocity skull base injuries on the battlefield are unique in comparison to most civilian sector trauma. With more than 43,000 United States military personnel injuries during Operations Iraqi Freedom (OIF) and Enduring Freedom (OEF), the most recent conflicts in Iraq and Afghanistan have significantly expanded the understanding of the physiology of modern battlefield trauma and how to appropriately address these injuries. The acute care principles of effective triage, airway management, and hemorrhage control in these injuries can be life saving and are reviewed here. Specific injury patterns and battlefield examples are reviewed as well, with a review of some of the lessons learned while providing care in a deployed setting. Utilization of the knowledge learned in Iraq and Afghanistan, which have improved casualty care of deployed service members, can be used both in future military conflicts and in civilian trauma care.

5230. Stevens, M. R., et al. (1998). "The use of osseointegrated implants in craniofacial trauma." The Journal of cranio-maxillofacial trauma **4**(1): 27-34.

The objective in treating patients with injuries sustained in craniofacial trauma is to reinstate preinjury facial projection and function. The capability of providing spatially related facial reconstruction is predicated on basic craniofacial surgical principles, generally accepted as the standard of care. These principles include early surgical intervention, immediate bone grafting, and the use of internal rigid fixation. The introduction of osseointegrated dental implants has significantly improved the overall reconstruction of patients with cranio-maxillofacial injuries, including soft tissue repair and cosmetic surgery. The purpose of this article is to review the utilization of dental implants in the context of maxillofacial trauma, using three cases to document the clinical procedure.

5231. Stewart, C. M. (1983). "Nursing management of gunshot wounds to the head." Journal of neurosurgical nursing **15**(5): 277-282.

5232. Stiernberg, C. M., et al. (1992). "Gunshot wounds to the head and neck." Archives of otolaryngology--head & neck surgery **118**(6): 592-597.

Gunshot wounds to the head and neck contribute to substantial medical, economic, and social problems in the United States today. The treatment of these patients requires the contemporary head and neck surgeon to be precisely informed in anatomy, wound ballistics, resuscitation, and surgical decision making. Ninety recent cases at the University of Texas Health Science Center affiliated hospitals in Houston were reviewed and are reported. Data show substantial trends in patient demographics and corroborate other reports in the trauma literature. Controversies in patient management continue, but current evidence favors a protocol of selective surgical exploration.

5233. Stievenart, J. L., et al. (1993). "A survey of different high resolution visualization modes of a volumetric object with applications." Surgical and radiologic anatomy : SRA **15**(1): 47-54.

In view of the variety of 3D representation techniques, a clinical study was carried out in order to evaluate their respective usefulness. It appears that a single technique cannot be claimed to be valid for all clinical situations and that a combination of representations brings more relevant information. Among the different techniques a clear delineation must be established between those which allow the accurate definition of landmarks (multiplanar reformation, surface representation), and those which do not (integral shading, reconstructed radiology). The main point is the possibility to recognize anatomical landmarks on these latter modes and to choose oblique cut planes in relation to them. Visualization quality is strongly dependent upon the acquisition protocol which must provide a spatial resolution as isotropic as possible.

5234. Stocchetti, N., et al. (2008). "Bryan Jennett and the field of traumatic brain injury. His intellectual and ethical heritage in neuro-intensive care." Intensive care medicine **34**(10): 1774-1778.

William Bryan Jennett, one of the leading figures in neurosurgery of the twentieth century, has died on 26 January 2008, at the age of 81. He made fundamental contributions to the field of traumatic brain injury (TBI) that still shape diagnosis, management and prognosis worldwide, in the second part of the last century. This paper is meant to gratefully acknowledge his contributions and to reflect on the implications that his work has for neurointensive care today. Starting from his early steps, we tried to highlight his fundamental work on diagnosis of severity in TBI, on rescue, treatment and prognosis of severe TBI. Moreover, his contribution in the definition of vegetative state, minimally conscious state and brain death has been emphasized. The contribution of Professor Bryan Jennett was in fact seminal in many aspects: the application of a common language in brain damage evaluation, where GCS and GOS are now universally employed; a critical approach to TBI diagnosis and treatment, in the search of proven better therapies; a quantitative approach to TBI prognosis, based on large clinical series and appropriate statistics; a strong commitment to the ethical implication of survival after severe injury, including the vegetative status; social responsibility in the diagnosis of brain death and in organ donors procurement. For these reasons, he can be considered one of the leading figures in neurosurgery and neurology of the twentieth century. This paper is meant to gratefully acknowledge his contributions and to reflect on the implications that his work has for neuro-intensive care today.

5235. Stocker, R. and O. Wruhs (1995). "[An unusual case of gunshot wound to the head]." Ein besonderer Fall einer Kopfschussverletzung. **21**(6): 298-302.

We are going to present a special case of head injury caused by a gunshot. In this case it resulted in a fracture of the skull, but the bullet did not penetrate the skull. It was deflected by the bone, leaving the body at an angle. But bone fragments, acting as secondary bullets, penetrated the brain. In spite of a massive cerebral trauma and brain injury, no retrograde amnesia could be diagnosed. The patient recovered to such an extent, that he could return to his former job. Special characteristics of head injuries caused by bullets will be referred to.

5236. Stockhausen, S., et al. (2017). "Homicide-suicide, double suicide or homicide followed by suicide 2 case reports." Archiv fur Kriminologie **239**(3-4): 87-98.

Cases in which several persons who died from an unnatural cause are found together are often difficult. It is necessary to exclude homicide committed by another person and to clarify whether the deaths are the result of a homicide-suicide or a joint suicide of persons wishing to die. Two cases in which couples with gunshot wounds to the head had been found lifeless in their homes are presented. In both cases, the deceased were of advanced ages and suffered from severe pre-existing diseases. Due to the circumstances at the scene, the results of the investigations and the autopsies as well as the suicide notes found, a double suicide was assumed in both cases. The husbands killed themselves after shooting their wives. Based on the presented cases the so-called double suicide and the need for a thorough investigation of the death scene with the problem of differentiating it from homicide-suicide and double homicide are discussed.

5237. Stockmann, P., et al. (2007). "Conventional radiographs: are they still the standard in localization of projectiles?" Oral surgery, oral medicine, oral pathology, oral radiology, and endodontics **104**(4): e71-75.

The penetration of air gun pellets in facial soft tissue can cause major problems during the removal of foreign bodies, although conventional radiography, computed tomography, image-guided surgical removal, and ultrasound have been applied to facilitate the procedure. It was the aim of the present case report to introduce a modified intraoperative method for the localization of air gun pellets, based on the use of radiopaque markers in conventional radiographs. A 66-year-old patient attempted to commit suicide by using an air gun. The pellet hit the right temporal region. A computed tomographic (CT) scan was acquired to localize the foreign body. The first attempt to remove the pellet through the penetrating wound failed. Because of a dislodgement of the pellet, the CT scan could no longer be used for the localization of the air gun pellet. As the air gun pellet was positioned under the zygomatic arch, ultrasound was unable to identify its position. Successful intraoperative localization of the projectile was performed after fixation of radiopaque markers to the skin in the region of the estimated localization, with conventional radiographs in 2 planes, acquired with a mobile dental x-ray device. Although the markers remained attached to the patient as reference makers, the air gun pellet was removed easily. The use of radiopaque markers in conventional radiographs in 2 planes allows fast, intraoperative localization of radiopaque foreign bodies within soft tissue. The procedure can be carried out with a conventional x-ray device that should be available in every oral and maxillofacial practice. The use of reference markers should be considered a standard procedure for the localization of radiopaque foreign bodies in the head and neck.

5238. Stoffel, M., et al. (2009). "Cerebral gunshot wounds: a score based on three clinical parameters to predict the risk of early mortality." ANZ journal of surgery **79**(11): 789-793.

BACKGROUND: To provide a score to predict the risk of early mortality after single craniocerebral gunshot wound (GSW) based on three clinical parameters., METHODS: All patients admitted to Baragwanath Hospital, Johannesburg, South Africa, between October 2000 and May 2005 for an isolated single craniocerebral GSW were retrospectively evaluated for the documentation of (i) blood pressure (BP) on admission; (ii) inspection of the bullet entry and exit site; and (iii) initial consciousness (n= 214)., RESULTS: Conscious GSW victims had an early mortality risk of 8.3%, unconscious patients a more than fourfold higher risk (39.2%). Patients with a systolic BP between 100 and 199 mm Hg had an 18.2% risk of mortality. Hypotension (<100 mm Hg) doubled this risk (37.7%) and severe hypertension (> or =200 mm Hg) was associated with an even higher mortality rate of 57.1%. Patients without brain spilling out of the wound ('non-oozer') exhibited a mortality of 19.7%, whereas it was twice as high (43.3%) in patients with brain spill ('oozer'). By logistic regression, a prognostic index for each variant of the evaluated parameters could be established: non-oozer:0, oozer:1, conscious:0, unconscious:2, 100 < or =RR(sys) < 200 mm Hg:0, RR(sys) < 100 mm Hg:1, RR(sys)>/= 200 mm Hg:2. This resulted in a score (0-5) by which the individual risk of early mortality after GSW can be anticipated., CONCLUSIONS: Three immediately obtainable clinical parameters were evaluated and a score for predicting the risk of early mortality after a single craniocerebral GSW was established.

5239. Stoiber, J., et al. (2002). "[Amniotic membrane transplantation with limbal stem cell transplantation as a combined procedure for corneal surface reconstruction after severe thermal or chemical burns]." Amnion-Limbus-Transplantation zur Oberflachenrekonstruktion nach schwerer Veratzung und Verbrennung. **99**(11): 839-848.

BACKGROUND: Severe thermal and chemical burns may result in limbal deficiency leading to persistent epithelial defects, complete conjunctival epithelial ingrowth and vascularisation of the cornea. If sufficiently severe, these burns may lead to very significant visual impairment. Amniotic membrane transplantation with limbal transplantation has recently been proposed as a new method for corneal surface reconstruction., PATIENTS AND METHODS: A total of 14 patients (age 18-62 years, mean age 42 years) with limbal deficiency resulting from thermal (n=1) or chemical burns (n=13) underwent surgery. The corneal pannus was completely removed and the amniotic membrane was grafted onto the cornea. Limbal transplantation using autografts obtained from contralateral eyes was performed simultaneously in seven cases. Allografts from a donor were transplanted in seven cases with bilateral involvement. These patients received oral cyclosporin A postoperatively. The mean follow-up time was 18 months., RESULTS: In all cases of limbal autografts the corneal surface showed a complete and stable epithelialisation within a few weeks. Out of seven patients with limbal allografts three displayed recurrent epithelial defects in the long term. The initially semitransparent amniotic membrane became more translucent and biomicroscopically invisible within several months after surgery. There was an increase in visual acuity in most cases, limited mostly by irregular astigmatism due to the initial stromal loss., CONCLUSIONS: Amniotic membrane transplantation with limbal transplantation allows reconstruction ocular surfaces severely damaged by chemical or thermal burns. In most cases, however, additional surgical procedures such as lamellar or penetrating keratoplasty are required for adequate visual rehabilitation.

5240. Stokely, M. E. and E. L. Orr (2008). "Acute effects of calvarial damage on dural mast cells, pial vascular permeability, and cerebral cortical histamine levels in rats and mice." Journal of neurotrauma **25**(1): 52-61.

UNLABELLED: Neurological complications after mild head injury can include vasogenic edema and/or subsequent development of epilepsy, conditions associated with elevated histamine. In the present study we assessed the potential of mast cells located in the dura mater to contribute to elevated cortical histamine and breakdown of the blood-brain barrier after minor head injury, modeled by either a parietal craniectomy or producing a groove in (scoring) the parietal bone surface to model a grazing head injury. We measured the following effects at 5-20 min after a unilateral parietal craniectomy (rats) or unilateral scoring of the parietal bone (mice): (1) mast cell integrity in subjacent dura mater; (2) subjacent vs. contralateral histamine in dura mater and cerebral cortex; (3) vascular permeability of cerebral cortical blood vessels subjacent to the injury, and; (4) the effects of an H(2)-receptor antagonist on cerebral cortical vascular permeability., RESULTS: Dural mast cells subjacent to the craniectomy became activated (degranulated) concomitant with (1) decreased histamine in dura mater subjacent to the craniectomy; (2) increased histamine in the subjacent cerebral cortex; and (3) extravasation of Evans blue-albumin which stained the subjacent cerebral cortex, indicating a localized breakdown of the blood-brain barrier. Similar results were observed in mice after scoring the parietal bone surface and, additionally, pretreatment with the histamine H(2)-receptor antagonist zolantadine (1 h before injury) dose-dependently inhibited extravasation of Evans blue-albumin. We conclude that even a minor grazing injury of the skull, in the absence of penetrating brain injury or concussion, can activate dural mast cells and elevate cortical histamine, a novel mechanism with potential contributions to neurotraumatic complications arising from a relatively minor or grazing head wound.

5241. Stone, J. A., et al. (1997). "Gunshot wounds of the brain: Influence of ballistics and predictors of outcome by computed tomography." Emergency radiology **4**(3): 140-149.

Gunshot wounds of the head commonly are encountered in the practice of emergency radiology. Radiologists play a vital role in the initial evaluation of patients who present after a gunshot injury and can guide the neurosurgeon's approach to surgery and the forensic pathologist's collection of evidence. It is useful to understand the ballistics that influence missile course and wound potential for accurate assessment of injury patterns that occur in gunshot wounds to the head. Additionally, it is imperative to recognize important prognostic findings on computed tomographic imaging to ensure optimal management of the patient.

5242. Stone, J. L., et al. (1981). "Traumatic subdural hygroma." Neurosurgery **8**(5): 542-550.

The authors report a series of 80 cases of traumatic subdural hygroma and discuss the clinical and radiological features, management, surgical results, and pathogenesis. Changes in mental status without focal signs of brain damage were noted in over 50% of the cases. A clinical course marked by stabilization without complete recovery of neurological function was found in over 40% of the cases of "simple hygroma." The lumbar cerebrospinal fluid often showed

hemorrhage and elevation of the protein content. Skull fractures were found in 39% of the cases, and subdural hygromas were associated with cerebral atrophy, cortical contusions, subdural hematomas, and overlying epidural hematomas. The characteristic angiographic and computed tomographic scan findings are discussed, as are surgical pathology and outcome. Several theories of pathogenesis are presented. The authors advocate simple burr hole drainage as the treatment of choice. Significant reaccumulation may occur occasionally.

5243. Stone, J. L., et al. (1995). "Demographics of civilian cranial gunshot wounds: devastation related to escalating semiautomatic usage." The Journal of trauma **38**(6): 851-854.

The demographics and outcome of patients with gunshot wounds to the head over the past 10 years at Chicago's Cook County Hospital was examined. The study group consisted of 476 consecutive patients admitted to this urban level I trauma center with a diagnosis of penetrating craniocerebral missile injury. All patients followed a protocol that included aggressive surgical management when indicated. The Glasgow Outcome Score was used to assess outcome. There is an alarming rise in firearm violence in general and craniocerebral injury in particular. Some patients with severe neurologic deficits and massive cerebral damage can benefit from aggressive treatment and make a good recovery. A large proportion of this violence is most likely attributable to gang activity. Factors correlating with poor outcome included hypotension, apnea, bihemispheric injuries, or ventricular penetration. Although aggressive surgical and medical management improves the outcome of these patients, much more stringent preventative measures are required to control this violent epidemic.

5244. Stone, J. L., et al. (1996). "Civilian cases of tangential gunshot wounds to the head." The Journal of trauma **40**(1): 57-60.

A series of 168 civilian cases of tangential gunshot wounds to the head is presented. Neurologic deficits on presentation were generally minimal. Computed tomographic (CT) scans were performed in 51% of patients, and abnormal CT findings were noted in 35% (18% of all patients). Major operative procedures were required in 9% of the patients. Serious sequelae of tangential injuries are described even with patients who initially have no neurologic abnormality. We suggest that a CT scan is warranted in all cases of tangential gunshot wounds to the head.

5245. Story, C., et al. (2016). "A Rare Case of Penetrating Trauma Resulting in Isolated Third Nerve Palsy." Neuro-Ophthalmology **40**(1): 32-36.

A 23-year-old male presented to the emergency department with right eye pain, right upper eyelid ptosis, blurry vision, and binocular diplopia that developed immediately after he bent over in a parking lot and the antenna of a car penetrated his right upper eyelid. An extensive workup was performed, and he was found to have an isolated traumatic oculomotor nerve palsy with pupil involvement. No other ocular findings of a traumatic injury were present. The patient was observed for 14 months, during which he continually improved, with almost complete resolution of his diplopia, anisocoria, and ptosis.

5246. Stosic, S., et al. (2005). "[Microvascular osteoseptocutaneous radial flap in reconstruction of mandible following war injury]." Vojnosanitetski pregled **62**(6): 429-434.

BACKGROUND: Vascularized osteoseptocutaneous radial flap is commonly used in the reconstruction of composite bony and soft tissue defects of the lower third of the face due to the outstanding quality of its cutaneous component. The aim was to evaluate the primary and overall success in the reconstruction of mandibular defects, following war injuries, with vascularized osteoseptocutaneous radial flap., METHODS: At the Department of Maxillofacial Surgery of the Military Medical Academy Belgrade, there were eight patients with this kind of defect following war injury, and the mandible was reconstructed with a vascularized osteoseptocutaneous radial flap. Bony compartment of the graft was harvested as up to 11 cm long segment of radial circumference., RESULTS: The localization and structure of the defect, features of a harvested compound graft, the procedure of the reestablishment of the mandibular continuity was presented as well as immediate and late complications during the consolidation period, and the primary successful reconstruction in 87.5% of the patients., CONCLUSION: The primary and overall success in the mandibular defects reconstruction with a vascularized osteoseptocutaneous radial flap was equal or even better than those presented in the literature on the reconstruction of the similar defects after tumor resections.

5248. Straka, L., et al. (2013). "A planned complex suicide by gunshot and vehicular crash." Forensic science international **228**(1-3): e50-53.

Complex suicide is usually defined as the application of more than one killing mechanism to ensure a fatal outcome. Herein we report an unusual case of a planned complex suicide of a 20 year old-male combining gunshot with coincidental intentional vehicular crash. The case was initially assumed to be a simple traffic accident until a rimfire pistol was found in close proximity to the deceased as well as gunshot wound of the head. This paper demonstrates the importance of careful inspection of the death scene, as well as the complex performance of autopsy examination to explain the manner of death and distinguish accidental deaths from suicides in such cases. Nevertheless, this assessment might by very difficult or even impossible. It has to be assumed that a high number of suicides in road traffic remain undetected.

5249. Strandvik, G., et al. (2020). "Rapidly fatal pneumococcal meningitis following non-penetrating traumatic brain injury." BMJ case reports **13**(2).

A previously healthy young man presented to hospital with severe traumatic brain injury following a motor vehicle collision. Within 24 hours of admission, and despite antibiotic coverage, he developed a fever. On the second day, the source of infection was discovered to be purulent pneumococcal meningitis. At 48 hours post-accident, he developed brain-stem death without evidence of raised intracranial pressure or trans-tentorial herniation. Initial CT scans of the head were essentially normal, but early repeat scans revealed evidence of pneumocephalus and possible frontal bone fracture. Current recommendations do not make room for targeted antibiotic prophylaxis in traumatic brain injury patients with traumatic skull fracture. We argue that our case demonstrates the need for aggressive targeted antibiotic prophylaxis in the presence of certain features such as frontal or sphenoid bone fracture and pneumocephalus.

5250. Strashun, A., et al. (1992). "Reversible increased technetium-99m-HMPAO cerebral cortical activity: a scintigraphic reflection of luxuriant hyperperfusion." Journal of nuclear medicine : official publication, Society of Nuclear Medicine **33**(1): 117-119.

A hemiparetic and aphasic patient, 3 days after acute traumatic transection of the left internal carotid artery requiring life-saving total embolic occlusion, revealed ipsilateral increased peripheral hemispheric 99mTc-HMPAO activity. Ten days postocclusion, HMPAO peripheral cortical flow normalized as hemiparesis and aphasia significantly cleared. The initial lateralized HMPAO hyperactivity pattern may reflect reactive hyperemia, a sign previously identified by contrast angiography and often associated with a better prognosis in evolving CVA. Evanescent peripheral cerebral hyperemia may represent beneficial cortical collateralization of the periinfarct area of a deeper lacunar (white matter) CVA.

5251. Strelzow, V. V. and W. S. Goodman (1978). "Nasoseptal perforation--closure by external septorhinoplasty." The Journal of otolaryngology **7**(1): 43-48.

The successful correction of perforations of the nasal septum is still difficult. This treatment has been greatly facilitated by the use of the external septorhinoplasty, without compromising the airway or causing cosmetic deformity. Supportive autogenous graft material is used routinely and bipedicled mucoperichondrial flaps are used when necessary. Seven consecutive patients have been successfully treated by this method.

5252. Strickland, R. D., et al. (1983). "Phenytoin-induced agranulocytosis after treatment for a gunshot wound to the face." Oral surgery, oral medicine, and oral pathology **56**(5): 500-501.

A case of phenytoin-induced agranulocytosis is presented. This syndrome is characterized by a decrease in the blood neutrophil count to very low levels. Patients are generally asymptomatic, but they may become febrile and develop an infection, which is frequently fatal. Practitioners treating trauma patients or other patients in whom phenytoin treatment is initiated should be aware of the potential development of agranulocytosis.

5253. Strohm, M. and D. Petersen (1987). "[Otogenic extradural pneumatocele, 36 years after a gunshot injury]." Otogene extradurale Pneumatozele, 36 Jahre nach Schussverletzung. **66**(1): 25-29.

In the reported case an extradural pneumatocele developed 36 years after the mastoid tip had been destroyed by a bullet. It had reached the occiput and led to destruction of the bone surrounding its distal end, so that air could be found directly under the galea. In the literature there are only few case reports referring the otogenic origin of a posttraumatic extradural pneumatocele. Furthermore, an overpressure in the middle ear cleft or mastoid could be excluded because of the presence of a tympanic membrane perforation. In spite of a chronically infected middle ear, there was no infection of the pneumatocele.

5254. Strojnik, T. (2004). "A review of civilian gunshot wounds to the head in northeast Slovenia: 1992 to 2002." Wiener klinische Wochenschrift **116 Suppl 2**: 19-23.

BACKGROUND: Surgical management of gunshot wounds to the head has remained a controversial issue. There are considerable regional differences in the causes of civilian gunshot wounds (GSW) to the head and various devices are used in different countries. The aim of our study was to review the demographic factors, treatment and outcome of patients with GSW to the head over the past 10 years at Maribor Teaching Hospital., PATIENTS AND METHODS: Thirty-seven patients with GSW to the head (35 male and 2 female; mean age 43.3 +/- 15.5 years) were included in the study. Clinical and radiological findings are described. Statistical analysis was used to find the effects of all independent variables on mortality and prognostic factors., RESULTS: The great majority (86.5%) of our patients suffered self-inflicted wounds. The weapon used was a stunning device in 54% of cases and a handgun in 46%. Alcohol consumption was documented in 40% patients. Nearly half (48.9%) of our patients were either industrial workers or farmers. Postresuscitation Glasgow Coma Scale (GCS) scores of 3-8 were recorded in 54%. The pupils were fixed and dilated in 32.4% of our patients; hypotension was documented in 8.1% and apnea in 27%. These parameters were significantly correlated with poor outcome. A bihemispheric lesion was found in 37.8%, a transventricular lesion in 54% and a multilobar lesion in 70.3% of patients. Those factors were also associated with poor outcome. The majority of patients (56.8%) underwent operation immediately, in 13.5% the operation was delayed and 29.7% of patients had no surgery. The overall mortality was 51.4%, a poor outcome was noted in 24.3% and a good one was achieved in 24.3%., CONCLUSION: The results of our study support previous ones stating that patients with GSW to the head can benefit from aggressive treatment and still make satisfactory recoveries. Clearly, there are ethical dilemmas involved in withholding operative treatment from any individual. Guidelines dictating when to surgically intervene must be made.

5255. Strub, W. M. and K. L. Weiss (2003). "Self-inflicted transorbital and intracranial injury from eyeglasses." Emergency radiology **10**(2): 109-111.

Orbital injuries are commonly seen in the emergency department, and if they are high-energy they can lead to concomitant intracranial injuries. Plain films, CT, MRI, and ultrasound are used in various combinations to evaluate the extent of these injuries. We describe a unique case of self-inflicted transorbital penetrating intracranial injury from the temporal wire rim of a pair of eyeglasses. Imaging well demonstrates the full course of the wire rim in situ, and pathoanatomic correlates are highlighted.

5256. Struckhoff, G. (1995). "Transforming growth factor beta 1 and parathyroid hormone-related protein control the secretion of dipeptidyl peptidase II by rat astrocytes." Neuroscience letters **189**(2): 117-120.

Meninges synthesize parathyroid hormone-related protein (PTHrP) and transforming growth factor (TGF beta 1). Both factors control the activity of the glial enzyme dipeptidyl peptidase II (DPP II): TGF beta 1 induces the secretion of enzyme activity by cultivated astrocytes in a dose dependent manner. The maximal effect is achieved with a concentration of 10 ng/ml and is dependent on the time of incubation. PTHrP itself has no effect on the release of DPP II

activity but considerably reduces the effect of TGF beta 1. It is assumed that DPP II influences the course of cicatrization after penetrating injuries of the brain and thus, meninges control glial scarring by the release of TGF beta 1 and PTHrP.

5258. Strunk, T., et al. (2014). "Infection-induced inflammation and cerebral injury in preterm infants." The Lancet. Infectious diseases **14**(8): 751-762.

Preterm birth and infectious diseases are the most common causes of neonatal and early childhood deaths worldwide. The rates of preterm birth have increased over recent decades and account for 11% of all births worldwide. Preterm infants are at significant risk of severe infection in early life and throughout childhood. Bacteraemia, inflammation, or both during the neonatal period in preterm infants is associated with adverse outcomes, including death, chronic lung disease, and neurodevelopmental impairment. Recent studies suggest that bacteraemia could trigger cerebral injury even without penetration of viable bacteria into the CNS. Here we review available evidence that supports the concept of a strong association between bacteraemia, inflammation, and cerebral injury in preterm infants, with an emphasis on the underlying biological mechanisms, clinical correlates, and translational opportunities.

5259. Stuehmer, C., et al. (2009). "Influence of different types of guns, projectiles, and propellants on patterns of injury to the viscerocranium." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **67**(4): 775-781.

PURPOSE: Gunshot injuries to the oral and craniomaxillofacial region vary with the type of gun used. Computed tomography (CT) is the standard diagnostic tool for assessing tissue damage in patients with gunshot injuries. Cone-beam computed tomography (CBCT) is a new imaging technique that has recently become available for clinical diagnosis. The objective of this study was to characterize injury patterns with a focus on gun types and identify the imaging modality that is best suited to assessing injuries caused by different gun types., PATIENTS AND METHODS: We present the cases of 14 patients who sustained gunshot injuries to the viscerocranium during the past 10 years. The injuries were caused by 8 basic combinations of handguns or long guns with soft lead core projectiles, partial or full metal-jacketed bullets, and different propellants. Diagnosis was based on clinical and radiological findings (including CT and CBCT)., RESULTS: We found a direct correlation between the gun/projectile combination on the one hand and the diameter of the wound track, tissue contamination, and tissue destruction on the other. Entrance and exit wounds are indicative of certain gun/projectile combinations. High-density projectiles cause severe artifacts in CT, unlike CBCT, making it difficult to evaluate anatomic structures in close proximity to the projectile., CONCLUSIONS: Every gun/projectile combination is associated with a typical pattern of injury. Even in the absence of the offending projectile, it is thus possible to narrow down the likely gun and/or projectile. In the diagnostic imaging of injuries caused by high-density projectiles, CBCT is more suitable than CT.

5260. Stuehmer, C., et al. (2008). "Cone beam CT imaging of airgun injuries to the craniomaxillofacial region." International journal of oral and maxillofacial surgery **37**(10): 903-906.

In airgun injuries, the removal of the projectile is often recommended. The material properties of airgun projectiles make it difficult to determine their precise anatomical location using conventional radiological techniques. Conventional X-rays give only a two-dimensional representation of projectiles and do not allow a foreign object to be located precisely. Multi-slice computed tomography (CT) has become a standard tool in diagnosis. Metal objects can cause artefacts in CT scans and make it difficult to identify adjacent anatomical structures. By contrast, cone-beam CT (CBCT) provides three-dimensional images largely free from metal artefacts. The authors present three cases of airgun injuries and discuss the diagnostic and treatment approaches used. CBCT has proved to be a useful diagnostic tool in planning the treatment of craniofacial airgun injuries. It is superior to CT in detecting hard-tissue structural damage in the immediate vicinity of high-density metal projectiles.

5261. Stuehmer, C., et al. (2008). "Intraoperative navigation assisted reconstruction of a maxillo-facial gunshot wound." Oral and maxillofacial surgery **12**(4): 199-203.

INTRODUCTION: This case report describes a suicidal gunshot wound to the head using a handgun (9 x 19 mm). During mandibular penetration, the solid hollow point projectile (Aktion4) was deformed but did not fragment. The mandible, mid-face, orbit, and nasal complex were severely damaged. Here, the authors present, for the first time, a new approach for bilateral mid-facial fractures., MATERIALS AND METHODS: For virtual reconstruction, a naso-orbito-ethmoidal complex of an unaffected skull (same age, sex, and ethnic group) was merged into the computed tomography (CT) data set. Based on this data set, a navigation assisted operation was performed., CONCLUSION: The favorable outcome leads us to recommend the technique of merging comparable CT data for reconstructive planning of bilateral mid-facial fractures.

5262. Sturdivant, N. M., et al. (2016). "Acetazolamide Mitigates Astrocyte Cellular Edema Following Mild Traumatic Brain Injury." Scientific reports **6**: 33330.

Non-penetrating or mild traumatic brain injury (mTBI) is commonly experienced in accidents, the battlefield and in full-contact sports. Astrocyte cellular edema is one of the major factors that leads to high morbidity post-mTBI. Various studies have reported an upregulation of aquaporin-4 (AQP4), a water channel protein, following brain injury. AZA is an antiepileptic drug that has been shown to inhibit AQP4 expression and in this study we investigate the drug as a therapeutic to mitigate the extent of mTBI induced cellular edema. We hypothesized that mTBI-mediated astrocyte dysfunction, initiated by increased intracellular volume, could be reduced when treated with AZA. We tested our hypothesis in a three-dimensional in vitro astrocyte model of mTBI. Samples were subject to no stretch (control) or one high-speed stretch (mTBI) injury. AQP4 expression was significantly increased 24 hours after mTBI. mTBI resulted in a significant increase in the cell swelling within 30 min of mTBI, which was significantly reduced in the presence of AZA. Cell death and expression of S100B was significantly reduced when AZA was added shortly before mTBI stretch. Overall, our data point to occurrence of astrocyte swelling immediately following mTBI, and AZA as a promising treatment to mitigate downstream cellular mortality.

5263. Stuss, D. T. and V. Anderson (2004). "The frontal lobes and theory of mind: developmental concepts from adult focal lesion research." Brain and cognition **55**(1): 69-83.

The primary objective in this paper is to present a framework to understand the structure of consciousness. We argue that consciousness has been difficult to define because there are different kinds of consciousness, hierarchically organized, which need to be differentiated. Our framework is based on evidence from adult focal lesion research. The different types of consciousness are associated with distinct brain regions, with the higher levels of consciousness related to self-awareness and theory of mind (both facets of consciousness), with an emphasis on the role of the frontal lobes. The secondary objective is to use this structure to suggest hypotheses about the potential effect of frontal dysfunction at various developmental stages, and including both congenital and acquired brain injury.

5264. Stylli, S. S., et al. (2000). "Induction of CD44 expression in stab wounds of the brain: long term persistence of CD44 expression." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **7**(2): 137-140.

We studied the expression of the hyaluronan receptor protein CD44 in the mouse brain in response to stab injuries. CD44 expression was strongly activated in the area surrounding the injury within 2 days and then persisted for over 2 months. The expression extended in a direct line the depth of the actual wound inflicted. It appears that CD44 may be involved in the wound healing processes following injury to the brain. 5265. Su, P., et al. (2021). "Trends in Operative Complex Middle and Upper Maxillofacial Trauma: A 17-Year Study." The Laryngoscope **131**(9): 1985-1989.

OBJECTIVES/HYPOTHESIS: Over 3 million incidents of facial trauma occur each year in the United States. This study aims to determine trends in operative middle and upper maxillofacial trauma in one of the largest US cities., STUDY DESIGN: Retrospective case-control study., METHODS: Retrospective chart review of all operative middle and upper maxillofacial trauma from July 1993 to July 2010 presenting to Los Angeles County Hospital, a Level I Trauma Center. Data included demographics, mechanism of injury, and fracture characteristics., RESULTS: Analysis was

performed for a total of 4,299 patients and 5,549 facial fractures. Mean patient age was 34.6, and most patients were male (88%). Between the two time periods (1993-2001 and 2002-2010), there was a 42% reduction in operative maxillofacial trauma (3,510 to 2,039). Orbital floor and zygomaticomaxillary complex fractures were the most prevalent types of fractures. Panfacial fractures demonstrated the largest reduction in number of fractures (325 to 5, P<0.01). Assault and motor vehicle accidents (MVA) were the two most common mechanisms of injury. Operative fractures due to MVAs decreased (390 to 214, P = .74), whereas fractures due to assault increased (749 to 800, P<0.01). Compared to adults, pediatric facial trauma (age < 18) were caused by a higher percentage of MVAs (27% vs. 13%), auto versus pedestrian (9% vs. 5%), and gunshot wounds (8% vs. 4%) (P<0.01)., CONCLUSIONS: Operative middle and upper maxillofacial trauma decreased over a 17-year period. Assault was the most significant mechanism of trauma overall. These trends suggest that focusing future prevention strategies on curtailing interpersonal violence may more effectively address the burden of facial trauma., LEVEL OF EVIDENCE: 3 Laryngoscope, 131:1985-1989, 2021.

5266. Suarez Pinilla, M. A., et al. (2000). "[Neurologic deficit secondary to shot wound in a hunting accident]." Deficit neurologico secundario a perdigonada por accidente de caza. **200**(12): 697-698.

5267. Subbotin, S. I., et al. (2000). "[The successful treatment of a penetrating gunshot wound of the skull and brain in a child]." Uspeshnoe lechenie ognestrel'nogo pronikaiushchego raneniia cherepa i golovnogo mozga u rebenka.(2): 25-27.

5268. Subke, J., et al. (2001). "[Gunshot reconstructions based on individually parametrical 3-dimensional victim models]." Schussrekonstruktionen anhand individuell parametrisierbarer dreidimensionaler Opfermodelle. **208**(3-4): 72-79.

In cases of lethal firearm injuries computer enhanced anatomical feasibility studies can provide unambiguous clues concerning self-versus extraneous infliction. To this end individualized digital 3-dimensional geometrical models of the victim and the weapon are generated true to scale with the help of the CAD software (POSER Version 4, egi.sys AG). All anatomical data relevant to the motion apparatus and the range of movement as well as the injuries of the individual victim are carefully documented and serve as input parameters for the digital geometrical model. The bullet path is visualized as a cylinder between entrance and exit wound. A series of simulation sequences then can be carried out by the variation of anatomically possible shot positions and the virtual grasp of the weapon. An exact alignment of the firearm's barrel and the bullet path is a reliable statement for the feasibility of self-infliction. In addition to circumstantial evidence the digital reconstruction of the firearm shot admits of unambiguous conclusions about the course of the traumatic event.

5269. Subke, J., et al. (2002). "[Fatal craniocerebral trauma in a young child. I: Forensic documentation, model generation and geometric impact conditions]." Todliches Schadelhirntrauma bei einem Kleinkind. Teil I: Forensische Dokumentation, Modellgenerierung und geometrische Impactbedingungen. **209**(5-6): 147-157.

The aim of forensic biomechanics is the reconstruction of traumatic events based on the pathological findings in the victim's morphology and on the traces and shapes of the traumatizing tools. The introduction of Streifenlichttopometrie into forensic science enables 3-dimensional and proportionally accurate documentation of the victim's body and injuring agent with submillimeter precision. The advantages of this method of documentation are the possibilities of producing animated models which correspond exactly to the body's shape and injury topography, and of ascertaining the physical parameters (centers of mass, moments of inertia) of the various body parts and the geometrical impact conditions for the reconstruction of the injury dynamics. This way of proceeding thus enables more precise models than hitherto possible for kinetic and dynamic reconstruction. In the case of an infant who was fatally injured by a wooden sculpture the generation and application of computer aided 3-dimensional reconstruction models are shown.

5270. Subramanian, A., et al. (2008). "A decade's experience with temporary intravascular shunts at a civilian level I trauma center." The Journal of trauma **65**(2): 316-316.

BACKGROUND: A 10-year review of temporary intravascular shunts (TIVS) at a regional trauma center., METHODS: Retrospective chart review of all patients treated with temporary intravascular shunts from January 1, 1997 to January 1, 2007., RESULTS: Seven hundred eighty-six patients were treated for vascular injuries. Sixty-seven (9%) had a total of 101 (72 arterial, 29 venous) TIVS placed to facilitate damage control or to allow for reconstruction of Gustilo IIIc fractures or limb replantation. Seven patients who, on trauma day 0, died or had an extremity which was deemed unsalvageable were excluded. Of 60 patients who met inclusion criteria, seven died from TBI (3%), MOF (3%), sepsis (2%), deceleration of care (2%), and loss of airway (2%), which was deemed preventable., CONCLUSIONS: TIVS have a shunt thrombosis rate of 5%, amputation rate of 18%, overall survival of 88%, and combination limb/patient survival rate of 73%. TIVS have an established role primarily in patients requiring either "damage control" for exsanguination or temporary vascular conduits during stabilization of Gustilo IIIc fractures. Truncal injuries are associated with the highest mortality likely due to accompanying multisystem trauma.

5271. Suddaby, L., et al. (1987). "The management of .22 caliber gunshot wounds of the brain: a review of 49 cases." The Canadian journal of neurological sciences. Le journal canadien des sciences neurologiques **14**(3): 268-272.

We analyzed the charts and CT scans of 49 cases of civilian .22 caliber gunshot wounds of the brain admitted to the University of Alberta and Royal Alexandra Hospitals between 1975 and 1985. The average age of the patients was 30 years, 88% were males, 88% were suicide attempts. There were no deaths among patients with an initial coma score above 12 whereas the mortality rate was 85% for those admitted with a score of 7 or less. All those with fixed pupils on admission died. The overall mortality rate of 61% is comparable to that of other series of civilian gunshot wounds including those in which more aggressive surgical management was undertaken. We recommend that no treatment be given those cases with an admission coma score of 3 and/or fixed pupils and that simple scalp wound debridement be employed with those having a coma score of 7 or less. Tract exploration and retrieval of bullet fragments is not indicated, as retained fragments carry a very low incidence of complications (e.g. abscess formation). In patients in good condition (GCS greater than or equal to 12) the management of intracranial hematomas should be independent of their etiology and approached aggressively.

5272. Suess, O., et al. (2002). "Self-inflicted intracranial injury caused by a crossbow arrow." European Journal of Trauma **28**(5): 310-313.

The availability of sophisticated hunting and sports weapons such as modern crossbows increases the incidence of uncommon types of accidental, suicidal, and homicidal head injuries. This report describes the case of a 47-year-old man with a nonfatal head injury due to a crossbow broadhead hunting arrow penetrating the left frontal lobe. The injury was accidentally self-inflicted by the intoxicated patient. A review of the literature has shown that self-inflicted head injuries caused by arrows are a very rare or, at least, a seldom reported entity. The mechanisms and pathophysiology of penetrating head injuries caused by different kinds of projectiles are discussed in order to clarify the management of these cases.

5273. Sugerman, D. E., et al. (2012). "Patients with severe traumatic brain injury transferred to a Level I or II trauma center: United States, 2007 to 2009." The journal of trauma and acute care surgery **73**(6): 1491-1499.

BACKGROUND: Patients with severe traumatic brain injury (TBI), head Abbreviated Injury Scale (AIS) score of 3 or greater, who are indirectly transported from the scene of injury to a nontrauma center can experience delays to definitive neurosurgical management. Transport to a hospital with appropriate initial emergency department treatment and rapid admission has been shown to reduce mortality in a state's trauma system. This study was conducted to see if the same finding holds with a nationally representative sample of patients with severe TBI seen at Level I and II trauma centers., METHODS: This study is based on adult (>=18 years), severe TBI patients treated in a nationally representative sample of Level I and II trauma centers, submitting data to the National Trauma Databank National Sample Program from 2007 to 2009. We analyzed independent variables including age, sex, primary payer, race, ethnicity, mode of transport, injury type (blunt vs. penetrating), mechanism of injury, trauma center level, head AIS, initial Glasgow Coma Scale (GCS), Injury Severity Score (ISS), and systolic blood pressure by transfer status. The primary outcome variable was inpatient death, with discharge disposition, neurosurgical procedures, and mean hospital, intensive care unit, and ventilator days serving as secondary outcomes., RESULTS: After exclusion criteria were applied (ISS < 16; age < 18 years; GCS motor score = 6; non-head AIS score >= 3; head AIS < 3; patients with missing transfer status, and death on arrival),

a weighted sample of 51,300 (16%) patients was eligible for analysis. In bivariate analyses, transferred patients were older (>=60 years), white, insured, less severely injured (head AIS score <= 4, ISS <= 25), and less likely to have sustained penetrating trauma (p < 0.001). After controlling for all variables, direct transport, 1 or more comorbidities, advanced age, head AIS score, intracranial hemorrhage, and firearm injury remained significant predictors of death. Being transferred (adjusted odds ratio, 0.79; 95% confidence interval, 0.64-0.96) lowered the risk of death., CONCLUSION: Patients with severe TBI who were transferred to a Level I or II trauma center had lower injury severity, including less penetrating trauma, and, as a result, were less likely to die compared with patients who were directly admitted to a Level I or II trauma center. The results may demonstrate adherence with the current Guidelines for Prehospital Management of Traumatic Brain Injury and Guidelines for Field Triage of Injured Patients, which recommend the direct transport of patients with severe TBI to the highest level trauma center. Patients with severe TBI who cannot be taken to a trauma center should be stabilized at a nontrauma center and then transferred to a Level I or II trauma center. Regional and national trauma databases should consider collecting information on patient outcomes at referral facilities and total transport time after injury, to better address the outcomes of patient triage decisions., LEVEL OF EVIDENCE: Prognostic study, level III; therapeutic study, level IV.

5275. Sugiura, S., et al. (2000). "Leukaemia inhibitory factor is required for normal inflammatory responses to injury in the peripheral and central nervous systems in vivo and is chemotactic for macrophages in vitro." The European journal of neuroscience **12**(2): 457-466.

The cytokine leukaemia inhibitory factor (LIF) is up-regulated in glial cells after injury to the peripheral and central nervous systems. In addition, LIF is required for the changes in neuropeptide expression that normally occur when the axons of sympathetic and sensory neurons are transected. We investigated whether LIF is also necessary for the initial inflammatory response that follows mechanical injury to the sciatic nerve and cerebral cortex of adult mice. We find that inflammatory cell infiltration into crushed sciatic nerve is significantly slower in LIF knock-out (KO) mice compared with wild-type (WT) mice. Similarly, the microglial and astroglial responses to surgical injury of the cortex are significantly slower in LIF KO mice compared with WT mice. Consistent with these in vivo results, LIF is chemotactic for peritoneal macrophages in a microchamber culture assay. Thus, LIF is a key regulator of neural injury in vivo, where it is produced by glia and can act directly on neurons, glia and inflammatory cells. We also find that the initial inflammatory response to cortical injury is diminished in interleukin (IL)-6 KO mice. Surprisingly, however, the inflammatory response in LIF-IL-6 double KO mice is very similar to that of the single KO mice, suggesting that these cytokines may act in series rather than in parallel in this response.

5276. Suhendar, A., et al. (2022). "Pediatric gunshot penetrating on transverse sinus without graft." Interdisciplinary Neurosurgery: Advanced Techniques and Case Management **27**.

A gunshot is a rare subset of penetrating head injury, and generally, the victim dies before arriving at the hospital. This paper reported an intracranial gunshot injury in an eight-year-old boy shooting by a hunter who has hunted a bird using an airgun. A missile projectile penetrated from the right zygoma and entering the transverse sinus. Vital signs were stable with GCS 14 from a physical examination. After the patient had an immediate craniotomy debridement, evacuated the foreign body (bullet) in C-arm guiding, the patient was administered to the pediatric intensive care unit (PICU) for three days. Than, patient was discharged from our hospital with a stable condition, GCS 15, without any significant neurological deficits.

5277. Suisa, H. and G. E. Sviri (2020). "Disseminated pneumocephalus secondary to air compressor injury." Acta neurochirurgica **162**(3): 509-512.

We report an unusual case of a young male patient who presented with severe pain and swelling of his left eyelid following an air compressor tip accident. He suffered extensive facial edema accompanied by deep tissue emphysema and an elevated intraocular pressure. On noncontrast CT scan, air was detected in the intraconal and extraconal orbital compartments, and intracranially within the subarachnoid spaces as well as in the suprasellar and

perimesencephalic cisterns. There were no detectable fractures. We presume that by perforating the orbital septum, Tenon's capsule, and the optic nerve sheath, air had managed to penetrate the cranium through the optic nerve subarachnoid space and into the intracranial subarachnoid space.

5279. Sulla, I., et al. (1990). "[Penetrating head injuries caused by animal anesthesia guns]." Penetrierende Kopfverletzungen mit Viehbetaubungsgeraten. **115**(4): 219-222.

An account is given of experience recorded from 15 patients who had been surgically treated for head injuries from animal stunning guns. All of them were male patients and were aged from 19 to 66 years. All cases were attempted suicides. Three patients died, including one of pyocephalus and two of injuries of vital structures. Eight patients whose first treatment had been restricted to wound suturing developed dangerous intracranial purulence. Seven patients of this group survived, following treatment of the bullet path. Patients with such injuries can be saved, if wound dressing is accompanied by removal of foreign bodies, bone fragments, blood clots, and devitalised tissue and if the dura mater is sealed watertight.

5280. Sullivan, D., et al. (2003). "The assassination of President John F Kennedy: a neuroforensic analysis--part 1: a neurosurgeon's previously undocumented eyewitness account of the events of November 22, 1963." Neurosurgery **53**(5): 1019-1027.

SUBSTANTIAL LITERATURE EXISTS on the assassination and subsequent pathological examination of President John F. Kennedy. The Warren Report, the United States Government's official report on the assassination, instead of providing definitive answers on the precise cause of President Kennedy's death, sparked intense and on-going debate. Since the publication of the Warren Report in September 1964, many issues have been woven into a wide array of theories concerning the assassination. One element continues to generate debate, namely, the exact sites of the wounds that President Kennedy sustained. A neuroforensic analysis of the wounds, from the perspective of the neurosurgeon, would establish a reasonable hypothesis for the mechanics of the shooting. Eyewitness accounts of the events surrounding the assassination represent one critical source of data for such an analysis. This report provides a previously undocumented neurosurgeon's eyewitness account of what transpired in Trauma Room 1 of Parkland Memorial Hospital on November 22, 1963.

5281. Sullivan, R. P., et al. (2011). "Increased risk of inpatient mortality among uninsured traumatic injury patients in a rural state trauma registry." Annals of emergency medicine **58**(4): S289.

Study Objectives: Recent research has demonstrated an increase in mortality for uninsured patients following traumatic injury independent of likely contributing factors such as age, race, injury severity, co-morbidities, mechanism of injury, and treating hospital. Previous studies have focused on patients in a national trauma database with a large proportion ofurban trauma centers, leading some to hypothesize that the increase in mortality is related to characteristics of injuries sustained in an urban environment. To determine whether an increased risk of mortality exists among uninsured trauma patients in a rural setting, we analyzed a state trauma registry from a predominantly rural state with markedly different patient demographics and injury characteristics relative to urban centers. Methods: This study was a retrospective review of the Iowa State Trauma Registry for the years 2002-2009 (N=80;,716). The State Trauma Registry contains records from all traumatically injured patients in the state of Iowa, including demographics, injury mechanism, hospital, and insurance data, as well as disposition at discharge. Exclusion criteria for this analysis included burns and age <18 years old. We used multivariate logistic regression analysis to estimate the risk of inpatient mortality byinsurance status at the time of injury. Several characteristics of the traumatic injury event including emergency department disposition, length of hospital and intensive care unit stay (days), transfer to a tertiary trauma center, hospital charges, and hospital discharge disposition were examined for their potential confounding effects on mortality. Results: A total of 63,702 patient records met inclusion criteria. Uninsured trauma patients were more likely to be male, non-white, 18-30 years old, have a penetrating injury and an intentional injury than those with commercial insurance. In unadjusted analyses, uninsured patients had a 50% (OR = 1.5 [CI: 1.21 - 1.77]) increased risk of mortality

compared to insured patients. Furthermore, a higher percentage of uninsured patients died in the emergency department (1.8%) than did those with commercial insurance (0.8%). After controlling for likely confounders (age, sex, injury severity score, mechanism and intent of injury, co-morbidities, and traumatic brain injury) the odds of mortality were largelyunchanged (adjusted OR = 1.5 [CI: 1.19 - 1.82]) suggesting that being uninsured, or an unknown mechanism for which being uninsured is a proxy, is stronglyrelated to risk of mortality. Conclusion: In a predominantly rural setting, uninsured patients were more likely to die following traumatic injury than their insured counterparts. This is in agreement with prior research findings showing increased mortality rates for uninsured patients in a predominantly urban national trauma registry. This finding suggests that insurance status and not the characteristics of an urban or rural environment contributes to increased risk of death from traumatic injuries. Further research is needed to identify the causative factors that contribute to increased mortality for the uninsured following traumatic injury, and to develop effective policies to address this healthcare inequity.

5283. Sun, D., et al. (2022). "Intrinsically Bioactive Manganese-Eumelanin Nanocomposites Mediated Antioxidation and Anti-Neuroinflammation for Targeted Theranostics of Traumatic Brain Injury." Advanced healthcare materials **11**(16): e2200517.

Overproduced reactive oxygen species and the induced oxidative stress and neuroinflammation often result in secondary injury, which is associated with unfavorable prognosis in traumatic brain injury (TBI). Unfortunately, current medications cannot effectively ameliorate the secondary injury at traumatic sites. Here, it is reported that intrinsically bioactive multifunctional nanocomposites (ANG-MnEMNPs-Cur, AMEC) mediate antioxidation and anti-neuroinflammation for targeted TBI theranostics, which are engineered by loading the neuroprotective agent curcumin on angiopep-2 functionalized and manganese doped eumelanin-like nanoparticles. After intravenous delivery, efficient AMEC accumulation is observed in lesions of TBI mice models established by controlled cortical impact method, evidenced by T1 -T2 magnetic resonance and photoacoustic dual-modal imaging. Therapeutically, AMEC effectively alleviates neuroinflammation, protects blood-brain barrier integrity, relieves brain edema, reduces brain tissue loss, and improves the cognition of TBI mice. Mechanistically, following the penetration into the traumatic tissues via angiopep-2 mediated targeting effect, the efficacy of AMEC is synergistically improved by combined functional moieties of curcumin and eumelanin. This is achieved by the alleviation of oxidative stress, inhibition of neuroinflammation via M1-to-M2 macrophage reprogramming, and promotion of neuronal regeneration. The as-developed AMEC with well-defined mechanisms of action may represent a promising targeted theranostics strategy for TBI and other neuroinflammation-associated intracranial diseases.

5284. Sun, G., et al. (2016). "Management Strategy of a Transorbital Penetrating Pontine Injury by a Wooden Chopstick." World neurosurgery **95**: 622.e627-622.e615.

BACKGROUND: Transorbital penetrating pontine injuries from small spear-like objects, which are extremely rare, provide neurosurgeons with life-threatening and challenging conditions to manage., CASE DESCRIPTION: We present an unusual case of transorbital penetrating pontine injury and discuss imaging, diagnosis, management strategy, and anatomy-injury correlation. A 23-year-old man sustained a penetrating cranial injury from a bamboo chopstick that extended from the right orbit to the pons and cerebellum. Using a frontotemporal approach, we successfully removed the chopstick. Follow-up studies confirmed a good outcome., CONCLUSIONS: Preoperative imaging, correct diagnosis, and surgical treatment are necessary to manage transorbital penetrating pontine injuries caused by spear-like objects, with specific attention paid to effective exposure and inventive means with total removal of the foreign object without causing further injury. A trajectory through the superior orbital fissure and paralateral to the cavernous sinus and into the pons seems to be the most prevalent and influences management of removal and injuries.

5285. Sun, G. H., et al. (2012). "Inpatients with gunshot wounds to the face." The Journal of craniofacial surgery **23**(1): e62-65.

Microvascular free tissue transfer (FTT) is an increasingly used method of reconstruction for traumatic defects of the head and neck. We describe the immediate management, FTT reconstruction techniques, and outcomes of 6 individuals who sustained maxillofacial gunshot trauma and were treated at a single tertiary-care level I trauma center. All 6 patients were white men with a mean age of 33 years. The mandible, nose, and orbital contents were the most frequently affected critical structures. All patients initially underwent primary wound debridement and tracheostomy, with concurrent maxillomandibular wire fixation and/or midface or mandible plate fixation in 5 patients. The mean time from injury to definitive FTT was 38 days. Five patients underwent fibula osteocutaneous FTT and 1 underwent radial forearm fasciocutaneous FTT. One patient also underwent concurrent local tissue rearrangement and pedicled flap surgery for nasal reconstruction. The mean hospital length of stay after FTT was 6 days. All FTT survived without necrosis. Oral incompetence and poor cosmesis from undesirable scarring patterns were the most common long-term complications. In summary, successful reconstruction of head and neck defects caused by gunshot trauma begins with airway stabilization, wound management, and bony fracture reduction and fixation. Definitive microvascular FTT is a useful method of repairing traumatic head and neck defects, although long-term functional and cosmetic complications may still occur.

5287. Sun, X.-c. and Y. Jiang (2008). "Genetic susceptibility to traumatic brain injury and apolipoprotein E gene." Chinese journal of traumatology = Zhonghua chuang shang za zhi **11**(4): 247-252.

Traumatic brain injury (TBI) is defined as an injury caused by a blow or jolt to the head or a penetrating head injury that disrupts the normal function of the brain. It is a common emergency and severe case in neurosurgery field. Nowadays, there are more and more evidences showing that TBI, which is apparently similar in pathology and severity in the acute stage, may have different outcomes. The known prognostic factors (such as age, severity of injury and treatments, etc.) explain only part of this variability and the concept of genetic susceptibility of traumatic brain injury has already been accepted by more and more people. It is now demonstrated that genetic polymorphism may play a key role in the susceptibility to TBI, even outcome following TBI. Although there are many genes that may involved in pathophysiological processes influencing TBI, apolipoprotein E gene has become one of the most extensive studied genes in neurotrauma and neurodegenerative disease and seems to take an important part in the neural responses to TBI. In this article, we will review the current understanding of the genetic susceptibility of TBI and the advancements regarding the impact of apolipoprotein E genotype on the severity and/or outcome following TBI.

5288. Sun, Z., et al. (2020). "VX765 Attenuates Pyroptosis and HMGB1/TLR4/NF-kappaB Pathways to Improve Functional Outcomes in TBI Mice." Oxidative medicine and cellular longevity **2020**: 7879629.

BACKGROUND: Traumatic brain injury (TBI) refers to temporary or permanent damage to brain function caused by penetrating objects or blunt force trauma. TBI activates inflammasome-mediated pathways and other cell death pathways to remove inactive and damaged cells, however, they are also harmful to the central nervous system. The newly discovered cell death pattern termed pyroptosis has become an area of interest. It mainly relies on caspase-1-mediated pathways, leading to cell death., METHODS: Our research focus is VX765, a known caspase-1 inhibitor which may offer neuroprotection after the process of TBI. We established a controlled cortical impact (CCI) mouse model and then controlled the degree of pyroptosis in TBI with VX765. The effects of caspase-1 inhibition on inflammatory response, pyroptosis, blood-brain barrier (BBB), apoptosis, and microglia activation, in addition to neurological deficits, were investigated., RESULTS: We found that TBI led to NOD-like receptors (NLRs) as well as absent in melanoma 2 (AIM2) inflammasome-mediated pyroptosis in the damaged cerebral cortex. VX765 curbed the expressions of indispensable inflammatory subunits (caspase-1 as well as key downstream proinflammatory cytokines such as interleukin- (IL-) 1beta and IL-18). It also inhibited gasdermin D (GSDMD) cleavage and apoptosis-associated spot-like protein (ASC) oligomerization in the injured cortex. In addition to the above, VX765 also inhibited the inflammatory activity of the high-mobility cassette -1/Toll-like receptor 4/nuclear factor-kappa B (HMGB1/TLR4/NF-kappa B) pathway. By inhibiting pyroptosis and inflammatory mediator expression, we demonstrated that VX765 can decrease blood-brain barrier (BBB) leakage, apoptosis, and microglia polarization to exhibit its neuroprotective effects., CONCLUSION: In

conclusion, VX765 can counteract neurological damage after TBI by reducing pyroptosis and HMGB1/TLR4/NF-kappaB pathway activities. VX765 may have a good therapeutic effect on TBI. Copyright © 2020 Zhezhe Sun et al.

5289. Sundaram, C., et al. (2004). "Cranial and intracranial actinomycosis." Clinical neuropathology **23**(4): 173-177.

Five patients with central nervous system actinomycosis are presented. There were risk factors in 2 patients like penetrating head injury and tetralogy of Fallot. All the cases were diagnosed by histopathology. Four patients recovered after surgery and antibiotic therapy, and 1 patient died.

5290. Sung, E. K., et al. (2014). "Injuries of the globe: what can the radiologist offer?" Radiographics : a review publication of the Radiological Society of North America, Inc **34**(3): 764-776.

Traumatic ocular injuries are a significant cause of blindness and visual deficits. In the setting of acute orbital trauma, urgent ophthalmologic evaluation and intervention are critical in preserving vision. However, in the acute trauma setting, clinical evaluation of the globe may be difficult in the presence of surrounding periorbital soft-tissue swelling and other associated injuries, and patient cooperation may be limited because of unresponsiveness, altered mentation, or sedation. Often, rapid access to imaging is part of the initial diagnostic evaluation, and radiologists may be the first to identify traumatic injuries of the globe. Because of this, radiologists should be familiar with normal orbital and globe anatomy at various imaging modalities and have a thorough understanding of the various patterns of ocular injury and their imaging appearances. Radiologists should also be familiar with the various mimics of ocular injury, including congenital and acquired conditions that may alter the shape of the globe, various types of ocular calcifications, and the different types of material used to treat retinal detachment. Such knowledge may help radiologists make accurate diagnoses, which facilitates prompt and appropriate patient care. Copyright RSNA, 2014

5291. Sungkar, A. A., et al. (2022). "Late-onset Seizure and Left Hemiparesis after Unusual Craniocerebral Penetrating Injury by a Rusty Sickle: A Case Report." Open access Macedonian journal of medical sciences **10**: 98-102.

BACKGROUND: Penetrating head injuries are a significant public health problem in worldwide, with an estimated 35.000 civilian deaths annually. Patients that survive to reach the hospital require rapid triage and imaging evaluation. This case report describes a patient with late-onset seizures and left hemiparesis after unusual craniocerebral penetrating injury by a rusty sickle. CASE PRESENTATION: A 26-year-old man reported that he had a sickle stabbed into the right-side parietal area. On admission, he had no neurological deficits. The rusty sickle was broken off just above the skull and did not protrude from the scalp. Computed tomography showed that the knife blade was in the parenchyma without underlying tract hematoma. Surgery was performed after 2 h of admission. Post-operatively, he recovered with no neurological deficit. After 16th days postoperatively, he was complaining of seizure and left hemiparesis. CT scan with contras showed edema and hypodense lesion at the right side of hemisphere. A course of intravenous phenytoin 100 mg/8 h and ceftriaxone 2 g/day was initiated. Physical therapy was done on the patient for 2 weeks. CONCLUSION: Traumatic brain injury (TBI) is the result of energy being transferred from an object to the human skull and underlying brain. Post-traumatic epilepsy is a common complication and can occur as early or late manifestations related to penetrating TBI. Prophylactic treatment of post-traumatic seizures (PTS) is currently not routinely recommended beyond 1 week following head injury (role of antiseizure prophylaxis). Phenytoin is the most rigorously tested AED for PTS.

5292. Sunshine, K., et al. (2020). "Antibiotic Prophylaxis in Penetrating Brain Injury: A Systematic Review of the Literature." Clinical neurosurgery **67**(SUPPL 1): 145.

INTRODUCTION: Civilian penetrating brain injury is a common pathology at trauma centers across the United States. The development of infection, including superficial wound infection, meningitis, or intracranial abscess can lead to significant morbidity in this patient population. Rates of infection vary among studies and there are few guidelines on interventions to prevent infections. METHODS: A systematic review of the literature was performed to identify studies regarding antibiotic use in civilian penetrating brain injury from 2000-2020. All types of studies were included. Abstracts were screened for inclusion based on English language, penetrating trauma involving dural puncture, age greater than 15 years, and patients within high income countries. Data was extracted to identify demographic information, type of penetrating object, type of intervention performed, prophylactic antibiotic regimen, rate and type of infection, and adverse events associated with antibiotics. RESULTS: Forty full text articles were identified, resulting in a study

population of 903 patients. Prophylactic antibiotics were administered in 577 patients (64.0%). Of the patients given prophylactic antibiotics, 8.32% developed infection [95% CI 6.07-10.57%] compared to 6.75% [95% CI 4.03-9.47%] in patients without prophylaxis. Of the patients with a documented antibiotic regimen (n = 71), 39.4% were given prophylaxis consisting of a single class of antibiotic. A variety of antibiotic classes were given for prophylaxis. Similarly, the duration of antibiotic prophylaxis varied throughout studies. CONCLUSION: Over the past 20 years, data has been published for many civilian patients with penetrating brain injury. In high income countries, antibiotic prophylaxis for these patients is not universal, with only a slight majority of patients receiving antibiotics with the intention of preventing infection. Further, antibiotic regimens vary widely between cases. Interestingly, our results show similar infection rates amongst patients regardless of the use of prophylaxis.

5293. Supomo and H. Darmawan (2018). "An Unusual Foreign Body in the Heart: A Case Report." Annals of thoracic and cardiovascular surgery : official journal of the Association of Thoracic and Cardiovascular Surgeons of Asia **24**(4): 205-207.

Penetrating foreign bodies in the heart is rare and may lead to life-threatening complications. Early diagnosis and removal are crucial for these rare cases. We report a case of accidental penetrating sewing needle in the right ventricle. The needle was successfully removed without open heart surgery and cardiopulmonary bypass (CPB), after accurate localization using transthoracic echocardiography (TTE).

5294. Supreeyathitikul, P., et al. (2020). "Epidemiology and Outcomes Following Open Globe Injury in Agricultural Region, an 11-Year Experience." Ophthalmic epidemiology **27**(4): 246-251.

PURPOSE: To determine the characteristics and epidemiology of open globe injury (OGI) in a third referral centre over 11 years., METHODS: The study was a retrospective observational study. The medical records of 978 OGI cases (a total of 998 eyes), admitted to Chiang Mai University Hospital, Thailand from January 2006 to December 2016, were reviewed., RESULTS: The mean age (SD) of patients was 39.1 (17.5) years. Patients were predominantly male (867, 88.7%). The age with the highest incidence of injury ranged from 41 to 60 years, in both genders. Most injuries happened at the workplace (64.8%), with flying objects from electric grass trimmers (23.9%) being the major injury-related mechanism. Penetration injuries were found in 479 eyes (48.0%). In elderly group (aged >60 years), a higher proportion of a globe rupture injuries were observed (13.3%). In general, intraocular foreign body group presented with better initial visual acuity (VA) compared to other injury types ($p< 0.001$). In all types of injury, final VA was significantly improved after treatment. However, rupture and perforation globe injuries had significantly worse final VA outcomes, compared to penetration and intraocular foreign body injuries ($p< 0.001$). With multivariable regression analysis, poor initial VA ($p< 0.001$), type of injury ($p= 0.028$), positive relative afferent pupillary defect (RAPD) ($p< 0.001$), and endophthalmitis ($p< 0.001$) were associated with poor visual outcomes., CONCLUSIONS: Work-related eye injury is a major cause of OGI. Poor initial VA, endophthalmitis, presence of RAPD, and rupture were the predictors for poor final visual outcomes.

5295. Suresh, V. and D. Powers (2018). "Foreign Body Removal in the Craniomaxillofacial Complex: Indications, Techniques, and Treatment." Craniomaxillofacial Trauma and Reconstruction Open **2**(1): e49-e54.

Foreign body migration in the deep spaces of the neck is particularly concerning due to the increased risk of damage to the great vessels and nerves. In addition, migration often cannot be easily predicted as objects may travel outside the confines of anatomic fascial planes. Although patients may be asymptomatic for years prior to presentation, timely removal of foreign bodies is ideal to preclude injury to important vascular and neurological structures as well as to prevent the development of recurrent infections and foreign body reactions. The authors report two cases of removal of migrated foreign bodies that presented at their institution. In one case, they report the use of intraoperative computed tomography (CT) imaging to help locate the position of a migrating dental needle. In another, they report the retrieval of a bullet fragment six months after the initial trauma. The classic method for retrieval of foreign bodies within the craniomaxillofacial complex centered around review of static radiographic imaging and a blind, broad exposure of the site in an attempt to localize and retrieve the material. This often resulted in iatrogenic injuries to surrounding structures or migration of the foreign body to a location, which may cause the patient additional harm. The utilization of intraoperative CT technology and computer navigation affords the craniomaxillofacial surgeon an additional tool for retrieval of these foreign bodies, often in a manner that affords minimally invasive surgical approaches, identification of

vital structures within the operative field, and decrease in overall operative time for removal. Referral to institutions, which have this technology, should be considered early in the operative care of patients who encounter retained foreign bodies in the craniomaxillofacial region.

5296. Surlin, C., et al. (1989). "[ENT involvement in lesions due to firearms]." Implicatii O.R.L. in leziuni prin arme de foc (consideratii in legatura cu 3 cazuri). **34**(2): 139-144.

5297. Susak, R., et al. (2010). "Predicting epilepsy in patient with open head injuries causedbywar missiles." Epilepsia **51**: 95-96.

Purpose: Detecting risk factors influencing the incidence of posttraumatic epilepsy after war missiles penetrating brain injuries. Method: We analyzed sixty-five patients regarding the following parameters: age, traumatic mechanism, type, extend and localization of injury, presence of intracranially retained foreign bodies, neurological deficits, appearance of epileptic phenomena, cognitive dysfunction and Elecroencephalographic changes. Result: Posttraumatic epilepsy was recorded in 14 patients (14/65 21.5%). Regarding the type of seizures there were six g.m., five complex partial and three motor partial seizures. Elecroencephalographic recording showed: focal changes in 15, normal EEG in 26, unspecific in three, unspecific + focal changes in 2 patients. Nineteen patients had not done EEG. Pathologic EEG changes are found in 11 of 14 patients who develop PTE (78.5% or 11/14). Nine pathological EEG was registered in 51 patient who did not develop PTE (17.6% or 9/51). Wounds in the parietal region and in the frontoparetial region resulted in the occurence of PTE in 3 cases each. Conclusion: The most important factors infuenting the incidence of PTE are: severity, extend and location of injury. The wounds in the frontal and parietal region were followed by epileptic seizures more frequently. Through-and-through brain injuries are more epileptogenic than others. Evidence of nurological deficit has strong correlation with PTE. There was no significant difference regarding the appearance of PTE in patients who are taking or those who are not taking AET. Considering our analyses we can not find sure predictors or specific parameters decisive for the future development of PTE.

5298. Suslu, H. T., et al. (2002). "[Self migrating intracranial bullets]." INTRAKRANYAL MERMI CEKIRDEKLERININ KENDILIGINDEN HAREKETI. **8**(3): 185-188.

We report herein two patients in whom bullets migrated into adjacent lateral ventricles in the brain and moved freely as a consequence of gravity. A rewiew ofthe literature suggests that spontaneous migration ofintracerebral bullets is being eased by cerebral softness, specific gravity of the bullet compared with brain tissue. ln patients undergoing the surgical removal of intracerebral or intraventricular bullets, an x-ray is recommended after final positioning.

5299. Süss, O. and F. Bode (2016). "Clinical Curiosity: Transnasal Head Trauma Caused by a Toilet Paper Holder." Indian Journal of Neurotrauma **13**(1): 35-38.

The risk of severe head injury during a seizure is usually small. Penetrating bony injuries to the skull caused by a fall on a sharp object during a seizure account for less than 3% of all ictal head injuries. Only few reports have been published on transoral, transnasal, and transorbital penetrating injuries suffered by patients who fell during a seizure. We report on a case of transnasal penetrating injury extending to the skull base and its treatment in a patient who fell on a toilet paper holder.

5300. Sutter, M. E., et al. (2010). "Transplant of multiple organs after suicide by acetaminophen overdose and self-inflicted gunshot wound." Clinical Toxicology **48**(6): 635.

Background: There are a shortage of organs available for transplant, and therefore many transplant centers are including poison related deaths. Few reports of organ donation after acetaminophen overdose exist. We describe the case of a 17-year-old male who had a simultaneous gunshot wound to the head in association with an acetaminophen overdose. Case report: A 17- year-old male was brought to the emergency department after a self inflicted gunshot wound to the head. His mother noted he had access to a recently purchased bottle of acetaminophen, which was missing 20 g. Upon arrival to the hospital, the patient was intubated without medication. He had a systolic blood pressure of 130 mmHg, a pulse of 111 beats per minute, a respiratory rate of 16 via bag assisted respirations and a

temperature of 36.5°C. Physical exam showed a single penetrating wound to the right temporal bone. The remainder of his physical exam was consistent with brain death. CT scan of his brain demonstrated a non-survivable head injury. Initial laboratories showed a hemoglobin, 11 g/ dL; platelets 218×103/mm3; sodium 138 mEq/L; potassium 2.9 mEq/L; chloride 104 mEq/L; bicarbonate 22 mEq/L; blood urea nitrogen 12 mg/dL; and creatinine 0.96 mg/dL. AST was mildly elevated at 50 IU/L and ALT was normal at 20 IU/L. INR was 1.26. Acetaminophen level drawn at arrival was 134 mg/L with unknown time of ingestion. N-acetylcysteine (NAC) therapy was initiated. Institutional policy for pediatric brain deaths required two exams on different days. Family expressed their interest in organ donation. Over the next 2 days his acetaminophen level declined to <10 mg/L. His AST and ALT never significantly increased. On day 2 organs were recovered and transplanted into six different recipients. The heart, lung, pancreas, liver and both kidneys were functioning well at 6 months. Discussion: Limited information exits on organ donation after acetaminophen ingestion. The patient's transaminases failed to change over the first 24 h. Surrogate markers such as acetaminophen half-lives were utilized to assess the risk of the donor organs while balancing optimal time of organ procurement without jeopardizing the other organs. Further prognostic testing needs investigation.

The EEG, quantity of cation proteins in neutrophils, the opioid peptides concentration in the CSF, were analysed in military personnel after a prolonged climatic and specific stress complicated by traumas, at the Kabul military hospital in Afghanistan. The brain functional reserve was significantly lower in the control subjects. A positive correlation between the brain functional reserve and the average cytochemical coefficient, was found in certain phases of traumatic disease alone. Accumulation of opioid peptides occurred under the adaptation to stress, being more evident in wounded soldiers.

5303. Suzuki, T., et al. (2013). "Blood-brain barrier transport of an essential amino acid after cerebral ischemia reperfusion injury." Acta neurochirurgica. Supplement **118**: 297-302.

Under pathophysiological conditions such as -cerebral ischemia-reperfusion (IR), damage to cerebrovascular endothelial cells causes alterations in the blood-brain barrier (BBB) function that can exacerbate neuronal cell injury and death. Clarifying changes in BBB transport in the early period of IR is important for understanding BBB function during therapy after cerebral ischemia. The present study was aimed at clarifying changes during IR in the BBB transport of L-phenylalanine (Phe) as a substrate of L-type amino acid transporter 1. An IR model was produced in mice by blood recirculation following occlusion of the middle cerebral artery. Permeability of the BBB to [(3)H]Phe was measured after IR injury using the brain perfusion method. Confocal microscopy of the IR injury showed no brain penetration of fluorescent tracer, thus confirming BBB integrity during 45 min of ischemia. Tight junction opening was not observed at 30 min after reperfusion following ischemia for 45 min. At the time of IR, [(3)H]Phe uptake into the brain appeared saturated. The Michaelis constant and maximum transport velocity in the IR group was reduced by 22 % compared with those in controls. These results suggest that the intrinsic transport clearance of Phe is slightly decreased in the early phase of IR.

5304. Sviri, G. E. (2015). "Massive cerebral swelling immediately after cranioplasty, a fatal and unpredictable complication: report of 4 cases." Journal of neurosurgery **123**(5): 1188-1193.

Cranioplasty after decompressive craniectomy (DC) is associated with increased morbidity, but the reported mortality rate is low. Recently, some authors have reported a rare unexplained complication of sudden death in association with massive cerebral edema immediately after cranioplasty. The author reports on 4 patients who underwent cranioplasty after DC between January 2005 and August 2010 at his department and died because of massive cerebral edema immediately after uneventful surgery and anesthesia. All 4 of the new cases reported involved young male patients who underwent decompressive hemicraniectomy after traumatic brain injury. They developed massive cerebral swelling immediately after uneventful cranioplasty (3 patients) or after removal of an epidural hematoma

several hours after surgery (1 patient). All 4 patients had a large skull defect and significantly sunken craniotomy site, and all were treated with a closed vacuum suction system that was placed under the scalp and kept open at the end of the cranioplasty procedure. After surgery, the patients' pupils became fixed and dilated, and brain CT scans showed massive brain edema. Despite emergency DC, the patients did not recover, and all 4 died. A MEDLINE search showed 8 similar cases that were reported previously. Fatal cerebral swelling after uneventful cranioplasty is a distinct clinical entity, although it is unpredictable. It is postulated that a negative pressure difference from the elimination of atmospheric pressure that had been chronically applied on the injured sinking brain in combination with the negative pressure applied by the closed subgaleal suction drain may lead to a massive brain shift toward the cranioplasty site and initiate a fatal vasomotor reaction.

5305. Sviri, G. E., et al. (1999). "Penetrating head injuries caused by a new weapon, the side dome." Military medicine **164**(10): 746-750.

The "side dome" is a mix of high and low explosives with a multitude of small metal balls molded within a specially designed half-sphere that directs the explosion wave and the projectiles in one direction to augment the harm. This weapon, originally designed by guerrilla and terrorist groups, is now used by regular armies. This report presents one craniocervical and eight cranial injuries caused by this new weapon and discusses the cases' various clinical features, the paucity of intracerebral cavitation damage along the missile track, the need for only minimally aggressive surgery, and the relatively favorable outcome. In all cases, the helmet offered good protection and the entry of the projectiles was just below its rim in an upward direction.

5306. Svoboda, N., et al. (2019). "Civilian and military gunshot wounds to the head." Ceska a Slovenska Neurologie a Neurochirurgie **82**(6): 670-676.

Aim: Gunshot wound to the head is one of the most severe injuries with high morbidity and mortality. Appropriately indicated extensive surgical treatment leads to improved patient prognosis. Thus, the evaluation of preoperative factors that would predict patients` prognosis is of high importance at the time of admission to the hospital. Methods: A retrospective analysis of the results of patients with gunshot head wounds hospitalized in the Military University Hospital in Prague during the period 2000-2018 was performed. Epidemiological data; Injury cause, type, and motive; Glasgow Coma Scale (GCS) on admission; CT scan findings; therapeutic approach; and clinical outcome according to the Glasgow Outcome Score Extended (GOSE) were evaluated and statistically analyzed. Results: 81 patients were enrolled in the study. Out of these 81 patients, 71 (88%) were injured in a civilian and 10 (12%) in a military setting. Mean GCS on admission was 5.8 (3-15). We operated on 18 patients. Mean GOSE after surgery was 2.8 (1-8). Patients with an overpenetration type of injury, with low GCS value on admission, with a higher number of injured brain lobes and with a bullet trajectory crossing the midsagittal and/or midcoronal plane had statistically significantly worse outcome ($P \leq 0.0001$). Conclusion: GCS on admission, injury cause and motive, and CT findings proved to be significantly important predictive factors. Chosen therapeutic approach should reflect these factors as they correlate with patient’s prognosis.

5307. Swain, S. K., et al. (2021). "Migrating Souvenir Bullet: The Management Dilemma." Annals of Neurosciences **28**(1-2): 79-81.

The cranio-cerebral trauma following gunshot injuries has high mortality and morbidity, with 66% to 90% victims dying before reaching hospital and only half of those treated in hospital surviving. However, in case of most salvageable patients, the question which poses dilemma to treating physicians is the decision as to when and why remove the retained missile. A 21-year-old man was observing a gunfight in the street from his balcony. Suddenly something struck his forehead and there was a small amount of bleeding toward the medial end of his left eyebrow. He had moderate headache and dizziness. Because of nonresolution of headache over seven days he was hospitalized and underwent X ray of the skull and CT of the head, which showed a retained metallic bullet in left inferior parieto-occipital region without any significant hemorrhage. As there was no neurological deficit or meningeal signs, he was managed conservatively. His symptoms improved gradually within next week and he was discharged home. His most recent follow-up was 28 months since injury and imaging showed migration of the bullet to the right inferior temporal region. As he was completely asymptomatic throughout, no intervention was offered. However, long-term follow-up for potential complications of migration, hydrocephalus, and abscess formation is advisable.

5309. Swanson, J. L. and J. A. Augustine (1992). "Penetrating intracranial trauma from a fishhook." Annals of emergency medicine **21**(5): 568-571.

Fishhook injuries rarely pose a true emergency, and only a few cases of posterior ocular injury from fishhooks have been described. We present a case of penetrating ocular, orbital, and cranial trauma produced by a broken fishhook. The morbidity and mortality as well as the initial emergency evaluation of penetrating foreign objects in the orbital-cranial region are discussed.

5310. Swartz, J. D., et al. (1985). "Computerized tomographic evaluation of the middle ear and mastoid for posttraumatic hearing loss." The Annals of otology, rhinology, and laryngology **94**(3): 263-266.

High resolution computerized tomography has been proven valuable in all aspects of temporal bone study. The importance of the procedure in evaluation of traumatic lesions, particularly of the middle ear, has been underemphasized. Damage to the middle ear may occur with blunt trauma, penetrating injury, or barotrauma. Conductive hearing loss and/or CSF otorrhea may result. Detailed evaluation of the ossicles is the hallmark of properly performed computerized tomographic evaluation.

5311. Swartz, W. M., et al. (1986). "The osteocutaneous scapular flap for mandibular and maxillary reconstruction." Plastic and reconstructive surgery **77**(4): 530-545.

Microfil injections in 8 cadavers and clinical experience with 26 patients have demonstrated a reliable blood supply to the lateral border of the scapula based on branches of the circumflex scapular artery. This tissue has been used successfully for reconstruction of a variety of defects resulting from maxillectomy and mandibular defects from cancer and benign tumor excisions. Advantages of this tissue over previous reconstructive methods include the ability to design multiple cutaneous panels on a separate vascular pedicle from the bone flap allowing improvement in three-dimensional spatial relationships for complex mandibular and maxillary reconstructions. The lateral border of the scapula provides up to 14 cm of thick, straight corticocancellous bone that can be osteotomized where desired. The thin blade of the scapula provides optimum tissues for palate and orbital floor reconstruction. There have been no flap failures and minimal donor-site complications.

5312. Sweeney, J. D., et al. (2011). "Management of Nonmissile Penetrating Brain Injuries: A Description of Three Cases and Review of the Literature." Skull Base.

Nonmissile penetrating intracranial injuries are uncommon events in modern times. Most reported cases describe trajectories through the orbit, skull base foramina, or areas of thin bone such as the temporal squama. Patients who survive such injuries and come to medical attention often require foreign body removal. Critical neurovascular structures are often damaged or at risk of additional injury resulting in further neurological deterioration, life-threatening hemorrhage, or death. Delayed complications can also be significant and include traumatic pseudoaneurysms, arteriovenous fistulas, vasospasm, cerebrospinal fluid leak, and infection. Despite this, given the rarity of these lesions, there is a paucity of literature describing the management of neurovascular injury and skull base repair in this setting. The authors describe three cases of nonmissile penetrating brain injury and review the pertinent literature to describe the management strategies from a contemporary cerebrovascular and skull base surgery perspective. © Thieme Medical Publishers.

5313. Sweeney, J. M., et al. (2011). "Management of nonmissile penetrating brain injuries: a description of three cases and review of the literature." Skull base reports **1**(1): 39-46.

5315. Sweet, D. J. and C. H. Sweet (1995). "DNA analysis of dental pulp to link incinerated remains of homicide victim to crime scene." Journal of forensic sciences **40**(2): 310-314.

Teeth endure postmortem degradation and extreme changes in ambient temperature and pressure better than most human tissues. This ability to resist deterioration allows the teeth to be studied as a method of establishing the identity of a decedent. Additionally, dental hard tissues, and in some instances soft tissues, may provide investigators with other sources of forensic data. In this case, a female homicide victim was transported to a location where her remains were burned. The high temperatures of a gasoline fire effectively incinerated the body precluding deoxyribonucleic acid (DNA) analysis from conventional sites. However, most of the teeth survived the conflagration. They were used to identify the victim. Additionally, the dental pulps were found to be an excellent source of high molecular weight genomic DNA. This proved to be an effective method to link the victim's body to biological evidence recovered from the site of the murder.

The authors have elaborated the technic for procurement of homografts from the lower jaw bone taken from cadaver-donors, without observing aseptic rules, with their subsequent ethylene epoxide sterilization in a portable chamber. Experimental studies have demonstrated that ethylene epoxide renders no negative effect on osteoplastic properties of the homograft, the rate of its reconstruction was dependent on the method of preservation. The results of osteohomoplasty for mandibular defects in 46 patients are summarized.

5317. Szabo, B. and I. Szabo (2011). "Intraorbital foreign bodies." Neuro-Ophthalmology **35**: S94.

AIM: To describe the clinical features and the management of unusual penetrating intraorbital foreign bodies. METHODS: We present the clinical history, preoperative photographs, pertinent imaging studies, and the pathologic findings of 13 patients with penetrating intraorbital foreign bodies were treated in our institution between the years 2000 and 2010. RESULTS: They represent 2.5% of the total of 511 patients who underwent orbital surgery during the period. 11 patients of the 13 were operated on. The characteristic clinical features at presentation in all the patients were: orbital pain, conjunctival haemorrhage, periorbital wound of entry and periorbital fistula. Additionally, chemosis was observed in 4 patients, palpebral oedema and swelling in 10, displacement of the eyeball and diplopia in 8, orbital cellulitis and abscess in 2 patients. CONCLUSIONS: An orbital foreign body may be frequently overlooked at presentation

because a small penetrating wound can be associated with minimal signs of inflammation. Meticulous history and physical examination, a strong clinical suspicion and appropriate imaging studies are crucial for diagnosing such an orbital foreign body. The two most important methods of screening neuroimagery are orbital ultrasound and CT-scan. In case of organic foreign body a high resolution CT-scan with 3D reconstruction and MRI with gadolinium are recommended. MRI is contraindicated in cases of presumed intraorbital metallic foreign bodies. Surgical treatment is aimed at the complete removal of the penetrating intraorbital foreign bodies, especially in those of organic origin. At times it is a simple procedure, but in others it may cause more damage than the trauma itself.

5319. Szarka, N., et al. (2017). "Enhanced myogenic response of cerebral arteries induced by pre-existing hypertension is intact after traumatic brain injury." FASEB Journal **31**(1).

Traumatic brain injury (TBI) impairs pressure-induced myogenic autoregulation of cerebral blood flow (CBF), which is associated with increased mortality and bad functional outcome of TBI patients. When blood pressure drops lack of myogenic autoregulatory function of cerebral vessels exposes brain tissue to hypoperfusion and ischemia; in case of high blood pressure it allows high blood volume to penetrate the brain exacerbating disruption of the blood brain barrier, development of hemorrhages and elevation of intracranial pressure. Hypertension, the most important cardiovascular risk factor in TBI patients, enhances myogenic tone of cerebral arteries via increased vascular production of 20- hydroxyeicosatrienoic acid (HETE), which protects brain tissue form pressure/volume overload but leads to increased susceptibility to cerebral ischemia. Although both effects may potentiate the vascular consequences of TBI, it is not known how hypertension modulates the effect of TBI on myogenic responses of cerebral vessels. To establish the effect of TBI on cerebral myogenic responses in hypertension we studied isolated middle cerebral arteries (MCA) of normotensive and spontaneously hypertensive rats (SHR) after severe impact acceleration diffuse brain injury. We found that TBI diminished myogenic constriction of MCAs in normotensive animals, but the 20-HETE mediated enhanced myogenic tone in SHRs was not affected by traumatic brain injury. These results suggest that following brain trauma hypertensive patients may be protected from high blood pressure, but are likely to be more prone to cerebral ischemia when blood pressure drops, and therefore require different therapeutic strategies than normotensive patients.

5320. Szleszkowski, L., et al. (2015). "The possibility of establishing causes of death on the basis of the exhumed remains of prisoners executed during the communist regime in Poland: the exhumations at Powazki Military Cemetery in Warsaw." International journal of legal medicine **129**(4): 801-806.

This study presents the results of the analysis of forensic examinations of the remains of 194 prisoners exhumed at Powazki Military Cemetery in Warsaw. In all probability, most of those buried there were judicially sentenced to death by firing squad or hanging in connection with activities of the Polish independence underground in its struggles with the postwar communist regime. Forensic medical research focussed on determining causes of death and reconstructing the mechanisms of injury leading to death. Most probable causes of death were found in 108 of 194 cases; of these, 76 were isolated gunshot wounds to the head, mostly directed to the occipital region. In 29 of 194 cases, only extensive skull fractures were observed, making it impossible to determine the mechanism of injury. The condition of these skulls do not permit the exclusion of injuries due to gunshots, which were very likely given the historical context of the studied location. In one case, it is assumed that the cause of death could be blunt force trauma to the head. In 86 of 194 cases, it was not possible to determine the cause of death. Of these cases, 20 skeletons were in such poor condition that erosive changes could have completely obliterated even very extensive head injuries leading to death. No injuries were observed that could be associated with execution by hanging.

5321. Szuflita, N. S., et al. (2020). "Penetrating Brain Injury Sustained by US Military Personnel in Iraq and Afghanistan, and the Use of Venous Thromboembolism Chemoprophylaxis: Initial and Interim Analysis." Clinical neurosurgery **67**(SUPPL 1): 142.

INTRODUCTION: There is evidence that US military personnel may have relatively high survival rates after penetrating brain injury (pTBI), which necessitates decisions regarding the timing, efficacy, and safety of venous

thromboembolism chemoprophylaxis (VTE PPx) in these patients. METHODS: Demographic and clinical data about US military personnel who sustained closed and penetrating brain injuries in Iraq and Afghanistan were abstracted from the Department of Defense Trauma Repository. Students T tests, Fisher's Exact Chi Square test, and Logistic regression models were used to describe the association between VTE PPx thromboembolic complications. These data are being supplemented with CT and MRI data to examine rates and predictors of intracranial hematoma expansion. RESULTS: To date, 326 records have been abstracted; 53.7% were pTBI. The most common mechanism of injury for pTBI was blast (75.4%) followed by gunshot wounds (18.3%). Overall mortality was 12.3% (18.9% pTBI vs 4.6% for closed head injury, P < .0001). VTE PPx was used in 63.8% of patients, and 16.6% received VTE PPx within 1 day of injury. There was no difference in the risk of DVT or PE among closed or pTBI based on the use or timing of VTE PPx. Administration of packed red blood cells was associated with an increased risk of DVT (OR 6.4, 95% CI 1.4-28.7), and PE (OR 5.2, 95% CI 1.1-23.8) after controlling for closed vs pTBI, as was the use of platelets (OR 7.0, 95% CI 2.0-24.3 for DVT and OR 5.6, 95% CI 1.6-20.0 for PE) and Fresh Frozen Plasma (OR 4.4, 95% CI 1.2-15.5 for DVT and OR 5.8, 1.3- 26.2 for PE). CONCLUSION: Penetrating brain injury in military personnel is often a survivable injury, and the risk of DVT and PE is low in both closed and pTBI, regardless of VTE PPx use. The use of blood products within 24 hours of injury is however, associated with an increased risk of thromboembolic complications. The rate of hemorrhagic expansion is currently being analyzed.

5322. Ta, C. N. and R. W. Bowman (2000). "Hyphema caused by a metallic intraocular foreign body during magnetic resonance imaging." American journal of ophthalmology **129**(4): 533-534.

PURPOSE: To report a 63-year-old man with a retained intraocular foreign body who developed a hyphema during magnetic resonance imaging (MRI) of the brain., METHODS: Case report and review of the current literature on ocular injury caused by intraocular foreign bodies when subjected to an electromagnetic field., RESULTS: Our patient underwent a brain MRI, and the intraocular foreign body caused a hyphema and increased intraocular pressure. The presence and location of the intraocular foreign body were determined by computed tomography (CT)., CONCLUSION: Magnetic resonance imaging can cause serious ocular injury in patients with ferromagnetic intraocular foreign bodies. This case demonstrates the importance of obtaining an occupational history, and, when indicated, a skull x-ray or CT to rule out intraocular foreign body before an MRI study.

5324. Tabibkhooei, A., et al. (2019). "Childhood Transorbital Skull Base Penetrating Injury: Report of 2 Cases and Review of Literature." World neurosurgery **131**: 213-216.

BACKGROUND: A foreign object penetrating the brain via orbit is a rare occurrence. Accurate diagnosis and immediate intervention is essential to prevent ophthalmic or neurological deficits and to reduce chances of infection or hemorrhage., CASE DESCRIPTION: We report 2 cases of transorbital orbitocranial penetrating injury of metal objects in children. Computed tomography scan was obtained to assess the extent of the injury and to locate the objects. According to the trajectory, the best craniotomy approach was performed, and the objects were safely removed without any complication. Our cases are unique because of the absence of any neurological deficit on admission, before and after the removal., CONCLUSIONS: The importance of transorbital orbitocranial penetrating injury cannot be neglected because of possible orbital and intracranial damage. Therefore, in this report we aim to heighten awareness of the complexity and severity of transorbital penetrating brain injury.

5325. Tabibkhooei, A., et al. (2018). "Penetrating brain injury with a metal bar and a knife: Report of two interesting cases." The neuroradiology journal **31**(2): 203-206.

Introduction Penetrating brain injury (PBI) is uncommon among the civilian population. Here, we report two interesting cases of PBI. Case presentation The first patient was a 20-year-old male who sustained a penetrating head injury with a metal bar during an accident at work. The patient underwent early surgical intervention, and related meningitis was treated with antibiotics. The patient was discharged 45 days later with no deficit. The second patient was a 34-year-old male who was the victim of a violence attack and was admitted to hospital. He was struck by a knife to his right temporal bone. A brain computed tomography scan and magnetic resonance imaging (MRI) demonstrated the tract

of the knife within the brain parenchyma. The patient underwent conservative treatment. After several weeks, the patient was discharged in good health. Conclusion Although severe PBI has a poorer prognosis than a blunt brain injury, in treating of these patients, aggressive and timely surgical intervention, proper wide-spectrum antibiotic administration, stringent and diligent care in the intensive-care unit and careful management of the associated complications are mandated.

5326. Tabish, A., et al. (2009). "Guidelines for managing minor head injuries." Journal International Medical Sciences Academy **22**(2): 81-83.

Globally, thousands of people sustain head injury everyday. Early diagnosis and appropriate management improves outcome but is sometimes more difficult to achieve than might be imagined, injury to the brain is most likely to result in death or permanent disability. Estimates of traumatic brain injury (TB1) incidence, severity, and cost reflect enormous losses to individuals, their families, and society. Authors prospectively studied 485 consecutive patients of traumatic brain injury, out of which 280 with GCS of 1 3, 4, and 1 5 were subjected to routine early CT scan of head after 4 hours of reporting to Emergency Patients with penetrating head injury were excluded. 15 % of patients had abnormal CT scans and only 4% needed surgical intervention Though a small number of patients harbour potentially lethal intracranial lesions yet. most of these cases are salvageable if diagnosed and treated early. There is a strong need for improved methods of initial assessment including early CT scan and are treatment subsequently lead to reduction in the number of unnecessary admissions and a more focussed head injury care.

5327. Tabuse, J., et al. (1989). "[Traumatic ophthalmic artery-superior ophthalmic vein fistula: a case report]." No shinkei geka. Neurological surgery **17**(3): 291-295.

Traumatic intraorbital arteriovenous fistula is rare and only 2 cases have been reported. The authors report the case of a 70-year-old man with consciousness disturbance after non-penetrating head injury. CT scan showed diffuse subarachnoid hemorrhage in the basal cistern, and angiography on the next day revealed ophthalmic artery-superior ophthalmic vein fistula in the right orbit. During the clinical course of this lesion, there was mild chemosis of the right eye, without palsy of extraocular muscles. Both papilledema and bruit were absent. Conservative treatment was chosen. On the 26th day after the head injury, repeated angiography showed complete disappearance of the fistula. The patient was discharged on the 39th day without neurological deficit. In the other two reported cases, intraorbital A-V fistulae were caused by direct-penetrating injury. But, in the present case the head injury was non-penetrating and blunt type. The pathogenesis was considered to be indirect injury of the intraorbital vessels at the retrobulbar portion, approximately where the artery and the vein crossed. As regards to treatment, simple observation may be the first choice, and spontaneous obliteration can be expected. If this does not occur, either embolization or ligation of the ophthalmic artery is suggested as the second choice as proposed by Freitas MAL et al.

5328. Taghavi, S., et al. (2021). "Preinjury Use of Marijuana and Outcomes in Trauma Patients." The Journal of surgical research **257**: 42-49.

BACKGROUND: Recent studies have examined the effects of marijuana in various populations; however, there has been limited research on the effect of marijuana use in severely injured trauma patients. We hypothesized that preinjury use of marijuana would be associated with improved outcomes in severely injured trauma patients., METHODS: All adult (18+ y) level I and level II trauma activations who presented to two large regional trauma centers between 2014 and 2018 were reviewed. Delta-9-tetrahydrocannabinol (THC)- indicated absence of drugs confirmed by testing and as THC + confirmed THC without another drug present., RESULTS: Of the 4849 patients included, 1373 (28.3%) were THC+. The THC + cohort was younger, had more males, and was more likely to be injured by penetrating mechanism ($P < 0.001$ for all) than THC-. THC + patients had shorter median length of stay (LOS) ($P < 0.001$) and intensive care unit LOS ($P < 0.001$). Mortality rate was lower in the THC + group (4.3% versus 7.6%, $P < 0.001$), but not in multivariate analysis. THC + patients with traumatic brain injury had shorter hospital LOS ($P = 0.025$) and shorter ventilator days ($P = 0.033$) than THC- patients. In patients with Injury Severity Score >=16, THC + patients had significantly lower intensive care unit LOS ($P = 0.009$) and mortality (19.3% versus 25.0% $P = 0.038$) than drug-negative patients., CONCLUSIONS: Although preinjury use of marijuana does not improve survival in trauma patients, it may provide some improvement in outcomes in patients with traumatic brain injury and those that are more severely injured

(Injury Severity Score >=16). The mechanism behind this finding needs further evaluation.

5330. Taha, J. M., et al. (1991). "Intracranial infection after missile injuries to the brain: report of 30 cases from the Lebanese conflict." Neurosurgery **29**(6): 864-868.

This study reviews the features of 30 intracranial infections complicating 600 penetrating head injuries from missiles in patients treated at the American University of Beirut Medical Center between 1981 and 1988. The follow-up period ranged from 1 month to 7 years (mean, 2.5 years). Sixteen patients had a brain abscess, 9 had cerebritis, 2 had an infected intracerebral hematoma, and 5 had meningitis. Infection developed 4 days to 7 years after the initial debridement. The infecting organisms were Gram positive in 11 patients (36%), Gram negative in 12 (40%), and a combination of Gram positive and Gram negative in 2 (7%). Twenty-four patients (80%) had wound dehiscence or cerebrospinal fluid leakage at the time the infection appeared. There was a 76% correlation between the organisms cultured from the dehiscent scalp wound and the brain. Twenty-three patients had intracranial retention of bone. Infection developed in 16 of the 30 patients (70%) around bone fragments, in 4 around a metallic fragment, in 2 around absorbable gelatin sponge, and in 3 along the missile tract; 2 had an infected intracerebral hematoma, and 3 had meningitis. At least one of the following risk factors was present in each patient: extensive brain injury, coma, trajectory through an air sinus, cerebrospinal fluid fistula, inadequate initial debridement, or incomplete dural closure. The incidence of intracranial infection in patients with postoperative retention of bone was 4% in the absence of scalp wound dehiscence, compared with 84.6% when wound dehiscence was present. Ten patients (43%) still retained a bone fragment measuring less than 1 cm after excision of a brain abscess or treatment of cerebritis or meningitis.(ABSTRACT TRUNCATED AT 250 WORDS)

5331. Taha, J. M., et al. (1991). "Missile injuries to the brain treated by simple wound closure: results of a protocol during the Lebanese conflict." Neurosurgery **29**(3): 380-384.

This is a prospective study of the treatment of penetrating missile injuries to the brain without intracranial surgery carried out at the American University of Beirut Medical Center between 1981 and 1988. Of 600 patients treated for missile injuries to the head, 32 satisfied the study criteria. There were 27 shrapnel and 5 bullet injuries. The mean patient age was 23 years (range, 3-51 years). Twenty patients had intracranial indriven bone fragments. Six patients had exposed brain tissue. The mean follow-up was 3.5 years (range, 1-7.5 years). The superficial entry wound was debrided and closed without drainage in the Emergency Room within a mean of 3 hours (range, 0.5-6 hours), and the patient received methicillin for 14 days. All patients survived and had no or improved neurological deficits. No leakage of the cerebrospinal fluid, infection, or seizures occurred in 31 patients. One patient with indriven bone fragments had leakage of the cerebrospinal fluid and developed seizures and a brain abscess 20 days after the injury. The management of penetrating missile injuries to the brain without intracranial surgery in a select patient population is a reasonable option. This treatment becomes important for a surgeon facing large numbers of casualties, or when operative personnel or resources are limited or unavailable.

5332. Taher, A. A. (1993). "Management and complications of middle- and upper-third facial compound injuries: an Iranian experience." The Journal of craniofacial surgery **4**(3): 153-161.

Surgery for 772 patients with middle- or upper-third facial injuries was carried out between 1984 and 1990 in two university hospitals in Tehran. The most common etiological factor was firearm injuries (69.04%; n = 533), followed by road traffic accidents (24.44%; n = 189). The most common associated nonfacial injuries were head injuries (36.97%; n = 285 followed by ocular injuries (23.18%; n = 179). Treatment of middle- or upper-third facial injuries ranged from minor repair to major surgery with autogenous or allogenous grafts. The complications associated with middle- or upper-third facial injuries were either postinjury complications or postoperative complications and ranged from minor infection to loss of vision.

5333. Taher, A. A. (1998). "Management of weapon injuries to the craniofacial skeleton." The Journal of craniofacial surgery **9**(4): 371-382.

One thousand one hundred thirty-five patients suffering from different types of facial injuries caused by various weapons were treated in two university hospitals in Tehran, Iran from 1984 to 1990. The referred patients suffered from one of three types of facial injuries: soft-tissues injuries, 9.16% (N = 104); bone fractures, 18.15% (N = 206); and soft-tissue injuries and bone fractures (mixed injuries), 72.69% (N = 825). The number of male patients was greater than females (1,123 males and 12 females). Anatomically the facial injuries were classified into seven groups (lower third; middle third; upper third; lower and middle third; lower and upper third; middle and upper third; and lower, middle, and upper third). Lower-third facial injuries were the most common injuries, 72.60% (N = 824); followed by the middle-third injuries, 36.30% (N = 412); and the upper-third injuries, 20% (N = 227). The mandible was the most common site of injury in the lower-third injuries, zygomatico-orbital fractures were the most common site in the middle-third injuries, and the frontal bone was the most common site in the upper-third injuries. Of the total number of patients, 3.17% were children (N = 36) with different types of maxillofacial injuries. The majority of the injuries (52.42%; N = 595) were from bullets. The most common injuries not associated with maxillofacial injuries were head and ocular injuries. The least common were abdominal injuries. The head injuries were classified into five grades according to clinical and computed tomographic findings. Treatment of facial injuries ranged from minor repair and/or closed reduction to major soft-tissue and/or bone reconstruction. Postinjury complications were very high. The follow-up period ranged from 3 months to 3 years. The aim of this study is to add our experience in the management of facial injuries to the literature.

5334. Tai, A., et al. (2017). "Civilian penetrating craniocerebral gunshot injuries: Post-operative management and complications." Clinical neurosurgery **64**: 275.

INTRODUCTION: Civillian cranial gunshot wounds (GSWs) remain a frequently lethal and highly morbid injury uncommon to many civilian trauma centers. The vast majority of these patients die prior to reaching medical care. Of those who do survive their initial injury, recent series have shown that over 50% will succumb to their injuries or in-the-hospital complications. Furthermore, experience from wartime theaters has taught us that these patients are vulnerable to a multitude of complications (i.e. CSF leak, wound breakdown, hydrocephalus, vascular injury). Thus, the need and potential for improvement in care and understanding of these patients is large.Here, we present our institution's series of cranial GSWs with an emphasis on detailing our complications. METHODS: We retrospectively performed a chart review from 2015-2017. RESULTS: We identified 9 patients that underwent operative intervention in the form of decompressive craniectomy following a craniocerebral gunshot injury at a level 1 trauma center in Washington, D.C. The average age of patients was 31 years (3 females, 6 males) and time to operative intervention from initial presentation was less than 4 hours in 7 out of 9 patients and less than 12 hours in all patients. All patients underwent further operation for a multitude of reasons of which wound breakdown and CSF leak were the most common. These complications extended the hospital initial hospitalization for the majority of patients beyond 2 weeks and were invariably the cause of readmission of these patients. CONCLUSION:Not only is aggressive and early intervention critical in caring for patients with cranial GSWs, but also it is important to be vigilant in looking for and preventing further secondary injury from subsequent complications such as wound infections/breakdown, CSF leaks, hydrocephalus and vasospasm. These almost inevitable complications must be anticipated in the treatment planning from the principal operation.

5335. Takahashi, C. E., et al. (2021). "Blunt and Penetrating Severe Traumatic Brain Injury." Neurologic clinics **39**(2): 443-469.

Severe traumatic brain injury is a common problem. Current practices focus on the importance of early resuscitation, transfer to high-volume centers, and provider expertise across multiple specialties. In the emergency department, patients should receive urgent intracranial imaging and consideration for tranexamic acid. Close observation in the intensive care unit environment helps identify problems, such as seizure, intracranial pressure crisis, and injury progression. In addition to traditional neurologic examination, patients benefit from use of intracranial monitors. Monitors gather physiologic data on intracranial and cerebral perfusion pressures to help guide therapy. Brain tissue oxygenation monitoring and cerebromicrodialysis show promise in studies.

5337. Takahashi, T. and T. Shimohata (2019). "Vascular Dysfunction Induced by Mercury Exposure." International journal of molecular sciences **20**(10).

Methylmercury (MeHg) causes severe damage to the central nervous system, and there is increasing evidence of the association between MeHg exposure and vascular dysfunction, hemorrhage, and edema in the brain, but not in other organs of patients with acute MeHg intoxication. These observations suggest that MeHg possibly causes blood-brain barrier (BBB) damage. MeHg penetrates the BBB into the brain parenchyma via active transport systems, mainly the l-type amino acid transporter 1, on endothelial cell membranes. Recently, exposure to mercury has significantly increased. Numerous reports suggest that long-term low-level MeHg exposure can impair endothelial function and increase the risks of cardiovascular disease. The most widely reported mechanism of MeHg toxicity is oxidative stress and related pathways, such as neuroinflammation. BBB dysfunction has been suggested by both in vitro and in vivo models of MeHg intoxication. Therapy targeted at both maintaining the BBB and suppressing oxidative stress may represent a promising therapeutic strategy for MeHg intoxication. This paper reviews studies on the relationship between MeHg exposure and vascular dysfunction, with a special emphasis on the BBB.

5338. Takamiya, M., et al. (2009). "An autopsy case related to a terrorist attack using a ball-bearing bomb." Legal medicine (Tokyo, Japan) **11**(2): 83-86.

We encountered an autopsy case related to a terrorist attack using a ball-bearing bomb. The decedent was a 51-year-old male without significant medical histories. During dinner in a restaurant, the perpetrator suddenly exploded a ball-bearing bomb, the blast from which blew the victim off his chair. The victim was found to be unresponsive, and pronounced dead. X-ray photographs taken before autopsy revealed six spherical shadows. Three penetrating wounds in the head, one in the neck and chest, and two in the left upper arm were observed in vivo. Six projectiles recovered from the body were identified as ball-bearings, one of which traveled through the midbrain, diencephalon, and left temporal lobe. Although blast injuries and penetrating wounds are often combined in bomb attack victims, penetrating brain injury would be the cause of death in this case. Lethal injuries to major organs can thus occur even though the destructive force of a ball-bearing bomb is weak. X-ray films were informative for detecting the ball-bearings in this case, suggesting that autopsy imaging is essential in cases of terrorism victims.

5339. Takanashi, Y., et al. (2002). "Penetrating brain injury with nasal entry by a plastic stick. Case report." Journal of neurosurgical sciences **46**(1): 25-27.

A case of a 52-year-old male presented with an unusual penetrating brain injury with nasal entry. At admission he had erythema of periorbital soft tissue in the left eye and epistaxis. His neurological condition was lethargic (Glasgow Coma Scale of 13) with nonfluent aphasia. Computed tomography scan revealed intracranial contusion hematoma in the left frontal lobe and fracture of the left frontal base, which were treated surgically. At the 6-month follow-up he still showed nonfluent aphasia. Disturbances, mostly cognitive, were noted on his psychological tests. A survey of the literature reveals a few cases of this nature in penetrating brain injury with nasal entry. A penetrating brain injury with nasal entry which causes nonfluent aphasia is discussing.

5340. Takarada-Iemata, M., et al. (2014). "Deletion of N-myc downstream-regulated gene 2 attenuates reactive astrogliosis and inflammatory response in a mouse model of cortical stab injury." Journal of neurochemistry **130**(3): 374-387.

N-myc downstream-regulated gene 2 (Ndrg2) is a differentiation- and stress-associated molecule predominantly expressed in astrocytes in the CNS. In this study, we examined the expression and the role of Ndrg2 after cortical stab injury. We observed that Ndrg2 expression was elevated in astrocytes surrounding the wounded area as early as day 1 after injury in wild-type mice. Deletion of Ndrg2 resulted in lower induction of reactive astroglial and microglial markers in the injured cortex. Histological analysis showed reduced levels of hypertrophic changes in astrocytes, accumulation of microglia, and neuronal death in Ndrg2(-/-) mice after injury. Furthermore, activation of the IL-6/signal transducer and

activator of transcription 3 (STAT3) pathway, including the expression of IL-6 family cytokines and phosphorylation of STAT3, was markedly reduced in Ndrg2(-/-) mice after injury. In a culture system, both of Il6 and Gfap were up-regulated in wild-type astrocytes treated with forskolin. Deletion of Ndrg2 attenuated induction of these genes, but did not alter proliferation or migration of astrocytes. Adenovirus-mediated reexpression of Ndrg2 rescued the reduction of IL-6 expression after forskolin stimulation. These findings suggest that Ndrg2 plays a key role in reactive astrogliosis after cortical stab injury through a mechanism involving the positive regulation of IL-6/STAT3 signaling. 5342. Talibi, S., et al. (2016). Long-term outcome of traumatic brain injury patients managed at a major trauma centre in England. **30:** 503.

Objectives: UHCW is the second busiest Major Trauma Centre in England according to TARN (Trauma Audit and Research Network). Managing patients with traumatic brain injury (TBI) constitutes a significant proportion of the workload. The objective of our study was to document the management and the long term outcome of TBI patients admitted to UHCW. Design: Data about patients with TBI managed at UHCW for the years 2013 and 2014 have been gathered. Subjects: Nil. Methods: Information about patients with TBI managed at UHCW was gathered from the following two sources: The Trauma Audit and Research Network (TARN) (for patients with severe head injury) and the i.Patient Manager (iPM) database maintained at the UHCW (for patients with mild and moderate head injury). Extended GOS (Glasgow Outcome Scale) questionnaires are being sent out to patients/carers/G.P.s to collect long-term outcome data. Results: 696 patients were admitted to the regional neurosurgical centre with TBI. The mean age of the patient was 57.6 (range 16- 100) years. 233 were female and 463 male. Admissions were due to 65 having had blunt trauma, 4 sustaining crush injuries, 295 falling less than 2 m, 134 falling more than 2 m, 182 after road traffic collision, 3 gunshot wounds to the head, 1 stabbing to the head, and 12 unknown. 193 admissions with TBI required intubation. The mean length of stay was 18 (range 0 to 210) days. Outcome at discharge: 437, good recovery; 42, moderate disability; 87, severe disability and 119, died. 11 were lost to follow-up. 539 patients required further rehabilitation. Long-term neurological outcomes (more meaningful) results are being collated and will be presented at the meeting. Conclusions: With neurological injury, long-term outcome is more relevant compared with outcome at discharge. TARN data does not include long-term outcome for head injured patients. With this study, we make the case for collection of long-term outcome data for TBI patients.

5343. Tama, M. and B. Khodorkovsky (2017). "Does specialty training and practice setting effect adherence to the pediatric emergency care applied research network (PECARN) criteria for pediatric head trauma?" Academic emergency medicine. Conference: **24**: S32.

Background: Pediatric head injuries account for a significant portion of emergency department (ED) visits. While computed tomography (CT) use in these patients can be a definitive diagnostic test, the effects of ionizing radiation exposure are a significant consideration. In the past ten years, the Pediatric Emergency Care Applied Research Network (PECARN) developed an algorithm for the utilization of CT scans when evaluating pediatric patients with head trauma. The goal of this study was to determine the effects of specialty training in addition to practice settings on the adherence to PECARN criteria. Methods: A retrospective study was conducted on a two campus hospital. Chart documentation was used to determine adherence to PECARN criteria. Inclusion criteria was any traumatic head injury within 24 hours in patients under the age of 18 years over a one-year period. Exclusion criteria was penetrating trauma, brain tumors, pre-existing neurological disorders, or neuroimaging at an outside facility. Specialty training was subdivided into three groups: pediatric emergency medicine (PEM), emergency medicine (EM), and general pediatrics (GP). The two hospital campuses are distinctly different practice settings. One being an academic practice setting, which is also a trauma center that has a dedicated pediatric ED, staffed by PEM, EM and GP physicians. The second campus is a community practice and is staffed solely by EM physicians. Statistical analysis was performed utilizing chi2 and the Cochran-Mantel-Haenszel (CMH) test. All analyses were two-sided, and a P-value of < 0.05 was considered statistically significant. Results: A total of 709 pediatric patients with traumatic head injuries were analyzed during the study period. CT scans were obtained on 119 (16.8%) patients. Overall adherence to PECARN criteria was 93%. No statistical difference was found between

different specialty training on the academic campus. Additionally, the rate of adherence amongst EM physicians at the academic and community settings was 94.8% vs. 86.5% respectively, which was statistically significant (P=0.004). Conclusions: Practice setting had an effect on adherence to PECARN criteria in pediatric patients with acute traumatic head injury. The same determination on adherence was not demonstrated among physicians with different specialty trainings.

5344. Tamaoka, J., et al. (2019). "Osteonecrosis of the jaws caused by bisphosphonate treatment and oxidative stress in mice." Experimental and Therapeutic Medicine **17**(2): 1440-1448.

Aging is a significant risk factor for the development of bisphosphonate-related osteonecrosis of the jaws (BRONJ). Accumulating evidence suggests that bone aging is associated with oxidative stress (OS), and OS is associated with osteonecrosis. To elucidate the mechanisms of the onset of BRONJ, the present study focused on OS and the effects of treatment with the pro-oxidant DL-buthionine-(S,R)-sulfoximine (BSO), an oxidative stressor, on healing of a surgically induced penetrating injury of the palate. Six-week-old C57BL/6J mice were randomly divided into four groups (n=5 each) and treated with or without zoledronic acid (ZOL) and with or without BSO (experimental groups: ZOL, BSO, and ZOL+BSO; control group: saline solution). A penetrating injury of the midline palate was surgically created using a root elevator. ZOL (250 µg/kg/day) was injected intraperitoneally every day from 7 days prior to the surgical treatment to 4 days following the surgical treatment. BSO (500 µg/kg/day) was administered 7 days prior to the surgical treatment as a single intraperitoneal injection. The maxillae were harvested at 5 days following the surgical treatment for histological and histochemical studies. The presence of empty osteocyte lacunae in the palatal bone was increased by ZOL and BSO treatment. The highest number of empty osteocyte lacunae was observed in the ZOL+BSO group. The number of tartrate-resistant acid phosphatase-posi-tive cells was decreased by ZOL treatment and increased by BSO treatment. The number of canaliculi per osteocyte lacuna was significantly decreased by BSO treatment. The mineral apposition rate was significantly lower in the treatment groups than the control group. Bisphosphonates and OS suppressed bone turnover. The present study has demonstrated that BSO treatment affects osteocytes, and OS in osteocytes exacerbaimpairment of the osteocytic canalicular networks. As a resbisphosphonates and OS may induce osteonecrosis followinvasive dentoalveolar surgery. OS has been identified as additional risk factor for the development of BRONJ.

5345. Tamrazian, E. and B. Mehta (2018). "Dysphagia and tongue deviation: Collette-sicard syndrome after blunt head trauma." Journal of Neuroimaging **28**(2): 229.

Background and Purpose: The jugular foramen and the hypoglossal canal are both apertures located at the base of the skull. The jugular foramen contains the cranial nerves, IX, X, and XI, involved in normal cough and gag reflex. The hypoglossal canal contains the cranial nerve XII, responsible for movements of the tongue. Therefore, multiple lower cranial nerve palsies tend to occur with injuries to these structures. The pattern of injuries tends to correlate with the combination of nerves damaged. Case: A 28-year-old male was involved in an AVP injury while crossing the highway. Patient was brought to a local Level I Trauma Center. On admission, he was complaining of a headache and inability to swallow his own saliva. Exam showed a Glasgow coma scale of 15, awake, alert, and oriented to date, place, and person, with dysphagia, tongue deviation to the right, uvula deviation to the left, and a depressed palate. No other abnormal findings were noted. Initial imaging showed B/L frontal traumatic subarachnoid hemorrhage, left frontal epidural hematoma, and a basilar skull fracture. On HD 4, he was transferred out of the intensive care unit with persistent tongue deviation and inability to swallow. Initial radiology read by a radiologist did not reveal any further structural abnormalities then the ones stated above. Neurology was consulted and imaging was reviewed by neuroimaging-trained neurologist, which demonstrated injury to the wall of the jugular foramen and the hypoglossal canal. Nasogastric tube feeding was initiation and patient had percutaneous endoscopic gastrostomy tube placed on HD 17 and discharged home. At 3-month follow-up, patient's tongue normalized to midline and his dysphagia resolved. Conclusion: Collette-Sicard syndrome is a rare condition/syndrome characterized by unilateral palsy of CN: IX, X, XII, and XII first described by Dr. Collete in 1915 and by Dr. Sicard. This condition was historically attributed to tumors of the skull base, coiling and dissections of the internal carotid artery, multiple myeloma, vasculitis, carotid fibromuscular dysplasia, shotgun injuries, idiopathic cranial polyneuropathy, atlas fractures, and occipital condyle fractures. This condition has been rarely described as a consequence of blunt head trauma. Injuries to the jugular foramen and the hypoglossal canal are rare as most blunt head traumas resulting in basilar skull fracture involve the condyles. In most cases, the condition is self-limiting with patients regaining most to all of their neurological functions within 6 months. Several theories have been

proposed for the pathophysiology of this syndrome. Nerve traction injuries and soft tissue edema compressing the cranial nerves are the leading two hypotheses. In conclusion, injuries with focal neurological deficits which were not apparent on initial imaging should be reviewed by relevant experts with concomitant knowledge of the patient's history.

5347. Tan, W.-F., et al. (2012). "Pretransplant neurological presentation and severe posttransplant brain injury in patients with acute liver failure." Transplantation **94**(7): 768-774.

BACKGROUND: Alterations in the central nervous system in patients with acute liver failure (ALF) present unique challenges in the perioperative period. In this retrospective study, we examined pretransplant neurological presentation and the incidence, clinical presentation, and risk factors associated with severe posttransplant brain injury (BI) in ALF patients undergoing orthotopic liver transplantation (OLT)., METHODS: After institutional review board approval, ALF patients who underwent OLT between 2004 and 2010 at our center were reviewed. Pretransplant neurological presentation and severe posttransplant BI were examined. Risk factors for the latter were identified., RESULTS: During the study period, 90 (67 adults and 23 children) ALF patients underwent primary OLT. Preoperatively, all patients developed encephalopathy, 6 had seizure activity, 32 had radiological evidence of cerebral edema, and 11 had severe cerebral edema. After OLT, 7 patients developed severe posttransplant BI. Of these 7 patients, 4 had brain death, and 3 had irreversible injury that precluded them from living independently. Severe pretransplant cerebral edema and a higher posttransplant international normalized ratio (odds ratios and 95% confidence intervals: 50.2, 5.8-433.5 [P<0.001] and 3.1, 1.1-8.8 [P=0.031], respectively) were risk factors associated with severe posttransplant BI., CONCLUSIONS: Pretransplant neurological complications were prevalent, and severe posttransplant BI occurred at a rate of 7.8% and was significantly associated with severe pretransplant cerebral edema and postoperative international normalized ratio. Our findings support the use of pretransplant computed tomography. If severe pretransplant cerebral edema is confirmed, efforts should be made to aggressively control intracranial pressure and select a proper donor to minimize the risk of severe posttransplant BI and futile transplantation.

5348. Tan, Y., et al. (1998). "A gross and microscopic study of cerebral injuries accompanying maxillofacial high-velocity projectile wounding in dogs." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **56**(3): 345-348.

PURPOSE: This study investigated the pathologic characteristics and some related factors of cerebral damage associated with maxillofacial high-velocity missile wounds., MATERIALS AND METHODS: Sixty dogs, divided into two groups, were wounded randomly by steel spheres weighting 1.03 g at impact velocities of 1,400 m/s (46 dogs) and 800 m/s (14 dogs). Six dogs served as controls. The maxillofacial wounds and cerebral injuries were examined grossly. The distance between the center of wound and the base of skull and the largest diameter of the wound were measured, and the incidence of the brain injury in the two groups was compared. The cerebral specimens, dissected at 1 and 6 hours after trauma, were observed by light and electron microscopy., RESULTS: Cerebral hyperemia, contusion, spotty hemorrhage, and intracerebral hematoma were found in some of the dogs. In the 1,400 m/s velocity missile wound group, the incidence of the brain injury was 71.7% (33 of 46), and in the 800 m/s group it was 7.1% (1 of 14) on macroscopic examination. Microscopic observation showed intracerebral microhemotomas and degeneration and necrosis of the nervous cells., CONCLUSION: High-velocity projectile maxillofacial wounds can induce associated brain injury.

5349. Tanaka, K., et al. (1985). "Pseudomonas labyrinthitis." Archives of oto-rhino-laryngology **242**(3): 273-277.

Pseudomonas aeruginosa is the gram-negative bacterial rod which is often isolated from chronic aural discharge. This microorganism may also cause necrotizing infection of the external auditory canal in certain patients with impaired host-defense mechanisms. Involvement of the inner ear by this microbe is extremely rare. In this communication, we report a case of pseudomonas labyrinthitis which resulted from traumatic middle ear injury. Infection produced massive granulations and extensive bone destruction of the otic capsule. This case shows that while P.aeruginosa is usually an avirulent opportunistic pathogen, it may also cause a highly destructive labyrinthitis if the inner ear is entered.

5350. Tanaka, T., et al. (1997). "Surgical extraction of traumatic orbital mercury." Ophthalmologica. Journal international d'ophtalmologie. International journal of ophthalmology. Zeitschrift fur Augenheilkunde **211**(6): 402-404.

Initial clinical observation of a 2-year-old boy whose right eyelid had been pierced by a glass thermometer 3 days earlier showed a scab-covered cicatrix and slight swelling in the eyelid. X-ray examination showed the broken thermometer tip, fine glass fragments, and mercury droplets beneath the eyelid and extending along the superior orbital margin. On surgical incision, glass fragments and the thermometer tip were found and extracted from the eyelid and orbital fatty tissue with forceps, and 70.3 mg of mercury droplets were readily removed from the same regions by suction via an elastic needle connected to an injection syringe. Blood mercury gradually rose from the normal range to a peak of 28.4 microg/dl 3 months after surgery, then declined during the following 7 months to a level of 15.1 microg/dl. No abnormality has been found in liver or renal function to present.

5351. Tancioni, F., et al. (1994). "Intracranial nail. A case report." Journal of neurosurgical sciences **38**(4): 239-243.

Penetrating cranio-cerebral trauma caused by fire-arm constitute the most frequent penetrating wounds in civilian ambit; in these cases the great extention of cerebral damage is the result of distructive forces generated by high velocity which moves this bodies. In civilian ambit cranio-cerebral wounds caused by penetrating bodies, but moved by low cinetic energy are increasing constantly, due to the development of industrial activities. The cases reported in literature are few; in the present paper we present the case of a cranio-cerebral wound caused by a nail, which is the longest nail ever reported in literature (9 cm). Cranio-cerebral penetrating wounds caused by nail are reported only as curious experience; none authors tried to standard the medical-surgical approach as for what concern the clinic valutation, as for treatment. We think that for these traumatic event, we can adapt the same valutations criteria used for wounds caused by fire-arms. For what concerns surgery of such injuries, we consider the emergency operation the best solution; generally in these cases the purpose of surgery is not the removal of devitalized tissues, evacuation of hematomas or removal of bone fragments or of penetrating bodies as happen in cases of penetrating bodies moved by high cinetic energy, but for the possible complications which can result immediately or after the trauma.

5352. Tandean, S., et al. (2017). "Pediatric gunshot penetrating head injury: A case report with 2-year follow-up." Medical Journal of Indonesia **26**(4): 302-306.

Gunshot is a rare subset of penetrating head injury, and generally the victim dies before arriving at the hospital. This paper reported a case of an intracranial gunshot injury in a 12 year-old boy that was shot by his friend, whose primary intention was to play around, using a revolver. A missile projectile penetrated from mid frontal and came out from right occipital. Vital signs were stable with GCS 8 from physical examination. A rational management strategy should permit a good outcome. The only complications that occured were hydrocephalus, yet it was managed by VP–shunt. Skull defect was closed using titanium mesh. A two-year follow-up showed a good result. The patient was able to do daily activity and back to school again.

5355. Tang, O. Y., et al. (2022). "The Impact of Frailty on Traumatic Brain Injury Outcomes: An Analysis of 691,821 Nationwide Cases." Clinical neurosurgery **68**(SUPPL 1): 116.

INTRODUCTION: Earlier research has demonstrated that patient frailty, a decline in physiologic reserve, is associated with higher morbidity and mortality for several neurosurgical conditions. However, the impact of frailty on traumatic brain injury (TBI) outcomes is poorly characterized. METHODS: We identified all adult admissions for traumatic intracranial hemorrhage (tICH) in the National Trauma Data Bank from 2007-2017. Frailty was quantified via the

validated mFI-5 metric (0-5), with mFI-5 =2 denoting frailty. Analyzed outcomes included in-hospital mortality, favorable discharge disposition (discharge home or to shortterm care), complications, ventilator days, and intensive care unit (ICU) and total length of stay (LOS). Multivariable regression was used to assess the association between mFI-5 and outcomes, adjusting for patient demographics (age, sex, insurance, transfer status), hospital characteristics (teaching status, trauma center level, bed size), injury severity on admission (penetrating injury, Glasgow Coma Scale [GCS], Injury Severity Score, hypotension, number of tICH subtypes), and neurosurgical procedures. RESULTS: 691,821 tICH admissions were analyzed. 63.2% were male and average age was 57.6 years (standard deviation=21.2). 43.5% were above 65 years of age. 18.0% of patients were classified as frail (mFI-5 = 2), and the percentage of frail patients grew from 7.9% in 2007 to 21.9% in 2017. Frailty was associated with increased odds of mortality (odds ratio [OR] = 1.36, P < 0.001) and decreased odds of favorable discharge disposition (OR = 0.72, P < 0.001). Frail patients also exhibited an elevated rate of complications (OR = 1.06, P < 0.001), including unplanned return to the ICU (OR = 1.55, P < 0.001) and operating room (OR = 1.17, P = 0.003). Finally, ventilator days (+12%, P < 0.001), ICU LOS (+11%, P < 0.001), and total LOS (+13%, P < 0.001) were significantly higher in frail patients. All associations with death and disposition remained significant following stratification for age, polytrauma, ICU stay, and GCS on admission. CONCLUSION: For tICH patients, frailty was associated with elevated mortality, unfavorable discharge disposition, complications, ventilator days, and LOS, regardless of age or injury severity. Further research into integrated care pathways for this high-risk population is warranted.

5357. Tang, Z., et al. (2012). "Dynamic simulation and preliminary finite element analysis of gunshot wounds to the human mandible." Injury **43**(5): 660-665.

OBJECTIVE: Due to the complications arising from gunshot wounds to the maxillofacial region, traditional models of gunshot wounds cannot meet our research needs. In this study, we established a finite element model and conducted preliminary simulation and analysis to determine the injury mechanism and degree of damage for gunshot wounds to the human mandible., METHODS: Based on a previously developed modelling method that used animal experiments and internal parameters, digital computed tomography data for the human mandible were used to establish a three-dimensional finite element model of the human mandible. The mechanism by which a gunshot injures the mandible was dynamically simulated under different shot conditions. First, the residual velocities of the shootings using different projectiles at varying entry angles and impact velocities were calculated. Second, the energy losses of the projectiles and the rates of energy loss after exiting the mandible were calculated. Finally, the data were compared and analysed., RESULTS: The dynamic processes involved in gunshot wounds to the human mandible were successfully simulated using two projectiles, three impact velocities, and three entry angles. The stress distributions in different parts of mandible after injury were also simulated. Based on the computation and analysis of the modelling data, we found that the injury severity of the mandible and the injury efficiency of the projectiles differ under different injury conditions., CONCLUSIONS: The finite element model has many advantages for the analysis of ballistic wounds, and is expected to become an improved model for studying maxillofacial gunshot wounds.

5358. Tani, P. M., et al. (1977). "An unusual knife injury to the orbit: a case report." Ophthalmic surgery **8**(4): 43-46.

A perforation of the left orbit by a five-inch knife blade was sustained by a 30-year-old woman. In spite of the knife's course through a myriad of vital structures, the only significant injury was a laceration of the lateral canthal tendon. Following surgical repair the patient recovered with no residual problems.

5359. Taniura, S., et al. (2004). "Transoral penetration of a half-split chopstick between the basion and the dens." AJNR. American journal of neuroradiology **25**(5): 871-872.

A 6-year-old girl was admitted for transoral penetrating injury by a half-split chopstick. Subsequent CT imaging examinations showed that the chopstick had passed between the basion and the dens and reached the subarachnoid space just at the medulla oblongata. A sagittal reconstructed CT scan was useful for the evaluation of the injury. Imaging findings and their clinical relevance are discussed.

5360. Tanmit, P., et al. (2021). "A life saving emergent temporary external carotid artery controlled in extensive craniofacial injury." International medical case reports journal **14**: 199-204.

Introduction: Craniofacial trauma may potentially have significant blood loss which may lead to death in some trauma patients. Case Report: We report a case of a 43-year-old male who had a lethal noncompressible arterial hemorrhage from a penetrating wound on his left frontotemporal and preauricular region. Extensive bleeding was successfully temporarily controlled by external carotid artery (ECA) occlusion. The definitive operation was completed in a staged fashion following a computed tomography angiography assessment extension of the injury. Conclusion: Temporarily controlling the bleeding from the carotid artery should be considered as a life saving procedure in a lethal craniofacial injury.

5361. Tanriover, N., et al. (2015). "Endoscopic Endonasal Transethmoidal Approach for the Management of a Traumatic Brain Abscess and Reconstruction of the Accompanying Anterior Skull Base Defect." The Journal of craniofacial surgery **26**(6): 1957-1959.

Skull base endoscopy in the treatment of brain abscesses has been rarely published. Moreover, endoscopic endonasal transethmoidal approach (EETA) for the treatment of brain abscess following a head trauma has been reported only in a few case reports. We report the management of a patient of intracerebral abscess and reconstruction of the accompanying anterior skull base defect through an EETA.Thirty-year-old male with a frontal lobe abscess due to a penetrating skull base trauma was operated via EETA. After drainage of the abscess, dural and bony defects were repaired to prevent any recurrence. Postoperative radiological imaging revealed prominent decrease in abscess size. The patient did not need any further surgical intervention, and antibiotherapy was adequate.EETA is safe and effective in the management of brain abscesses. Skull base endoscopy provides direct visualization of the abscess cavity through a minimal invasive route, facilitates wide exposure of surrounding neurovascular structures within the operative field, and enables concurrent closure of the skull base defect.

5362. Tarasidis, G. S., et al. (2017). "Hearing Preservation After Penetrating Cochlear Injury." The Annals of otology, rhinology, and laryngology **126**(2): 163-165.

OBJECTIVES: To share results and recommendations for management of penetrating cochlear injury., METHODS: A patient underwent repair of a penetrating cochlear injury after a projectile led to a traumatic cochleostomy with a narrow miss of the facial nerve and intracranial carotid artery., RESULTS: Postoperatively, the patient's audiogram demonstrated a pure tone average of 47.5 dB for air conduction and 35 dB for bone conduction, worse in the high frequencies, with a Word Recognition Score of 76%., CONCLUSIONS: Hearing loss from a penetrating cochlear injury can be mitigated with early repair, minimizing inner ear trauma, and steroid use to treat posttraumatic labyrinthitis.

5363. Tarbet, C., et al. (2021). "White-eyed blowout fracture with muscle entrapment misdiagnosed as increased intracranial pressure: An important clinical lesson." The American journal of emergency medicine **48**: 375.e371-375.e373.

Patients with white-eyed blowout fracture with muscle entrapment in the pediatric population may be misdiagnosed as increased intracranial pressure (ICP) due to the similarity in presenting symptoms. A delay in the correct diagnosis can lead to permanent sequelae including diplopia, permanent loss of vision, and death. In this case report we discuss the treatment of a male pediatric patient who presented in the ED with nausea, confusion, and restricted eye gaze. He was misdiagnosed with increased intracranial pressure and was admitted to the PICU. Subsequent consultation by ophthalmology allowed for the correct diagnosis of a trapdoor fracture. The patient was taken to the OR for emergent orbitotomy with reduction of the fracture and release of the entrapped muscle. Symptoms of white-eyed orbital blowout fractures with muscle entrapment easily mimic symptoms of head trauma with increased ICP. Misdiagnosis of trapdoor orbital fractures with entrapment can be avoided by ordering and critically reviewing an orbital CT and requesting an ophthalmologic consultation in the ED to evaluate extraocular movement. This report should help to increase awareness of symptoms of white-eyed orbital blowout fractures with muscle entrapment, prevent confusion with elevated ICP, and assist accurate and timely diagnosis in the ED to arrange appropriate management and surgical intervention to ensure best outcomes.

5364. Tartaglione, T., et al. (2012). "Importance of 3D-CT imaging in single-bullet cranioencephalic gunshot wounds." La Radiologia medica **117**(3): 461-470.

PURPOSE: The aim of this paper is to demonstrate that computed tomography (CT) and three-dimensional (3D) CT imaging techniques can be useful tools for evaluating gunshot wounds of the skull in forensic medicine. Three purposes can be achieved: (1) identifying and recognising the bullet entrance wound - and exit wound, if present; (2) recognising the bullet's intracranial course by studying damage to bone and brain tissue; (3) suggesting hypotheses as to the dynamics of the event., MATERIALS AND METHODS: Ten cadavers of people who died of a fatal head injury caused by a single gunshot were imaged with total-body CT prior to conventional autoptic examination. Three-dimensional-CT reconstructions were obtained with the volume-rendering technique, and data were analysed by two independent observers and compared with autopsy results., RESULTS: In our experience, CT analysis and volumetric reconstruction techniques allowed the identification of the bullet entrance and exit wounds and intracranial trajectory, as well as helping to formulate a hypothesis on the extracranial trajectory to corroborate circumstantial evidence., CONCLUSIONS: CT imaging techniques are excellent tools for addressing the most important questions of forensic medicine in the case of gunshot wounds of the skull, with results as good as (or sometimes better than) traditional autoptic methods.

5365. Tatar, S., et al. (2016). "Clinical analysis of facial fractures: A ten years study of 300 cases." Journal of Experimental and Clinical Medicine (Turkey) **33**(4): 221-224.

The reasons and types of facial fractures and their treatment approaches are different, depending on the age group, and these fractures constitute an important part of the practice of plastic surgery. Demographic characteristics, etiologies of fractures, fracture types, and treatment approaches were evaluated in patients who underwent an operation due to facial fractures between 2006 and 2016. A total of 300 patients were operated on at our clinic over a period of ten years. The reason for the fracture was often motor vehicle collisions in the adult patient group, while the reason was falls and accidents in the pediatric age group. Mandibular fractures ranked first among other types of fracture and orthopedic injuries ranked first among systemic injuries. The preferred treatment approach was open surgery in adult patients and conservative therapies in the pediatric age group. The present study carried out a retrospective review of 300 cases and demographic characteristics, etiologies, fracture types, accompanying injuries, and treatment approaches were presented in consideration of the current literature.

5366. Tatiya Harish, S., et al. (2018). "Five-year retrospective analysis of profile of firearm deaths in pune region." Medico-Legal Update **18**(2): 25-28.

A firearm is any weapon which discharges a missile by the expansive force of the gases produced by burning of an explosive substances. According to the World Health Organization, firearms are used in two thirds of all homicide cases and one fifth of suicide cases. India’s rates of violence vary greatly and in majority of firearm related injuries illegal, unlicensed weapons are used. The objective of the study is to outline the pattern of firearm injuries and deaths in this area and compare it with the pattern seen in other parts of the world. In the present study, the medicolegal autopsies conducted between January 2012 to December 2016 at B.J. Government Medical College and Sassoon General Hospital, Pune, Maharashtra were analyzed retrospectively. Males were more commonly affected than females; while highest number of deceased belonged to age group of 21 to 40 years. Majority of firearm deaths were homicidal in nature; while Revenge for personal enmity and Land Dispute, Business/political rivalry were the leading circumstances leading to firearm deaths. Firearm injuries were solely present without any other injuries in majority of the cases and lung, heart and brain were common internal organs affected.

5367. Tatli, M., et al. (2006). "Anesthesia dolorosa caused by penetrating cranial injury." European neurology **56**(3): 162-165.

Anesthesia dolorosa (AD) is an uncommon complication of surgical treatments for trigeminal neuralgia. Its incidence is around 0.8%. To our best knowledge, AD caused by a penetrating cranial injury has not been reported previously. We report the case of a 31-year-old male patient with left-sided neuropathic keratitis and AD that began 18 years earlier, following a penetrating cranial injury with a knife to the left postauricular area. The patient was successfully treated by a carbamazepine and gabapentin combination. In conclusion, penetrating cranial injury is

uncommon but may cause a serious neurologic disturbance. In the differential diagnosis of AD, a penetrating injury should be kept in mind. In these cases, treatments should be effective and immediate; otherwise, this may result in catastrophic consequences such as neurotrophic keratitis and blindness. Ophthalmologists should be aware of these potential problems. Copyright (c) 2006 S. Karger AG, Basel.

5368. Tattoli, L., et al. (2019). "An unusual work-related fatality: the importance of scene investigation combined with autopsy findings." Forensic science, medicine, and pathology **15**(3): 513-515.

Transorbital penetrating intracranial injuries are uncommon amongst the civilian population, but they can be found in fatal work-related accidents. An unusual case of accidental fatal penetrating intracranial injury in a 44-year-old man at work is reported. He was working in a building site driving a tractor with a rear- mounted flail mower. While he was mowing grass close to a crane, he became unconscious and then comatose. A cranium X-Ray and a brain CAT scan taken before he died revealed the presence of a metallic foreign body in the left occipital area that had penetrated the left eyelid and orbital bone. At autopsy, a fragment of a frayed electrical copper cable was found stuck in the brain. Investigation at the scene found a cable with the same characteristics of the fragment recovered from the victim's brain protruding from the ground just beneath the tractor. It was concluded that the mower blades had severed the cable and propelled a fragment of it upwards, striking the man in the head.

5369. Tattoli, L., et al. (2014). "Three rounds as "tandem bullets": unusual findings in a case of a suicidal gunshot to the head." Forensic science, medicine, and pathology **10**(4): 613-618.

We report an unusual case of suicide in which three 7.65 caliber projectiles were found in the single gunshot wound to the head of a 53-year-old man. Based on data collected at the death scene, CT scan, autopsy findings, and ballistics analysis, the events were reconstructed as follows: two 7.65 mm rounds had already been fired from the 9 mm Makarov pistol the subject was using but, being a smaller caliber, the cartridges had slipped forward and lodged within the barrel. When a third 7.65 mm cartridge was chambered and the gun fired for the third time, the nose of the last bullet hit the lodged bullets and all three rounds were propelled out of the muzzle in tandem as a single shot. Ballistic investigations confirmed that the kinetic energy of the three tandem bullets would have been sufficient to perforate the skull. In cases of gunshot wounds where the manner of death is unclear, a number of well-described circumstantial parameters, such as an atypical anatomical location of the gunshot, unusual firearm, or ammunition, as well as ambiguous autopsy findings, can raise doubts about the manner of death. In very rare cases, despite a single entrance wound, two or more bullets are recovered from the body, fired by the same weapon at the same time (the so-called "tandem bullet" phenomenon). Injuries by "tandem bullets" have crucial implications in gunshot deaths because of the mismatch between the number of entrance and exit wounds and the number of bullets found in or near the body.

5370. Taupin, A., et al. (2013). "Dental implant rehabilitation supported by distracted bone: A 10 years experience." European Surgical Research **50**(2): 90.

Introduction: The dental implant rehabilitation is one of the ultimate challenge of the management of patients who have experienced ballistic trauma of the face. Distraction osteogenesis is a surgical technic proven to be efficient in the reconstruction of multi tissular defects that are characteristics of this type of injury. The authors present the results of their experience in terms of dental implant rehabilitation supported by distracted bone over 10 years. Objectives: The objective of this study is to clarify the elements concurring to the success of dental implant rehabilitation after distraction osteogenesis of the jaw. Materiel/Patients and Methods: 3 patients treated in the department of maxillofacial and plastic surgery of the Universatory Hospital of Caen (France) have undergone such surgery and received an denatl implant rehabilitation after mandibular distraction osteogenesis. Results: Results: Several well known undesirable events occured during distraction osteogenesis leading to improved distraction procedure and devices. Among all implants placed in distracted bone, only one has to be removed because of infection. Implant stability in distracted bone is comparable to the stability of those placed in healthy bone. Every patient are satisfy by their implant dental rehabilitation and have recovered their masticatory function. Conclusion: Distraction osteogenesis is a unique surgical technic that allows a three-dimensional and especially multitissular reconstruction that allows dental implant rehabilitation in safe and quality conditions.

5371. Tavlasoglu, M., et al. (2012). "Bleeding control of vertebral artery transection in its second part due to gunshot injury." Heart Surgery Forum **15**: S123.

OBJECTIVE:The vertebral arteries arise from the subclavian arteries, one on each side of the body, and then enter deep to the transverse process of the level of the 6th cervical vertebrae (C6). Or occasionally (in 7.5% of cases) at the level of C7. They then proceed superiorly, in the transverse foramen of each cervical vertebra until C1. This path is largely parallel to, but distinct from, the route of the carotid artery ascending through the neck. At the C1 level the vertebral arteries travel across the posterior arch of the atlas through the suboccipital triangle before entering the foramen magnum. Therefor the vertebral artery may be divided into four parts. The first part runs upward and backward between the Longus colli and the Scalenus anterior muscles, the second part runs upward through the foramina in the transverse processes of the C6 to C2 vertebrae, third part of the artery is covered by the Semispinalis capitis and is contained in the suboccipital triangle, a triangular space bounded by the Rectus capitis posterior major, the Obliquus superior, and the Obliquus inferior muscles, and the fourth part pierces the dura mater and inclines medialward to the front of the medulla oblongata. Because of the sheltered course of vertebral artery, its injuries only emerge as a result of gunshots. The spread of tissue damage is regarding to the mass of the bullet and its kinetic energy. In this article we present bleeding control method of vertebral artery transection in the second part of its course. METHODS:34 year-old male patient due to gunshot injury of the left vertebral artery were delivered to our clinic. We could not control bleeding in the first attempt; however we decided to find the proximal end of the vertebral artery in the departure point from subclavian artery. Subsequently the patient was turned on right lateral decubitus position to be dissected the suboccipital triangle (third part of vertebral artery). Afterwards vertebral artery had ben ligated before it entered the cranial cavity. RESULTS:As a result, the bleeding of vertebral artery transection in the second part can be controlled by ligating proximal end just close to departure point and distal end just before entering the cranial cavity. CONCLUSIONS:It should be kept in mind that patient had to be placed in lateral decubitus position to be reached to the first and third part of vetebral artery to control its bleeding.

5372. Taware, A. A., et al. (2015). "Kronlein shot-evisceration of brain: A case report." Journal of Forensic Medicine and Toxicology **32**(2): 42-45.

Close range shot gun wounds of head produce a very devastating injury leading to evisceration of brain. Many a times it is misinterpreted as explosion injury. The current case discusses autopsy features and mechanism of this injury caused to a 12 year old boy who while playing misfired the shotgun accidentally and succumbed to death.

5373. Tawfilis, A. R., et al. (2002). "Alloplastic reconstruction of a temporal bone and glenoid fossa defect." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **60**(9): 1079-1082.

5374. Tay, J. S. and J. S. Garland (1987). "Serious head injuries from lawn darts." Pediatrics **79**(2): 261-263.

Serious injuries secondary to lawn darts have not been reported. In this article two cases of penetrating skull injuries are reported. One patient developed a polymicrobial brain abscess necessitating surgical drainage and a prolonged hospitalization. Psychologic function was diminished at discharge. The second child required surgical repair of a depressed skull fracture. Thirteen lawn dart head injuries have been reported to the Consumer Product Safety Commission between 1983 and 1985. These injuries are summarized along with the reported cases to point out the seriousness (neurologic impairment in 5/10 head injuries) of such injuries and warn parents and physicians of the potential dangers of this game.

5375. Taylor, A. G. and J. C. Peter (1997). "Patients with retained transcranial knife blades: a high-risk group." Journal of neurosurgery **87**(4): 512-515.

Sixty-six patients with transcranial stab wounds presenting to Groote Schuur Hospital over a 2-year period are reviewed. Two groups were identified, those with retained knife blades at presentation (Group A, 13 patients) and those without (Group B, 53 patients). An increased incidence of vascular complications was observed in Group A, (eight of 13 patients) compared with 11 of 53 patients in Group B ($p < 0.01$, chi-square test). The mortality rate was also higher in Group A, with deaths in three of 13 patients compared with four of 53 in Group B. Increased mortality was a result of

vascular injury, and in two patients neurological deterioration occurred only after knife blade removal. Possible reasons for these findings are that retained blades tend to be deeply penetrating with a potential for more cerebral and vascular injury, and there is a higher incidence of petrous bone penetration that results in carotid artery injury.

5376. Taylor, C. and A. J. Macnab (2001). "Pediatric eye injury due to Avena fatua (wild oats)." Pediatric emergency care **17**(5): 358-360.

OBJECTIVE: We report on florid and unusual ophthalmic physical signs in three children where the trauma was caused by seeds from Avena fatua, a grass common in western North America., DESIGN: Case series and literature review., SETTING: Three local emergency departments (ED) during the fall of 1998., PATIENTS OR PARTICIPANTS: Three children reporting to an ED with an acutely painful eye from which the foreign body was identified botanically as Avena fatua., INTERVENTIONS: None., MAIN OUTCOME MEASURES: Symptoms, interventions, duration of problem., RESULTS: Three male children (6, 10, 14 years) presented separately following incidents in which they had sustained direct eye injury. Each child immediately experienced severe pain and profuse watering of the eye. Severe localized edema of the conjunctiva and inflammation was evident with conjunctival vessel injection leading to bleeding, reminiscent of a chemical "burn." Initially, two children appeared to have an eyelash caught behind the lower lid. In both instances, the emergency physicians initially dismissed the possibility of there being a significant foreign body, but because of the severity of the pain, conjunctival vessel injection, and edema, they attempted to remove the "lash." Removal of the foreign body proved difficult in all three cases, requiring far greater traction than anticipated. Intact seedpods had become embedded in the subconjunctival space. Ophthalmic analgesia relieved the pain immediately, but in one child who was treated with topical antibiotic alone, significant pain was experienced for 18 hours, until steroid-antibiotic therapy was instituted. All injuries occurred in late summer when the grass propagates., CONCLUSIONS: The physical signs of scleral vasculitis and conjunctival edema can be mistaken for chemical injury or allergic chemosis, but where a foreign body resembling a hair or eyelash is visible, the presence of a seed-pod retained in the subconjunctival space must be considered, particularly if the patient reports exposure to wild grass. Application of local analgesia, foreign body removal, and steroid-antibiotic treatment is recommended.

5377. Taylor, D. M., et al. (2002). "An analysis of marine animal injuries presenting to emergency departments in Victoria, Australia." Wilderness & environmental medicine **13**(2): 106-112.

OBJECTIVE: To describe the epidemiology of marine animal injury in Victoria, Australia, in order to identify risk factors and recommend prevention strategies., METHODS: Retrospective, descriptive study of patients with marine animal injuries who presented to Victorian emergency departments between October 1995 and June 2000. Data were obtained from the Victorian Emergency Minimum Dataset. The main outcome measures were the marine animal involved; the nature, time, and place of injury; and subject demographics and activity., RESULTS: Two hundred five injuries were identified, and males predominated (71.7%, P < .01). Injuries were most frequent during summer and when jellyfish were most prevalent. Various fish species, stingrays, jellyfish, and sharks were incriminated in 83 (40.5%), 46 (22.4%), 42 (20.5%), and 5 (2.4%) injuries, respectively. Most (65.9%) injuries occurred during leisure or sport, and 72 (35.1%) occurred in a place of recreation. Spikes, spines, and barbs caused 82 (40.0%) injuries, and stings caused 54 (26.3%) injuries. Bites were uncommon. Most injuries were to the limbs, with the hands or feet injured in 127 (62.0%) patients. Forty (19.5%) injuries were associated with a retained foreign body. Only 17 (8.3%) patients required admission to the hospital., CONCLUSIONS: Marine animal injury is seasonal but rarely serious. Vigilance is required when handling fish, and protective gloves, footwear, and clothing are recommended where appropriate. Clinicians should consider retained foreign bodies in penetrating injuries. Warnings are recommended when jellyfish are most prevalent.

5378. Teddy, P. J., et al. (1984). "Traumatic cerebral flaccid paraplegia." Paraplegia **22**(5): 320-324.

Two cases of paraplegia caused by head injuries sustained in recent military conflicts are presented. The underlying pathological disturbances could be related to the CT scan appearances and are discussed in the light of previously reported series. Both cases were remarkable for an early and prolonged paraplegia which was flaccid, rather than spastic, and for the sensory impairment produced.

5379. Teeter, W., et al. (2016). "REBOA improves mean blood pressure (MBP) and shock index (SI) as measured by Continuous Vital Signs (CVS) even in patients arriving in arrest." Shock **45**(6): 58.

Introduction: Resuscitative Endovascular Balloon Occlusion of the Aorta (REBOA) has been shown in both translational research and several case series to be a potentially life-saving procedure. Methods: We recorded systolic (SBP) & diastolic (DBP) blood pressure, heart rate (HR), and end-tidal CO2 (EtCO2) values every 2 seconds before (Pre), and after (Post) aortic occlusion (AO). Mean arterial blood pressure (MBP), shock index (SI), and pulse pressure (PP) were calculated from these values. Patients were included if they arrived without or lost a pulse prior to undergoing to REBOA at the diaphragm (Zone 1) and at least 15 minutes of continuous vital sign (CVS) monitoring. AO time was recorded in the medical record or determined by real-time video monitoring. Results: 14 patients met inclusion criteria, arriving to the trauma center in arrest or arresting shortly after arrival. Mean age (± SD) was 41 (± 18 years), mean injury severity score (ISS) was 35 (+15), 79% were male, 10 sustained blunt injuries, and 4 sustained penetrating injuries. Seven patients experienced return of spontaneous circulation (ROSC) following AO by REBOA. Early deaths included 11 patients who expired in the ED and 1 in the OR, all within 2 hours. Of these, 10 patients died from hemorrhagic shock and one from severe TBI. Two patients died in the ICU, both from multisystem organ failure. None of the patients surviving to the ICU died from hemorrhagic shock, with two patients surviving around 12 hours, and one patient surviving almost 9 days. Significant improvements in CVS pre- vs. post-AO were detected at 5 minutes for MBP (55.7 ± 36.3-87.7 ± 51.4 mmHg; $p < 0.005$), SI (1.4 ± 0.8-1.1 ± 0.6; $p < 0.004$), and EtCO2 (14.0 ± 11.2- 18.4 ± 12.1 mmHg; $p < 0.004$). Improvement in SI was significant at 10 minutes (1.4 ± 0.9-1.1 ± 0.7; $p < 0.004$), and EtCO2 was significantly improved at all intervals ($p < 0.004$). Improvements approaching significance were seen in mean SI, SBP, MBP and EtCO2 over all intervals. Conclusion: Improvements in SI, MBP, and EtCO2 occur after REBOA, even in patients without signs of life on arrival. CVS monitoring, along with video recording of the procedure to accurately record time of AO, provides reliable data in order to study the technique and physiologic consequences of REBOA (Table Presented).

5380. Teff, R. J. (2010). "Use of neurosurgical decision-making and damage-control neurosurgery courses in the Iraq and Afghanistan conflicts: a surgeon's experience." Neurosurgical focus **28**(5): E9.

A shortage of Coalition neurological surgeons in the Iraq conflict prompted a creative approach to standardized neurosurgical care in 2007. After formulation of theater-wide clinical pathway guidelines, a need for standardized triage and neurological resuscitation was identified. The object was to establish a simple, reproducible course for medics, forward surgical and emergency room personnel, and other critical care providers to quickly standardize the ability of all deployed health care personnel to provide state-of-the-art neurosurgical triage and damage-control interventions. The methods applied were Microsoft PowerPoint presentations and hands-on learning. The year-long project resulted in more than 100 individuals being trained in neurosurgical decision making and in more than 15 surgeons being trained in damage-control neurosurgery. At the year's conclusion, hundreds of individuals received exceptional neurosurgical care from nonneurosurgical providers and a legacy course was left for future deployed providers to receive ongoing education at their own pace.

5382. Teitelbaum, G. P., et al. (1998). "Endovascular coil occlusion of a traumatic basilar-cavernous fistula: technical report." Neurosurgery **42**(6): 1394-1398.

OBJECTIVE AND IMPORTANCE: We describe an unusual case of an 8-year-old male patient presenting with a traumatic basilar artery aneurysm associated with a basilar-cavernous fistula., CLINICAL PRESENTATION: The fistula occurred as the result of an accident involving a vehicle and a pedestrian. The patient originally presented in a coma and with a dense left hemiparesis., INTERVENTION: The traumatic basilar aneurysm and basilar-cavernous fistula were successfully occluded by endovascular coil embolization in two sessions. By 6 months after injury, the patient had made an excellent neurological recovery, requiring only a left leg brace for walking., CONCLUSION: Endovascular coil embolization provided an effective treatment option in the case of this complex and unusual arteriovenous fistula. We discuss the radiological and clinical features of related traumatic neurovascular lesions.

5383. Teixeira, R. R., et al. (2016). "Mild Traumatic Brain Injury: A Brief Review." Brazilian Neurosurgery.

Considered to be the main cause of invalidity and death, besides being extremely costly to the health care system, cranioencephalic trauma can be defined as an alteration of the normal brain function that can be caused by collisions, abrupt head movements or even penetrating injuries. Traumatic brain injuries (TBI) can be classified as mild, moderate or severe. In the case of mild TBI, there is a great variability in its classification, which can be based on the Glasgow coma scale (between 13 and 15), alterations in consciousness, amnesia, the International Classification of Diseases, Ninth Revision (ICD-9), and even on the abbreviated injury scale (AIS). Due to the importance of mild TBI (it corresponds to 75% of all TBIs and, according to the Centers for Disease Control and Prevention [CDC], there are ~ 500 new cases per every 100,000 persons per year), the present report consists of a brief review of the epidemiology, diagnosis and possible prognosis of this type of injury. Further understanding is paramount, since mild TBI is one of the few disorders in medicine in which the benign classification can be misleading and still be associated to further complications.

5386. Tekavcic, I. and V. A. Smrkolj (1996). "The path of a wounding missile along the spinal canal: a case report." Spine **21**(5): 639-641.

STUDY DESIGN: The authors report a penetrating gunshot injury to the cervical spine at the C6 level, with retention of the missile within the spinal canal at the T10 level., OBJECTIVES: The treatment of this patient involved debridement of entrance wound on the day of admission and laminectomies in the cervical and thoracic levels 3 days after the incident., SUMMARY OF BACKGROUND DATA: The migration of a foreign body along the intracranial part of the central nervous system has been reported in the literature, but we have found no report of an intercanal gunshot wound measuring 30 cm with complete liquefaction of the cord., METHODS: On admission, a 21-year-old man had an entrance wound on the right side of neck. He had complete paraplegia and could not flex the wrist. The cervical spine radiograph revealed a fracture of the C5 arch and metallic fragments in the spinal canal. A radiograph of the thoracic and lumbar spine disclosed a bullet trapped at the T10 level. Laminectomies at C6-C7 and T9-T10 were performed and the bullet and its fragments were removed. The ruptured dura was replaced by lyophilized dura., RESULTS: The wounds healed without infection. On discharges the patient's neurologic status was unchanged., CONCLUSIONS: Laminectomies and removal of metallic foreign bodies were performed to reduce the risk of infection in the spinal canal and to prevent toxic effects of dissolved metals on uninjured parts of the central nervous system.

5387. Tekkok, I. H., et al. (1996). "Posttraumatic gas-containing brain abscess caused by Clostridium perfringens with unique simultaneous fungal suppuration by Myceliophthora thermophila: case report." Neurosurgery **39**(6): 1247-1251.

OBJECTIVE AND IMPORTANCE: Gas-containing brain abscesses are rare, and the vast majority are caused by Clostridium perfringens. Significant simultaneous fungal infection in a bacterial abscess is even rarer. We present such a case and review the literature., CLINICAL PRESENTATION: A 21-month-old male patient sustained a penetrating head injury in a barnyard, developed a gas-containing left parietal brain abscess, and presented with high fever, galeal swelling, and seizure., INTERVENTION: The patient initially underwent debridement of his wound and then repeated aspirations. The initial cultures revealed pure growth of Clostridium perfringens. Despite appropriate antibiotic therapy, serial neuroimaging did not demonstrate a decrease in the size of the cavity. An excision had to be undertaken 6 weeks after the injury. The culture from the excised specimen revealed an unexpected growth of a saprophytic and opportunistic fungus, Myceliophthora thermophila. Antifungal treatment consisting of the administration of liposomal amphotericin B and itraconazole was then performed. The child was well and neurologically intact 6 months after the excision., CONCLUSION: Our review revealed 38 cases of clostridial brain abscess in the literature. Despite the reputation of the organism, the outcome with clostridial brain abscesses was relatively benign. The main characteristics of clostridial brain abscesses are highlighted, with reference to their optimal treatment. Our review also revealed that

fungal infection after a penetrating head injury is extremely rare and often fatal. Our case seems to be the first in the medical literature with growth of M. thermophila as a causative agent for intracranial suppuration.

5388. Tellier, A., et al. (1990). "Long-term effects of severe penetrating head injury on psychosocial adjustment." Journal of consulting and clinical psychology **58**(5): 531-537.

The long-term effects of severe penetrating head injury on adjustment levels were studied. Forty-one World War II veterans who suffered penetrating injury to the brain were interviewed 40 years after their initial injury using the Washington Psycho-Social Seizure Inventory (WPSI). The results support a comparable behavioral impact of right and left hemispheric lesions. Similarly, no significant relations were found between anterior and posterior locus of damage and psychosocial difficulties, although the results pertaining to the right-anterior group could be interpreted as suggestive of much greater maladjustment in all life dimensions assessed by the WPSI. Findings are discussed in terms of theoretical positions on hemispheric specialization and long-term expectancies that hold implications for planning rehabilitation programs for such patients.

5389. Temiz, C., et al. (2005). "Penetrating injury of cranium: a case report." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES **11**(4): 352-355.

A 38 year-old male patient treated for paranoid schizophrenia for five years was found on a chain saw table at his workplace with a great parasagittal, linear active bleeding wound from left occiput to medial portion of left orbita. He was unconscious.with a Glascow coma score of 5 points as 1-3-1. Cranial radiographies revealed a bone defect from left occipital region to left medial border of orbita. CT scan showed also a great linear tissue damage involving left lateral ventricle, and an intracerebral hematoma located mainly at left frontoparietal region. An emergent left frontoparietal craniotomy was performed. Four centimetres laterally midline, there was a linear, vertical tissue wound. Hemostasis was achieved at first and intracerebral haematoma evacuated. At one week postoperatively, his eyes started to react to verbal commands. At 7 months postoperatively he was attempting to cooperate with eye movements and writing. He was right hemiplegic, aphasic and on the right side deep tendon reflexes were hyperactive. His Karnofsky score was almost 40 points. Cranial injuries due to chain saw accidents are very rare. Early surgical procedures (incl. decompression) combined with aggressive antibiotherapy seem to have a great survival benefits. However best long-term results show that this type of injuries have a great rate of mortality and morbidity despite all surgical and medical treatment procedures.

5391. Temkar, S., et al. (2017). "Pseudo retinitis pigmentosa in a case of missed intraocular foreign body." BMJ case reports **2017**.

A 35-year-old man presented with history of painless, progressive loss of vision in the left eye for the past 7 years. There was history of trauma to the same eye with an iron object 7 years prior. Fundus examination revealed pigmentary retinopathy (unilateral advanced retinitis pigmentosa (RP)-like picture). X-ray orbits were suspicious of retained intraocular foreign body (IOFB). CT orbits confirmed the presence of IOFB. Electroretinogram revealed depressed responses. Right eye examination was within normal limits. A diagnosis of siderosis bulbi with unilateral pseudo RP-like fundus was made. No surgical intervention was planned for IOFB in view of poor visual prognosis.

5392. Temkin, N., et al. (2011). "Latin American pilot traumatic coma data bank: Baseline characteristics." Journal of neurotrauma **28**(6): A113.

PURPOSE: The South American and Caribbean region has one of the highest rates of traumatic brain injuries (TBIs) in the world. Despite this, there is little data about the characteristics of these injuries and the people injured. METHODS: The Latin American Pilot Traumatic Coma Data Bank (LAPTCDB) prospectively collected information on 748

non-penetrating TBIs in teenagers and adults at 8 centers in 5 low- and middleincome countries (LMICs) in South America. To be included, patients had to arrive at the study hospital within 24 hours of injury and have a Glasgow Coma Scale score (GCS) of 3-8 at admission or deteriorate to that level within 48 hours. GCS motor had to be 5 or less if the patient was intubated. RESULTS: Patients were entered between 2008 and 2010. Half of the participants were in their teens or 20s; beyond the 20s, the number of cases decreased with each decade. Less than 10% were over 60. Unlike in high income countries, motorcycle crashes were the most common cause of injury; assaults were rare. For patients arriving directly, half arrived at the study hospital within an hour; 2/3 arrived by ambulance. Information about pre-hospital treatment was rarely available. Most patients arrived without intubation or sedation. Hypotension on admission was documented in only about 25% of cases, although this underestimates the overall occurrence of this secondary insult as pre-hospital blood pressure was rarely reported and blood pressure was recorded hourly or less in the emergency department (ED). About one third of subjects had no assessment of hypoxia through the time of resuscitation. Over 1/3 of participants had CT with Marshall classification DI-III. CONLUSIONS: TBI in LMICs has many different characteristics from that in high income countries and deserves further study.

5393. Temkin, N., et al. (2012). "Latin American pilot traumatic coma data bank: Baseline characteristics." Brain injury **26**(4-5): 762.

Objectives: The South American and Caribbean region has one of the highest rates of traumatic brain injuries (TBIs) in the world. Despite this, there is little data about the characteristics of these injuries and the people injured. Methods: The Latin American Pilot Traumatic Coma Data Bank (LAPTCDB) prospectively collected information on 552 non-penetrating TBIs in teenagers and adults at 9 centers in 5 low- and middle-income countries (LMICs) in South America. To be included, patients had to arrive at the study hospital within 24 hours of injury and have a Glasgow Coma Scale score (GCS) of 3-8 at admission or deteriorate to that level within 48 hours. GCS motor had to be 5 or less if the patient was intubated. Results: Patients were entered between 2008 and 2011. Half of the participants were in their teens or 20 s; beyond the 20 s, the number of cases decreased with each decade. Less than 10% were over 60. Unlike in high income countries, motorcycle crashes were the most common cause of injury; assaults were rare. Half arrived at the study hospital within two hour; 3/5 arrived by ambulance. Information about pre-hospital treatment was rarely available. Most patients arrived without intubation or sedation. Hypotension on admission was documented in only about 12% of cases, although this underestimates the overall occurrence of this secondary insult as pre-hospital blood pressure was rarely reported and blood pressure was recorded hourly or less in the emergency department (ED). About one third of subjects had no assessment of hypoxia through the time of resuscitation. Over 1/3 of participants had CT with Marshall classification DI-III. Conclusions: TBI in LMICs has many different characteristics from that in high income countries and deserves further study.

5394. Temkin, N. R. (2003). "Risk factors for posttraumatic seizures in adults." Epilepsia **44**(s10): 18-20.

PURPOSE: Traumatic brain injury has long been known to be a cause of epilepsy. Most information on risk factors for developing posttraumatic seizures is from before computed tomography (CT) scanning became universal. This article looks at factors about the injury or individual that put people at especially high risk of developing posttraumatic seizures., METHODS: We considered 783 cases at high risk of developing seizures, followed up for 2 years as part of seizure prophylaxis studies. Cumulative incidence of seizures in subgroups and standardized incidence ratios were used to identify factors related to unprovoked seizure risk., RESULTS: Subgroups with significantly elevated risk include those with evacuation of a subdural hematoma; surgery for an intracerebral hematoma; Glasgow Coma Scale in the severe range of 3 to 8; early seizures, especially delayed early seizures; time to following commands of a week or more; depressed skull fracture that was not surgically elevated; dural penetration by injury; at least one nonreactive pupil; and parietal lesions on CT scan., CONCLUSIONS: Both the risk factors and the time course of the risk are important for designing seizure-prophylaxis studies and, if an effective prophylactic regimen is identified, for deciding on appropriate candidates for prophylaxis.

5395. Temkin, N. R. (2009). "Preventing and treating posttraumatic seizures: the human experience." Epilepsia **50 Suppl 2**: 10-13.

Posttraumatic epilepsy presents an ideal target for prevention efforts. Traumatic brain injury (TBI) is common, characteristics that put people at high risk such as penetrating injury or subdural hematoma or provoked seizures are

easily identified, and the latency between the injury and the onset of epileptic seizures is frequently short. Several drugs have been tested for their ability to prevent provoked seizures and epilepsy after TBI. We describe the design of those studies and their results. Phenytoin and carbamazepine significantly reduce the incidence of provoked seizures. Phenobarbital and the combination of phenobarbital and phenytoin also look promising for reducing provoked seizures, but small sample sizes in the studies evaluating these drugs do not allow definitive conclusions. None of the drugs studied (phenytoin, phenobarbital, their combination, carbamazepine, valproate, or magnesium) have shown reliable evidence that they prevent, or even suppress, epileptic seizures after TBI. For most of the regimens tested (the phenytoin/phenobarbital combination being the exception), the best estimate of effect is under a 25% reduction in posttraumatic seizures, well less than the 50% reduction most studies were designed to detect. The evaluation of the tested drugs has serious limitations, however, and antiepileptic drugs (AEDs) developed since 1980 and other compounds have barely been tested at all. Better understanding the process of epileptogenesis, testing treatments that demonstrate antiepileptogenic effects in the laboratory, and performing thorough preclinical and phase II evaluations before attempting definitive trials should greatly improve the chance of identifying ways to prevent posttraumatic epilepsy, providing the ultimate cure for this condition.

5396. Temkin, N. R., et al. (1991). "Management of head injury. Posttraumatic seizures." Neurosurgery clinics of North America **2**(2): 425-435.

Posttraumatic seizures are relatively common among patients with severe head injuries, with major risk factors being penetrating head wound, hematoma, depressed skull fracture, and, for late seizures, early seizures. Management of late posttraumatic seizures, if they do develop, follows the treatment of patients with epilepsy. Their treatment should be determined by the type of seizure (i.e., partial or generalized) and the individual responsiveness of the patient to drug therapy. Prophylactic administration of antiepileptic drugs to prevent posttraumatic epilepsy has been frequently tried. The data supports a short-term but not a long-term effect of the most commonly used drug, phenytoin. A decision of whether to use prophylaxis, with what, and for how long needs to consider the likely benefit (i.e., the chance of seizures if untreated and the likelihood that the proposed treatment will substantially reduce that chance) and risk (i.e., medical or behavioral adverse effects) of this treatment strategy.

5397. Temkin, N. R., et al. (1995). "Causes, prevention, and treatment of post-traumatic epilepsy." New horizons (Baltimore, Md.) **3**(3): 518-522.

Post-traumatic seizures often occur after severe head injury. Acutely, these seizures complicate management of the head-injured patient by increasing intracranial pressure and causing postictal decreases in level of consciousness. In the long term, epilepsy can have a negative effect on the patient's functioning and integration into society. The more severe the head injury, the more likely that post-traumatic seizures will occur. The risk of late seizures exceeds 30% for patients with penetrating head injury, intracerebral hematoma, subdural hematoma, depressed skull fracture, or seizure within the first week after injury. Late post-traumatic seizures are treated the same as any epileptic seizures of the same type. Phenytoin and carbamazepine are effective in preventing seizures in the first week after head injury, but are not effective in preventing late seizures. Both additional antiepileptic drugs and neuroprotective agents that may lessen the damage that leads to seizures are being investigated to determine if they are effective in preventing the occurrence of post-traumatic epilepsy.

5398. Temple, N., et al. (2015). "Neuroimaging in adult penetrating brain injury: a guide for radiographers." Journal of medical radiation sciences **62**(2): 122-131.

Penetrating brain injuries (PBI) are a medical emergency, often resulting in complex damage and high mortality rates. Neuroimaging is essential to evaluate the location and extent of injuries, and to manage them accordingly. Currently, a myriad of imaging modalities are included in the diagnostic workup for adult PBI, including skull radiography, computed tomography (CT), magnetic resonance imaging (MRI) and angiography, with each modality providing their own particular benefits. This literature review explores the current modalities available for investigating PBI and aims to assist in decision making for the appropriate use of diagnostic imaging when presented with an adult PBI. Based on the current literature, the authors have developed an imaging pathway for adult penetrating brain injury that functions as both a learning tool and reference guide for radiographers and other health professionals. Currently, CT is recommended as the imaging modality of choice for the initial assessment of PBI patients, while MRI is important

in the sub-acute setting where it aids prognosis prediction and rehabilitation planning, Additional follow-up imaging, such as angiography, should be dependent upon clinical findings.

5399. Tender, G. C. and D. Awasthi (2003). "Risk stratification in mild head injury patients: the head injury predictive index." The Journal of the Louisiana State Medical Society : official organ of the Louisiana State Medical Society **155**(6): 338-342.

BACKGROUND: Mild Head Injury has classically been defined as patients with a Glasgow Coma Scale (GCS) of 13 to 15. While most of these patients do well, some suffer serious outcomes. The objective of this study was to identify the group at high risk for poor outcome., METHOD: Analysis of 255 consecutive patients who presented to the Medical Center of Louisiana at New Orleans with GCS from 13 to 15 was performed. A new Head Injury Predictive Index (HIPI) based on Focal Neurological Signs, the verbal response and eye-opening components of the GCS, and CT findings was used to stratify patients into "high" and "low" risk groups., RESULTS: There were 10 in-hospital decompensations and 7 poor outcomes at discharge. The study shows that the HIPI was predictive of both poor outcomes and in-patient decompensations., CONCLUSION: When compared to GCS, the inclusion of computed tomographic and focal neurological data gives the HIPI more power in predicting poor outcome and in-hospital decompensations in the mild head injury group.

5400. Tenenholz, T., et al. (1999). "Orbital assault with a pencil: evaluating vascular injury." AJR. American journal of roentgenology **173**(1): 144.

5401. Teng, B., et al. (2014). "Removal of infratemporal fossa foreign body under C-arm." The Journal of craniofacial surgery **25**(4): 1313-1314.

A 12-year-old boy presented to our emergency department after being shot in the face. A computed tomographic scan revealed a bullet through the posterolateral wall of the maxillary sinus into the right infratemporal area, just adjacent to the skull base. We elected transantral approach with the help of endoscopy and C-arm. The bullet was successfully removed. Little is known on the best strategy for removing the infratemporal foreign body. Our experience in this case provides a safe and effective way for such injury.

5402. Teng, T. S., et al. (2019). "Traumatic transnasal penetrating injury with cerebral spinal fluid leak." EXCLI journal **18**: 223-228.

CSF leak in penetrating skull base injury is relatively rare compared to close head injury involving skull base fracture. We report a 5-year-old boy presented with epistaxis and impacted pencil into the left nostril. The child was hemodynamically stable without any neurological deficit. Intraoperatively, there was a nasal septal defect posteriorly with anterior skull base fracture associated with CSF leak. The pencil was removed from the left nostril and the CSF leak was repaired using harvested abdominal fat under the same setting. Computed Tomography (CT) of the brain showed right cribriform plate fracture with small pneumocranium. Postoperatively, a prophylactic antibiotic was given for seven days and he was discharged well. Subsequent clinic visits up to one-year postoperative period showed no recurrence of the CSF leak. History taking, physical examination and CT imaging give valuable diagnostic values in managing the penetrating skull base injury. Early intervention for removal of the foreign body and repair of the CSF leak is advocated to prevent catastrophic complication.

5403. Tenn-Lyn, N. A., et al. (2006). "Potential organ donors referred to Ontario neurosurgical centres." Canadian journal of anaesthesia = Journal canadien d'anesthesie **53**(7): 732-736.

PURPOSE: Eleven hospitals in Ontario are adult neurosurgical centres (ONCs). Patients transferred to ONCs from community hospitals with acute intracranial emergencies often have non-survivable injuries, and may be returned to the referring hospital for end-of-life care. These referring hospitals may not be familiar with neurological determination of death, or organ donation. Our objective was to determine the number of patients with severe brain injuries assessed in ONC emergency departments where progression to brain death may be reasonably expected, and to determine their outcome., METHODS: A one-year retrospective cohort study was undertaken using a convenience sample of patients

transferred to eight ONCs for neurosurgical assessment, with evidence of either (a) brain death in the emergency department, or (b) severe brain injury who met criteria of a reasonable likelihood of progression to brain death. The outcome of these patients to disposition from the ONC was determined by chart review., RESULTS: Three thousand four hundred and forty-seven patients were identified of whom 141 met inclusion criteria. Eleven patients (7.8%) were pronounced dead in the emergency department, 96 (68.1%) patients were admitted, and 34 (24.1%) were transferred back to their referring hospital. Fourteen patients (9.9%) became organ donors: two died in the emergency department and 12 died following admission., CONCLUSIONS: A significant number of patients transferred to ONCs have an injury with a likelihood of progressing to brain death, but only a small proportion of these patients become organ donors. Emergency department triage, assessment and admission decisions for patients with intracranial catastrophes should consider diagnostic criteria for brain death and recognition of donor potential as part of end-of-life care.

5404. Tenzin, T., et al. (2011). "Wilhelm Tell's failure: surgical management and follow up of a transcranial compound bow injury in a two year old child." Clinical neurology and neurosurgery **113**(6): 515-517.

5405. Teplyshova, A., et al. (2019). "Predictors of post-traumatic seizures in adults." European Journal of Neurology **26**: 792.

Background and aims: Traumatic brain injury (TBI) is a frequent cause of seizures and epilepsy. The number of prospective follow-up studies in this field is limited. The purpose of the present study was to evaluate incidence and risk factors for posttraumatic seizures (PTS), as well as epilepsy after TBI in a consecutive cohort of patients in Moscow. Methods: It was the prospective study of patients (18 year and older) hospitalized with TBI in two emergency hospitals in Moscow. Patients were evaluated at admissions and followed for 2 years. Results: 237 patients with TBI (178 men, 59 women) were included. Seizures occurred in 49 patients (20.7%). Incidence of early seizures (ES) was 18.1%, late seizures (LS) - 6.3%. Majority (85%) of ES occurred on the first day after trauma. In multivariate analysis, ES were a significant risk factor for LS (OR=8.3 95%, CI 3-25, p=0.0002). The proportion of patients with severe TBI was significantly higher in the ES group (p=0.000033). ES were more frequent in bilateral lesions (p=0.04). Subdural hematoma, depressed skull fracture and alcohol abuse were significant risk factors for ES and LS. Penetrating injury was a significant risk factor only for LS (p=0.03). ES were the important predictor of mortality - 18/43 (41.9%) of patients with ES died vs 8/194 (4.1%) of patients without ES (p=0.0000). Conclusion: ES are a significant predictor of LS and are associated with severe TBI, bilateral lesions, increased risk of mortality. Subdural hematoma, depressed skull fracture, alcohol abuse were reliable predictors of ES and LS.

5406. Tepper, O. M., et al. (2011). "Use of virtual 3-dimensional surgery in post-traumatic craniomaxillofacial reconstruction." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **69**(3): 733-741.

Traumatic craniofacial injuries often present as difficult reconstructive challenges for maxillofacial surgeons. Reconstruction is often complicated by significant soft tissue loss, comminuted bony fragments, a tenuous blood supply, and wound contamination. For panfacial injuries, restoration of normal facial width, facial height, and sagittal projection may be difficult to achieve. Marked swelling may limit the surgeons' ability to palpate and recognize subtle bony defects and malunion. Furthermore, a true 3-dimensional assessment of bony alignment may not be possible with traditional surgical exposures to the craniofacial skeleton. This article builds on previous work that introduced the use of 3-dimensionally guided surgery for microvascular free-flap reconstruction of the craniofacial skeleton. Use of this technology improves the planning, timing, and overall precision of microvascular reconstructive surgery. Based on this experience, a similar approach to reconstructing patients with significant craniofacial trauma has been adopted.

5407. Ter-Asaturov, G. P. and M. V. Lekishvili (2009). "[Experimental study of the efficacy and clinical use of Perfoost in cases of defect substitution and correction of face supporting tissues]." Stomatologiia **88**(4): 17-23.

Positive properties and perspectivity of demineralized osseous allogenic implants were pointed to. Experimental model of primary osseous plasty of mandible defects was described. The comparison of character and pace of reparative osteogenesis in experimental bone defects with Perfoost use and without transplantation was done. Perfoost had

expressed osteoinductive and osteoconductive properties providing quicker reparative osteogenesis. In clinic osseous plasty operations of upper, middle and lower parts of face were done with the use of Perfoost. All in all 14 operations in 13 patients were conducted: in 3 patients - contour plasty of frontal region of head, in 5 patients- deformation correction of zygomatic region, lower edge and bottom of eye-socket; in 5 patients - defect substitution of mandible body and branch of the 8-10 cm length (in combination with titanium plates). In 2-3 months after operation the first signs of transplant rebuilding were detected during X-ray control. The expressed rebuilding of Perfoost with its substitution by newly formed bone was seen in 1-1.5 year. No complications followed, terms of observation - up to 8 years.

5409. Teruya, J. and E. A. Hussein (2011). "Blood supply operation during egyptian revolution." Transfusion **51**: 249A.

Background/Case Studies: The Egyptian revolution took place following a popular uprising that began January 25, 2011. Millions of protesters demanded the overthrow of Egyptian president Hosni Mubarak's regime. Many people suffered from life threatening injuries, after violent clashes between security forces and protesters. Study Design/Methods: The overall management of Cairo University blood bank operation was described, in an attempt to establish a standard effective plan to manage blood supply during crisis. Results/Findings: The Blood Center of Cairo University is a nonprofit independent blood bank. It is about 1 mile away from Tahrir square, where the revolution took place. An average of 140 units were collected daily, before the revolution. Three days after the uprising, thousands of Egyptians rushed to the hospital, even during curfew, to alleviate blood shortage. 81% of donors were first time donors. 3,425 units were collected in only 3 days and thousands of donors were turned away because of the limited storage capacity of the Blood Bank. A strategy was established to handle sudden influx of donors. Approximately 20-30 donors were handled at a time. The Blood Bank is used to accommodating such large numbers of donors during religious holidays. However, a barcode error caused a delay in processing of 1,000 units into components and they were used as stored whole blood. Apheresis platelets were donated during the first 2 weeks by protesters who were particularly motivated to donate for 2 victims with liver injury due to gunshot wound (GSW). The usual positive rate of HCV antibody in Egyptian donors is 3.8%. However, the positive rate of HCV markers in the collected units was only 1.6%. The frequency of positive HBs antigen, HIV antibody and syphilis antibody was 1.23%, 0.058% and 0.029%, respectively. An average of 25 elective operations were cancelled daily for 10 days. Operating theatres were used only for emergency operations. Total 183 victims received 557 units of blood and 228 units of FFP and cryoprecipitate in 8 days. Most injuries were due to GSW (55 patients), stab wound (39 patients) and cerebral hemorrhage (35 patients). Twenty patients underwent vascular surgery due to femoral and popliteal artery injury, 23 patients had orthopedic surgery and 11 patients had internal bleeding. A blood surplus developed which met the hospital needs for 1 month. Other areas in the country also had too much blood at this point. Blood collection returned to near normal operation three weeks after the end of the revolution. Conclusion: Revolution resulted in an influx of first time donors with a relatively low positive rate of HCV antibody. It is important to educate first time donors about the benefit of regular donation and plan for a potential shortage by scheduling those who were turned away. For future crisis like this situation, systematic approach to spread donors evenly on a daily basis is needed.

5410. Testerman, G. M. and L. M. Dacks (2007). "Multiple self-inflicted nail gun head injury." Southern medical journal **100**(6): 608-610.

Penetrating brain injury resulting from nail-gun use is a well-characterized entity, one that is increasing in frequency as nail guns become more powerful and more readily available to the public. We present a case and offer management strategies for a 50-year-old male with two intracranial penetrating nail gun injuries. Nail gun brain injuries are commonly intentionally self-inflicted. Suicide should be considered when straight nails cause wounds to the chest, head, or abdomen. The primary preoperative concern is formation of a traumatic pseudoaneurism, which prompts both preoperative and follow-up cerebral angiography. Surgery for combined intracranial and extracranial injury may require the collaborative expertise of colleagues from the fields of ophthalmology, otolaryngology, and oral maxillofacial surgery. A rational management strategy should permit these patients to be discharged with no additional injury.

5412. Teubner, E., et al. (2007). "[The prosthetic rehabilitation of a patient after gunshot wound and initial maxillofacial surgical reconstruction. A case report]." Die defektprothetische Versorgung eines Patienten mit Status nach einer Schussverletzung und chirurgischer Rekonstruktion. Ein Fallbericht. **117**(6): 612-632.

An improvement of prognosis after tumour therapy as well as a rather high number of multiple traumas in the craniofacial area imply a high treatment need for craniofacial tissue defects. For a successful rehabilitation of these individuals, reconstructive oral and maxillofacial surgery and prosthodontics must collaborate closely and synergistically. Besides medical and psychological findings, functional and esthetical aspects need to be taken into account. In this case report the prosthetic reconstruction of a patient with a tooth-supported telescopic defect prosthesis in the maxilla and with a multiple-unit implant-supported fixed prosthesis plus two full ceramic crowns in the mandible is shown. The prosthetic solution was indicated after maxillofacial reconstruction due to the consequence of a suicide attempt.

5413. Teulières, M., et al. (2021). "Bone lengthening with a motorized intramedullary nail in 34 patients with posttraumatic limb length discrepancies." Journal of Clinical Medicine **10**(11).

The Fitbone® motorized nail system has been used to correct limb length discrepancies (LLD) for several years. This study focuses on its application in posttraumatic limb lengthening surgery, its outcome and challenges. Materials and methods: A prospective, single center study was conducted between 2010 and 2019 in patients treated with motorized lengthening nails. The inclusion criteria were symptomatic LLD of 20 mm or more. An imaging analysis was done using TraumaCad® software (Brainlab AG, Munich, Germany) to compare frontal alignment angles and limb length discrepancy (LLD) on preoperative and latest follow-up radiographs of the lower limbs. Results: Thirty-four patients were included with a mean age of 28.8 ± 9.7 years, a mean follow-up of 27.8 ± 13 months and a mean hospital stay of 4.4 ± 1.7 days. The mean LLD was 44 ± 18 mm in 29 femoral and 32 ± 8 mm in 4 tibial cases, which was reduced to less than 10 mm in 25/34 (74%) patients. The mean healing index was 84.6 ± 62.5 days/cm for femurs and 92 ± 38.6 days/cm for tibias. The mean time to resume full weight-bearing without walking aids was 226 days ± 133. There was no significant difference between preoperative and final follow-up alignment angles and range of motion. The mechanical lateral distal femoral angle (mLDFA) was corrected in the subgroup of 10 LLD patients with varus deformity of the femur (preoperative 95.7° (±5.0) vs. postoperative 91.5° (±3.4), p = 0.008). According to Paley's classification, there were 14 problems, 10 obstacles and 2 complications. Discussion: Six instances of locking screw pull out, often requiring reoperation, raise the question of whether a more systematic use of blocking screws that provide greater stability might be indicated. Lack of compliance can lead to poor outcomes, patient selection in posttraumatic LLD patients is therefore important. Conclusion: Limb lengthening with a motorized lengthening nail for posttraumatic LLD is a relatively safe and reliable procedure. Full patient compliance is crucial. In-depth knowledge of lengthening and deformity correction techniques is essential to prevent and manage complications.

Many contact gunshots produce a muzzle imprint in the skin of the victim. Different mechanisms have been discussed in literature as being responsible for the creation of the muzzle imprint. Experimenting upon the synthetic non biological skin-skull-brain model, our goal was to document and study the creation of the muzzle imprint with the aid of high-speed photography. In our experiments, we could document with our high-speed photography (at exposure rates in the range of nanoseconds) the bulging, the pressing against the muzzle, and the splitting of the artificial skin. Furthermore, it was possible to photographically record the back pattern of synthetic tissue particles. And, the soot and gunpowder cavity could be reproduced experimentally. In conclusion the experiments completed with the skin-skull-brain model, using high-speed photography for documentation, show the promising possibilities of experimental ballistics with body models.

5420. Thali, M. J., et al. (2002). "High-speed documented experimental gunshot to a skull-brain model and radiologic virtual autopsy." The American journal of forensic medicine and pathology **23**(3): 223-228.

The authors documented and evaluated experimental gunshots to a skull-brain model with high-speed photography and subsequent radiographic examination for comparison of the morphologic findings in the model. The artificial skull was a polyurethane ball constructed in layers, with a porous diploe sandwiched between a tabula externa and a tabula interna. The brain itself was simulated with gelatin 10% at 4 degrees C, a material well known in wound ballistics. Gunshots were fired at the model from a distance of 10 m and documented with high-speed photography (up to 50 million frames/sec). Subsequently, a complete examination of the artificial skull was performed, including spiral computed tomography (with two-dimensional and three-dimensional reconstructions) and classic skull autopsy. The high-speed photographs clearly showed the dynamic development of the skull fracture system from an external perspective. The subsequent radiographic examination of the entire head volume created two-dimensional reformations in any plane and three-dimensional reconstructions of the gunshot injury of the polyurethane skull-brain model, especially the wound channel and the fracture system. Thanks to the model and high-speed photographs, the dynamic development of the morphology of a gunshot wound could be documented and studied. The data from computed tomography, using two-dimensional and three-dimensional postprocessing with a perspective view, were very similar to those from classic head autopsy, but derived in a hands-off and nondestructive manner. This examination method leads the way to radiographic digital autopsy or virtual autopsy.

5421. Thali, M. J., et al. (2002). "A study of the morphology of gunshot entrance wounds, in connection with their dynamic creation, utilizing the "skin-skull-brain model"." Forensic science international **125**(2-3): 190-194.

The goal of this study was to document the dynamic effects created within, and the developing mechanisms of a gunshot entrance wound to the skin utilizing high-speed photography and the "skin-skull-brain model". The high-speed photography was taken with an Imacon 468/Hadland-Photonics camera. Full metal jacketed, 9 mm Luger projectiles were fired at the target model from a distance of 10 m. During the evaluation of the "skin-skull-brain model", it was possible to show that injuries inflicted to this model are fully comparable to the morphology of equivalent real gunshot entrance wounds. It has been possible to document and study the dynamic process of the "bullet-skin-interaction" in the

gunshot entrance wound. The development of the morphologic terms of the entrance wound are discussed. In combination with high-speed photography, this "skin-skull-brain model" is a perfect tool for the documentation and the study of the dynamic development of gunshot entrance wounds in the skin.

5422. Thali, M. J., et al. (2003). "A high-speed study of the dynamic bullet-body interactions produced by grazing gunshots with full metal jacketed and lead projectiles." Forensic science international **132**(2): 93-98.

Experimenting upon a synthetic, non-biological Skull-Brain Model, our goal was to document and study the bullet-body interaction of grazing (glancing, tangential) gunshots. Thanks to the high-speed study of the dynamic bullet-body interaction it was possible to document the glancing behavior of projectiles with a resolution of 50 million pictures per second. It was possible to demonstrate the differing deformation and fragmentation patterns between the 9mm Luger full metal jacketed projectile and the 38 Smith & Wesson (S & W) lead round nose projectile. In a true-to-life manner the morphologic fracture systems could be documented by utilization of the model in dependence of the projectile's behavior, deformation, and fragmentation. Based on these experimental studies with body models, conclusions could be drawn for surgical and reconstructive forensic questions in real cases. In summary, model substitutes offer a suitable basis for the study of the bullet-body interaction because the experiments are reproducible, totally independent of the biological variances of corpse and animal experiments, and are harmless from the ethical perspective.

5423. Thali, M. J., et al. (2003). "New horizons in forensic radiology: the 60-second digital autopsy-full-body examination of a gunshot victim by multislice computed tomography." The American journal of forensic medicine and pathology **24**(1): 22-27.

The goal of this study was the full-body documentation of a gunshot wound victim with multislice helical computed tomography for subsequent comparison with the findings of the standard forensic autopsy. Complete volume data of the head, neck, and trunk were acquired by use of two acquisitions of less than 1 minute of total scanning time. Subsequent two-dimensional multiplanar reformations and three-dimensional shaded surface display reconstructions helped document the gunshot-created skull fractures and brain injuries, including the wound track, and the intracerebral bone fragments. Computed tomography also demonstrated intracardiac air embolism and pulmonary aspiration of blood resulting from bullet wound-related trauma. The "digital autopsy," even when postprocessing time was added, was more rapid than the classic forensic autopsy and, based on the nondestructive approach, offered certain advantages in comparison with the forensic autopsy.

5424. Thali, M. J., et al. (2003). "Image-guided virtual autopsy findings of gunshot victims performed with multi-slice computed tomography and magnetic resonance imaging and subsequent correlation between radiology and autopsy findings." Forensic science international **138**(1-3): 8-16.

Because the use of radiology in modern forensic medicine has been, until today, mostly restricted to conventional X-rays, which reduces a 3D body to a 2D projection, a detailed 3D documentation of a gunshot's wound ballistic effects was not possible. The aim of our study was to evaluate whether the progress in imaging techniques over the last years has made it possible to establish an observer-independent and reproducible forensic assessment using multi-slice computed tomography (MSCT) and magnetic resonance imaging (MRI) technologies for the documentation and analysis of gunshot wounds. The bodies of eight gunshot victims were scanned by MSCT and by MRI; the data of these imaging techniques were post-processed on a workstation, interpreted and subsequently correlated with the findings of classical autopsy. With the spiral CT and MRI examinations and the subsequent 2D multi-planar reformation (MPR) and 3D shaded surface display (SSD) reconstruction, the entire gunshot-created complex skull fractures and brain injuries (such as wound channels and deeply-driven bone splinters) could be documented in complete and graphic detail. CT and MRI also documented vital reaction to the gunshot by demonstrating air emboli in the heart and blood vessels and the classic pattern of blood aspiration to the lung. Gunshot residues deposited within and under the skin were visible. In conclusion, we think that the radiological methods of MSCT and MRI have the potential to become a routine "virtual autopsy" tool in the future. Bullets and relevant histological samples from specific sites then might be won in image-guided minimally invasive fashion via percutaneous biopsy. The rapid application of developing radiological methods may lead to new horizons in forensic documentation and intravital as well as postmortem examination.

5426. Thelin, E. P., et al. (2015). "Biochemical response to hyperbaric oxygen treatment of a transhemispheric penetrating cerebral gunshot injury." Frontiers in neurology **6**(MAR).

Hyperbaric oxygen (HBO) therapy has been suggested a treatment option in order to reduce the development of secondary insults succeeding traumatic brain injury. This case report studied the course of a 23-year-old gentleman with a close range transhemispheric gunshot wound. The biochemical parameters, using a multi-modal monitoring in the neuro-intensive care unit, improved following HBO treatment.

5427. Theunissen, C. M. M. C., et al. (2015). "[Oculocardiac reflex associated with orbital floor fracture; the value of a reliable patient history]." Oculo-cardiale reflex bij een orbitabodemfractuur; het belang van een betrouwbare anamneses. **160**: A9641.

BACKGROUND: The oculocardiac reflex presents when traction is applied to ocular muscles or on compression of the eyeball in the orbit. It is a vasovagal reaction that may be accompanied by bradycardia, nausea and vomiting., CASE DESCRIPTION: A 6-year-old boy presented with vomiting and acute pain in his right eye, but no history of trauma. On physical examination we found no abnormalities other than bradycardia. Ocular examination showed an elevation restriction and slight depression restriction as well as ptosis of the affected eye. A cerebral MRI scan showed a blow-out fracture of the orbital floor with herniation of the inferior rectus muscle. The oculocardiac reflex explained the bradycardia and vomiting. Later, the boy told us that he had in fact hit his eye with his own knee., CONCLUSION: When patients present with acute pain in the eye and vasovagal symptoms, the oculocardiac reflex that can accompany a fracture of the orbital floor should be considered. The early recognition and treatment of this fracture are necessary to prevent permanent motility restrictions of the eye. A patient's history is not always reliable and should not limit a differential diagnosis.

5428. Thierauf-Emberger, A. and S. Pollak (2014). "Penetrating head injury by a nail screw: Reflections about the cause of the accident." Rechtsmedizin **24**(6): 508-512.

Penetrating injuries to the skull are mainly seen in gunshot injuries but can also be caused by powder-actuated tools and nail guns used in the construction industry. They fire screws and nails which reach a high kinetic energy and can even perforate bony structures if they have a free flight. The presented case deals with a 22-month-old boy who was taken to an emergency department with a penetrating injury to the head. According to the parents the child sustained the injury in a fall from a tricycle. The head of a nail which had penetrated the skull to a depth of 4.5 cm was found in the skin of the forehead. The circumstances of the incident and the medical findings suggested that the boy had been accidentally hit by a free flying nail from an industrial nail gun. The intracranial foreign body was removed and the postoperative clinical course was uneventful.

5429. Thiex, R., et al. (2004). "Delayed oedema in the pyramidal tracts remote from intracerebral missile path following gunshot injury." Neuroradiology **46**(2): 140-143.

A 60-year-old man developed a severe left hemiparesis and central facial palsy, accompanied by somnolence and dysarthria 9 days after a gunshot wound to the right temporal region, from which he slowly recovered over 3 months. MRI disclosed bilateral oedema of the pyramidal tracts. This was interpreted as a consequence of the impact of the pressure wave caused by the bullet, after excluding an infectious or vascular cause.

5430. Thoeny, A. L., et al. (2017). "Hitting the Nail on the Head: A Case Report Demonstrating the Importance of a Multidisciplinary Approach to an Unusual Penetrating Intracranial Injury." A & A case reports **9**(7): 212-215.

A 28-year-old man presented with a penetrating injury by a nail gun to the head. Imaging revealed a nail abutting the superior sagittal sinus without active extravasation. An anesthesia-led multidisciplinary team devised a

detailed perioperative plan including conception of a complex decision tree, coordination of care, and resource utilization. In the operating room, the nail was removed under general anesthesia, with blood products and equipment for craniotomy readily available, and imaging modalities reserved for immediate use. This case highlights the importance of a multidisciplinary approach to challenging penetrating head injuries and the crucial role anesthesiologists have as leaders in perioperative care.

5431. Tholpady, S. S., et al. (2014). "Epidemiology, demographics, and outcomes of craniomaxillofacial gunshot wounds in a level I trauma center." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **42**(5): 403-411.

BACKGROUND: Gunshot injuries to the craniomaxillofacial region are a challenge to the trauma and reconstructive surgeon. Although management of these injuries has been standardized and early rather than late intervention is advocated, the patient characteristics before, during, and after have been poorly elucidated., METHODS: A prospectively maintained Level I trauma center database was queried as to gunshot wounds of the craniomaxillofacial skeleton. Over a five-year period (2007-2011), 168 patients were identified with these injuries. Charts were reviewed as to demographics, presentations, and outcomes and these were tested for significant relationships with hospital length of stay, numbers and types of procedures, morbidity, and mortality., RESULTS: Gunshot wounds to the craniofacial skeleton resulted in 71 deaths in this patient population. Those that died were significantly older, presented with a lower GCS, had a shorter LOS, and a higher INR than those that lived. Subgroup analysis of mechanism demonstrated mortality was more likely to occur as a result of self-inflicted injury in whites and due to assault in the African-American population., CONCLUSIONS: Data gathered from this study disputes some commonly held beliefs regarding the epidemiology of gunshot injuries and should allow for better characterization of which outcomes are consistent with which presentations. Copyright Published by Elsevier Ltd.

5432. Thomas, A. and B. George (2016). "An audit of moderate-to-severe acute head injury patients in Chris Hani Baragwanath Academic Hospital." Brain injury **30**(5-6): 742-743.

Objectives: Head injury is a devastating condition in developing countries like South Africa, contributing significantly to mortality and morbidity. The factors affecting outcome like age, gender, mechanism of injury, clinical, radiological findings and treatment are reported. Their relation to outcome (Glasgow Outcome Score) of treatment is analysed. Methods: This is a retrospective, descriptive and demographic profile study. The sample group consists of moderate-to-severe head injury patients admitted in the neurosurgical unit of Chris Hani Baragwanath Hospital from January 2011 to June 2012. The data includes age, gender, nature of head injury (scalp, skull, intracranial), mode of injury (fall from height, road traffic accident, fire arm injury, assault, blast injury), condition at presentation [Glasgow Coma Scale (GCS)], pupillary reaction, Computed Tomography (CT) scan findings, treatment received and outcome [Glasgow Outcome Score (GOS)] of treatment. Results: A total of 292 patients was enrolled in the study, 258 males (88.3%) and 34 females (11.6%). In the age distribution 50 patients were below 19 years, 161 patients were between 20-39 years, 60 patients 40-59 years and 21 patients above 60 years. The various mechanisms of injury noted were assault in 127 patients, pedestrian vehicular accident in 50 patients, motor vehicular accident in 33 patients, motor bike accidents in four patients, train accidents in two patients, gunshot injury in six patients, fall from height in 35 patients and struck by heavy object in five patients. One hundred and twenty-three patients had a GCS between 3-5, 72 patients GCS between 6-8 and 97 patients GCS 8-12. One hundred and ninety-two patients had equal and reacting pupils after the head injury, 52 patients unilateral fixed pupils and 10 patients bilateral fixed pupils. The Computed tomography (CT) of the brain showed 287 patients with focal intracranial findings, 107 with diffuse brain injury and 168 patients with features of raised intracranial pressure. One hundred and twenty-nine patients (44.1%) were surgically treated and 163 patients (55.8%) treated conservatively with medical treatment. The variables age, mechanism of injury, GCS, pupillary reaction, raised intracranial pressure and type of management was compared to GOS and found to be statistically significant. Conclusions: The outcome of patients with moderate-to-severe head injury has no effect on gender, but has a significant relationship between age and mortality. The mechanism of head injury has a direct effect on the prognosis with gunshot head having the worst outcome. The important prognostic factors affecting the outcome include: age of patients, severity of head injury (GCS), pupillary reactivity to light and the pathology of the brain CT scan. The unfavourable prognostic factors are: old age, non-reacting pupils to light, severe head injury (low GCS) and raised ICP after head injury. Medical or surgical management have similar mortality rate.

5434. Thomas, J., et al. (2017). "Case report: Household chores: Hazardous to health?" British Journal of Oral and Maxillofacial Surgery **55**(10): e144.

Introduction: To some housework and more specifically ironing is a tedious task. Any link to trauma in the literature is sparse. Case Report:A44 year old female attended Accident and Emergency department at James Cook University Hospital after tripping whilst ironing and falling onto a nearby fish tank. She presented with a single 3 cm laceration in the submental region which contained what appeared to be a small shard of glass. Clinical review demonstrated a rapidly expanding haematoma in the submental space. The airway was secured with an ET tube as a matter of urgency. CT angiogram revealed this laceration was an entry wound for a large shard of glass retained within the tissues: extending from the laceration beneath the chin to the base of tongue then through the pharynx and soft palate extending to the pituitary fossa passing within 1mm of the ICA. The neckwas explored to gain control of the major vessels. Multiple varied sized pieces of glass were removed, followed by debridement and lavage. GentafleeceTM foam was packed into the wounds and a tracheostomy placed. Recovery was complicated by an aspiration pneumonia presenting a challenge to the microbiologists to cover common microflora found in tropical fish tanks. Discussion: The management of this case demonstrate the need to follow a safe, military style approach to penetrating head and neck trauma: expecting the unexpected from a simple penetrating wound. This poster and imaging also provide anecdotal evidence for the avoidance of household chores by Oral and Maxillofacial surgeons.

5435. Thomas, M. and H. Whittet (1991). "Atypical meningitis complicating a penetrating head injury." Journal of neurology, neurosurgery, and psychiatry **54**(1): 92-93.

5436. Thomas, M. D. and K. Siu (1987). "An unusual cranial injury caused by an industrial nail-gun." The Medical journal of Australia **147**(11-12): 602-603.

An unusual case of an industrial nail-gun injury is presented. A 36-year-old man was struck in the back of his neck by a nail, which was fired from a high velocity Ramset nail-gun. The nail passed through the foramen magnum to lodge in front of the brainstem. In spite of the close proximity of the nail's trajectory to the upper cervical spinal cord and the brain stem, no major neurological damage resulted. The nail was removed successfully the following day. This case illustrates the potential for serious injury from nail-guns.

5437. Thomas, S., et al. (2007). "Endoscopic removal of foreign body from the anterior cranial fossa." The Journal of laryngology and otology **121**(8): 794-795.

Intracranial foreign bodies are typically removed via a craniotomy, which carries significant peri-operative risks. Nasal endoscopy for removal of intracranial foreign bodies is rare and has been attempted only a few times. Here, we describe a case in which nasal endoscopy was employed to successfully remove an air rifle pellet from the anterior cranial fossa, with subsequent repair of the associated cerebrospinal fistula. We thus advocate nasal endoscopy as an alternate line of management for the removal of foreign bodies from the anterior cranial fossa when possible, due to its significantly lower associated morbidity, provided adequate neurosurgical backup is available if required.

5438. Thomas, S. G., et al. (2009). "Brain abscess in a non-penetrating traumatic intracerebral hematoma: case report and review of literature." Neurology India **57**(1): 73-75.

We report a 57-year-old man who presented one month after sustaining a traumatic right temporal intracerebral hematoma with history of headache, left hemiparesis and altered sensorium of two days duration. A diagnosis of right temporal resolving hematoma was made on computed tomography scan. However, his sensorium progressively deteriorated and he underwent craniotomy and partial excision of an abscess. He was treated with appropriate antibiotics for six weeks despite of which he did not improve and died nine months later. We conclude that

there should be a high index of suspicion for brain abscess in patients with traumatic intracerebral hemorrhage if the clinical and radiological picture is different from the expected course of a resolving hematoma.

5439. Thompson, J. T., et al. (1993). "Infectious endophthalmitis after penetrating injuries with retained intraocular foreign bodies. National Eye Trauma System." Ophthalmology **100**(10): 1468-1474.

PURPOSE: To determine the risk factors and prognostic indicators of infectious endophthalmitis in eyes with penetrating injury and retained intraocular foreign body., METHODS: From the National Eye Trauma System (NETS) Registry, 492 eyes with intraocular foreign bodies were reviewed for signs of infectious endophthalmitis., RESULTS: Thirty-four eyes (6.9%) with intraocular foreign bodies had evidence of infectious endophthalmitis, and 31 (91.2%) of those eyes had signs of infection at the time of removal of the intraocular foreign body. The majority of eyes with an intraocular foreign body with or without endophthalmitis were in patients between 10 and 39 years of age, but the risk of endophthalmitis developing increased with age, especially in patients 50 years of age or older with delayed primary repair (P = 0.005). Endophthalmitis was more likely to develop in eyes with home or occupational injuries (33/358, 9.2%) than in those with injuries from other settings (1/128, 0.8%; P = 0.001). Infectious endophthalmitis was much less likely to develop in eyes with primary repair within 24 hours of the injury (10/287 = 3.5%) than in eyes with primary repair more than 24 hours after the injury (22/164, 13.4%; P < 0.0001). Bacilli or staphylococci were isolated in 21 (95%) of 22 eyes with positive cultures. Visual prognosis was reasonably good with 15 (58%) of 26 eyes attaining a visual acuity of 20/200 or better., CONCLUSIONS: Removal of a retained intraocular foreign body within 24 hours of injury markedly reduces the risk of infectious endophthalmitis developing. Older persons are at high risk for endophthalmitis developing after retaining an intraocular foreign body when there is delayed surgical repair.

5440. Thompson, K., et al. "Pharmacological treatments for preventing epilepsy following traumatic head injury." (8).

Background, Head injury is a common event and can cause a spectrum of motor and cognition disabilities. A frequent complication is seizures. Antiepileptic drugs (AED) such as phenytoin are often used in clinical practice with the hopes of preventing post-traumatic epilepsy. Whether immediate medical intervention following head trauma with either AEDs or neuroprotective drugs can alter the process of epileptogenesis and lead to a more favorable outcome is currently unknown. This review attempted to address the effectiveness of these treatment interventions. This review updates and expands on the earlier Cochrane review., Objectives, To compare the efficacy of antiepileptic drugs and neuroprotective agents with placebo, usual care or other pharmacologic agents for the prevention of post-traumatic epilepsy in people diagnosed with any severity of traumatic brain injury., Search methods, We searched The Cochrane Epilepsy Group's specialized register, CENTRAL, MEDLINE, ClinicalTrials.gov and World Health Organization International Clinical Trials Registry Platform (ICTRP) in January 2015. We searched EMBASE, Biological Abstracts and National Research Register in September 2014 and SCOPUS in December 2013. The Cochrane Epilepsy Group performed handsearches of relevant journals., Selection criteria, We included randomized controlled trials (RCTs) that include AEDs or neuroprotective agents compared with placebo, another pharmacologic agent or a usual care group. The outcomes measured included a seizure occurring within one week of trauma (early seizure), seizure occurring later than one week post-trauma (late seizure), mortality and any adverse events., Data collection and analysis, Two review authors independently assessed study quality and extracted the data. We calculated risk ratios (RR) and 95% confidence intervals (CI) for each outcome. We used random-effects models in the meta-analyses and performed pre-defined subgroup and sensitivity analyses., Main results, This review included 10 RCTs (reported in 12 articles) consisting of 2326 participants The methodological quality of the studies varied. The type of intervention was separated into three categories; AED versus placebo or standard care, alternative neuroprotective agent versus placebo or standard care and AED versus other AED. Treatment with an AED (phenytoin or carbamazepine) decreased the risk of early seizure compared with placebo or standard care (RR 0.42, 95% CI 0.23 to 0.73; very low quality evidence). There was no evidence of a difference in the risk of late seizure occurrence between AEDs and placebo or standard care (RR 0.91, 95% CI 0.57 to 1.46; very low quality evidence). There was no evidence of a significant difference in all-cause mortality between AEDs and placebo or standard care (RR 1.08 95% CI 0.79 to 1.46,very low quality of evidence). Only one study looked at other potentially neuroprotective agents (magnesium sulfate) compared with placebo. The risk ratios were: late seizure 1.07 (95% CI 0.53 to 2.17) and all-cause mortality 1.20 (95% CI 0.80 to 1.81). The risk ratio for occurrence of early seizure was not estimable., Two studies looked at comparison of two AEDs (levetiracetam, valproate) with phenytoin used as the main comparator in each study. The risk ratio for all-cause mortality was 0.53 (95% CI 0.30 to 0.94). There was no evidence of treatment benefit of phenytoin compared with another AED for early seizures (RR 0.66,

95% 0.20 to 2.12) or late seizures(RR 0.77, 95% CI 0.46 to 1.30)., Only two studies reported adverse events. The RR of any adverse event with AED compared with placebo was 1.65 (95% CI 0.73 to 3.66; low quality evidence). There were insufficient data on adverse events in the other treatment comparisons., Authors' conclusions, This review found low-quality evidence that early treatment with an AED compared with placebo or standard care reduced the risk of early post-traumatic seizures. There was no evidence to support a reduction in the risk of late seizures or mortality. There was insufficient evidence to make any concl sions regarding the effectiveness or safety of other neuroprotective agents compared with placebo or for the comparison of phenytoin, a traditional AED, with another AED.

5441. Thomson, D. U., et al. (2013). "Computed tomographic evaluation to determine efficacy of euthanasia of yearling feedlot cattle by use of various firearm-ammunition combinations." American journal of veterinary research **74**(11): 1385-1391.

OBJECTIVE: To evaluate with CT the efficacy of various combinations of firearms and ammunitions to penetrate and disrupt the brain tissue of cadaveric heads of feedlot steers., SAMPLE: 42 fresh cadaveric heads of 12- to 18-month-old Bos taurus steers., PROCEDURES: For each of 7 combinations of firearms and ammunitions (.22-caliber rifle firing a long rifle 30-grain plated lead solid- or hollow-point round, .223-caliber carbine firing a 50-grain ballistic-tip round, 9-mm pistol firing a 124-grain total metal jacket round, .45-caliber automatic Colt pistol [ACP] firing a 230-grain full metal jacket round, and 12-gauge shotgun firing a 2.75-inch 1.25-ounce No. 4 birdshot shell or a 1-ounce rifled slug), 6 cadaveric heads were shot at an identical distance (3 m), angle, and anatomic location. Heads were scanned with third-generation CT, and images were evaluated to determine extent of penetration, projectile fragmentation, cranial fracture, and likelihood of instantaneous death (>= 30% destruction of brain tissue or a brainstem lesion). RESULTS -41 of 42 skulls were penetrated by the projectile. Instantaneous death was considered a likely consequence for 83% (25/30) of heads shot with a rifle-fired .22-caliber solid-point round, pistol-fired .45-caliber ACP round, carbine-fired .223-caliber round, and shotgun-fired birdshot and slug. Of the 18 heads shot with pistol-fired 9-mm and .45-caliber ACP rounds and rifle-fired .22-caliber hollow-point rounds, only 6 had brainstem lesions. CONCLUSIONS AND CLINICAL RELEVANCE- Results suggested that gunshots delivered by all firearm-ammunition combinations except rifle-fired .22-caliber hollow-point rounds and pistol-fired 9-mm rounds were viable options for euthanasia of feedlot cattle.

5442. Thumbikat, P., et al. (2009). "Acute spinal cord injury." Surgery **27**(7): 280-286.

Acute spinal cord injuries may arise due to blunt injuries or to penetrating trauma, such as stab or gunshot injuries. The severity of injury varies both in terms of neurological segmental level, and the sensorimotor pattern of neurological deficit (ASIA category). The initial ATLS assessment of all trauma patients includes a thorough neurological examination to identify acute spinal cord injury. Their management requires discussion with a dedicated spinal injuries unit, and, if appropriate, transfer for specialist care. Spinal injuries units have multidisciplinary teams that can manage the medical and surgical aspects of patient care together with nursing expertise to avoid decubitus ulceration and other complications of spinal cord injury, and a full rehabilitation team to manage the physical, social, financial, and emotional aspects of rehabilitation.

5443. Tian, D., et al. (2006). "The clinical classification, diagnosis and treatment of penetrating craniofacial injuries." Chinese Journal of Emergency Medicine **15**(3): 206-208.

Objective: To study the clinical classification, diagnosis and treatment of penetrating craniofacial injuries. Methods: Thirty-six patients with penetrating craniofacial injuries and treated in our hospital between Janurary 1994 to Janurary 2005 were retrospectively studied. The patients' age ranged from 1.5 to 50.0 years old, with a mean age of 24.5 years old. The penetrating location: via orbital portion in 18, via ethmoid in 8 patients, via middle cranial fossa in 5 patients, via posterior cranial fossa in 3 patients and via sphenoid sinus in 2 patients. Results: Twenty-two patients recovered well, 4 had slight disability, 3 patients had middle disability, 7 died. The aesthetic and functional results were good in 25 patients, facial cicatricial contracture was in 3 patients, maxillofacial skeleton collapsed in 1 patient. Among the patients with cerebrospinal fluid (CSF) leak, 20 were cured after operation, 2 needed another revision. There were no epilepsy, intracranial infection, wound infection in the follow-up period. Conclusion: Transorbital penetrating craniocerebral injuries is the most common type of penetrating craniofacial. injuries. It is difficult to treat the patients with penetrating craniofacial injuries, with high mortality and disability rate. Medical record and the change of vital signs should be payed attention to. It is important to treat brain injuries and debride thoroughly as early as possible.

5444. Tian, S. and M. J. Middleton (2012). "Onobotulinum toxin type a injections for refractory chronic daily and migraine headaches in a combat veteran with history of traumatic brain injury and a gun shot wound to face: A case report." PM and R **4**(10): S332.

Case Description: A 48-year-old male combat veteran from Persian Gulf War (PGW). The patient suffered a left facial gunshot wound (GSW) in 2005 during active combat. The patient developed severe chronic daily (CD) and migraine (M) headaches that were debilitating and refractory to multiple treatments. He has a complex medical history including traumatic brain injury. Setting: Tertiary care Veteran Affairs medical center. Results or Clinical Course: After clinical assessment, onobotulinum toxin type A (Botox) 100 U was injected to the following muscles: corrugator, frontalis, temporalis, occipital region, cervical paraspinals, trapezius, and levator scapulae. The onset of relief for CD/M headache was approximately 5 days after injection. He was headache-free (no CD or M) for 1 month with decrease in CD pain from 10/10 to a 7/10 on visual analogue scale (VAS) for the 2nd and 3rd months after initial Botox injection. The headache further improved after the second series of Botox 200 U: CD from constant daily to 2 days a week, and only lasting seconds;Mfrom every other day, to once a week (VAS 5/10), and lasting 30 minutes on average. Patient continues to receive Botox injections in varied doses based on clinical assessments every 3 months. Continued improvement in CD/ M headaches has been observed. Discussion: Recent literature suggests combat veterans have higher incidence of migraine, which is often associated with other psychosocial disorders such as PTSD, anxiety and adjustment disorders that make migraine often refractory to conventional treatments. This is a rare case of debilitating migraine headache associated with facial GSW during the PGW. The injection of Botox over the head and neck substantially improved the symptoms without side effects. Conclusions: The refractory CD/M headache from combat veterans can be effectively treated with repetitive Botox injections.

5447. Tighe, S. Q., et al. (1992). "Resuscitation in northern Iraq." Injury **23**(7): 448-450.

The principles of Advanced Trauma Life Support (ATLS) were adopted by a Royal Navy surgical team deployed to northern Iraq. Over a 6-week period, 18 casualties of both military and civil trauma required active resuscitation, 10 being under the age of 16 years. Triage of multiple casualties was necessary on three occasions. Two patients died. It was difficult to exclude cervical spine injury. Venous cut-down was frequently unsuccessful, so that internal jugular vein cannulation was life-saving. Crystalloid was used as the primary infusion without apparent disadvantage. Cross-matched blood was unavailable and one patient died with haemolysis after massive transfusion. Hypothermia was a problem despite the high environmental temperature. Laboratory and radiological facilities were extremely limited. Non-medical staff were trained most effectively to assess vital signs, although sophisticated monitors became available. These problems are discussed and compared with previous experience. Recommendations are made to improve future outcome.

5448. Till, J. S. and J. R. Marion (1987). "Cerebrospinal fluid masquerading as tears." Southern medical journal **80**(5): 639-640.

We have described a 14-month-old white boy with a laceration of the right upper eyelid draining CSF. Careful evaluation, including computerized tomography, revealed a penetrating injury of the right frontal fossa. Determination of the glucose level in fluid draining from upper eyelid lacerations aids in the diagnosis of CSF fistulas.

5449. Tillman, N., et al. (2011). "Severe TBI outcomes associated with implementation of comprehensive guidelines in a children's hospital." Critical care medicine **39**: 221.

Introduction: Pediatric traumatic brain injury (pTBI) is a major cause of morbidity and mortality in children. In adults, using guidelines to manage TBI patients is well established, resulting in improved outcomes. Since the 2003 publication of national guidelines for the acute management of severe pTBI, data is lacking on the impact of the guidelines on physician compliance and effect on patient outcomes. Hypothesis: A hospital-specific severe pTBI guideline based on the 2003 guidelines along with a guideline-specific computerized order set will decrease practice variation, and be associated with positive patient outcomes in a pediatric institution. Methods: In 2008, a pTBI guideline at Children's Healthcare of Atlanta was initiated by a multidisciplinary team; however, there was noticeable practice variation and the guideline was not consistently utilized. The guideline was further refined in 2010. The patient population was defined and data collection standardized. Electronic medical record tools were developed to «hardwire» the guideline usage and report outcome measures. Specific guideline improvements included defined ranges & response for ICP/CPP, panic values & time for response, ranges for temp and CO2 control, documentation of GCS, and monitoring parameters for hyperosmolar therapy and EEG use. Education efforts included combined physician and nursing quality meetings. The updated guideline was implemented in March 2011 along with a guideline-specific order set. Scorecard measures from the first quarter of implementation (Apr-Jun 2011) were compared to the same time period one year prior (Apr-Jun 2010), as a historical control. Results: Patients < 18 years old that suffered a TBI with GCS <9 and admitted to the PICU were retrospectively identified for each quarter (n = 28, 2010, n = 24,2011). Compliance with ordering the guideline increased from 7.1% to 54.0% (100% for patients with an ICP monitor). Average LOS (non-rehab) decreased from 9.5 to 7.4 days. Avg ICU LOS decreased from 7.9 to 6.7 days. Conclusions: A multidisciplinary effort to develop, educate and implement a comprehensive severe TBI guideline led to increased compliance and was associated with improved outcome measures.

5450. Timmons, T., et al. (2011). "Catastrophic brain injury: Less doom and gloom than expected." Neurocritical care **15**(1): S245.

Introduction The aim of this study was to determine the mortality rate in patients who present with a Glasgow Coma Score (GCS) less than 6 and identify risk factors for death. Methods A retrospective analysis of patients with an admission GCS <6 and Head AIS >2 admitted to a single Level I trauma center over an 18-month period was performed. Mortality, baseline demographics, and injury characteristics were recorded. Pupil exam, the neurosurgical consultants' GCS, and the need for craniotomy were collected. In order to control for pre-hospital therapies that may artificially lower the admission GCS, the subset of patients with a GCS less than 6 at the time of neurosurgical evaluation was also evaluated. Univariate and multivariate analyses were performed to identify variables associated with mortality. Results 116 (45.3%) of 256 identified patients survived. In univariate analysis, older age, penetrating injury, lower motor GCS, and increased ISS were associated with mortality ($p<0.05$). 19 patients (15.6%) who presented with bilaterally nonreactive pupils survived vs. 68 (75.6%) who presented with equal reactive pupils ($p<0.0001$). Surprisingly, 77(39.7%) patients with a GCS 3 at admission survived, including four in arrest on arrival. Patients who underwent craniotomy had a higher survival rate (64.8 vs. 35.2%, $p=0.001$). Of 162 patients with a persistently low GCS at the time of neurosurgical evaluation, there were 45 (27.8%) survivors. Factors associated with survival in this subset were the same. In multivariate analysis, age (OR=1.04, $p<0.0001$), ISS (1.04, $p=0.002$), nonreactive pupils (OR=12.8, $p<0.0001$), and penetrating injury (OR=4.6, $p=0.009$) were associated with mortality while GCS motor score on admission was not. Conclusions Younger age, lower ISS, blunt injury and pupil reactivity were all prognostic factors for survival. In light of the higher than expected survival in this group of severely brain injured patients, aggressive treatment of these patients is warranted.

To understand the causes and patterns of shark attacks on humans, accurate identification of the shark species involved is necessary. Often, the only reliable evidence for this comes from the characteristics of the wounds exhibited by the victim. The present case report is intended as a reappraisal of the Luengoni, 2007 case (International Shark Attack File no. 4299) where a single shark bite provoked the death of a swimmer by haemorrhagic shock. Our examination of the wounds on the body of the victim, here documented by so-far unpublished photographic evidence, determined that the shark possessed large and homodontous jaws. This demonstrates that the attacker was a tiger shark, not a great white shark as previously published.

5457. Tobin, G. R., et al. (1981). "The split latissimus dorsi myocutaneous flap." Annals of plastic surgery **7**(4): 272-280.

Consistent proximal branching of the latissimus dorsi neurovascular anatomy permits surgical splitting of the myocutaneous unit into two flaps. Either or both branches of the split flap can be independently transferred. Experimental and clinical applications of this flap, which illustrate several of its uses and advantages, are presented. Applications include simultaneous provision of cover and lining flaps for head and neck reconstruction, motor transfers with split muscle branches, preservation of motor function in the flap donor site with one split muscle branch, and microvascular free tissue transfer of the branched flap or of individual branches.

5458. Tokdemir, M., et al. (2007). "Forensic value of gunpowder tattooing in identification of multiple entrance wounds from one bullet." Legal medicine (Tokyo, Japan) **9**(3): 147-150.

Multiple entrance gunshot wounds can give useful information in forensic evaluation of deaths from homicide and suicide. Although the presence of multiple entrance gunshot wounds does not absolutely exclude the possibility of suicide, they are important to the forensic investigators and pathologists in cases of assault, attempted homicide and suicide as they provide important clues for determination of number of shots fired and direction of firing. We present a case of 16 years of young woman who was shot to death by her husband. External examination revealed an entrance wound with semi-lunar shot residue at the dorsal side of her left hand at 5th metacarpus, and exit wound on the hypothenar muscle. There was also a second wound entrance located on her left zygoma. Direction of the bullet was downward traveling from left-to-right. Initially it was thought that there were two close shots, but when her left hand was placed over the malar area her face, it was determined that the gunshot powder tattoos were completing the nature of a single shot from a close distance. Crime scene investigation revealed only one cartridge casing. The autopsy and radiography findings showed that the bullet was entered from dorsal site of the left hand exiting from the palm and re-entering from the zygomatic region, hit the base of the skull, and remained in the soft tissue of the right mandible after passing the soft palate. The bullet was caused an incomplete laceration of the right internal arteria carotid and she died of internal and external bleeding. Detailed investigation of gunshot residues can provide important information for clarification of close distance gunshot wounding. We present this case due to its interesting nature, and to highlight the importance of detailed investigation of the gun powder residues in cases with multiple entry wounds.

5459. Tokita, Y., et al. (2001). "Regulation of neuregulin expression in the injured rat brain and cultured astrocytes." The Journal of neuroscience : the official journal of the Society for Neuroscience **21**(4): 1257-1264.

In this report, we investigated whether reactive astrocytes produce neuregulins (glial growth factor 2/heregulin/acetylcholine receptor-inducing activity or neu differentiation factor) and its putative receptors, ErbB2 and ErbB3 tyrosine kinases, in the injured CNS in vivo. Significant immunoreactivities with anti-neuregulin, anti-ErbB2, and anti-ErbB3 antibodies were detected on astrocytes at the injured site 4 d after injury to the adult rat cerebral cortex. To elucidate the mechanisms for the upregulation of neuregulin expression in astrocytes, primary cultured astrocytes were treated with certain reagents, including forskolin, that are known to elevate the intracellular level of cAMP and induce marked morphological changes in astrocytes. Western blot analysis showed that the expression of a 52 kDa membrane-spanning form of a neuregulin protein was enhanced in cultured astrocytes after administration of forskolin. The upregulation of glial fibrillary acidic protein was also observed in astrocytes treated with forskolin. In contrast, inactivation of protein kinase C because of chronic treatment with phorbol ester 12-O-tetradecanoyl phorbol 13-acetate downregulated the expression of the 52 kDa isoform, although other splice variants with apparent molecular sizes of 65 and 60 kDa were upregulated. These results suggest that the enhancement of neuregulin expression at injured sites is induced, at least in part, by elevation in intracellular cAMP levels and/or a protein kinase C signaling pathway. The neuregulin expressed on reactive astrocytes may stimulate their proliferation and support the survival of neurons surrounding cortical brain wounds in vivo.

5460. Tokitsu, M., et al. (1990). "[Skullbase-penetrating injuries caused by umbrella tips: case reports]." No shinkei geka. Neurological surgery **18**(2): 189-192.

Two cases of skullbase-penetrating injuries caused by umbrella tips are reported. Case 1: 24-year-old male. Admitted with disturbance of consciousness, left hemiparesis, nasal bleeding, and laceration of left lower eyelid because of having been stabbed by an umbrella tip. Pupils and fundi revealed no definite findings. Plain skull X-ray showed turbid ethmoid sinus and fracture of planum sphenoidale. Cranial CT showed right putaminal hematoma with intraventricular hemorrhage and pneumocephalus. Increased ICP necessitated surgery two days after the injury. Dural laceration of planum sphnoidale, laceration of left optic nerve, right rectal gyrus contusion and rebleeding from the right lenticulostriate branch were observed. Dural plasty and removal of hematoma with external decompression were carried out. He had a good postoperative course, but left visual loss and left hemiparesis remained. Case 2: 29-year-old male. Admitted with excoriation of his right nostril because of having been stabbed by an umbrella tip, severe headache, and nasal discharge. Oculomotor palsy was observed as well as CSF rhinorrhea and meningeal irritability. Plain skull X-ray showed niveau in sphenoidal sinus, pneumocephalus, and fracture of sella turcica. His complaint disappeared after conservative therapy. We reviewed the literature and found only 4 similar cases. The skullbase, because of its anatomical character, is likely to be penetrated in orbital and periorbital injury caused by umbrella tips. Cases which include disturbance of consciousness have a poor prognosis. We hope the fact that umbrella tips can easily become life-threatening objects will come to the attention of the general public so that similar cases may be avoided.

5461. Tolias, C. and J. Wasserberg (2002). "Critical decision making in severe head injury management." Trauma **4**(4): 211-221.

The management of severe head injury (SHI) remains a major challenge not only for neurosurgeons but also for all other health professionals involved in the care of trauma patients. Any trauma patient with SHI is at risk of further neurological deterioration if appropriate measures are not instituted from the start of his or her treatment. Secondary insults due to ischaemic, hypotensive, and metabolic or other causes are still common, even in the most advanced neurocritical care settings. Management controversies are widespread and few decision options can be supported by Class I evidence. This article attempts to provide an up-to-date review of the published recommendations that could help health professionals in their management of SHI.

5462. Toman, E., et al. (2015). "Craniectomy and cranioplasty: The UK military experience." British journal of neurosurgery **29**(4): 453.

Objectives. To describe the indications, complications and outcomes in UK military personnel requiring craniectomy in recent conflicts. Design. Retrospective audit Subjects. 21 UK military personnel Methods. JTTR search: UK survivors who underwent craniectomy and cranioplasty from mechanisms of explosion, blunt trauma and gunshot wound from 2004 to 2014 Notes from Role 3 and 4 hospitals. Results. All male, mean age 24 years. 18 had open cranial injuries and 17 had penetrating fragments. Explosive blast was the most common mechanism (52%). 13 patients had an

ISS of 75. Median time to cranioplasty was 9 months. Overall infective complication rate was 33%. No patients remained in a vegetative state - the GOS ranged from 3 to 5. Conclusions. This is the largest study to date evaluating the UK military population that have undergone decompressive craniectomy. Nevertheless the numbers are small compared to published US data. Craniectomies were most commonly performed for personnel with open blast injuries with associated penetrating fragments. The infective complication rate is likely related to the initial injury pattern, predisposing these patients to infection. This cohort of patients is young and fit, undoubtedly contributing to unexpected survival in those with ISS of 75. It is clear that access to neurosurgical intervention in theatre remains imperative for good long-term outcomes in this cohort of patients.

5463. Tomazic, P. V., et al. (2010). "Ethmoid roof CSF-leak following frontal sinus balloon sinuplasty." Rhinology **48**(2): 247-250.

INTRODUCTION: Though clear indications for its clinical application are not established yet, balloon sinuplasty technology per se is considered safe and very few severe complications have been mentioned in literature as of today., CASE REPORT: We report the case of a 36-year-old female patient who presented with right sided rhinorrhea from a CSF-leak in the ethmoidal roof after balloon sinuplasty, aimed at her right frontal sinus. Apparently, the surgeon was unaware of having penetrated the skull base through the lateral lamella of the cribriform plate intraoperatively. CSF rhinorrhea became evident 3 weeks postoperatively only when fever, headaches and moderate nausea developed. Upon revision, diameter, size and shape of the bony defect exactly matched with the tip of a standard sinus balloon catheter device, as could be demonstrated and documented. A small posttraumatic encephalocele had intermittently blocked the leak. Endoscopic surgery and duraplasty were performed under intrathecal fluorescein control, applying CT image-guided navigation. Since two-layer fascia lata closure of the defect, the patient has remained free of symptoms without any evidence of CSF leakage., CONCLUSION: Balloon sinuplasty per se is considered a safe technique, though in inexperienced hands or wrongly applied, complications may occur, as with any surgical tool rigid enough to breach through skull base.

5464. Tominaga, G. T., et al. (1993). "Emergency thoracotomy with lung resection following trauma." The American surgeon **59**(12): 834-837.

Over a 7-year period, 9443 trauma patients were evaluated with 2934 (31%) sustaining chest trauma. Of these, 347 (12%) patients required thoracotomy, with 12 patients undergoing emergency lung resection. Mean age was 23.1 years with mean Injury Severity Score of 32. Mechanism of injury was blunt in three (25%), gunshot wound in seven (58%), and stab wound in two (17%). Associated injuries included head injury in two (17%), intra-abdominal injury requiring laparotomy in four (33%), cardiac injury in three (25%), and great vessel injury in one (8%). Indications for operation included persistent hemorrhage in 11 and suspected tracheobronchial disruption in one. Non-anatomic lung resection was performed in five patients, lobectomy in three patients, and pneumonectomy in four patients. Overall mortality was 33 per cent: 20 per cent for non-anatomical lung resection, 33 per cent for lobectomy, and 50 per cent for pneumonectomy. All survivors fully recovered except for one patient with an associated head injury. Our experience supports the selective use of lung resection, including pneumonectomy, to immediately control hemorrhage and to impact survival in severe chest trauma.

5465. Tommasino, N., et al. (2014). "A model to predict progression in brain-injured patients." Transplantation proceedings **46**(9): 2950-2952.

INTRODUCTION: The study of brain death (BD) epidemiology and the acute brain injury (ABI) progression profile is important to improve public health programs, organ procurement strategies, and intensive care unit (ICU) protocols. The purpose of this study was to analyze the ABI progression profile among patients admitted to ICUs with a Glasgow Coma Score (GCS) <=8, as well as establishing a prediction model of probability of death and BD., MATERIALS AND METHODS: This was a retrospective analysis of prospective data that included all brain-injured patients with GCS <=8 admitted to a total of four public and private ICUs in Uruguay (N = 1447). The independent predictor factors of death and BD were studied using logistic regression analysis. A hierarchical model consisting of 2 nested logit regression models was then created. With these models, the probabilities of death, BD, and death by cardiorespiratory arrest were analyzed., RESULTS: In the first regression, we observed that as the GCS decreased and age increased, the probability of death rose. Each additional year of age increased the probability of death by 0.014. In the second model, however, BD

risk decreased with each year of age. The presence of swelling, mass effect, and/or space-occupying lesion increased BD risk for the same given GCS. In the presence of injuries compatible with intracranial hypertension, age behaved as a protective factor that reduced the probability of BD., CONCLUSIONS: Based on the analysis of the local epidemiology, a model to predict the probability of death and BD can be developed. The organ potential donation of a country, region, or hospital can be predicted on the basis of this model, customizing it to each specific situation.

5466. Tompkins, P., et al. (2013). "Brain injury: neuro-inflammation, cognitive deficit, and magnetic resonance imaging in a model of blast induced traumatic brain injury." Journal of neurotrauma **30**(22): 1888-1897.

Blast wave-induced traumatic injury from terrorist explosive devices can occur at any time in either military or civilian environments. To date, little work has focused on the central nervous system response to a non-penetrating blast injury. We have evaluated the effect of a single 80-psi blast-overpressure wave in a rat model. Histological and immunochemical studies showed an early inflammatory response, tissue damage and the initiation of apoptosis. With regard to inflammation, polymorphonuclear leukocytes and lymphocytes infiltrated brain parenchyma within 1 h post-blast. Glial-fibrillary protein, cyclo-oxygenase-2ir, interleukin-1beta and tumor necrosis factor were present by 1 h and remained detectable at three weeks post-injury. High mobility group box-1 protein was detectable at three weeks. With regard to tissue damage, S100beta and 4-hydroxynonenal were present at 1 h and remained detectable at three weeks. Amyloid precursor protein was detectable at three weeks. As for apoptosis, Cleaved Caspase-3 was detectable at three weeks. Morris water maze assessment of cognitive function showed that blast injured animals required significantly more time to reach the platform on day 1 of training and traveled a greater distance to get to the platform on days 1 and 2. Blast-injured animals showed a significant increase in swimming speed ($p<0.001$), increased total distance traveled ($p<0.001$) and increased number of entries into the previous quadrant that had contained the escape platform ($p<0.05$). Magnetic resonance imaging showed hyperintense regions in the somatosensory area within 1 h. T2 relaxation times and apparent diffusion coefficients show increasing trends in both somatosensory and cortical regions. These data indicate an early and lasting response of brain tissue to non-penetrating blast over-pressure injury. This early inflammatory response is indicative of a mild traumatic brain injury. There is evidence of early hippocampal dysfunction.

5467. Tong, J. Y., et al. (2021). "Radiological characteristics of mixed composition intraorbital foreign body." BMJ case reports **14**(10).

Orbital trauma is commonly complicated by retention of intraorbital foreign bodies. A 39-year-old man presented following a penetrating injury to the right orbit, with CT evidence of foreign bodies in the right anterior and posterior medial orbit. The foreign bodies were found to be a mixed composition of metal and wood. Characterising wood on CT imaging is difficult due to its radiolucency and low density, which can be mistaken for air in the setting of traumatic orbital emphysema. Increasing the window width on bone window settings can be used to distinguish wood from air, which is crucial for facilitating its complete surgical removal.

5468. Tong, Y., et al. (2004). "Diagnosis and treatment of penetrating craniocerebral injury." Chinese journal of traumatology = Zhonghua chuang shang za zhi **7**(5): 259-265.

OBJECTIVE: To evaluate the clinical characteristics and present the experience in the treatment of patients with penetrating craniocerebral injury (PCCI)., METHODS: The data of 7 cases with PCCI by foreign body were retrospectively studied and compared with associated literatures. The strategies of diagnosis and treatment of PCCI were analyzed. In this series, 3 cases underwent emergency debridements and 4 cases underwent craniotomies. All patients received surgical intervention within 3 hours after admission., RESULTS: Outcomes were good in 3 cases, moderate disability was in 2 cases, severe disability in 1 case and persistent vegetative state in 1 case. One case developed wound and intracranial infection, but made good recovery after treatment. During the follow-up period, one patient died one month after discharge and other six patients (range from 8 months to 3 years) recovered well and no epilepsy, leakage of cerebrospinal fluid (CSF), or traumatic vascular disease occurred., CONCLUSIONS: Early diagnosis and prompt debridement are the fundamental factors affecting the outcome of PCCI. CT scans are the mainstay in evaluating PCCI and three dimensional (3D) images reconstructed from spiral CT scans provide more information. Efficient debridement should be performed as early as possible. Minimizing the degree of surgical management of PCCI is preferred when there is no indication for aggressive operation. It is important to stress the rapid and effective management of CSF

leakage in early stage of PCCI. Use of prophylactic broad-spectrum antibiotics is recommended for patients with PCCI. Traumatic vascular injury should be paid attention to after PCCI.

5469. Topping, T. M., et al. (1982). "Traumatic wound dehiscence following penetrating keratoplasty." The British journal of ophthalmology **66**(3): 174-178.

Four young male patients with keratoconus had traumatic dehiscence of the surgical wound after penetrating keratoplasty. Two were rendered aphakic by the trauma, and in one patient the lens was dislocated posteriorly. In each case the dehiscence was repaired by resuturing the original corneal graft. Despite marked corneal oedema in the immediate postoperative period all four grafts deturgesced and subsequently cleared. The follow-up has been a minimum of 23 months. We recommend therefore primary resuturing of traumatic wound dehiscence after keratoplasty, anterior vitrectomy if the lens dislodged, and prophylactic antibiotics postoperatively. The clearing of the initially oedematous grafts in each case illustrates the resilience of the corneal endothelium.

5470. Torabi, K., et al. (2010). "Prosthodontic rehabilitation of a shotgun injury: a patient report." Journal of prosthodontics : official journal of the American College of Prosthodontists **19**(8): 634-638.

This report describes the prosthodontic rehabilitation of a shotgun patient traumatized in the maxillary, mandibular, and nasal areas resulting in severe problems in her esthetics, phonetics, and mastication. The patient was treated with removable partial prostheses using tooth, soft tissue, and implant support.

5471. Torche Velez, E., et al. (2021). "Transorbital penetrating intracranial injury, with cavernous sinus involvement." Neurocirugia.

Transorbitary intracranial penetrating traumatic injuries are uncommon in the pediatric population, and may occur in the context of domestic, sporting or school accidents. They can extend to skull base and compromise vascular structures such as cavernous sinus and internal carotid. We present a case of 6 years-old girl that suffered an intracranial transorbital penetrating injury with a wooden pencil that crossed from the medial edge of left orbit, transetmoidal and trans-sphenoidal, entering the right sellar region and leaving its end in contact with carotid artery (cavernous segment). After pre-surgical studies, foreign body removal was performed with endoscopic surgery + endovascular control in case of carotid injury. After removing the foreign body, a CSF fistula occurred and was repaired. Patient recovered adequately, without neurological deficit, without postoperative CSF fistula, without CNS infection or oculomotor alteration.

5472. Tosun, F., et al. (2005). "Analysis of different surgical approaches for the treatment of cerebrospinal fluid rhinorrhea." Minimally invasive neurosurgery : MIN **48**(6): 355-360.

The current treatment method for cerebrospinal fluid (CSF) rhinorrhea is surgical repair of the fistula. The aim of this study was to analyse different surgical approaches used for the treatment of CSF rhinorrhea regarding several preoperative and postoperative variables to determine the optimal method in these patients. Patients' charts were retrospectively reviewed to get the required data. Twenty-six patients who underwent different types of surgical approach for the treatment of CSF rhinorrhea were included in the study. Patients who had extensive comminuted fractures of the anterior cranial base and additional brain injury besides CSF rhinorrhea, mostly as a result of gunshot injuries, underwent craniotomy (n = 14). Osteoplastic frontal sinusotomy was used in two patients with a dural defect located at the posterior wall of the frontal sinus. Uncomplicated CSF fistulas in ten patients, located at the anterior and posterior ethmoid roof and in the sphenoid sinus, were closed with an endonasal endoscopic approach. Postoperative success rate was higher (97 % for intracranial approach, 100 % for extracranial external and endonasal endoscopic approach) for all techniques. Anosmia was the most frequent permanent complication (n = 5), seen after craniotomy. In conclusion, endonasal endoscopic approach can be preferred for the closure of uncomplicated CSF fistula, located at the anterior or posterior ethmoid roof and in the sphenoid sinus, due to its minimal postoperative morbidity. Uncomplicated CSF fistula, located at the posterior wall of frontal sinuses can be repaired extradurally with osteoplastic frontal sinusotomy. Intracranial approaches should be reserved for more complicated CSF rhinorrhea which results from extensive comminuted fractures of the anterior cranial base and is accompanied with intracranial complications.

5473. Toth, B. A., et al. (1988). "Computer-designed prostheses for orbitocranial reconstruction." Plastic and reconstructive surgery **81**(3): 315-324.

Three-dimensional imaging is an adjunct to preoperative evaluation and surgical management in some patients with complex anatomic defects of various etiologies. Deformities defined by conventional computerized tomography can be viewed as accurate three-dimensional images calculated from the original scan. The images are viewed on a high-resolution video monitor and can be photographed for a permanent record. A computer-controlled milling device can use these data to fabricate prostheses. The prostheses aid reconstructive surgery through use as an alloplastic implant, as a template to fashion autogenous bone grafts, or as a model for tissue removal. We have utilized three-dimensional imaging in combination with computer-assisted prosthesis manufacture in six patients with complex orbitocranial deformities. Four patients have undergone reconstructive surgery with satisfactory results and no complications thus far. The use of computer-designed prostheses adds a new aspect to orbitocranial reconstructive surgery that facilitates increased accuracy in the correction of anatomic defects.

5474. Toupin, J. M., et al. (1996). "[Selective indications of skull radiography after head injury in children]." Indications selectives de la radiographie du crane apres traumatisme de la voute chez l'enfant. **82**(3): 201-207.

PURPOSE OF THE STUDY: Skull X-rays are systematically performed on children after head injuries in most hospitals. However, the discovery of a skull fracture as an isolated finding rarely warrants intervention. In february 1994, we stopped performing systematical skull X-rays in children after head injuries. We report the results of this experience., MATERIALS AND METHODS: Since February 1994, only children with possible skull penetration, depressed fracture, or presenting signs of basilar fracture had X-ray examination. Facial injuries were excluded in this study. In case of focal neurologic signs, neurosurgical consultation, or emergency CT examination, or both were performed. In case of change of consciousness at the time of injury or subsequently, the child was hospitalised for clinical observation for 48 hours, but no X-ray examination was performed. Children without any neurological signs or change of consciousness were discharged to their homes after they were given a head-injury instruction sheet, and if a second person could observe them for signs indicating that they belong to a higher risk group, but no X-ray examination was performed., RESULTS: An average of 241 children per month were presented at the Children Emergency Unit after head trauma. An average of twenty-one X-ray examinations per month were performed instead of 194/month before february 1994. This represented a decrease of 2000 X-ray examinations per year. There was no undiagnosed neurological complication, and the number of children staying in the hospital for clinical supervision did not increase., DISCUSSION: Skull radiographies only show fractures and do not afford visibility of either brain or blood to demonstrate an intracranial injury. The presence of a skull fracture without neurological abnormalities is of little significance. Harwood-Nash reported that 60 per cent of the children with extradural hematoma, 85 per cent of the children with subdural hematoma and 35 per cent of the children with brain damage did not have any associated skull fracture. Clinical examination is essential, and it would be a mistake to be reassured about the severity of a head trauma because skull X-rays are normal., CONCLUSION: Routine skull X-rays after head trauma are not justified either for financial or radioprotection reasons. In this study, more than half of the children were less than five years old and ran a higher risk of irradiation.

5475. Tourigny, J., et al. (2020). "Efficacy of the Brain Injury Guidelines for complicated mild traumatic brain injuries." Canadian Journal of Emergency Medicine **22**: S69-S70.

Introduction: The Brain Injury Guidelines (BIG) stratifies complicated mild traumatic brain injury (mTBI) patients into 3 groups to guide hospitalization, neurosurgical consultation and repeat head-CT. BIG-1 patients could be managed safely without neurosur-gical consultation or transfer. Systematic transfer to neurotrauma centers provide few benefits to this subgroup leading to overtriage. Similarly, unnecessary clinical and radiological follow-ups utilize significant health-care resources. Objective: to validate the safety and efficacyof the BIG for complicated mTBIs. Methods: We performed a multicenter historical cohort study in 3 level-1 trauma centers in Quebec. Patients ≥16 years old assessed in the Emergency Department (ED) with complicated mTBI between 2014 and 2017 were included. Patients with penetrating trauma, cerebral aneurysm or tumor were excluded. Clinical, demographic and radiological data, BIG variables, TBI-related death and neurosurgical intervention were collected using a standardized form. A second reviewer assessed all ambiguous files. Descriptive statistics, over- and under-triage were calculated. Results: A total of 342 patients' records were assessed. Mean age was 63 ± 20, 7 and 236 (69 %) were male. Thirty-five patients were classified

under BIG-1 (10.2%), 110 under BIG-2 (32.2%) and 197 under BIG-3 (57.6%). Twenty-six patients (7%) required neurosurgical intervention, all were BIG-3. 90% of TBI-related deaths occurred in BIG-3 and none were classified BIG-1. Among the 192 transfers (51%), 14 were classified under BIG-1 (7.3%) and should not have been transferred according to the guidelines and 50 under BIG-2 (26%). In addition, 40% of BIG-1 received a repeat head computed tomography, although not indicated. Similarly, 7 % of all patients had a neurosurgical consult even if not required. Projected implementation of BIG would lead to 47% of overtriage and 0.3% of undertriage. Conclusion: Our results suggest that the Brain Injury Guidelines could safely identify patients with negative outcomes and could lead to a safe and effective management of complicated mTBI. Applying these guidelines to our cohort could have resulted in significantly fewer repeat head CTs, neurosurgical consults and transfers to level 1 neurotrauma centers.

5476. Toussaint-Thorin, M., et al. (2013). "Incidence and risk factors of post-traumatic epilepsy in children: A rench prospective cohort (TGE cohort)." Annals of Physical and Rehabilitation Medicine **56**: e300.

Acquired brain injury in children often result in severe cognitive and behavioral impairments. They are significantly worsened by associated epilepsy. In the literature, the incidence rates of post-traumatic epilepsy in children and adults with traumatic brain injury (TBI) vary between 8 and 30% [1]. Objective.- To explore incidence and risk factors of post traumatic epilepsy in a prospective cohort of children with severe accidental TBI. Methods.- Mono-centric prospective cohort study. Children, aged 0 to 15 years, consecutively admitted in the intensive care unit of the paediatric neurosurgery department-Necker Hospital for severe accidental TBI were included. Data on TBI severity, initial intensive care monitoring, and the onset of post-traumatic epilepsy were prospectively collected over two years. The following risk factors were taken into account in the analysis: Glasgow coma scale, length of coma, presence of a penetrating skull fracture, hypo-perfusion brain, early seizures. Results.- Eighty-one children were included. There were 65 survivors [66% males: mean age 8.12 years (DS=4,6)]. Five children developed a posttraumatic epilepsy, the incidence was 7.7% [95% CI 0.9%-14.4%]. They developed epilepsy within the first 12 months post-injury. Only one of those five children had presented early seizures. Among the risk factors studied only the duration of coma was significantly associated with the onset of post-traumatic epilepsy (p = 0.02). Mean coma duration was 11 days (range: 5-16) in the subgroup with post-traumatic epilepsy versus 5 days (range: 1-23) in children without epilepsy. Discussion.- Post-traumatic epilepsy occurred after severe pediatric TBI, but the incidence is low. To our knowledge, this is the first study reporting data from a prospective cohort of children with severe accidental TBI. Our findings about the risk factors of post-traumatic epilepsy onset are consistent with data from the literature, as TBI severity is the most frequently reported factor.

5479. Tran, T. H. C., et al. (2005). "Traumatic globe rupture following penetrating keratoplasty." Graefe's archive for clinical and experimental ophthalmology = Albrecht von Graefes Archiv fur klinische und experimentelle Ophthalmologie **243**(6): 525-530.

PURPOSE: To evaluate the mechanism, clinical characteristics, management and visual outcome of ocular trauma following penetrating keratoplasty (PK)., METHODS: Twenty-six patients (13 men, 13 women) who suffered surgical wound dehiscence after PK because of ocular blunt trauma between 1994 and 2001 were included in this retrospective study. Graft dehiscence was managed with primary wound closure in all patients. Visual acuity, intraocular pressure, and funduscopy were evaluated in the follow-up., RESULTS: The mean age at trauma was 50+/-24 years (range 9-88 years). Mean interval between transplantation and trauma was 45.5+/-64 months (range 1 month to 20 years). Globe rupture occurred at the graft-host junction in all patients. Nine of 13 phakic eyes (69.2%) presented lens expulsion. Eight of nine pseudophakic eyes (88.9%) had lost their implants. Retinal detachment occurred in seven eyes (27%) within 3 months following the trauma. Five patients (19.2%) underwent vitreous surgery for posterior segment damage. Two eyes (7.7%) were regrafted. At the last examination, only seven eyes (27%) had visual acuity of 20/200 or better., CONCLUSIONS: Traumatic wound dehiscence may occur, and the prognosis is poor after the injury. Globe

rupture at the graft-host junction showed persistence of wound weakness even a long time after PK. Prevention of ocular trauma should be performed following PK.

5480. Travkin, A. G. and V. P. Derevianko (1997). "[Chemiluminescence of peripheral blood T and B lymphocytes in patients with burn leukoma after lamellar keratoplasty]." Khemiliuminestsentsiia T- i B-limfotsitov periphericheskoi krovi bol'nykh s ozhogovymi bel'mami posle posloinoi keratoplastiki. **113**(1): 25-27.

Lamellar keratoplasty was carried out in 50 patients after eye burns. The following methods were used in the study: assessment of the intensity of chemiluminescence, electron microscopy, and assessment of T-lymphocyte subpopulations by cytofluorograph (USA) and OCT monoclonal antibodies (USA). Free-radical activation was detected by chemiluminescence during the first hours of keratoplasty in the recipient's peripheral blood leukolymphocytic suspension, whereas immunocorrecting lymphocytes did not change during this period. On days 1-2 statistically reliable changes occurred in the immune system. By day 5 electron microscopy of the leukolymphocytic suspension showed cooperation of immunocompetent cells. The course of the corneal transplant taking in was for 2 years associated with the T-helper to T-suppressor imbalance, increase of chemiluminescence level, and detection of immune lymphocytes and their cooperation under electron microscope. The authors claim that primary formed peroxides act as nonspecific participants of metabolism by altering the functional activity of immunocompetent cells; hence, a new trend in the study of cell-mediated immunity appears: immunobiophysical.

5481. Treib, J., et al. (1996). "High-velocity bullet causing indirect trauma to the brain and symptomatic epilepsy." Military medicine **161**(1): 61-64.

Epilepsy is a frequent consequence after missile wounds of the brain. So far, no epilepsy cases with missile injury have been described in which epilepsy ensued without direct missile injury of the brain. During World War II, in 1941, our patient, then a soldier in the German army, suffered a bullet injury to the head; the bullet entered the cranium at the base of the nose. The bullet penetrated the head below the base of the cranium and remained stuck subcutaneously left of the second cervical vertebra. In the field hospital the patient suffered from focal seizures. The fits ceased within a few years under medication. In 1990 the seizures returned, this time with secondary generalization. In our case, a 7.62-mm bullet from the Russian Tokarev military pistol was used, which is known to have the highest muzzle velocity of all handguns available (> 500 m per second). We suspect that the so-called hydrodynamic effect of this high-velocity bullet caused an indirect trauma to the brain. This case shows that symptomatic epilepsy can occur after a penetrating head injury, without direct injury to brain tissue by a missile. High-velocity missiles are increasingly used in armed conflicts around the world. In light of the case reported here, in which the initial epilepsy was exacerbated more than 50 years after the wounding event, physicians must consider this possibility when dealing with veterans presenting with seizures. This case also has implications for the payment of benefits and pensions.

5482. Trikha, V., et al. (2018). "Midterm results of trochanteric flip osteotomy technique for management of fractures around the hip." Hip international : the journal of clinical and experimental research on hip pathology and therapy **28**(2): 148-155.

INTRODUCTION: In this study, we aimed to investigate safety and efficacy of the trochanteric flip osteotomy with surgical hip dislocation technique in selected displaced acetabular and femoral head fractures with clinico-radiological outcome and potential complications., MATERIALS AND METHODS: We retrospectively reviewed 32 patients from January 2009 to June 2014. Selected displaced acetabular fractures with comminution and/or cranial extension of posterior wall, marginal impaction, intraarticular fragment, femoral head fractures and hip fracture-dislocations were operated by this modified approach of trochanteric flip osteotomy and surgical hip dislocation. Patients were evaluated for fracture reduction, femoral head viability, trochanteric union, abduction power, and functional evaluation was done by Merle d'Aubigne-Postel scoring system. Minimum follow-up was 24 months., RESULTS: Reduction was judged to be anatomical in 84.38% of cases, and within 1-3 millimetres in 9.38% of cases. All osteotomies healed in an anatomical position. Heterotopic ossification was found in 2 patients limited to Brooker class I. Osteonecrosis developed in 1 patient. 2 patients developed arthritis of the hip as sequelae of poor reduction. Abduction power was MRC 5/5 in all except in 1 patient (4/5). Mean Merle d'Aubigne-Postel score was 16.18; overall good to excellent result was achieved in 87.5% of cases., CONCLUSIONS: Trochanteric flip osteotomy with surgical dislocation allows better intraarticular assessment, control of intraarticular fragments, assists accurate reduction and the fixation of complex acetabular and

femoral head fractures, without compromising femoral head vascularity and abductor strength. This technique has provided excellent midterm results in the management of complex injuries around the hip.

5483. Tripathi, M., et al. (2018). "Eye in the brain." Neurology India **66**(3): 883-884.

5484. Trivelato, F. P., et al. (2017). "Pipeline embolization device for the treatment of a traumatic intracranial aneurysm in a child." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **33**(5): 869-872.

INTRODUCTION: Traumatic intracranial aneurysms in children are rare and may occur as the result of closed or penetrating head trauma. Their natural history seems to be more aggressive. Most traumatic aneurysms have complex shape, tending to have a large neck or even a fusiform morphology., CASE REPORT: We present a case of a traumatic carotid artery aneurysm in a 9-year-old girl that was successfully treated with pipeline embolization device., DISCUSSION: Due to its dissecting nature, wall friability and lack of a substantial neck can make surgical clipping and selective coiling difficult and risky. Although endovascular parent artery occlusion is the best approach in the acute phase, in some situations it is not possible or very risky. In such scenario the use of flow diverter devices would be an alternative approach. Additionally, we discuss the potential advantages and risks of flow diverter deployment inside a developing vessel.

5485. Trnka, J. and W. P. Golema (2017). "Example of suicidal gunshot wound to the head with a blank actuated projectile shot from Keseru-type revolver as an example of danger connected with use of firearms replicas that can be bought without license." Przypadek samobojczego postrzalu glowy z rewolweru hukowo-kinetycznego typu Keseru" jako przyklad niebezpieczenstw zwiazanych z uzywaniem replik broni dostepnych bez zezwolenia. **67**(4): 275-280.

In January 2011 a body of 56-year old man was sent to Wroclaw Forensic Medicine Department. He was supposed to shoot himself with a noisemaker revolver. During the forensic autopsy a wound to the right temporal area was found, furthermore a hole in right temporal bone and a gunshot wound canal leading from right to left, slightly to the back and up. A deformed, metallic, 5.5 mm BB shot was found in the canal. The revolver found alongside the body was also examined. It was capable of projecting rubber or metal BB shots actuated by a blank cartridge discharge. Test shots were measured in the chronograph (5.5 mm metal BB shots). Peak initial velocity of the projectile reached around 120 m/s. This revolver does not require any license to buy and own. It is also not necessary to register it. Authors highlight the dangers connected with the use of such firearms as well as not sufficient legal regulations concerning this type of weapons.

5486. Trofimov, A. O., et al. (2013). "The characteristics of management of concomitant craniofacial injury complicated by cerebrospinal fluid rhinorrhea." Sovremennye Tehnologii v Medicine **5**(3): 74-77.

The aim of the investigation was to reveal the characteristics of the management of penetrating craniofacial injury against the background of polytrauma, and develop the algorithm of preoperative examination and treatment of concomitant craniofacial trauma complicated by cerebrospinal fluid rhinorrhea based on the use of modern neuroimaging techniques. Materials and Methods. 637 sufferers with major concomitant injuries underwent treatment in Nizhny Novgorod Regional Traumatology Centre from 2010 to 2012. 85 patients (13.34%) had concomitant cerebral and facial skeleton injuries, among them there were 62 (9.7%) cases with cerebrospinal fluid rhinorrhea revealed on admission. Mean age of those suffered from craniofacial injury was 31.2±13.9 years (min - 16; max - 88). The severity of injuries according to ISS (Injury Severity Score) was 35.15±17.40 scores (min - 9; max - 77). Results. Concomitant injury of brain and bones of the facial skeleton in polytrauma was found in 13.3% of patients with polytrauma. 9.7% cases were found to have penetrating craniofacial injuries. Relying on the experience obtained, we suggested the algorithm of preoperative assessment and planning of surgical management of craniofacial injury complicated by cerebrospinal fluid rhinorrhea using modern neuroimaging techniques based on the assessment of a patient's condition. The use of the algorithm in everyday practice in patients with penetrating craniofacial injury and polytrauma enables to improve the diagnosis and objectify the time optimal for surgical management of cerebrospinal fluid rhinorrhea, reduce the lethality up to 8%, and the morbidity of pyoinflammatory complications - up to 4.8%.

5487. Trokel, M., et al. (2006). "Variation in the diagnosis of child abuse in severely injured infants." Pediatrics **117**(3): 722-728.

OBJECTIVE: Diagnosis of child abuse is difficult and may reflect patient, practitioner, and system factors. Previous studies have demonstrated potential lethal consequences if cases of abuse are missed and suggested a role for continuing medical education in improving the accuracy of diagnosis of suspected abuse. Although the majority of injured American children are treated at general hospitals, most published studies of severe injury resulting from child abuse have been conducted at children's hospitals. The objective of this study was to evaluate the role of hospital type in observed variations in the frequency of diagnosis of child physical abuse among children with high-risk injuries., METHODS: Hospital discharge data were evaluated, and adjusted rates of abuse diagnosis were reported according to hospital type. A regression model estimated the number of cases of abuse that would have been diagnosed if all hospitals identified abuse as frequently as observed at pediatric specialty hospitals. This study consisted of children who were <1 year old and admitted to US hospitals in 1997 for treatment of traumatic brain injury or femur fracture, excluding penetrating trauma or motor-vehicle-related injury. A total of 2253 weighted cases were analyzed., RESULTS: The proportion of patients with a medical diagnosis of child abuse varied widely between hospital types: 29% of the cases were diagnosed as abuse at children's hospitals compared with 13% at general hospitals. An estimated 178 infants (39% of total) with these specific injuries would have been identified as abused had they been treated at children's rather than general hospitals., CONCLUSIONS: Hospital type was associated with large variations in the frequency of diagnosis of child abuse. This variation was not related to observed differences in the patients or their injuries and may result from systematic underdiagnosis in general hospitals. This result has implications for quality-improvement programs at general hospitals, where the majority of injured children in the United States receive emergent medical care.

5488. Trost, O., et al. (2008). "Re: Reconstruction of bony mandibular and maxillary defects with one single transfer of a free fibula osteocutaneous flap." Journal of plastic, reconstructive & aesthetic surgery : JPRAS **61**(11): 1385-1387.

5489. Trubner, K., et al. (2010). "[Suicidal extraneurocranial shot into the mouth]." Samobojczy postrzal w glowe poprzez otwarte usta z pozaczaszkowym przebiegiem kanalu postrzalowego. **60**(2-3): 127-131.

A case of a 51-year-old man who killed himself with a pistol-shot into his mouth is reported. The track of the bullet passed exactly in the median level completely extraneurocranially; the cause of death was a subtotal destruction of the cervical spinal cord (C2/C3). The synoptic assessment of the scene of death, the autopsy findings, the results of the securing of evidence and the criminological investigations allowed for drawing the only conclusion that the man had committed suicide.

5490. Truog, R. D., et al. (2006). "Sudden traumatic death in children: "we did everything, but your child didn't survive"." JAMA **295**(22): 2646-2654.

When caring for children who become suddenly and catastrophically ill, clinicians must simultaneously attend to a complex and rapidly evolving medical situation, as well as to the equally challenging demands of establishing compassionate relationships with family members and communicating well with colleagues. An 18-month-old toddler was brought to the hospital with severe head injury after being struck by a car. Over a period of hours, her condition evolved from prognostic uncertainty to the diagnosis of brain death and considerations of organ donation. Against this medical backdrop, the clinicians successfully established a trusting relationship with family members by careful attention to their emotional, informational, and care needs as they absorbed the devastating prognosis, took in the results of the brain death examination, and considered the option of organ donation. This case illustrates the importance of interdisciplinary communication, the vital role of social workers and other psychosocial providers with expertise in working with families, and the critical significance of mutual care and support for the clinicians who accompany families through these tragic life events.

5491. Truog, R. D. and F. G. Miller (2014). "Changing the conversation about brain death." The American journal of bioethics : AJOB **14**(8): 9-14.

We seek to change the conversation about brain death by highlighting the distinction between brain death as a biological concept versus brain death as a legal status. The fact that brain death does not cohere with any biologically plausible definition of death has been known for decades. Nevertheless, this fact has not threatened the acceptance of brain death as a legal status that permits individuals to be treated as if they are dead. The similarities between "legally dead" and "legally blind" demonstrate how we may legitimately choose bright-line legal definitions that do not cohere with biological reality. Not only does this distinction bring conceptual coherence to the conversation about brain death, but it has practical implications as well. Once brain death is recognized as a social construction not grounded in biological reality, we create the possibility of changing the social construction in ways that may better serve both organ donors and recipients alike.

5493. Tsai, W.-C., et al. (2004). "Pediatric traumatic brain injuries in Taiwan: an 8-year study." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **11**(2): 126-129.

Background. This study is intended to determine the causes of pediatric traumatic brain injuries (PTBI) in children aged 14 years or less, and to identify various types of craniocerebral damage resulting from different mechanisms of injury. Methods . From July 1, 1993 to June 30, 2001, a survey on PTBI was conducted in Taiwan. The data of patients used in this study were collected from 56 major hospitals among the age group of 0-14 years. The items in the traumatic brain injury survey included sex, age, causes of injuries, severity, and the eventual outcome. Results . A total of 5349 cases were identified. The male-to-female ratio was 1.69: 1. The incidence rate was higher in the age groups of 4-9 years and 10-14 years. The main cause of PTBI was traffic injury, which accounted for 2537 of the cases (47.3%), followed by falls, 2160 (40.3%). Of all traffic injuries, motorcycle-related injury had the highest incidence, followed by the pedestrian and bicycle-related injury. This study also showed that 83.2% of the patients had mild injury, 9.8% had moderate injury, and 7.0%, severe injury. Conclusions . The results of this study suggest that it is important to decrease all the risk factors in the environment of homes and public areas as much as possible. Helmet wearing and the development of public transportation are essential for the prevention of head injury.

5494. Tsaloumas, M. D., et al. (1998). "Two cases of retention of wooden foreign bodies in orbit of eye." BMJ (Clinical research ed.) **316**(7141): 1363-1364.

5495. Tseng, S. H. and W. W. Cheng (1997). "Intracranial non-ballistic penetrating foreign body." Journal of Surgical Association Republic of China **30**(5): 372-376.

The management of four patients with non-ballistic penetrating intracranial foreign body injuries is presented. Craniotomy or craniectomy to remove the foreign body was done in all four patients, and an associated intracerebral hematoma was evacuated in one. In each case, the injured area was debrided and the dura was repaired. Prophylactic antibiotics were used to prevent infection. All four patients regained clear consciousness and full ambulation after surgery, although one lost his vision because the foreign body had injured his eyes.

5496. Tsilimbaris, M. K., et al. (1998). "Needle entrance into the maxillary sinus during retrobulbar anesthesia." Ophthalmic surgery and lasers **29**(7): 602-605.

Three patients are presented to whom an accidental needle entrance into the maxillary sinus occurred during retrobulbar anesthesia. In all cases air was aspirated during the aspiration check at the end of needle advancement, and the patients reported a bitter taste after the injection of a small quantity of anesthetic. After withdrawal and careful reinsertion of the needle, maxillary sinus entrance was avoided and a successful retrobulbar block was achieved. Two of the patients had no history of previous facial trauma or surgery, whereas the third had suffered a recent blowout fracture of the orbital floor. The authors suggest that air aspiration or anesthetic passage into the pharynx during retrobulbar anesthesia should raise the suspicion of maxillary sinus entrance, even in patients without any history of facial trauma or surgery. The early recognition of sinus entrance can prevent retrobulbar block failure and reinjection of a second anesthetic dose.

5497. Tsokos, M. (2011). "Heat-induced post-mortem defect of the skull simulating an exit gunshot wound of the calvarium." Forensic science, medicine, and pathology **7**(2): 227-228.

5498. Tsokos, M. and S. Schroder (2006). "Black thyroid: report of an autopsy case." International journal of legal medicine **120**(3): 157-159.

A distinctive but very rare side effect of exposure to minocycline is black pigmentation of the thyroid gland. Until 2002, not more than 30 cases of black thyroid had been reported in the English literature. We report on a 24-year-old woman with known antemortem ingestion of minocycline. The woman suffered from a depressive disorder with repeated suicide attempts and committed suicide by a gunshot to the head. At autopsy, the thyroid gland showed coal-black coloration. Upon histology, clumps of black-brown pigment were seen in the colloid, and a granular precipitate of this pigment was noted in the apical portions of the follicular epithelial cells. The diagnosis of minocycline-associated black thyroid was established. Forensic pathological significance of black thyroid may arise from the fact that hypothyroidism has been occasionally associated with minocycline-related black thyroid and that hypothyroidism may contribute to the development of depressive disorders (and thus, in given cases, may be responsible for suicide attempts). Under this assumption, the presence of black thyroid would represent more than just a morphological curiosity in specific cases.

5499. Tsranchev, I., et al. (2021). "Penetrating Brain Trauma due to Air Gun Shot - a Case Report." Folia medica **63**(6): 977-980.

Cases of severe injuries caused by air guns are really uncommon, but they can lead to a fatal outcome. Usually, these injuries occur in children due to their not fully developed skull bones or in adults through less resistant and thin regions of the cranium. Most of them are accidental events, followed by low percentage of suicidal attempts. In this paper, we present the case of a 68-year-old man suffering from severe depression, with self-inflicted air gun injury to the head. The patient was admitted to the hospital in a coma with a Glasgow Coma Scale (GCS) score of 8, with severe penetrating head injury manifested with brain contusion and intraventricular bleeding seen at the CT examination. Metal particles from the projectile were seen inside the brain. The entry wound had inverted margins, abraded collar and skin defect. The additional neurological examination of the patient showed symptoms of increased intracranial pressure. The treatment started with the air gun wound care. Craniotomy surgery was also done and bone fragments around the entry wound were successfully extracted with subsequent debridement and duraplasty. The patient was treated with new-generation combined antibiotics for preventing inflammatory complications. On the nineteenth day, the patient was discharged with mild hemiparesis on the left side and with GCS score of 15.Air-gun traumatic cases with head injury or with injury to other parts of the body are often mistaken for firearm accidents, because air guns are seriously underestimated devices. Nevertheless, they could lead to severe health consequences and severe disability. This case highlights the necessity of strict monitoring of air guns by the responsible government institutions which should apply the same regulations in controlling these weapons as they implement in controlling the firearm guns. Presence of severe depression, mental illnesses, and neoplasms are risk factors for committing suicide with this type of weapons and the control over the air weapons in this group of people should be stricter.

5500. Tsuei, Y.-S., et al. (2005). "Civilian gunshot wounds to the brain." Journal of the Chinese Medical Association : JCMA **68**(3): 126-130.

BACKGROUND: Civilian gunshot wounds to the brain are relatively rare, and a much-neglected subject in Taiwan. We present our experience with 16 patients who sustained gunshot wounds to the brain, and then identify factors determining the respective outcomes., METHODS: From 1988-2002, data from 16 patients with civilian gunshot wounds to the brain, who were treated at Taichung Veterans General Hospital, were retrospectively reviewed. Historical information, clinical manifestations, and imaging findings were described. Based on Glasgow Outcome Score (GOS), patients were divided into a poor-outcome group (GOS, 1-2) and satisfactory-outcome group (GOS, 3-5) for further analysis., RESULTS: The overall mortality rate was 31.3% (5 of 16 patients). Thirteen patients underwent surgery, and the

surgical mortality rate was 15.4% (2 of 13 patients). Of the 7 patients with a Glasgow Coma Scale (GCS) score of more than 8, all survived with satisfactory outcomes; of the 9 patients with a GCS score of less than 8, 8 had poor outcomes (5 died, and 3 were in a persistent vegetative state); $p < 0.005$ between the 2 GCS groups. In addition, the rate of satisfactory outcome was significantly higher in 7 patients with limited brain injury, as determined by computed tomography (CT) scan, than in 8 patients with extensive brain injury (86% vs 25%; $p < 0.05$)., CONCLUSION: GCS score on admission, and the extent of brain injury as visualized by CT scan, seem to be the 2 most significant predictors of outcome in cranio-cerebral gunshot wounds. Patients with a GCS score of more than 8, or brain lesions limited to a single lobe of the brain, may benefit from aggressive management.

5501. Tsutsumi, S., et al. (2011). "The Virchow-Robin spaces: delineation by magnetic resonance imaging with considerations on anatomofunctional implications." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **27**(12): 2057-2066.

INTRODUCTION: The Virchow-Robin spaces (V-R spaces) are well-known, but not systematically understood fluid-filled perivascular spaces that allow the convexity and basal perforating vessels to penetrate deep into the cerebral parenchyma., OBJECTIVE: This study aims to delineate anatomical characteristics of the normal V-R spaces by MR imaging with considerations on clinical and anatomofunctional implications of the V-R spaces., METHODS: In this prospective study with 3T magnetic resonance (MR) imaging, the whole extent of the intracranial V-R spaces was classified into basal, cortical, subcortical, paraventricular, and brainstem segments, on the basis of the topological difference in 105 control subjects. Morphological characteristics in each segment of the V-R spaces are described. For comparison with the neuroimaging appearance, V-R spaces were histologically examined in cadaveric human brains. The physiological functions of the V-R spaces and pathognomonic implications of unusually dilated, but asymptomatic, V-R spaces encountered in five subjects are discussed., RESULTS: The V-R spaces were found to form a complicated, while anatomically highly consistent, intraparenchymal canal network distributed over the whole cerebral hemispheres and connect the cerebral convexity, basal cistern, and ventricular system., CONCLUSION: The V-R spaces may be essential for drainage routes of cerebral metabolites, additional buoyancy for the brain, and maintenance of homogenous intracranial pressure. MR imaging may be more advantageous in depicting the V-R spaces than histological examination.

5502. Tucker, D. I., et al. (2013). "Characterization and management of mandibular fractures: lessons learned from Iraq and Afghanistan." Atlas of the oral and maxillofacial surgery clinics of North America **21**(1): 61-68.

Fractures of the mandible are among the most common facial injuries. Invasiveness of treatment should be determined by the extent of injury: degree of displacement, number of fractures, the patient's health status, and concomitant injuries. Complex, comminuted, and avulsive injuries frequently seen in combat will require coordination with multiple specialties to provide the best treatment. Stabilization treatment with arch bars or external fixators and splints is often desirable when fractures are highly comminuted or the soft tissue envelope is compromised by tissue loss or burns. In severe injuries, many times reconstruction will take several surgeries. Debridement of necrotic tissue and devascularized bone and skin grafting often are necessary before reconstruction. Microvascular or myocutaneous flaps should be considered with significant tissue loss and osteocutaneous flaps when large continuity defects are present. Most mandible fractures are repaired in a single operation. Those caused by explosives and high-velocity projectiles are more complex. Research should continue to focus on improving outcomes for these patients. Advances in tissue engineering, bone regeneration, and composite tissue allografting will have to continue if we hope to restore facial form and function for our combat wounded.

5503. Tucker, L. B., et al. (2012). "Behavioral consequences of traumatic brain injury: A comparison of multiple injury models in the laboratory mouse." Journal of neurotrauma **29**(10): A113.

Introduction Basic laboratory research on traumatic brain injury (TBI) employs a wide variety of injury models to study the molecular, cellular, and behavioral consequences of TBI in an attempt to identify recovery mechanisms and therapeutic targets. Behavioral recovery after TBI is a critical determining factor in evaluating the efficacy of potential therapies, and the usefulness of a specific behavioral test depends on the nature, severity, and location of the injury; time after injury at which the test is performed; and specific protocol or procedure of testing. Methods Mice (male C57Bl/6J) sustained a TBI by controlled cortical impact (CCI; a penetrating injury) at a parietal or frontal location, weight-drop (a concussive injury), or high-intensity-focused ultrasound (HIFU; a novel blast-like paradigm), and post-injury

behaviors on multiple measures of motor activity, cognition, and anxiety were compared. Sham-operated (craniectomy) and non-operated mice were used as controls. Results Mice that received a CCI brain injury showed greater differences or deficits on all behavioral measures than mice that received concussive or blast-like injuries, although the functional differences were location- dependent, with greater differences observed in animals that sustained hippocampal damage. Motor deficits after injury, if present, typically resolved within a few days whereas cognitive deficits persisted for several weeks. Conclusions The results from this direct comparison of brain injury models in the laboratory mouse emphasize the importance of carefully considering the nature of the TBI when choosing the specific tests, protocols, and timing of behavioral assessments after injury.

5504. Tudor, M. (1998). "Prediction of outcome in patients with missile craniocerebral injuries during the Croatian War." Military medicine **163**(7): 486-489.

The factors assumed to exert an influence on the outcomes of 176 patients who sustained head injuries through projectiles during the Croatian War were evaluated. The type of projectile, wound age, retained foreign bodies, and patient sex and age had no significant influence on outcome. Patients with a Glasgow Coma Scale score of 3 to 5 had 7.3 times higher relative risk of poor outcome than those with a score of 6 to 15. Patients with penetrating injuries (47%), with a projectile's path traversing both hemispheres (45.5%), and with intracranial hematomas (49%) had significantly poorer outcomes than patients without such lesions. Infections were more common in patients with retained foreign bodies in wounds that were older than 48 hours (43%) and in patients with cerebrospinal fluid fistulas (50%). In assessing the outcomes of missile head injuries in wartime, the Glasgow Coma Scale score, type of head wound, site of skull penetration, endocranial projectile path, intracranial hematomas, and complications, especially infectious, represent reliable predictors of outcome.

5505. Tudor, M., et al. (2005). "Complications of missile craniocerebral injuries during the Croatian Homeland War." Military medicine **170**(5): 422-426.

OBJECTIVE: Complications of penetrating craniocerebral injuries in war can be early (during the first week after wounding) or late (after that period). Postoperative hematomas, infections, seizures, and cerebrospinal fluid fistulas (CSFFs) are counted among the early complications, whereas foreign bodies migrating intracranially, seizures, infections, and posttraumatic hydrocephalus represent late complications. A total of 176 patients with well-defined head injuries from missiles, sustained during the Croatian Homeland War (1991-1995), developed a total of 61 (34.5%) complications., METHODS: A retrospective statistical analysis of the medical records of the patients in our series was performed to determine the risk factors for the onset of complications, which have unfavorable effects on outcomes., RESULTS: There were a total of 28 (15.9%) infections (deep or superficial), 21 (11.9%) cases of CSFFs, 9 (5.11%) cases of early epilepsy, and 3 cases of post-traumatic hydrocephalus. A total of 47.6% of patients with CSFFs developed intracranial infections. Of eight patients with meningoencephalitis, five had CSFFs and four had intracranially retained foreign bodies. Only one patient developed a cerebral abscess. Two patients died because of infectious complications (13.3%). Post-traumatic hydrocephalus (1.7%) required shunt placement. For 60% of patients with deep-seated intracranial infectious complications and 76% of patients with CSFFs, reoperations had to be performed, whereas this was the case for only 8% of patients without infections (chi2 = 43.6, p = 0.00001)., CONCLUSIONS: Intracranially retained foreign bodies, wound age, wound site, and operations performed outside the neurosurgical services were the main risk factors for the development of complications. Complications themselves exerted a very unfavorable influence on outcomes. The development of complications reflects very reliably the neurosurgical technique applied.

5506. Tudor, M., et al. (2008). "[Unusual open craniocerebral injury caused by sickle's tip]." Neobicna otvorena kraniocerebralna ozljeda zetelackim srpom. **62**(1): 85-88.

A nine years old girl suffered an unusual penetrating injury to the head caused by a sickle's tip sticked into the skull bones during a lavender harvest on island of Hvar. GCS score was 15. A sickle's blade and its handle were clearly seen coming out of the frontal bone, hanging free, while its tip was firmly sitting in the skull bones! After a neuroradiological diagnostical work up (skull x rays and CT scans) that confirmed intracranial penetration she was operated as an emergency. An osteoclastic craniotomy was done, a and a sickle thereafter easily extracted. Lacerated and contused brain and the penetrating canal were debrided and dura defect covered with a patch. Broad spectrum

antibiotics were administered after antitetanic prophylaxis. Postoperative course was uneventful especially regarding infection. One year after the accident she goes normaly to school.

5507. Tuft, S. J. and A. J. Shortt (2009). "Surgical rehabilitation following severe ocular burns." Eye (London, England) **23**(10): 1966-1971.

Chemical and thermal burns can cause devastating injuries to the anterior segment. The consequences of alkali injuries are notoriously severe due to the rapid penetration of these agents into the ocular tissues. Denaturation of tissue, inflammation, and scarring leads to loss of function. An understanding of the pathogenesis of tissue damage has lead to a rational approach to treatment. Emergency irrigation of the eye is essential and there is a 'window of opportunity' during the first 7-10 days after injury when medical treatment can significantly limit the potentially blinding consequences. The acute injury is followed by early and late reparative phases during which the prognosis can be further improved by surgical intervention. Early surgical intervention is targeted at protecting the ocular surface and encouraging re-epithelisation. Later, surgical treatments are directed at ocular surface reconstruction and restoration of vision. However, before any attempt is made at surface reconstruction, the ocular surface environment must be optimised by division of symblepharon, and correction of lid deformity and trichiasis. If there is conjunctivalisation of the corneal surface, limbal stem cell transplantation can restore a corneal epithelial cell phenotype, and transplantation of in vitroamplified corneal epithelial stem cells has been developed as an alternative to keratolimbal transfer techniques. Keratoplasty and cataract surgery may then be necessary to clear the visual axis. Finally, keratoprosthesis is an option for the most severely damaged eyes.

5508. Tumialan, L. M., et al. (2009). "CT venography used for preoperative planning of foreign body extraction in penetrating craniocerebral trauma: technical case report." The Journal of trauma **66**(2): 567-569.

5509. Tumialan, L. M. and N. Theodore (2012). "Basilar artery thrombosis after reduction of cervical spondyloptosis: a cautionary report." Journal of neurosurgery. Spine **16**(5): 492-496.

Traumatic cervical spondyloptosis is a rare clinical entity typically associated with complete neurological deficit. The inherent mechanics of this fracture-dislocation pattern contorts the vertebral arteries in such a way that it may result in dissection or compromised flow through those vessels. Thus, intimal injury or thrombus from stasis of flow may result. Reduction of the spondyloptosis restores flow to the vertebral arteries, but it also may mobilize thrombus or propagate an intimal dissection within the previously contorted vessel. The authors review their experience in the care of a 43-year-old man who sustained C4-5 spondyloptosis while riding an all-terrain vehicle. On arrival, the patient demonstrated no motor function below C-4 but had sensation to the nipple line (American Spinal Injury Association Spinal Cord Injury Classification B). The patient's cranial nerve examination was unremarkable. Computed tomography of the cervical spine demonstrated complete spondyloptosis at C4-5. The patient was immediately placed in cervical traction and taken to the operating room for open reduction of the fracture dislocation, decompression of the spinal cord, and stabilization with an interbody graft and cervical plate. Preoperative cervical traction was successful in only partial reduction of the fracture dislocation. Open reduction was achieved with exposure of the C-4 and C-5 bodies and sequential distraction. After anatomical alignment was achieved, an interbody graft was placed and a cervical plate secured. A subsequent decline in the patient's level of consciousness prompted CT of the head, which showed evidence of a basilar artery thrombosis. A CT angiographic study demonstrated patency of the vertebral arteries, but a mid-basilar artery thrombosis. The patient progressed to brain death 24 hours after reduction of the fracture dislocation. The degree of contortion of the vertebral arteries in cervical spondyloptosis in the upper cervical spine may result in stasis of flow with subsequent formation of thrombus or intimal injury. After anatomical reduction, restoration of flow within the vertebral arteries may mobilize the thrombus or propagate an intimal dissection and result in subsequent embolic events. Endovascular evaluation may be warranted immediately after anatomical reduction of a high cervical spondyloptosis for evaluation of the vertebral arteries and possible thrombus dissolution or retrieval.

5510. Tuncer, N., et al. (2007). "Intracranial sewing needle in a man with seizure: a case of child abuse?" Forensic science international **168**(2-3): 212-214.

Physical abuse in infancy can cause persistent neurological deficits. Although intracranial foreign bodies are generally secondary to penetrating trauma or surgical procedures, rarely they also occur as a result of child abuse. A 32-year-old man presented with the complaint of generalized tonic clonic seizures to the Neurology Department of Marmara, University Hospital. Computerized tomography (CT) scan revealed a sewing needle located within the temporal lobe. The location and the position of the needle suggested that it must have been introduced in infancy through the lamdoid suture before the closure of it, as an unsuccessful deliberate homicide attempt or accidental injury.

5511. Tung, J.-N., et al. (2010). "Presence of secretory cellular apoptosis susceptibility protein in cerebrospinal fluids of patients with intracerebral hemorrhage caused by stroke and neurotrauma." Neuro endocrinology letters **31**(3): 390-398.

OBJECTIVE: The blood-brain barrier (BBB) is a specialized structure that separates blood vessels from the central nervous system (CNS) and restricts the entry of biomolecules and cells into the brain. Matrix metalloproteinase-2 (MMP-2) produced by interferon-gamma-activated microglia (brain macrophages) is essential for disrupting the glia limitans of BBB, which is critical for lymphocytes penetration into brain capillaries in various CNS disorders. The cellular apoptosis susceptibility (CSE1L/CAS) protein has been shown to regulate MMP-2 secretion., METHODS: We examined if CSE1L played a role in regulating the progression of intracerebral brain hemorrhage disorders., RESULTS: CSE1L was detected by immunoblotting in cerebrospinal fluids (CSFs) of patients with intracerebral hemorrhage brain disorders, including stroke and neurotrauma. Interferon-gamma treatment induced CSE1L expression and increased the secretions of CSE1L and MMP-2 by U937 macrophages. Moreover, tranfection of U937 macrophages with siRNA that targeted CSE1L inhibited interferon-gamma-induced CSE1L and MMP-2 secretion by U937 macrophages. The numbers of lymphocytes in CSF were correlated with the levels of CSE1L and MMP-2 in patients' CSF., CONCLUSIONS: Our results suggest that CSE1L plays a role in regulating MMP-2-mediated BBB breakdown and it may be a target for control of BBB permeability in intracerebral brain hemorrhage disorders.

5512. Tunthanathip, T., et al. (2020). "Traumatic cerebrovascular injury: Prevalence and risk factors." The American journal of emergency medicine **38**(2): 182-186.

BACKGROUND: Traumatic cerebrovascular injury (TCVI) is uncommon in traumatic brain injury (TBI). Although TCVI is a rare condition, this complication is serious. A missed or delayed diagnosis may lead to an unexpected life-threatening hemorrhagic event or persistent neurological deficit. The object of this study was to determine the prevalence and risk factors associated with TCVI., METHODS: The authors retrospectively reviewed medical records and neuroimaging studies of 5178 patients with TBI. The association of various factors was investigated using time-to-event statistical analysis. A TCVI which resulted in an occlusion, arteriovenous fistula, pseudoaneurysm or cerebral artery transection was defined as an event., RESULTS: Forty-two patients developed a TCVI after injuries with an overall prevalence of 0.8%. The risk factors for an intracranial arterial injury based on univariate analysis using the Cox proportional hazard regression were penetrating injury, severe head injury, orbitofacial injury, basilar skull fracture, subdural hematoma, and cerebral contusion. In multivariable analysis, the two variables that were independently associated with TCVI were basilar skull fracture (odds ratio [OR] 22.1, 95% confidence interval [CI] 11.5-42.2) followed by orbitofacial fracture (OR 13.6, 95% CI 6.8-27.3)., CONCLUSIONS: Although TCVI is a rare complication of TBI, early investigation in high-risk patients may be necessary for early treatment before an unexpected fatal event occurs.

5513. Tunthanathip, T., et al. (2019). "Traumatic cerebrovascular injury: clinical characteristics and illustrative cases." Neurosurgical focus **47**(5): E4.

OBJECTIVE: Traumatic cerebrovascular injury (TCVI) is a rare and serious complication of traumatic brain injury (TBI). Various forms of TCVIs have been reported, including occlusions, arteriovenous fistulas, pseudoaneurysms, and transections. They can present at a variety of intervals after TBI and may manifest as sudden episodes, progressive symptoms, and even delayed fatal events. The purpose of this study was to analyze cases of TCVI identified at a single institution and further explore types and characteristics of these complications of TBI in order to improve recognition and treatment of these injuries., METHODS: The authors performed a retrospective review of cases of TCVI identified at their institution between 2013 and 2016. A total of 5178 patients presented with TBI during this time period, and 42 of these patients qualified for a diagnosis of TCVI and had adequate medical and imaging records for analysis. Data from

their cases were analyzed, and 3 illustrative cases are presented in detail., RESULTS: The most common type of TCVI was arteriovenous fistula (86.4%), followed by pseudoaneurysm (11.9%), occlusion (2.4%), and transection (2.4%). The mortality rate of patients with TCVI was 7.1%., CONCLUSIONS: The authors describe the clinical characteristics of patients with TCVI and provide data from a series of 42 cases. It is important to recognize TCVI in order to facilitate early diagnosis and treatment.

5514. Tunthanathip, T. and S. Udomwitthayaphiban (2019). "Development and Validation of a Nomogram for Predicting the Mortality after Penetrating Traumatic Brain Injury." Bulletin of emergency and trauma **7**(4): 347-354.

OBJECTIVE: To determine the factors associated with mortality in penetrating brain injury (PTBI) and proposed the nomogram predicting the risk of death., METHODS: A retrospective cohort study was conducted on all patients who had sustained PTBI between 2009 and 2018. Collected data included clinical characteristics, neuroimaging findings, treatment, and outcomes. Prognostic factors analysis was conducted using a forest plot. Therefore, the nomogram was developed and validated. For the propose of evaluation, the nomogram's sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), Receiver Operating Characteristic (ROC) curve and the area under the receiver operating characteristic (AUC) were determined for validating the optimal cut-off point of the total scores., RESULTS: During the study period, 62 individuals enrolled. In the univariate analysis, factors associated with the morality were normal pupils' reactivity to light (OR 0.04, p < 0.001), hypotension (OR 9.91, p<0.001), hypoxia (OR 10.2, p=0.04), bihemispheric injuries (OR 19.0, p=0.001), multilobar injuries (OR 21.5, p< 0.001), subarachnoid hemorrhage (OR 6.9, p= 0.02), intraventricular hemorrhage (OR 26.6, p= 0.006), basal cistern effacement (OR 28.8, , p<0.001), midline shift >5 mm (OR 0.19, p<0.001) were significantly associated with death. In multivariable analysis, hypotension (OR 8.82, p=0.03), normal pupils' reactivity to light (OR 0.07, p =0.01), midline shift >5 mm (OR 18.23, p<0.007) were significantly associated with death. The nomogram's sensitivity, specificity, PPV, NPV, and AUC for predicting mortality (total score >= 100) were 80%, 92.6%, 72.7%, 95.0%, and, 0.86 respectively., CONCLUSIONS: PTBI is the fatal injury depend on both clinical and neuroimaging parameters. The nomogram is the alternative method providing prognostic parameters toward implication for clinical decision making.

5515. Tuppurainen, K., et al. (1997). "Wooden foreign particles in the orbit--spontaneous recovery." Acta ophthalmologica Scandinavica **75**(1): 109-111.

A six-year-old boy consulted an ophthalmologist, because another boy had hit his right eye with a tree branch. There were slight corneal erosions, and a superficial small wound in the oedematous upper lid. The erosions healed in 2 days, but the lid showed progressive ptosis and oedema. Computed tomography revealed a hyperdense, tight structure, which was suspected to be a foreign particle. An orbital exploration was made three times, but the foreign body was not found. After prolonged suppuration, two wooden particles appeared spontaneously 4 and 5.5 months after the trauma. After that, the suppuration subsided and the wound healed.

5516. Turan Suslu, H., et al. (2005). "[A statistical analysis for the identification of factors effecting prognosis of civilian patients with cranial gunshot wounds]." Atesli silahla basindan yaralanmis sivil hastalarda prognozu etkileyen faktorlerin ayrimi icin istatistiksel bir calisma. **11**(3): 206-211.

BACKGROUND: Patients with civil cranial gunshot injuries who were treated in our hospital were statistically analyzed for the factors acting on 7 days survival and prognosis without regarding treatment modalities., MATERIAL AND METHOD: Patients were divided into two groups according to the mortality rates in 7 days following the trauma without regarding treatment modalities. Initial GCS score, pupillary response to light, coagulopathy, ventricular penetration and number of hemispheres affected are 5 differentials evaluated separately and in combination for their effects on mortality rates within 7 days posttraumatically and their statistical significance., RESULTS: Thirty six male (75%) and 12 female (25%) patients included in the study. Total and 7 day- survival rates were 27% (13/48), and 31% (15/48) respectively. Among GCS scores, pupillary defects, coagulopathy, intraventricular penetration, the number of hemispheres affected, the most important prognostic factors of the patients living less than 7 days were found to be primarily coagulopathy and then pupillary defects. The other variables were not significantly effective and the results were in accordance with the literature., CONCLUSION: In civilian patients with cranial gunshot injuries pupillary defect

and coagulopathy were statistically significant prognostic factors. We think that aggressive medical and surgical treatment will be beneficial even if the patients' neurological status is deteriorating.

5517. Turbin, R. E., et al. (2006). "Patterns of transorbital intracranial injury: a review and comparison of occult and non-occult cases." Survey of ophthalmology **51**(5): 449-460.

The authors present an illustrative case of occult transorbital penetrating intracranial injury in a child, and review the literature concerning patterns of low-velocity, non-projectile injury during the era of modern CT and MRI study. Review of the mechanism of injury and analysis of surface entry site of penetration in 38 cases suggests recurring patterns of injury in occult and non-occult cases. A classification system based on surface entry zone site is applied to these injuries. Knowledge of the classification system should increase clinical suspicion for this type of often occult, penetrating orbito-cranial injury and direct appropriate investigation to provide earlier detection and diagnosis of the transorbital, intracranial penetration.

5518. Turco, L., et al. (2017). "Penetrating Bihemispheric Traumatic Brain Injury: A Collective Review of Gunshot Wounds to the Head." World neurosurgery **104**: 653-659.

BACKGROUND: Head injuries that cross midline structures of the brain are bihemispheric. Other terms have been used to describe such injuries, but bihemispheric is the most accurate and should be standard nomenclature. Bihemispheric head injuries are associated with greater mortality and morbidity than other penetrating traumatic brain injuries (TBIs). Currently, there is a tendency to manage severe gunshot wounds (GSWs) to the head nonoperatively, despite reports of improved outcome in military patients treated aggressively. Thus, controversy exists in the management of civilian TBI., METHODS: PubMed was searched for query terms, and PRISMA guidelines were used. Studies were selected by relevance and inclusion of data regarding etiology, diagnosis, and management of bihemispheric TBI. Case reports, studies not in English, and records lacking information on mechanism or bihemispheric injuries were excluded., RESULTS: Thirteen studies were included and most contained level IV evidence. The mean mortality rate of all head GSWs was 62% in adults and 32% in children. Bihemispheric GSWs had greater mortality rates of 82% in adults and 60% in children. There was a larger proportion of self-inflicted injury in studies with greater rates of bihemispheric injuries., CONCLUSIONS: Bihemispheric injuries have greater mortality rates than other penetrating TBI. Violation of midline brain structures such as the diencephalon and mesencephalon, increased rate of self-inflicted wounds, and lack of a standard management algorithm may increase the lethality of these injuries. Although bihemispheric injuries historically have been considered nonsalvageable, an aggressive surgical approach has been shown to improve outcomes, particularly in the military population.

5519. Turco, L. M., et al. (2019). "Hormone replacement therapy in brain-dead organ donors: a comprehensive review with an emphasis on traumatic brain injury." The journal of trauma and acute care surgery **86**(4): 702-709.

BACKGROUND: Organ shortage is an ongoing problem in the United States. Most donor organs are procured following brain death and a significant portion of brain-dead donors result from devastating brain injury. Without a standard practice for hormone replacement therapy (HRT) in the setting of brain death, a comprehensive review of the literature was deemed necessary., METHODS: A search of published literature was conducted with terms "TBI" or "brain injury" or "head injury" AND "hormone" or "management" AND "organ" AND "donor" or "donation." Abstracts and full texts were screened for relevance and inclusion of information on HRT. Additional studies were selected from references cited within these. Excluded studies were non-English, nonhuman based, or had small sample size, (i.e., case reports or series with fewer than five subjects)., RESULTS: Fifteen studies were selected for inclusion and contained Level III or Level IV evidence. Combinations of thyroid hormone, insulin, and corticosteroids were the most commonly cited HRT. Ninety-three percent of studies found a significant increase in organ procurement rate among donors who received HRT. Hormone replacement therapy was administered after brain death declaration in eight studies. Only two studies specifically explored the effects of starting HRT earlier and identified even greater procurement rates. Four studies were specific to traumatic brain injury (TBI); the remaining 11 studies involved TBI in 22% to 89% of the sample., CONCLUSION: Organ shortage remains a growing problem in the United States. Donor management including HRT has been proposed to combat the endocrine derangement associated with brain death and, in particular, TBI. While the existing literature reported compelling outcomes using HRT, there remains a need for further Level I and Level II evidence studies to define optimal practice., LEVEL OF EVIDENCE: Review article, level IV.

5520. Tureyen, K. (2001). "Traumatic intracranial aneurysm after blunt trauma." British journal of neurosurgery **15**(5): 429-431.

Traumatic intracranial aneurysms are rare and represent less than 1% of all cerebral aneurysms. This type of aneurysm develops after blunt or penetrating head trauma. Surgical clipping and/or endovascular occlusion are the definitive treatments. This report describes the very unusual case of a patient who has survived for 2 years with conservative management alone.

5521. Turgeon, A., et al. (2009). "Mortality and incidence of withdrawal of life support measures in ICU patients with severe TBI: A canadian multicenter retrospective study." Critical care medicine **37**(12): A389.

Introduction: Mortality following severe traumatic brain injury (TBI) ranges from 30 to 50%. However, very little is known about the process of dying in this specific patient population, including the incidence of withdrawal of life support measures (WLSM) and how prognosisis determined. In order to evaluate in-hospital mortality, incidence of WLSM among TBI deaths and the rationale for WLSM in patients with severe TBI in Canada, we conducted a multicenter retrospective cohort study in 6 Canadian Level I trauma centers. Hypothesis: Important variation exists in hospital mortality and the incidence of WLSM in patients with severe TBI in trauma centers across Canada. Methods: We identified mechanically ventilated patients admitted in participating ICUs between January 2005 and December 2006 suffering severe TBI (Glasgow Coma Scale (GCS) ≤ 8) by ICD-10 codes. We excluded patients younger than 16 years-old and those with penetrating TBI. Data from 720 patients was collected using a standardized case report form by trained data abstractors (random selection of 120 patients/center). We compared non-adjusted hospital mortality and WLSM using the Chi-square test. Age and GCS-adjusted odds ratios (OR) for hospital mortality and WLSM were calculated using hierarchical logistic regression analysis (Proc Glimmix, SAS v9.2). Results: Most patients were male (77%) with a mean age of 42 [95%CI: 41-44], a median GCS of 3 [IQ 3-6] with 57% admitted following a motor vehicle collision. The observed hospital mortality was 32% [28-34%] ranging from 11 to 44% among centers ($p<0.01$). Seventy percent of patients died following WLSM (45 to 86% between centers, $p<0.01$). One center had both a lower hospital mortality (OR 0.37 [0.21-0.66]) and a lower proportion of deaths following WLSM (0.30 [0.16-0.56]) compared with the other centres. Except for one center, the most evocated reason to justify WLSM was poor chance of survival. Poor long-term neurological prognosis was the second most common reasonand a long-term neurological prognosis incompatible with patient's wishes was the next most common reason. Non-neurological co-morbidities were rarely documented as reasons justifying WLSM. Intensivists were more involved than neurosurgeons in the documentation of prognosis in most centres. Neurological exams, CT-scans and clinical experience were, in order, the most important tests or reasons to support the documentation of prognosis. Conclusions: We found variation in hospital mortality and mortality following WLSM between centers. The important incidence ofmortality following WLSM in patients with severe TBI and the difference inmortality between centers outline the need to develop clinical prediction models to aid clinicians in assessing neurological prognosis and standardize their approach to end of life care.

5522. Turgeon, A., et al. (2009). "Practice variation in the management and treatment of increased intracranial pressure in severe traumatic brain injury in Canada: A canadian multicentre retrospective cohort study." Critical care medicine **37**(12): A435.

Introduction: Following severe traumatic brain injury (TBI), episodes of elevated intracranial pressure (ICP) are associated with significant morbidity and increased risk of mortality. Recent guidelines recommend ICP monitoring in several situations and suggest treatment strategies to standardize management of severe TBI with increased ICP(1). Hypothesis: That uncertainty in effectiveness results in practice variability in the use of ICP monitoring and in the treatment of raised ICP exists among intensive care units (ICU). Methods: We performed a multicenter retrospective cohort study in 6 level I trauma centers in Canada. We included mechanically ventilated patients admitted to participating ICUs between January 2005 and December 2006 with severe TBI (Glasgow Coma Scale (GCS) ≤ 8) identified by ICD-10 codes. We excluded patients younger than 16 y.o. or suffering from penetrating TBI. We calculated that a random selection of 120 patients per center would be sufficient to detect an absolute difference of 20% in ICP monitoring use and in treatment strategies for raised ICP between centres (type I error of 5% and type II errorof 20%). A pretested and standardized case report form was used by trained data abstractors to collect data on the first 14 days of ICU stay. We used the Chi-square test to compare frequency of use of monitoring and treatment strategies between

centers. Results: A total of 720 patients were included inthis study. 77% of patients were male with a mean age of 42 [95%CI: 41-44] anda median GCS of 3 [IQ: 3-6] admitted following motor vehicle collision (57%).The use of any ICP monitoring ranged from 14% to 54% across centers and 3% to 33% of patients had extraventricular drains inserted (p<.01). When increased ICP occurred, mannitol was used in 5 to 68% of patients, hypertonic saline in 1 to 33%, therapeutic hypothermia in 0 to 21%, paralytics in 2 to 22%, barbiturates in 0 to 3%, and vasopressors (to target a specific cerebral perfusion pressure) in 24 to 52% (all p <.01). The use of decompressive craniectomy ranged from 0 to 22% of patients (p<.01). Jugular venous oxygen saturation (SjO2) monitoring ranged from 0% to 12% between centers (p<.01) and hospital mortality was 32% [95%CI: 28-34]. Conclusions: We found wide practice variation in monitoring and treatment of increased ICP across centers. The low frequency of use of ICP monitoring in all participating centers is not consistent with current recommendations (1).

5523. Turina, D., et al. (2001). "War head injury score: an outcome prediction model in War casualties with acute penetrating head injury." Military medicine **166**(4): 331-334.

OBJECTIVE: To evaluate in war casualties with acute penetrating head injury whether the summed War Head Injury Score (WHIS) is a better predictor of mortality than either the Glasgow Coma Scale (GCS) score or the Injury Severity Score (ISS) alone and to establish its specific applicability., METHODS: Sensitivity, specificity, correct outcome prediction, and discrimination were assessed in 43 patients in the war group (ballistic injuries) and 41 patients in the civil group (nonballistic injuries) during the period 1991 to 1995. The new model was generated using the sum of GCS scores and ISS, to which a coded value was applied for summation., RESULTS: In the war group, the mortality rate was 23%; the sensitivity and specificity of WHIS were 100% and 79%, the sensitivity and specificity of GCS score were 90% and 85%, and the sensitivity and specificity of ISS were 100% and 49%, respectively. In the civil group, the mortality rate was 39%; the sensitivity and specificity of WHIS were 87% and 76%, the sensitivity and specificity of GCS score were 63% and 90%, and the sensitivity and specificity of ISS were 100% and 56%, respectively., CONCLUSION: With regard to civilians, war casualties with acute penetrating head injury more often have multiple injuries. WHIS represents a new scoring system that incorporates both GCS score and ISS.

5524. Turkcuoglu, P. and S. Aydogan (2006). "Intracranial foreign body in a globe-perforating injury." Canadian journal of ophthalmology. Journal canadien d'ophtalmologie **41**(4): 504-505.

CASE REPORT: To report a case with an intracranial foreign body in the setting of a globe-perforating injury. A 53-year-old man experienced a sudden pain in his right eye while he was breaking a stone with a sledgehammer. Upon examination, a 1.5 mm superomedial corneoscleral perforation site was noted. Cranial sections of axial orbital computed tomography (CT) revealed a foreign body at the middle cranial fossa., COMMENTS: A high index of suspicion is required to detect an intracranial foreign body in ocular injuries. Orbital CT must be included in preoperative evaluation of these patients and cranial sections must also be examined carefully.

5525. Turkoz, D. and C. Demirel (2021). "Retrospective clinical evaluation of patients undergoing surgery for acute epidural hematoma." Journal of Experimental and Clinical Medicine (Turkey) **38**(2): 187-191.

We aimed to evaluate mortality-associated factors among patients with acute epidural hematoma due to head trauma. Demographic characteristics, preoperative Glasgow Coma Scale score, epidural hematoma aetiology and radiological findings, accompanying systemic trauma results, hospitalisation duration, sequelae, and mortality features of patients experiencing epidural hematoma between 2014 and 2018 were evaluated. Overall, 79 patients were examined. The most frequent epidural hematoma aetiology was traffic accidents (51.9%), with temporal region being the most common epidural hematoma location (38 [48.2%] patients). Among all, 12 (15.2%) patients died and 67 (84.8%) were discharged. Of them, 57 (85.1%) patients were discharged without and 10 (14.9%) with neurological sequelae. Age>65 years (p=0.001) and low Glasgow Coma Scale score (p<0.05) were significantly associated with higher mortality. Overall mortality rate was 91.7% (p<0.001) in patients with systemic trauma accompanying epidural hematoma, with thoracic (12%) and orthopaedic (9%) trauma being the most common. Cranial injuries included linear fracture, 78.5%; pneumocephalus, 48.1%; cerebral contusion, 44.3%; traumatic subarachnoid haemorrhage, 32.9%; acute subdural hematoma; 26.6%, and collapse fracture, 15%. All cranial injuries except linear fractures were associated with high mortality (p<0.05). Epidural hematoma is associated with high mortality. Aetiology, Glasgow Coma Scale score, cranial pathology, age, and additional trauma are the major predictive mortality-associated factors.

5526. Turliuc, D. M., et al. (2015). "Intraorbital foreign body." Revista medico-chirurgicala a Societatii de Medici si Naturalisti din Iasi **119**(1): 179-184.

Penetrating orbitocranial injuries caused by intraorbital foreign body are a rare cause of morbidity being most common among young people. The term intraorbital foreign body refers to a foreign body that occurs within the orbit but outside the ocular globe. We report the case of a 12-year-old male child who sustained a right cranial facial trauma due to accidental fall on a piece of wood, which penetrated intraorbitally. Native cranial magnetic resonance imaging (MRI -1.5 T) revealed the presence of an intraorbital foreign body, 6 cm long and 1.5 cm wide, near the orbital apex. In our patient, early surgical extraction of the foreign body had a decisive role on his full recovery. In this case, although a large foreign body penetrated the entire length of the orbit, it did not cause damage to any intraorbital structure. Vision and right ocular globe function had an excellent prognosis.

5527. Turner, O. A. and A. T. Laird (1966). "Meningioma with traumatic etiology. Report of a case." Journal of neurosurgery **24**(1): 96-98.

5528. Tutton, M. G., et al. (2000). "Screwdriver assaults and intracranial injuries." Journal of accident & emergency medicine **17**(3): 225-226.

Four patients with intracranial penetrating injuries from screwdrivers are presented. Two cases were fatal; the others were left with functional deficits. In two of the patients a penetrating injury was not suspected initially because the history was limited and the significance of the small entry wounds were not appreciated. Unless these wounds are carefully examined a penetrating injury is easily overlooked.

5529. Twaij, S., et al. (2009). "Acute traumatic orbital cerebrospinal fluid cystocele mimicking orbital abscess." Journal of AAPOS : the official publication of the American Association for Pediatric Ophthalmology and Strabismus **13**(5): 491-493.

Posttraumatic cranio-orbital cerebrospinal fluid (CSF) fistula is rare, occurring when there is a communication between orbit and subarachnoid space. This communication can be caused by orbital tumors with intracranial extension or can be a result of orbital surgery. Low suspicion for traumatic orbital CSF fistula can lead to delay in diagnosis, which increases the risk of meningitis. We report a cranio-orbital CSF cystocele and fistula that mimicked orbital cellulitis in a 3-year-old boy following an orbitocranial penetrating injury.

5530. Tyagi, G., et al. (2020). "An unusual case of penetrating skull injury." Interdisciplinary Neurosurgery: Advanced Techniques and Case Management **21**.

Penetrating injury to the skull with a sharp object such as a screw driver is unusual and requires emergent and assiduous management. A middle aged male had presented to us with such an injury with the penetrating object embedded firmly in his temporal bone going intracranially. He underwent craniotomy with careful removal of the embedded object whose tip was rooted in the petrous temporal bone and barely missing the vital structures like petrous carotid artery and the inner ear. Patient had an uneventful post op course and follow up of 8 weeks. A penetrating screwdriver injury to the skull is a rare occurrence with high morbidity and mortality. Imaging to ascertain the intracranial structures involved followed by early and careful retrieval in the operating room form the mainstay of treatment.

5531. Tzelikis, P. F., et al. (2015). "Traumatic wound dehiscence after corneal keratoplasty." Arquivos brasileiros de oftalmologia **78**(5): 310-312.

PURPOSE: To assess patient characteristics, risk factors, outcomes, and the treatment of wound dehiscence (WD) in patients after corneal keratoplasty., METHODS: Retrospective chart review of 11 eyes of 11 patients with corneal grafts who underwent repair of WD from January 1, 2004 to December 31, 2012 at Hospital Oftalmologico de Brasilia., RESULTS: Eight (72.7%) patients were men and three were women. Six (54.5%) patients had deep anterior lamellar keratoplasty (DALK) and 5 had penetrating keratoplasty. The mean age at trauma was 31.1 years. The mean

time from corneal keratoplasty to WD was 12.82 months (range, 3-33 months). The mean best-corrected visual acuity of patients before trauma was 20/60 (0.48 logMAR) and after final treatment was 20/160 (0.90 logMAR) (P=0.15). In one case, visual acuity decreased to no light perception because of retinal detachment and phthisis bulbi. Accidental blunt trauma and fall were the most common causes of WD., CONCLUSION: Patients who undergo corneal keratoplasty have a life-long risk of WD. The full-thickness rupture at the graft-host junction in our study suggests that the junction remains vulnerable, even following DALK, and can rupture with trauma. In our series, depending upon the severity of the trauma, postkeratoplastic WD can be associated with a good visual prognosis.

5532. Uberti, M., et al. (2021). "Clinical Significance of Isolated Third Cranial Nerve Palsy in Traumatic Brain Injury: A Detailed Description of Four Different Mechanisms of Injury through the Analysis of Our Case Series and Review of the Literature." Emergency medicine international **2021**.

Third cranial nerve palsy (3cnP) following traumatic brain injury (TBI) is a worrying neurological sign and is often associated with an expanding mass lesion, such as extradural or acute subdural haematomas. Isolated 3cnP can be found in the absence of posttraumatic space-occupying mass lesion, yet it is often considered as a devastating prognostic factor in the context of diffuse axonal injury (DAI). Through the analysis of five exemplificative cases and a thorough review of the literature, we identified four possible mechanisms leading to 3cnP: (1) a partial rootlet avulsion at the site of exit from the midbrain, representing a direct shearing injury to the nerve; (2) a direct traction injury due to the nerve stretching against the posterior petroclinoid ligament at the base of the oculomotor triangle secondary to the downward displacement of the brainstem at the time of impact; (3) a direct vascular compression as a result of internal carotid artery (ICA) dissection or pseudoaneurysm; (4) an indirect injury caused by impaired blood supply to the third nerve in addition to the detrimental biochemical effects of the underlying brain injury itself. Understanding the exact mechanism underlying the onset of 3cnP is key to provide an informed clinical decision-making to the patients and ensure their best chances of recovery. Our experience corroborates data from the literature showing that, even in Grade III DAI, prompt recognition of isolated 3cnP can guide adequate treatment. Nonetheless, even when an overall good neurological outcome is achieved, recovery of isolated 3cnP is dismal, and only rarely the visual deficit completely resolves.

5533. Udoh, D. O., et al. (2010). "Self-inflicted transparietal intraventricular nail: Case report and surgical technique." African Journal of Neurological Sciences **29**(2).

Background Deliberate self-harm with stone- or hammer-driven nail through the cranium is unusual. The need is stressed for comprehensive radiological evaluation with computed tomography (CT) scan, with or without angiography, and removal through an open cranial procedure under general anaesthesia, rather than extraction through a burrhole under local anesthetic infiltration. Methods We present here a 27-year old male who presented at our Teaching Hospital setting with a self-inflicted hand-driven intracranial nail to the left parietal region. He had a detailed neurological examination, was evaluated pre-operatively with computerised tomography of the brain and underwent an open cranial procedure under general anaesthesia for nail retrieval. Psychiatric unit evaluated and managed him for chronic depression. Results The transparietal, intraventricular 10cm long nail was retrieved and associated abscess evacuated by an open cranial procedure. Pre-operative neurological impairments regressed and his mood stabilized with anti-depressants. He was discharged without further deficits and has remained well for over four years Conclusion Self-inflicted hand-driven intracranial nail is a very rare form of penetrating cranio-cerebral trauma. Preoperative computerised tomography scan of the brain, meticulous open cranial removal under general anaesthesia and psychiatric management enable discharge without further injury or deficits. On the other hand, removal through a burrhole or just pulling out the nail would not allow intraoperative visualisation of associated lesions; the latter also predispose to further vascular and parenchymal brain injuries, worsening neurolological impairments. © 2002 African Journal of Neurological Sciences.

5534. Udwadia, R. A., et al. (1994). "A transethmoid transorbital foreign body." The Journal of laryngology and otology **108**(5): 441-442.

5535. Uemura, A., et al. (2001). "Usefulness of gradient-echo T2*-weighted MR imaging in evaluation of transorbital penetrating cerebral injury." Clinical imaging **25**(3): 163-166.

Transorbital penetrating cerebral injury can cause severe morbidity if not identified and treated. After the removal of the object and without the clinical information, even the chance of suspicion of penetrating cerebral injury might be missed in the first investigation. We report a case of transorbital penetrating cerebral injury caused by a metal rod and diagnosed by MRI including gradient-echo T2*-weighted imaging.

5536. Ugurlu, K., et al. (2007). "Reconstructing wide palatomaxillary defects using free flaps combining bare serratus anterior muscle fascia and scapular bone." Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **65**(4): 621-629.

PURPOSE: Wide palatomaxillary defects, mostly after tumor resections, can cause severe functional and esthetic problems. Although prosthetic obturator devices or local flaps are mostly adequate for uncomplicated small-size defects, free flaps are preferred for a 3-dimensional multitissue reconstruction of more complicated defects. Regarding the anatomical structure of the palatomaxillary region, the flap must be thin enough to separate the oral and nasal cavities while not compromising palatal function, yet rigid enough for adequate dental restoration. This goal is usually accomplished with a combined or complex free flap. Numerous free flaps containing both soft tissues and bone have been described in the literature. In this study, we present a novel use of the free scapular bone flap combined with serratus anterior fascia and its functional and esthetic results., PATIENTS AND METHODS: Nine cases are presented whose wide composite palatomaxillary defects were repaired with free angular scapular bone flap combined with serratus anterior fascia based on the subscapular vascular system, between 1999 and 2003. Scapular bone wrapped with the naked serratus anterior fascia, like a sandwich, was used to repair the palate., RESULTS: The naked fascia was epithelialized with the help of the surrounding mucosa in 4 to 6 weeks. Results were satisfying with regard to breathing, eating, speech, and facial contour after follow-ups for 2 months to 6 years., CONCLUSION: For the reconstruction of wide palatomaxillary defects, a combined flap of angular scapular bone wrapped with naked serratus anterior fascia was conceived useful for obtaining satisfactory functional and esthetic results.

5537. Uhl, E., et al. (1999). "Influence of platelet-activating factor on cerebral microcirculation in rats: part 2. Local application." Stroke **30**(4): 880-886.

BACKGROUND AND PURPOSE: Platelet-activating factor (PAF) is involved in the development of secondary brain damage after ischemic and traumatic brain injury. On the basis of data from studies in peripheral organs, we hypothesized that PAF-mediated effects after cerebral injury could be secondary to alterations in cerebral microcirculation., METHODS: Changes in cerebral microcirculation focusing on leukocyte-endothelium interactions were quantified with the use of a closed cranial window model in Sprague-Dawley rats (n=33) by means of intravital fluorescence microscopy. The brain surface was superfused with PAF in concentrations from 10(-3) (n=3) to 10(-12) mol/L (n=6) for 20 minutes (5 mL/h)., RESULTS: PAF 10(-4) mol/L (n=4) increased the number of rolling and adherent leukocytes in venules from 9.7+/-0.4 to 19.7+/-2.3 cells/100 mm. min (P=NS versus control) and from 2.2+/-0.5 to 4.3+/-0.7 cells/100 mm. min (P<0.05 versus control), respectively. Lower concentrations did not elicit leukocyte-endothelium interactions. Vessel diameters remained unchanged except for a transient increase of arteriolar diameters during superfusion with PAF 10(-4) and 10(-6) mol/L (n=6). Although only a limited area of the brain surface was exposed to PAF, the mediator induced a significant dose-dependent transitory arterial hypotension and caused irreversible circulatory shock at the high concentration (PAF 10(-3) mol/L). Arterial hypotension after administration of PAF 10(-3) mol/L could be attenuated by the intravenous pretreatment with the PAF antagonist WEB 2170BS., CONCLUSIONS: PAF, when locally released after brain injury, can penetrate the blood-brain barrier and induce systemic effects, including arterial hypotension. Its role as a mediator in the development of secondary brain damage seems, at least in the initial phase, not to be associated with disturbances of cerebral microcirculation or activation of leukocytes.

5538. Ulker, P. (2016). "The effect of acute and short term normobaric hyperoxia on hemorheologic parameters." Biorheology **53**(3-4): 171-177.

Backround:Possible toxic effects of hyperoxia have been reported previously. However, the number of studies investigating the influence of hyperoxia on blood cells is limited and there are no data regarding its hemorheological effects., OBJECTIVE: The aim of this study was to investigate the effects of acute hyperoxia, performed in human

subjects at normal atmospheric pressure, on the rheological properties of blood., METHOD: The study was conducted with 12 brain death patients mechanically ventilated in the intensive care unit. The patients were ventilated with 21%, 40%, and 100% oxygen before induction of apnea testing performed for diagnosis of brain death. Blood samples were obtained at each oxygen concentration value for all patients., RESULT: The results of the study indicated no significant change of red blood cell aggregation, deformability and plasma or whole blood viscosity associated with acute hyperoxia at normobaric conditions., CONCLUSION: The results of the study suggest that application of normobaric hyperoxia does not have detrimental effects on hemorheological parameters in brain death patients, and that organs considered for donation from such subjects are not adversely affected by abnormalities of blood flow and tissue perfusion.

5539. Ulutaş, M. and M. Seçer (2014). "Shrapnel injury of isolated third cranial nerve." Journal of neurological surgery reports **75**(2): e217-e219.

Isolated third nerve palsy develops in numerous intracranial pathologies such as closed head trauma, tumor, and aneurysm. Isolated oculomotor nerve palsy caused by shrapnel injury is uncommon. After a penetrating intracranial shrapnel injury, our patient with oculomotor ophthalmoplegia underwent surgery. Microsurgery removed the shrapnel that was applying pressure on the third nerve, resulting in contusion. A partial recovery associated with regeneration was observed at month 9. Extraocular muscle surgery should be planned if palsy does not resolve over a prolonged period of time.

Measures aimed at the prevention of complications gain foremost importance when timely surgical treatment of a penetrating craniocerebral wound cannot be conducted. Experimental research and clinical experience have shown that the administration of 50 000--100 000 U of an antibiotic (kanamycin, monomycin, hectamycin, chloramphenicol) into the wound soon after an open penetrating injury had been inflicted to the skull and brain protects the wound from microbial contamination. This provides the possibility for postponing the plastic operation of the defect in the dura mater.

5541. Umesh, S. R. and S. R. Pejavar (2015). "Pattern and distribution of injuries in fatal road traffic accidents - A postmortem study conducted in BTGH, Gulbarga." Medico-Legal Update **15**(2): 137-142.

Deaths due to Road Traffic Accidents (RTA) are increasing at an alarming rate throughout the world. Thereby it poses itself as a major epidemiological and medicolegal problem. With increasing use of vehicles, injuries due to them are so common nowadays that it is necessary to be able to assess the injuries, the mechanisms by which they are caused and the cause of death. The study of injuries associated with fatal outcome helps in implementation of measures to prevent fatalities due to RTAs. Hence, the present study was conducted to know, pattern and distribution of injuries in victims of fatal RTAs, victim's age and sex and survival period. In addition, an attempt was also made to know the cause of death.

Penetrating brain trauma is an infrequent event and is associated to high mortality rates. The may be caused by projectiles or locally introduced objects. Among the latest, the most frequent agents are blades. We report the case of a

male that suffered a penetrating traumatic injury in the context of an aggression. The trajectory ran through the mastoid with the distal portion resting over the sigmoid sinus. The foreign body was surgically extracted with no further complications. We describe the differential characteristics in the management of these injuries.

5545. Unden, J., et al. (2004). "Serial S100B levels before, during and after cerebral herniation." British journal of neurosurgery **18**(3): 277-280.

Protein S100B has been shown to increase in serum and cerebrospinal fluid (CSF) in various neurological diseases. However, the levels of S100B in conjunction with cerebral herniation have not been studied and the significance of extracerebral S100B has become an important issue. We report on a multi-trauma patient in whom cerebral herniation occurred 2 days after admission. Following this, organ-harvesting procedures were performed for transplantation. We measured serial serum S100B during both the ongoing herniation and the following extracerebral surgery. We found that S100B levels seemed to peak immediately prior to cerebral herniation and then decreased shortly thereafter and concluded that the source of the measured serum S100B in this patient was of predominately cerebral origin. In conjunction with the organ harvesting procedure S100B levels increased, indicating that extracerebral sources of the protein also exist.

5546. Ung, H., et al. (2017). "Intracranial EEG fluctuates over months after implanting electrodes in human brain." Journal of neural engineering **14**(5): 056011.

OBJECTIVE: Implanting subdural and penetrating electrodes in the brain causes acute trauma and inflammation that affect intracranial electroencephalographic (iEEG) recordings. This behavior and its potential impact on clinical decision-making and algorithms for implanted devices have not been assessed in detail. In this study we aim to characterize the temporal and spatial variability of continuous, prolonged human iEEG recordings., APPROACH: Intracranial electroencephalography from 15 patients with drug-refractory epilepsy, each implanted with 16 subdural electrodes and continuously monitored for an average of 18 months, was included in this study. Time and spectral domain features were computed each day for each channel for the duration of each patient's recording. Metrics to capture post-implantation feature changes and inflexion points were computed on group and individual levels. A linear mixed model was used to characterize transient group-level changes in feature values post-implantation and independent linear models were used to describe individual variability., MAIN RESULTS: A significant decline in features important to seizure detection and prediction algorithms (mean line length, energy, and half-wave), as well as mean power in the Berger and high gamma bands, was observed in many patients over 100 d following implantation. In addition, spatial variability across electrodes declines post-implantation following a similar timeframe. All selected features decreased by 14-50% in the initial 75 d of recording on the group level, and at least one feature demonstrated this pattern in 13 of the 15 patients. Our findings indicate that iEEG signal features demonstrate increased variability following implantation, most notably in the weeks immediately post-implant., SIGNIFICANCE: These findings suggest that conclusions drawn from iEEG, both clinically and for research, should account for spatiotemporal signal variability and that properly assessing the iEEG in patients, depending upon the application, may require extended monitoring.

5547. Unger, R. R., et al. (1976). "[Space requiring intracranial conditions and pregnancy]." Raumfordernde intrakranielle Prozesse und Schwangerschaft. **37**(3): 177-189.

Gravidity and the intracranial process are discussed in view of the question of whether to carry out an interruption of pregnancy or to carry the pregnancy to full term and end it by means of Cesarean section, on the basis of literature and 5 observations.--It is recommended to work out an individual plan of treatment together with the obstetrician and the neurologist. It was shown that there is a possibility of an operative treatment of intracranial processes of different genesis even in the advanced stage of pregnancy and with the continuation pregnancy.

5549. Uppuluri, A., et al. (2021). "Orbital Floor Fractures Concurrent with Acute Open-Globe Injuries." Ophthalmology **128**(4): 626-628.

5550. Uppuluri, A., et al. (2020). "Geographic trends in adult open globe injuries (OGIs)." Investigative Ophthalmology and Visual Science **61**(7).

Purpose : To identify geographic trends in demographic variables, cost, and management of adult OGIs in the United States from 2002-2014. Methods : We used the 2002-2014 National Inpatient Sample (NIS) Database in conjunction with diagnosis codes from the International Classification of Diseases, Ninth Revision to identify cases with a primary diagnosis of OGI. Once we identidied all cases of OGIs, we removed the pediatric cases (0-20 years of age) and divided the adult data into four geographic regions as supplied by the NIS Database: Northeast, Midwest, South, West. Cases in these regions were compared with respect to sex, race, age, ocular findings, ocular surgeries, and cost of admission. Results : We identidied 34,485 weighted cases of adult OGIs occurring between 2002-2014 (8457 in the Northeast, 6072 in the Midwest, 12264 in the South, and 7692 in the West). The ratio of men to women was roughly 2.33 to 1 across all geographic regions. The South had the highest rate (42.0%) of OGIs occurring in patients 21-40 years of age and the West had the highest rate (18.0%) of OGIs occurring in patients over 81 years of age. Penetrating injuries were the most common types of OGI seen in all regions (82.0-85.7%), and rates of intraocular foreign bodies (IOFBs) were between 11.9% and 12.9%. Rates of endophthalmitis were highest in the Midwest and South (1.9%). The prevalence of concurrent orbital fractures was highest in the Midwest (11.1%). The rates of vitrectomy and enucleation ranged from 12.4% to 14.2% and 2.7% to 5.5%, respectively. The average length of stay was 2-3 days in all regions. The average cost per day was highest in the West ($18,140.30). Conclusions : In our analysis of the NIS Database, we found that the South had the highest prevalence of OGIs between 2002 and 2014. The ratio of men to women and the breakdown of OGIs by age group (21-40, 41-60, 61-80, and 81+) were both similar across geographic regions. The prevalence rates of penetrating injuries, IOFBs, and ruptures in all four regions were comparable. The prevalence of endophthalmitis and orbital fractures was highest in the Midwest and South. Rates of pars plana vitrectomy were consistent throughout the United States, but rates of enucleation were higher in the Midwest and South. While the average length of stay was comparable across the regions, the average cost per day was 37-50% greater in the West as compared to other regions.

5551. Urban, M., et al. (1994). "Pancreatitis associated with remote traumatic brain injury in children." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **10**(6): 388-391.

Vomiting, abdominal distension, and feeding intolerance are common findings following brain injury in children, and are usually attributed to the brain injury or to delayed gastric emptying: a specific cause is usually not sought. We report six children who developed mild to moderate pancreatitis at least 7 days following apparently isolated brain injury, a previously unreported association. Five of the six patients received drugs that are known or suspected pancreatotoxins; all recovered without changes in the medications. When children develop feeding intolerance or upper gastrointestinal symptoms following traumatic brain injury pancreatitis should be suspected.

5552. Urbanova, P., et al. (2017). "The virtual approach to the assessment of skeletal injuries in human skeletal remains of forensic importance." Journal of forensic and legal medicine **49**: 59-75.

While assessing skeletal injuries in human skeletal remains, forensic anthropologists are frequently presented with fractured, fragmented, or otherwise modified skeletal remains. The examination of evidence and the mechanisms of skeletal injuries often require that separate osseous elements be permanently or temporarily reassembled or reconstructed. If not dealt with properly, such reconstructions may impede accurate interpretation of the evidence. Nowadays, routine forensic examinations increasingly incorporate digital imaging technologies. As a result, a variety of PC-assisted imaging techniques, collectively referred to as the virtual approach, have been made available to treat fragmentary skeletal remains. The present study employs a 3D virtual approach to assess mechanisms of skeletal injuries, and provides an expert opinion of causative tools in three forensic cases involving human skeletal remains where integrity was compromised by multiple peri- or postmortem alterations resulting in fragmentation and/or incompleteness. Three fragmentary skulls and an incomplete set of foot bones with evidence of perimortem fractures (gunshot wounds) and sharp force trauma (saw marks) were digitized using a desktop laser scanner. The digitized skeletal elements were reassembled in the virtual workspace using functionalities incorporated in AMIRA R version 5.0

software, and simultaneously in real physical space by traditional reconstructive approaches. For this study, the original skeletal fragments were substituted by replicas built by 3D printing. Inter-method differences were quantified by mesh-based comparison after the physically reassembled elements had been re-digitized. Observed differences were further reinforced by visualizing local variations using colormaps and other advanced 3D visualization techniques. In addition, intra-operator and inter-operator error was computed. The results demonstrate that the importance of incorporating the virtual approach into the assessment of skeletal injuries increases with the complexity and state of preservation of a forensic case. While in relatively simple cases the virtual approach is a welcome extension to a traditional approach, which merely facilitates the analysis, in more complex and extensively fragmentary cases such as multiple gunshot wounds or dismemberment, the virtual approach can be a crucial step in applying the principles of gunshot wounds or sharp force traumatic mechanisms. The unrestricted manipulation with digital elements enabling limitless repairs and adjustments to a "best-case scenario" also produced smaller inter-operator variation in comparison to the traditional approach.

5553. Ursprung, R., et al. (2022). "Gunshot wounds to the head: a comparison of postmortem magnetic resonance imaging, computed tomography, and autopsy." Acta radiologica (Stockholm, Sweden : 1987) **63**(4): 513-519.

BACKGROUND: Postmortem imaging has become a powerful diagnostic tool in forensics. Postmortem computed tomography (PMCT) is often used currently to complement and sometimes even replace an autopsy., PURPOSE: To compare PMCT, postmortem magnetic resonance imaging (PMMRI), and autopsy findings for gunshot wounds to the head., MATERIAL AND METHODS: Cross-sectional study. We performed a retrospective analysis of 24 cases with gunshot wounds to the head that underwent both PMCT and PMMRI between 2011 and 2018 at the Institute of Forensic Medicine, University of Zurich (Switzerland)., RESULTS: Our study confirms that PMCT and, to a slightly lesser degree, PMMRI provide additional information that is valuable when combined with autopsy findings. Air embolism was solely detected in PMCT (67% vs. 0% at autopsy). A retained bullet or projectile and bone fragments were diagnosed more frequently with PMCT (42%, 67%, and 92%) than at autopsy (33%, 42%, and 46%). Soft tissue lesions were more often detected with PMMRI than with PMCT. With regard to autopsy, subdural hemorrhage and ventricular hemorrhage were slightly more frequently diagnosed with PMMRI (63% and 75% vs. 38% and 58% at autopsy). Intracerebral hemorrhage was by far most often diagnosed with PMMRI (92%) compared with both PMCT (38%) and autopsy (14%)., CONCLUSION: All three modalities should ideally be considered in cases of craniocerebral gunshot wounds. However, it might be conceivable that depending on the forensic query, PMCT and PMMRI may be an adequate replacement for an autopsy.

5554. Ustaoglu, M., et al. (2020). "Demographic characteristics and visual outcomes of open globe injuries in a tertiary hospital in Istanbul, Turkey." European journal of trauma and emergency surgery : official publication of the European Trauma Society **46**(3): 549-556.

PURPOSE: To evaluate the demographic characteristics and visual outcomes of patients with open globe injury (OGI) in a tertiary hospital in Istanbul, Turkey., METHODS: The data of patients admitted with OGI to Sisli Hamidiye Etfal Training and Research Hospital, Istanbul, Turkey from January 2012 to December 2017 were reviewed retrospectively, and 100 of the 154 patients were included in the study., RESULTS: There were 79 (79%) male and 21 (21%) female patients with the average age of 33.7 +/- 20.7 (1-83). Presentation of the patients was more frequent in the first 3 days of the week (Monday 20%; Tuesday 17%; and Wednesday 20%) and within working hours (8 a.m.-5 p.m., 71%). The most common injury type was penetrating injury (75%), which was mostly caused by sharp objects (metal objects 32% and broken glass 22.7%). The ocular trauma score (OTS) was significantly higher in patients with penetrating injury and intraocular foreign body injury ($p < 0.001$), and those results were correlated with better visual prognosis. The patients with penetrating injury among the injury types and zone I injury among the injury zones had the highest final visual acuity. Patients in the age group of 0-14 years had statistically better visual outcome when compared to those in the other age groups ($p = 0.003$)., CONCLUSIONS: The higher initial visual acuity and OTS, penetrating injury, zone I injury and pediatric age are good prognostic factors for OGI. Additionally, scheduling a prepared surgical team and tools in working hours will be beneficial according to the frequency of admissions.

5555. Uusitalo, R. J. and J. Lehtosalo (1989). "Visual, refractive, and keratometric results of epikeratophakia in children. A two-year follow-up." Archives of ophthalmology (Chicago, Ill. : 1960) **107**(3): 358-363.

Fifty-two patients under the age of 16 years (68 eyes) received epikeratophakia grafts for the correction of aphakia. In 27 eyes, epikeratophakia was a primary procedure combined with lensectomy. Fifteen children underwent bilateral surgery. Overall, the success rate was 91%, and with repeated surgery it was 94%. The average change in refractive error was 15.9 diopters (D) and the average spectacle overcorrection was +0.3 D. Sixty-one percent (35/57) of the eyes were within 1 D of emmetropia and 97% (55/57) were within 3 D of emmetropia. Overall, the refraction was stable in the follow-up between six months and 1 1/2 years following surgery. However, a myopic shift of 2.0 D occurred between six months and 1 1/2 years in very young children following refractive surgery. The corneal curvature was measured only in older children and showed an average increase of 10.7 D. Visual acuity results in verbal patients were comparable to those in patients with contact lenses. The majority of smaller children demonstrated improvement in visual acuity with a combination of epikeratophakia and amblyopia therapy.

5556. Uysal, E. and Y. A. Acar (2020). "Pneumomediastinum, pneumocephalus, and bilateral pneumo-orbita in the same patient: a rare dangerous coexistence but a lucky prognosis." JPMA. The Journal of the Pakistan Medical Association **70**(9): 1655-1656.

Trauma is the leading cause of mortality and morbidity among young adults. In the emergency department, blunt and penetrating traumas must be evaluated carefully especially for life-threatening conditions. High-pressure air is a rare penetrating trauma type. Pneumomediastinum, pneumocephalus, and bilateral pneumo-orbita are all dangerous conditions and coexistence of them is extremely rare. There is no consensus for the treatment of this concurrence and, moreover, there is no opportunity for future randomized studies. Hence, in this study, we report a pneumomediastinum, pneumocephalus, and bilateral pneumo-orbita case after high-pressure air trauma and resolution with supportive care without any complication.

5557. Vaca, E. E., et al. (2013). "Facial fractures with concomitant open globe injury: mechanisms and fracture patterns associated with blindness." Plastic and reconstructive surgery **131**(6): 1317-1328.

BACKGROUND: Treatment of facial fractures in the setting of open-globe injuries poses a management dilemma because of the often disparate treatment priorities of multidisciplinary trauma teams and the lack of prognostic data regarding visual outcomes., METHODS: Patients in the University of Maryland Shock Trauma Registry sustaining facial fractures with concomitant open-globe injuries from January of 1998 to August of 2010 were identified. Odds ratios were calculated to identify demographic and clinical variables associated with blindness, and multivariate regression analysis was performed., RESULTS: A total of 99 patients were identified with 105 open-globe injuries. Seventy-nine percent of injuries were blinding, whereas 4.8 percent of globes achieved a final visual acuity greater than or equal to 20/400. Blindness was associated with penetrating injury, increasing number of facial fractures, zygomaticomaxillary complex fracture, admission Glasgow Coma Scale score less than or equal to 8, and globe injury spanning all three eye zones. Fracture repair was performed more frequently (62.5 percent) and more quickly (average time to fracture repair, 4.5 days) in cases of primary globe enucleation/evisceration when compared with complete (21.2 percent; 8 days; p=0.35) or incomplete (42.9 percent; 11 days; p=0.058) primary globe repair., CONCLUSIONS: Penetrating injury mechanism and zone of eye injury appear to be better indicators of visual prognosis than facial fracture patterns. Given the high rates of blindness, secondary enucleation, and delay of fracture repair in patients that were not primarily enucleated, the authors recommend that orbital fracture repair not be delayed in the hopes of eventual visual recovery in cases of high-velocity projectile trauma., CLINICAL QUESTION/LEVEL OF EVIDENCE: Risk, III.

5558. Vadamalai, K., et al. (2020). "A Nail in The Brain: Delayed Traumatic Pseudoaneurysm." Neurocritical care **32**(1): 357-358.

5559. Vaicys, C., et al. (2000). "Successful recovery after an orbitocranial injury." The Journal of trauma **49**(4): 788.

5560. Vaishnav, Y. J., et al. (2020). "Delayed Diagnosis of an Occult Wooden Orbital Foreign Body." Rhode Island medical journal (2013) **103**(5): 49-51.

An orbital foreign body should be suspected in cases of penetrating orbital injury, but they are not typically seen with low-velocity trauma and no obvious penetrating injury. Wooden foreign bodies are difficult to distinguish from orbital fat on computed tomography (CT), and without a high degree of suspicion for a foreign body, techniques to distinguish wood in the orbit may not be utilized. The authors present here a case of an initially unrecognized wooden orbital foreign body in the setting of orbital trauma where the patient denied any possibility of a foreign body and no evidence of a penetrating injury. The diagnosis was eventually made with an interdisciplinary review of the imaging between the orbital service and radiology, and the foreign body was subsequently removed via orbitotomy. Surgeons should maintain a high index of suspicion when there is a question of a foreign body on imaging, and a low threshold to involve radiology colleagues in the diagnostic evaluation.

5561. Vajkoczy, P., et al. (1999). "Penetrating craniocerebral injuries in a civilian population in mid-Europe." Clinical neurology and neurosurgery **101**(3): 175-181.

Our current neurosurgical understanding of civilian penetrating craniocerebral injuries is based on US metropolitan series. It is unknown whether all principles applied to these patients are relevant in the Mid-European setting with its distinct epidemiology. The objective of this study was to characterize our patients with penetrating craniocerebral injuries, to analyze their outcome, and to identify relevant prognostic factors. Thirty-two patients with penetrating craniocerebral injuries were entered into the study. Patient evaluation comprised neurological, laboratory and radiographic analyses. Motivating factors were suicide (75%), assault (13%), and accident (9%). Initial GCS score, coagulopathy on admission, and radiographic extent of injury could be identified as outcome predictors ($P < 0.001$). An aggressive therapeutic approach to patients with GCS 3-7 reduced mortality when compared to a conservative management (67 vs. 91%). Due to major differences in epidemiology and outcome of our penetrating craniocerebral injury patients when compared to major US metropolitan series, current therapeutic strategies applied to this patient population in mid-Europe should be reconsidered. The results of our study justify an aggressive neurosurgical approach even in those patients that are thought to have a deleterious prognosis. Predictive variables identified in this study and a novel CT-grading algorithm may help in decision making.

5562. Vajpayee, R. B., et al. (2000). "Large-diameter lamellar keratoplasty in severe ocular alkali burns: A technique of stem cell transplantation." Ophthalmology **107**(9): 1765-1768.

PURPOSE: To evaluate the efficacy of large-diameter lamellar keratoplasty in cases of severe ocular alkali burns., DESIGN: Prospective, noncomparative, interventional case series., PARTICIPANTS: Nine eyes of nine patients with severe ocular alkali burns (grade III/IV) exhibiting corneal vascularization, conjunctivalization, and chronic inflammation were recruited from the Cornea Clinic of Dr. Rajendra Prasad Centre for Ophthalmic Sciences, New Delhi, a tertiary eye care center., INTERVENTION: Large-diameter lamellar keratoplasty was performed using McCarey-Kaufman media-preserved donor corneas. The patients were followed up for a minimum of 6 months., MAIN OUTCOME MEASURES: Symptomatic relief, time to epithelialization, best-corrected visual acuity, Schirmer I, tear film break-up time, and central corneal clarity were the parameters evaluated., RESULTS: The mean duration between the injury and surgery was 29.5 +/- 19.4 months. No intraoperative complications were seen. Successful epithelialization of the ocular surface was achieved in all but one eye, and the mean time to epithelialization was 5.2 +/- 4.9 days. One eye had a persistent epithelial defect which was managed with a bandage soft contact lens. All patients achieved symptomatic relief. The preoperative best-corrected visual acuity was </=1/60 in all the patients. There was a significant improvement in vision in six eyes postoperatively ($P = 0.013$). The corneal clarity was grade 2+ or better in five eyes and 1+ in four eyes. No recurrence of corneal vascularization or signs of rejection were seen in any eye during the mean follow-up of 7.4 +/- 3.2 months. Causes of no improvement of vision included the presence of subepithelial nebulomacular haze in one eye caused by persistent epithelial defect and residual stromal haze., CONCLUSIONS: Large-diameter lamellar keratoplasty is a useful therapeutic modality in cases of severe alkali burns. It is a single-stage procedure that provides a stable ocular surface because of stem cell supplementation and may visually rehabilitate the patient.

5563. Vakil, M. T. and A. K. Singh (2017). "A review of penetrating brain trauma: epidemiology, pathophysiology, imaging assessment, complications, and treatment." Emergency radiology **24**(3): 301-309.

Gunshot injuries are the most common cause of penetrating brain injury (PBI) and carry a high morbidity and mortality. The incidence of PBI has increased over the last decade with an estimated 35,000 civilian deaths annually.

Patients that survive to reach the hospital require rapid triage and imaging evaluation. CT findings in conjunction with the Glasgow Coma Scale are typically used to determine which patients are surgical candidates. Radiologists should be familiar with the various injury patterns and imaging findings which are poor prognostic indicators, notably brainstem, bilateral hemispheric, multilobar, or transventricular injuries. Post-traumatic complications, including intracranial infections, cerebrospinal fluid leaks, traumatic intracranial aneurysms, intraventricular hemorrhage, dural venous sinus thrombus, and bullet fragment migration, also have specific imaging features and serious treatment implications. In this article, we review the initial imaging evaluation of penetrating brain injury using computed tomography with and without angiography. We also describe the imaging features of various post-traumatic complications and their treatment implications. Finally, we discuss the clinical and imaging parameters that serve as important prognostic indicators and the surgical management.

5564. Valassina, A., et al. (2013). "Pelvic ring injuries in children: Long term results." Journal of Orthopaedics and Traumatology **14**(1): S15.

Introduction Pediatric pelvic ring injuries are rare lesions (incidence: 1/100000 people per year). Mortality can reach 25 %, even though bony lesion is rarely the direct cause of death. Due to the rarity of these lesions only few published reports exist in the literature with long term results and there is no general consensus about treatment strategies. Aim of the study is to report the long-term results about the treatment of pelvic ring injuries and to suggest new treatment strategies based on biomechanical-developmental criteria. Materials and methods All the patients with an age from 0 to 14 years and pelvic ring injury were included in the study. Type of fracture (modified Torode and Zieg classification system), associated organ lesions, type of treatment and complications were recorded. The outcome measures adopted were:Majeed score, radiographic evaluation (Keshishyan's method) and the measure of leg length discrepancy. Results Twelve patients were included in the study (median age: 9.9 years, range: 1-14). The types of fracture were: 1 patient with type I, 1 with type II (gunshot injury), 4 with type IIIA (out of which 2 with quadrant lesions), 2 with type IIIB and 4 with type IV. Five (42 %) patients presented hemodynamic instability. Associated injuries were: traumatic brain injury (34 %); thoracic injuries (25 %); abdominal and urogenital lesions (25 %). No arterial embolisation was needed. All type IV fractures and the gunshot injury were treated surgically. The mean follow-up time was 6.8 years (range: 1-9 years). At the last follow-up the pelvic asymmetry improved of 51.4 %and the median Majeed score was 80/80. Only one patient with significant leg length discrepancy (3 cm) showed poor result in terms of pain and function. No other complications were recorded. No patient died. Discussion Pelvic ring injuries in children are rarely associated with life-threatening haemorrhages. The biomechanical characteristics of the paediatric pelvis make the quadrant dislocations and stable ring lesions more frequent until 7-8 years of age. After this age pelvic lesions become even more similar to the adult types. The potential of residual growth and remodelling process allow to compensate even high grade of dislocations. Nevertheless, the characteristics of the growth process don't allow to compensate vertical displacement. Conclusions Unstable pelvic ring injuries have to be managed surgically by ORIF even in the children. Stable lesions and quadrant dislocations may be treated conservatively, even if the fractures with vertical displacement >1 cm have little chance of remodelling and need surgical treatment.

5565. Valdes, E., et al. (2020). "Special considerations in the assessment of catastrophic brain injury and determination of brain death in patients with SARS-CoV-2." Journal of the neurological sciences **417**: 117087.

INTRODUCTION: The coronavirus disease 2019 (Covid-19) pandemic has led to challenges in provision of care, clinical assessment and communication with families. The unique considerations associated with evaluation of catastrophic brain injury and death by neurologic criteria in patients with Covid-19 infection have not been examined., METHODS: We describe the evaluation of six patients hospitalized at a health network in New York City in April 2020 who had Covid-19, were comatose and had absent brainstem reflexes., RESULTS: Four males and two females with a median age of 58.5 (IQR 47-68) were evaluated for catastrophic brain injury due to stroke and/or global anoxic injury at a median of 14 days (IQR 13-18) after admission for acute respiratory failure due to Covid-19. All patients had hypotension requiring vasopressors and had been treated with sedative/narcotic drips for ventilator dyssynchrony. Among these patients, 5 had received paralytics. Apnea testing was performed for 1 patient due to the decision to withdraw treatment (n = 2), concern for inability to tolerate testing (n = 2) and observation of spontaneous respirations (n = 1). The apnea test was aborted due to hypoxia and hypotension. After ancillary testing, death was declared in three patients based on neurologic criteria and in three patients based on cardiopulmonary criteria (after withdrawal of support (n = 2) or cardiopulmonary arrest (n = 1)). A family member was able to visit 5/6 patients prior to

cardiopulmonary arrest/discontinuation of organ support., CONCLUSION: It is feasible to evaluate patients with catastrophic brain injury and declare brain death despite the Covid-19 pandemic, but this requires unique considerations.

5566. Valdivia, M., et al. (2007). "Effect of posttraumatic donor's disseminated intravascular coagulation in intrathoracic organ donation and transplantation." Transplantation proceedings **39**(7): 2427-2428.

INTRODUCTION: Our aim was to evaluate the influence on yield and function of intrathoracic organs from donors after severe cranial trauma complicated by disseminated intravascular coagulation (DIC)., MATERIALS AND METHODS: This retrospective observational study in a patient cohort with severe cranial trauma reading to brain death compared the number of harvested thoracic organs among individuals with versus without previous DIC. We examined exclusions for organ donation and their probable relationship to DIC. We also analyzed blood components transfused to normalize coagulation parameters. The organ recipients were followed for 1 month to detect acute graft failure., RESULTS: Among 147 organ donors, 37 were brain dead after suffering severe cranial trauma and 13 met DIC criteria upon admission. We did not observe demographic differences among donors, although there was a trend for DIC donors to be younger (32 +/- 10 vs 40 +/- 21 years old; P = .11). Twenty-eight donors (12 with DIC and 16 without) and 29 donors (13 with DIC and 16 without) met age and medical criteria for potential heart or lung donation, respectively. Donation exclusion was related to trauma instead of DIC itself. We did not find any difference among the number of cardiac and lung organs harvested from organ donors with DIC (67% and 31%, respectively) or without DIC (75% and 44%, respectively). All DIC donors had clinical bleeding and received multiple units of blood products. Organs were harvested 37 +/- 23 (13 to 80) hours after admission. All patients had normalized coagulation parameters at surgery. In the postoperative evolution, none of the cardiac or lung recipients from DIC donors met primary graft failure criteria., CONCLUSIONS: We concluded that hearts and lungs from donors with previous DIC were suitable for transplant recipients.

5567. Valentine, J., et al. (1984). "Gunshot injuries in children." The Journal of trauma **24**(11): 952-956.

Ninety consecutive patients between 2 and 15 years of age sustaining gunshot wounds were analyzed and a management algorithm evolved. Key management steps included fluid resuscitation in the field by trained paramedical personnel and recognition of the severity of the wound when large-caliber or shotgun injuries were encountered. Arteriograms were most helpful in locating vascular injuries; venograms were inaccurate. Morbidity was directly related to missile size and impact area, and to the number of organs injured. Any hospitalization beyond 2 weeks' duration should have social service, home-bound school service, psychiatry, and physical therapy in consultation. During a 5-year period only two of the 90 patients died secondary to hemorrhagic shock.

5568. Valesova, L., et al. (2003). "[Primary pars plana vitrectomy in the treatment of penetrating eye injuries involving intraocular foreign bodies in the vitreous body]." Primarni pars plana vitrektomie v lecbe penetrujiciho poraneni oka zasahujiciho do sklivce s nitroocnim cizim teliskem. **59**(4): 228-238.

The method of choice in the treatment of penetrating eye injuries affecting the vitreous body with an intraocular foreign body is in the majority of patients primary pars plana vitrectomy with transvitreal extraction of the foreign body (FB). During the period from April 1999 till September 2000 the authors treated thus at the Ophthalmological Clinic of the General Faculty Hospital and 1st Medical Faculty Charles University Prague 26 eyes of 26 young men with an average age of 34 years. The mean interval between the injury and primary PPV was 8.5 days. The patients were followed up on average for 23.5 months. The entrance of the penetrating injury was in 17 eyes in the cornea or limbus, in 9 eyes in the sclera. In two eyes posttraumatic endophthalmitis developed. The intraocular FB was 6 mm2 in size in 16 eyes and 6-20 mm2 in 10 eyes. In primary PPV we indicated in 14 eyes internal tamponade with gas or silicone oil. On account of late retinal complications which developed as a result of proliferative vitreoretinopathy we indicated in eight eyes PPV reoperation. At the end of the investigation period in 3 eyes inoperable detachment of the retina developed. As the main negative prognostic factor for final visual acuity the authors evaluated a size of the FB greater than 6 mm2, other negative prognostic factors are the scleral entrance injury, complications of the entrance injury (prolapse of the iris, vitreous body, haemophthalmus) and the development of posttraumatic exogenous endophthalmitis.

5569. Valle, E. J., et al. (2014). "Do all trauma patients benefit from tranexamic acid?" The journal of trauma and acute care surgery **76**(6): 1373-1378.

BACKGROUND: This study tested the hypothesis that early routine use of tranexamic acid (TXA) reduces mortality in a subset of the most critically injured trauma intensive care unit patients., METHODS: Consecutive trauma patients (n = 1,217) who required emergency surgery (OR) and/or transfusions from August 2009 to January 2013 were reviewed. At surgeon discretion, TXA was administered at a median of 97 minutes (1-g bolus then 1-g over 8 hours) to 150 patients deemed high risk for hemorrhagic death. With the use of propensity scores based on age, sex, traumatic brain injury (TBI), mechanism of injury, systolic blood pressure, transfusion requirements, and Injury Severity Score (ISS), these patients were matched to 150 non-TXA patients., RESULTS: The study population was 43 years old, 86% male, 54% penetrating mechanism of injury, 25% TBI, 28 ISS, with 22% mortality. OR was required in 78% at 86 minutes, transfusion was required in 97% at 36 minutes, and 75% received both. For TXA versus no TXA, more packed red blood cells and total fluid were required, and mortality was 27% versus 17% (all $p < 0.05$). The effects of TXA were similar in those with or without TBI, although ISS, fluid, and mortality were all higher in the TBI group. Mortality associated with TXA was influenced by the timing of administration ($p < 0.05$), but any benefit was eliminated in those who required more than 2,000-mL packed red blood cells, who presented with systolic blood pressure of less than 120 mm Hg or who required OR (all $p < 0.05$)., CONCLUSION: For the highest injury acuity patients, TXA was associated with increased, rather than reduced, mortality, no matter what time it was administered. This lack of benefit can probably be attributed to the rapid availability of fluids and emergency OR at this trauma center. Prospective studies are needed to further identify conditions that may override the benefits from TXA., LEVEL OF EVIDENCE: Therapeutic study, level IV.

5570. Valle, G., et al. (1994). "Tc-99m HMPAO SPECT in a cerebral gunshot wound." Clinical nuclear medicine **19**(8): 699-702.

The authors examined regional cerebral blood flow by using Tc-99m HMPAO SPECT studies in a patient who received a gunshot wound to the brain. Although the presence of the retained bullet's fragments adversely affected the quality of CT images and contraindicated MRI studies, the SPECT examination did not have the same constraints and allowed both therapy assessment and prognostic evaluation. The repair of the cortical defect could also be assessed.

5571. Valoriani, S., et al. (2017). "Sharp Force Trauma Death in a Young Individual From Medieval Gloucester." The American journal of forensic medicine and pathology **38**(2): 111-114.

The authors of the present work evaluate the trauma observed on the skeletal remains of an individual from medieval Gloucester and reconstruct the events that led to his death. The almost complete skeleton was recovered from the cemetery of St Owen and dates to the late medieval period. Several methods were used to determine the sex and age of the individual. The anthropological examination showed that the remains belonged to a young male, between the ages of 17 and 19 years. The young man also had antemortem pathologies that were related to his diet and lifestyle, as he appears to have had iron-deficiency anemia and Schmorl nodes. The trauma observed on the remains consisted of 3 cut marks located on the cranium, left radius, and right scapula. The cuts seem to have been inflicted by a heavy weapon, such as a sword. The trauma pattern observed is consistent with defensive action, and the fact that this skeleton was the only one in the collection that has evidence of trauma suggests that this was a case of interpersonal violence.

5572. Van Arsdell, G. S., et al. (1991). "Bullet fragment venous embolus to the heart: case report." The Journal of trauma **31**(1): 137-139.

This report describes a case of bullet fragment embolus to the heart following a small-caliber gunshot wound to the mouth. Skull and C-spine films appeared to account for the projectile; however, chest X-ray followed by fluoroscopy and two-dimensional echocardiography demonstrated a venous missile embolus in the right heart. The bullet was palpated, trapped in the right ventricle, and easily extruded.

5574. van Beurden, H. E., et al. (2003). "Fibroblast subpopulations in intra-oral wound healing." Wound repair and regeneration : official publication of the Wound Healing Society [and] the European Tissue Repair Society **11**(1): 55-63.

The objective of this study was to characterize fibroblasts at sequential time points during intra-oral wound healing in the rat. Experimental wounds were made at several time points in the mucoperiosteum of the palate of 35-day-old Wistar rats. Fibroblasts were cultured from the biopsies under standard conditions for the same number of passages. The expression of the integrin subunits alpha 1, alpha 6, and beta 1; and the intermediate filaments alpha-smooth muscle actin and vimentin were analyzed by flow cytometry. Western blot analysis was performed at 0, 8, and 60 days postwounding to confirm the expression of both intermediate filaments. The phenotypic profiles of fibroblasts cultured from subsequent stages in the wound healing process differed considerably. We conclude that distinct fibroblast phenotypes can be isolated from different stages in wound healing. These phenotypes remained stable during in vitro culturing. In addition, cryosections of the wound areas were made at identical time points and were immunohistochemically stained for the same antigens. The immunohistochemical staining correlated well to the flow-cytometric data. These results suggest the occurrence of multiple subpopulations of fibroblasts with a specialized function during wound healing. We hypothesize that undesirable consequences of wound healing might be prevented through the modulation of specific fibroblast subpopulations.

5575. Van Caelenberg, A. I., et al. (2010). "Computed tomography and cross-sectional anatomy of the head in healthy rabbits." American journal of veterinary research **71**(3): 293-303.

OBJECTIVE: To obtain a detailed anatomic description of the rabbit head by means of computed tomography (CT)., ANIMALS: 6 clinically normal Dendermonde White rabbits weighing 3 kg and raised for human consumption and 1 Netherland dwarf rabbit., PROCEDURES: The commercially raised rabbits were slaughtered in a slaughterhouse, flayed, and decapitated. The dwarf rabbit was euthanatized. Two hours later, each rabbit head was positioned with the ventral side on the CT table to obtain transverse and sagittal, 1-mm-thick slices. Dorsal images were obtained by placing each head perpendicular to the table. Immediately after the CT examination, 3 heads were frozen in an ice cube at -14 degrees C until solid and then sectioned at 4-mm-thick intervals by use of an electric band saw. Slab sections were immediately cleaned, photographed, and compared with corresponding CT images. Anatomic sections were examined, and identified anatomic structures were matched with structures on corresponding CT images., RESULTS: The bone-window CT images yielded good anatomic detail of the dentition and the bony structures of rabbit skulls. The soft tissue structures that could be determined were not better identifiable on the soft tissue-window CT images than on the bone-window images., CONCLUSIONS AND CLINICAL RELEVANCE: CT images of the heads of healthy rabbits yielded detailed information on the skull and some surrounding soft tissue structures. Results of this study could be used as a guide for evaluation of CT images of rabbits with various cranial and dental disorders.

5576. van Dellen, J. R. and R. Lipschitz (1978). "Stab wounds of the skull." Surgical neurology **10**(2): 110-114.

Sixteen cases of penetrating stab wounds of the head, where the knife blade has still been in situ on arrival at hospital, are presented. The indications for cerebral angiography, to establish vascular injury, and the spectrum of presentation are discussed. A technique of safe removal is described. There were no fatalities in the cases reviewed.

5577. van den Bergh, B., et al. (2015). "Conservative treatment of a mandibular condyle fracture: Comparing intermaxillary fixation with screws or arch bar. A randomised clinical trial." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **43**(5): 671-676.

INTRODUCTION: A mandibular condyle fracture can be treated conservatively by intermaxillary fixation (IMF) or by open reposition and internal fixation (ORIF). Many IMF-modalities can be chosen, including IMF-screws (IMFS). This prospective multi-centre randomised clinical trial compared the use of IMFS with the use of arch bars in the treatment of mandibular condyle fractures., RESULTS: The study population consisted of 50 patients (mean age: 31.8 years). Twenty-four (48%) patients were allocated in the IMFS group. Twenty-six (52%) patients were assigned to the arch bars group. In total 188 IMF-screws were used (5-12 screws per patient, mean 7.83 screws per patient). All pain scores were lower in the IMFS group. Three patients developed a malocclusion (IFMS-group: one patient, arch bars-group: two patients). Mean surgical time was significantly shorter in the IMFS group (59 vs. 126 min; $p<0.001$). There were no needlestick injuries (0%) in the IMFS group and eight (30.7%) in the arch bars group ($p=0.003$). One IMF-screw fractured

on insertion (0.53%), one (0.53%) screw was inserted into a root. Six (3.2%) screws loosened spontaneously in four patients. Mucosal disturbances were seen in 22 patients, equally divided over both groups., CONCLUSION: Considering the advantages and the disadvantages of IMFS, and observing the results of this study, the authors conclude that IMFS provide a superior method for IMF. IMFS are safer for the patients and surgeons.

5578. van den Brink, W. A., et al. (1998). "Monitoring brain oxygen tension in severe head injury: the Rotterdam experience." Acta neurochirurgica. Supplement **71**: 190-194.

Cerebral ischemia is considered the central mechanism leading to secondary brain damage in patients with severe head injury. We investigated the technique of continuous monitoring of local brain tissue oxygen tension as parameter for cerebral oxygenation. Eighty-two patients with non penetrating severe head injury were studied. No complications of the monitoring technique were seen. Postmeasurement calibration of the catheters showed a very low zero drift and acceptable sensitivity drift. Low PbrO2 values were seen within the first 12 to 24 hours of injury. Early occurrence of values below 10 mm Hg indicated a poor prognosis. Comparative measurements between two catheters performed in six patients showed differences in absolute values measured, but a good correlation of relative changes was observed. We conclude that continuous monitoring of PbrO2 is reliable, clinically applicable and provides the clinician with a better insight in cerebral oxygenation and hopefully should help in targeting therapy towards improved cerebral oxygenation.

5579. van den Munckhof, P., et al. (2012). "Open-wound treatment for gunshot to the brain." Journal of neurosurgery. Pediatrics **10**(1): 64-66.

The authors report a case of a gunshot wound to the brain in a 2.5-year-old girl. To treat the uncontrollably elevated intracranial pressure, the patient underwent bilateral decompressive craniectomy and experimental open-wound treatment. She recovered to a good functional level.

5580. van Dijck, J. T., et al. (2018). "Decision making in very severe traumatic brain injury (Glasgow Coma Scale 3-5): a literature review of acute neurosurgical management." Journal of neurosurgical sciences **62**(2): 153-177.

INTRODUCTION: Patients presenting with an early Glasgow Coma Scale (GCS) Score of 3-5 after blunt or penetrating skull-brain assaults are categorized as having sustained a very severe traumatic brain injury (vs-TBI). This category is often overlooked in literature. Impact on patients and families lives however is huge and the question "whether to surgically treat or not" frequently poses a dilemma to treating physicians. Little is known about mortality and outcome, compared to what is known for the group of severe TBI patients (s-TBI) (GCS 3-8). The main goal of this review was creating more awareness for the neurosurgical treatment of this patient group., EVIDENCE ACQUISITION: A literature search (2000-2017) was conducted discussing "severe TBI (GCS 3-8)", "(neuro)surgical management" and "outcome". Ultimately 45 out of 2568 articles were included for further analysis., EVIDENCE SYNTHESIS: Mortality rates and unfavorable outcome are high for s-TBI patients and as expected higher for vs-TBI patients. Mortality rates reach up to 100% for specific subgroups with GCS=3 and bilaterally fixed dilated pupils. Functional outcome was generally poor, but sometimes, although seldom, favorable in specific groups of vs-TBI patients after neurosurgical intervention. Factors like initial GCS, pupillary abnormalities and age seem to be associated with worse outcome., CONCLUSIONS: Overall this literature review showed high rates of unfavorable outcome and mortality for vs-TBI patients. However, some studies, reporting relatively low mortality rates, reported "good" outcome for specific groups of vs-TBI patients. It is concluded that clinical decision making, in particular those on treatment limitations, should never be taken based on the GCS alone.

5581. van Dijke, J. H. M. and D. Schakenraad (2011). "[A toddler with a haematoma of an eye after a fall]." Een peuter met een hematoom van een oog na een val. **155**(18): A2193.

A 2-year-old boy had fallen at home with a pencil in his hand. On physical examination we found only some blood in the inner corner of his right eye, but MRI showed a traumatic pencil tract into his frontal lobes.

5582. Van Hulle, C., et al. (2021). "Veterans in AD prevention clinical trials: An evaluation of the association of tbi on memory and global cognition." Journal of Prevention of Alzheimer's Disease **8**(SUPPL 1): S75-S76.

Background: Traumatic Brain Injury (TBI) is a risk factor for developing Alzheimer's Disease (AD). TBI occurs more frequently among veterans than non-veterans and therefore warrants special consideration in AD prevention clinical trials of aging Veterans. Objectives: To determine if the presence of TBI is associated with poorer cognitive function relative to peers without TBI, we compared baseline performance on tests of memory and global cognition among VA-eligible veterans stratified by probable TBI. Methods: Participants were drawn from an on-going 18-month, randomized, placebo-controlled clinical trial studying the effects of high-dose eicosapentaenoic acid (icosapent ethyl) on neuroimaging and cerebrospinal fluid AD biomarkers and cognition; the Brain Amyloid and Vascular Effects (BRAVE) of Eicosapentaenoic Acid Study (NCT02719327). Participants were VA -eligible Veterans ages 50-75 with no diagnosis of memory disorder or impairment. Participants were excluded if they were unable to safely take the study medication or participate in MRI or lumbar puncture procedures. Study analyses included N=114 Veterans who were seen for a prestudy screening and baseline visit. Cognitive assessments were administered prior to randomization. For this analysis, we selected three measures of memory function (Digit Symbol Substitution task, a test of working memory speed; Free and Cued Selective Reasoning test [FCSRT] free recall, a measure of associative memory; Logical Memory Delayed Recall) and one measure of global cognition (Mini Mental State Exam [MMSE]). Criteria for probable TBI was adapted from the DSM-V. Participants were designated as probable TBI based on self-reports of an impact or other event causing rapid movement or displacement of the brain within the skull (blast, accident, fall, bullet wound, or fragment), resulting in loss of consciousness (N=34), loss of memory (N = 11) dazed or confused state (N = 44), concussion or other head injury (N = 34). TBI data were missing for two participants. Participants also completed the Mini International Neuropsychiatric Interview (MINI), which identified current PTSD. Other sufferers of PTSD were identified through self-report or diagnosis indicated in electronic health records. We used Ordinary Least Square (OLS) linear regression with age and education as covariates. Education was coded into 5 categories: No high school diploma, high school diploma or GED; technical school graduate or 2 year college/associate's degree; some college but not a 2 or 4 year degree; 4 year college degree; some post-baccalaureate education. Results: Most enrollees in BRAVE are male (N=94, 86%) and white (107, 97%). Mean age is 65.5 years (SD = 6.7). Seventeen enrollees (15%) report no college experience, 29 have an associate's degree or degree from a technical school (26%), 25 report some college experience but no degree (23%), 25 (23%) have a 4 year degree, and 14 reported some post-baccalaureate college (13%). Half (N=55) of enrollees met criteria for TBI; 27 indicated the event occurred during deployment. TBI and non-TBI groups were comparable on age, education, gender, race, and depression rating. Those with TBI had a slightly greater incidence of PTSD diagnosis (18 vs 11, p=.10) and were more likely to report two or more deployments (19 vs 8, p= .07). However, covarying for age and education level, the TBI group did not differ from non-TBI group on Digit symbol substitution (b = 0.87, p = .41), FCSRT free recall (b = -0.53, p = .53), or logical memory delayed (b = 0.81, p= .13). Enrollees with probable TBI scored higher than those without probable TBI on the MMSE (b = 0.63, p = .003, TBI group mean = 28.7 [SD = 1.3], non-TBI group mean = 27.8, [SD = 1.7]). Conclusion: Ensuring people from diverse backgrounds join clinical trials is key to advancing health equity. Increasing enrollment of Veterans into AD prevention clinical trials is critical in that they are at higher risk for AD than the general population. In this study, the probable TBI group was indistinguishable from the non-TBI gro p on baseline measures of memory and outperformed the non-TBI group on measure of global cognition. The criteria used to assign TBI may have been overly broad, although our sample is in line with national statistics showing that a third of those with probable TBI also have PTSD. TBI has been shown to lower the age of dementia onset, however, the BRAVE sample is relatively young and may not be experiencing even subtle cognitive deficits yet. For this study, probable TBI was reduced to a simple dichotomy, but many factors can affect short- and long-term recovery from TBI including type of injury, age, and existing comorbidities. Incorporating these complexities into future research will be critical to finding effective therapies to prevent or treat AD in Veterans.

5583. Van Lierde, K. M., et al. (2015). "Longitudinal progress of overall intelligibility, voice, resonance, articulation and oromyofunctional behavior during the first 21 months after Belgian facial transplantation." Journal of communication disorders **53**: 42-56.

PURPOSE: The purpose of this study is to document the longitudinal progress of speech intelligibility, speech acceptability, voice, resonance, articulation and oromyofunctional behavior in a male facial transplant patient 8 days, 15 days, 5 months, 12 months and, finally, 21 months after surgery., METHOD: Identical objective (Dysphonia Severity Index, nasometry, acoustic analysis) and subjective (consensus perceptual evaluation, Dutch speech intelligibility test; flexible videolaryngostroboscopy/naso-endoscopy) assessment techniques and questionnaires (speech and voice

handicap index, oral health impact profile, facial disability index) were used during each of the five postsurgical assessments., RESULTS: The pattern of results shows a longitudinal progress of speech intelligibility and acceptability and of the interactive processes underpinning overall speech intelligibility. Vocal quality is normal and resonance is characterized by hypernasality. The phonetic inventory is complete but four phonetic disorders remain. Outcomes pertaining to articulation (formant analysis) show evident progress over time. Lip functions are improving but still decreased., CONCLUSIONS: Transplantation of the face in this patient has largely restored speech. To what extent resonance, articulation, and lip functions can be enhanced by the permanent use of a palatal obturator, by specialized facial and lip movement exercises in combination with motor-oriented speech therapy, is subject for further research. Learning outcomes Facial transplantation: Readers will be able to (1) describe the relationship between facial transplantation and the impact on speech and oromyofunctional behavior, (2) identify variables that influence the outcome after facial transplantation, (3) define an assessment protocol after facial transplantation, (4) define facial transplantation.

5584. Van Lierde, K. M., et al. (2014). "Speech characteristics one year after first Belgian facial transplantation." The Laryngoscope **124**(9): 2021-2027.

OBJECTIVES/HYPOTHESIS: Facial transplantation has progressed over the past 8 years. We did the first Belgian facial transplantation by vascularized composite tissue allotransplantation and report the 1-year follow-up regarding speech and oromyofunctional behavior., STUDY DESIGN: Outcome study., METHODS: The recipient, a 56-year-old man, had his face severely injured due to a ballistic injury. In January 2012, in a 20-hours surgical procedure, a digitally planned facial composite tissue allotransplantation was performed consisting of a large amount of bone together with the soft tissue of the entire lower two-thirds of the face. Speech intelligibility, voice, resonance, articulation, and oromyofunctional behavior were measured 12 months after the transplantation using objective and subjective assessment techniques., RESULTS: No intraoperative surgical complications occurred, and the postoperative course was uneventful. Survival of the graft was complete, the bony structures-both maxillae and part of the left mandible-and mucosal lining of the nasal cavities and hard palate could all be vascularized by connecting only the facial vessels. Twelve months after transplantation, the speech intelligibility is normal in words, but slightly impaired in sentences due to moderate hypernasality. Two articulation disorders and lip incompetence are present. Facial emotional readability was present but decreased., CONCLUSION: Speech outcome, as one of several determinants of feasibility, can be a positive argument when considering the option of facial allotransplantation.

5585. van Lierop, A. C., et al. (2009). "Retained knife blades in the ear, nose and throat: three cases." The Journal of laryngology and otology **123**(3): 351-355.

OBJECTIVE: To discuss the management and to review the literature regarding retained knife blades in the head and neck., CASE REPORT: We present three cases in which patients presented with retained knife blades in the head and neck region; in two of these, the diagnosis was delayed by more than eight weeks. In all patients, the retained knife blade was removed through the pathway of insertion, without significant sequelae., DISCUSSION: The methods of removal, appropriate radiological investigations and patient profiles are discussed., CONCLUSIONS: We propose that radiography be performed on all patients presenting with facial stab injuries which are anything more than superficial. We further suggest that the direct extraction of sharp objects through the pathway of insertion is safe if radiological studies show no risk of vascular injury.

5586. van Netten, J. J., et al. (2018). "Diabetic Foot Australia guideline on footwear for people with diabetes." Journal of foot and ankle research **11**: 2.

BACKGROUND: The aim of this paper was to create an updated Australian guideline on footwear for people with diabetes., METHODS: We reviewed new footwear publications, (inter)national guidelines, and consensus expert opinion alongside the 2013 Australian footwear guideline to formulate updated recommendations., RESULT: We recommend health professionals managing people with diabetes should: (1) Advise people with diabetes to wear footwear that fits, protects and accommodates the shape of their feet. (2) Advise people with diabetes to always wear socks within their footwear, in order to reduce shear and friction. (3) Educate people with diabetes, their relatives and caregivers on the importance of wearing appropriate footwear to prevent foot ulceration. (4) Instruct people with diabetes at

intermediate- or high-risk of foot ulceration to obtain footwear from an appropriately trained professional to ensure it fits, protects and accommodates the shape of their feet. (5) Motivate people with diabetes at intermediate- or high-risk of foot ulceration to wear their footwear at all times, both indoors and outdoors. (6) Motivate people with diabetes at intermediate- or high-risk of foot ulceration (or their relatives and caregivers) to check their footwear, each time before wearing, to ensure that there are no foreign objects in, or penetrating, the footwear; and check their feet, each time their footwear is removed, to ensure there are no signs of abnormal pressure, trauma or ulceration. (7) For people with a foot deformity or pre-ulcerative lesion, consider prescribing medical grade footwear, which may include custom-made in-shoe orthoses or insoles. (8) For people with a healed plantar foot ulcer, prescribe medical grade footwear with custom-made in-shoe orthoses or insoles with a demonstrated plantar pressure relieving effect at high-risk areas. (9) Review prescribed footwear every three months to ensure it still fits adequately, protects, and supports the foot. (10) For people with a plantar diabetic foot ulcer, footwear is not specifically recommended for treatment; prescribe appropriate offloading devices to heal these ulcers., CONCLUSIONS: This guideline contains 10 key recommendations to guide health professionals in selecting the most appropriate footwear to meet the specific foot risk needs of an individual with diabetes.

5587. Van Sickels, J. E., et al. (1979). "Vascular injury and penetrating facial trauma." Journal of oral surgery (American Dental Association : 1965) **37**(3): 195-197.

Three patients with gunshot wounds to facial and vascular structures were described. They demonstrate the importance of angiography in the acute care phases of treatment. In one case, angiography lead to eventual surgical management of an arteriovenous fistula. The other two cases described arterial injury that required careful surgical follow-up to detect delayed complications.

5588. van Veen, E., et al. (2018). "Brain death and postmortem organ donation: report of a questionnaire from the CENTER-TBI study." Critical care (London, England) **22**(1): 306.

BACKGROUND: We aimed to investigate the extent of the agreement on practices around brain death and postmortem organ donation., METHODS: Investigators from 67 Collaborative European NeuroTrauma Effectiveness Research in Traumatic Brain Injury (CENTER-TBI) study centers completed several questionnaires (response rate: 99%)., RESULTS: Regarding practices around brain death, we found agreement on the clinical evaluation (prerequisites and neurological assessment) for brain death determination (BDD) in 100% of the centers. However, ancillary tests were required for BDD in 64% of the centers. BDD for nondonor patients was deemed mandatory in 18% of the centers before withdrawing life-sustaining measures (LSM). Also, practices around postmortem organ donation varied. Organ donation after circulatory arrest was forbidden in 45% of the centers. When withdrawal of LSM was contemplated, in 67% of centers the patients with a ventricular drain in situ had this removed, either sometimes or all of the time., CONCLUSIONS: This study showed both agreement and some regional differences regarding practices around brain death and postmortem organ donation. We hope our results help quantify and understand potential differences, and provide impetus for current dialogs toward further harmonization of practices around brain death and postmortem organ donation.

5589. van Vugt, A. B. (2003). "Pitfalls in penetrating trauma." Acta chirurgica Belgica **103**(4): 358-363.

In Western Europe the most frequent cause of multiple injuries is blunt trauma. Only few of us have experience with penetrating trauma, without exception far less than in the USA or South-Africa. In Rotterdam, the Erasmus Medical Centre is a level I trauma centre, situated directly in the town centre. All penetrating traumas are directly presented to our emergency department by a well organized ambulance service supported by a mobile medical team if necessary. The delay with scoop and run principles is very short for these cases, resulting in severely injured reaching the hospital alive in increasing frequency. Although the basic principles of trauma care according to the guidelines of the Advanced Trauma Life Support (ATLS) (1-2) are the same for blunt and penetrating trauma with regard to priorities, diagnostics and primary therapy, there are some pitfalls in the strategy of management in penetrating trauma one should be aware of. Simple algorithms can be helpful, especially in case of limited experience (3). In case of life-saving procedures, the principles of Damage Control Surgery (DCS) must be followed (4-5). This approach is somewhat different from "traditional" surgical treatment. In the Ist phase prompt interventions by emergency thoracotomy and laparotomy are carried out, with only two goals to achieve: surgical control of haemorrhage and contamination. After temporary life-

saving procedures, the 2nd phase is characterized by intensive care treatment, dealing with hypothermia, metabolic acidosis and clotting disturbances. Finally in the 3rd phase, within 6-24 hours, definitive surgical care takes place. In this overview, penetrating injuries of neck, thorax, abdomen and extremities will be outlined. Penetrating cranial injuries, as a neurosurgical emergency with poor prognosis, are not discussed. History and physical examination remain the corner stones of good medical praxis. In a work-up according to ATLS principles airway, breathing and circulation should be evaluated with great care. Neurovascular examination related to trauma of the spinal cord, peripheral nerves as well as vascular involvement should be carried out also in extremity injuries. Physical examination should be completed by localization of all stabwounds, in- and outshot openings as well as recto-vaginal examination and inspection of the oropharynx.

5590. van Walsum, A. D., et al. (2001). "[Local and regional in-hospital trauma care following fireworks depot explosion in Enschede]." De lokale en regionale intramurale traumaopvang bij de Enschedese vuurwerkramp. **145**(48): 2330-2335.

UNLABELLED: On Saturday 13 May, 2000 at about 15:30 h, the Dutch city of Enschede was struck by the explosion of a midtown firework depot. Twenty-two people were killed and almost 1,000 people were wounded. A complete district with 1,000 houses was destroyed. In total, 527 victims were treated in one of the regional hospitals, 76 (14%) of whom were admitted and 451 (84%) were treated as outpatients. Of the clinically treated victims, 11 patients were triaged as T1 and needed immediate intervention, 63 patients were triaged as T2 where treatment within six hours was indicated, and two T3 patients did not need urgent treatment. The outpatients mainly suffered secondary blast injuries to the head and extremities due to flying debris. Of the 11 T1 patients, 10 underwent acute surgery; intervention radiology was performed in one patient. The injuries of the severely wounded T1 patients consisted of penetrating thoracic, abdominal and skull injuries, as well as blunt abdominal trauma and compound fractures. Two patients from the disaster area underwent acute vascular surgery for acutely burst aortic aneurysms. The in-hospital trauma care was characterised by the spontaneous arrival of a large number of extra medical personnel. The regional distribution of the trauma patients was adequate. The regional capacity of the emergency rooms, IC-units and operating facilities proved to be sufficient. Routing of lightly-wounded patients was found to be important. The communication in all phases of the disaster management appeared to be poorly structured., CONCLUSION: During the initial trauma care, the routing of vast numbers of ambulant, lightly-wounded patient, as well as extra doctors and nurses, needs careful planning.

5591. Vander, J. F. and C. C. Nelson (1988). "Penetrating orbital injury with cavernous sinus involvement." Ophthalmic surgery **19**(5): 328-330.

Penetrating orbital injuries may involve intracranial structures as well. We report an unusual case of permanent visual loss, temporary complete ophthalmoplegia, and penetration of the internal carotid artery following penetrating nail injury. CT scanning and arteriography are important diagnostic tests to consider prior to removal of an orbital foreign body. This case also demonstrates the importance of delaying repair of traumatic ptosis and ophthalmoplegia.

5592. VanderArk, G. D., et al. (1970). "Repair of cerebrospinal fluid fistulas using a tissue adhesive." Journal of neurosurgery **33**(2): 151-155.

5593. Vane, D. W., et al. (2001). "Emotional considerations and attending involvement ameliorates organ donation in brain dead pediatric trauma victims." The Journal of trauma **51**(2): 329-331.

PURPOSE: The purpose of this study was to ascertain a strategy for maximizing parental consent for organ donation in traumatically injured children suffering from brain death. Our hypothesis was that appropriate attending surgeon involvement and delay in evaluating children for brain death leads to an increased percentage of organ donors., METHODS: From January 1993 to August 1999, the records of all children who died in a Level I trauma center were evaluated. Those children suffering brain death that were suitable for organ donation were entered into the study. Cases were reviewed for patient demographics, time to entry into brain death protocol (measured from time of admission), time to parent notification about brain death (measured from time of admission), specific attending involved in the case (with level of involvement), and success of organ donation request. In all, 43 charts were reviewed., RESULTS: Of 43 deaths, 33 were deemed suitable for donation. Age of suitable donors ranged from 1 month to 18 years. In all, 11 attending physicians were involved in the care of these children. Overall, 20 of 33 were organ donors (60%). When the

attending surgeon was involved, donation success for organ retrieval was 86%, whereas if the attending was not involved personally, the success rate dropped to 23% ($p < 0.04$). One senior pediatric surgeon obtained a success rate of 12 of 12 children. It was this surgeon's policy to not initiate brain death protocols in children immediately on entry into the emergency room, but rather to delay initiation until family could be gathered and spend time with the affected child in order that the family could recover from the initial shock of trauma (always at least overnight). When time to initiation of brain death protocol was examined, success was obtained when a delay of 15.5 hours was respected, versus 7.0 hours when donation was requested but denied ($p < 0.03$)., CONCLUSION: These data indicate that attending involvement is important when parents of brain dead children are asked about organ retrieval ($p < 0.04$). Delay in initiating brain death protocols in order for family members to deal with the shock of the initial trauma appears to increase willingness to participate in organ donation.

5594. Vanlierde, M. J. (1989). "Post-traumatic asymptomatic saccular aneurysm of the internal carotid artery." The Journal of laryngology and otology **103**(1): 115-116.

A patient presented with mild upper airway obstruction after being shot from behind through the neck and soft palate. Two days later he developed palsies of the IXth to XIIth cranial nerves inclusive on the traumatised side. These palsies resolved spontaneously after three weeks. Further investigation revealed the presence of a saccular aneurysm of the internal carotid artery. The internal carotid artery was ligated after gradual closure for three days using a Preston clamp.

5595. Vaqas, B., et al. (2013). "An occult intracranial foreign body introduced via a conjunctival wound." Trauma (United Kingdom) **15**(3): 252-256.

We present a case of a 23-year-old man who suffered a facial assault. An intracranial foreign body, a socket from a socket wrench, was introduced into the cranial cavity via a medial conjunctival entry wound which presented with minimal physical signs. The entry wound and the foreign body were missed during the patient's first presentation to an emergency department leading to a delay in diagnosis. Subsequent periorbital swelling and visual blurring prompted delayed investigation leading to detection of the foreign body. This case report highlights the need for a high index of suspicion of intracranial complications when assessing ocular injuries. The mechanism of the penetrating injury, the ophthalmological findings and the surgical and antibiotic management are discussed.

5596. Vaquero, J., et al. (1982). "Pneumocephalus after air rifle wound of the brain." Neuroradiology **23**(3): 161-162.

5597. Varelas, P. N., et al. (2017). "Primary Posterior Fossa Lesions and Preserved Supratentorial Cerebral Blood Flow: Implications for Brain Death Determination." Neurocritical care **27**(3): 407-414.

BACKGROUND: Patients with primary posterior fossa catastrophic lesions may clinically meet brain death criteria, but may retain supratentorial brain function or blood flow. These patients could be declared brain-dead in the United Kingdom (UK), but not in the United States of America (USA). We report the outcome of adult patients with primary posterior fossa lesions without concurrent major supratentorial injury., METHODS: Henry Ford Hospital database was reviewed over a period of 88 months in order to identify all adult patients with isolated brainstem or posterior fossa lesions. We excluded patients with concurrent significant supratentorial pathology potentially confounding the clinical brain death examination. One more patient from a different hospital meeting these criteria was also included., RESULTS: Three patients out of 161 met inclusion criteria (1.9% of all brain deaths during this period). With the addition of a fourth patient from another hospital, 4 patients were analyzed. All four patients had catastrophic brainstem and cerebellar injuries meeting the clinical criteria of brain death with positive apnea test in the UK. All had preserved supratentorial blood flow, which after a period of 2 h to 6 days disappeared on repeat testing, allowing declaration of brain death by US criteria in all four. One patient became an organ donor., CONCLUSIONS: Patients with primary posterior fossa catastrophic lesions, who clinically seem to be brain-dead, evolve from retaining to losing supratentorial blood flow. If absent cerebral blood flow is used as an additional criterion for the declaration of death by neurological criteria, these patients are not different than those who become brain death due to supratentorial lesions.

5598. Vargas, J., et al. (2022). "A clinical decision tool to predict the need for cervical imaging in children less than 8 years." Critical care medicine **50**(1 SUPPL): 794.

INTRODUCTION/HYPOTHESIS: Pediatric cervical spine injury (CSI) occurs in 1-2% of pediatric blunt traumas. If unrecognized, there is significant risk of neurologic disability. Identification of CSI based solely on history in infants and children is problematic as cognitive development limits the reliability of the exam. We previously identified 6 risk factors that increased the odds of having a CSI in children < 8 years. The objective of this study was to determine the probability of not having a CSI in the absence of these risk factors in children < 8 years who sustained trauma. METHODS: This is a reanalysis of study data in which 6 risk factors for having a CSI after trauma were identified (cervical spine tenderness, motor vehicle injury, loss of consciousness (LOC), distracting injury, displaced skull fracture, and ventricular hemorrhage). Data were obtained from children < 8 years with traumatic injury admitted to 1 of 3 level 1 pediatric trauma centers between August 2007 and August 2017. CSI was defined as 1) radiographic evidence of CSI, or 2) radiographic evidence of CSI and/or treatment due to clinical concern. Negative predictive values (NPV) were calculated, first including the absence of all 6 risk factors and then including fewer. RESULTS: Of 5187 patients evaluated, 80(1.7%) had a CSI based upon radiography and 111(2.1%) based on clinical concern. 1045 patients did not have any of the 6 risk factors and only 1(0.10%) had a CSI by radiography and 4(0.38%) by clinical concern. Not including the absence of neck tenderness in the model had little effect on the NPV. However, when only absence of motor vehicle injury, LOC, displaced fracture and ventricular hemorrhage remained in the model, the probability of CSI by radiography (6/2212 (0.27%) or clinical concern (10/2208 (0.45%) increased. Use of only absence of LOC was a poor negative predictor of CSI (radiography: 40/4290 (0.92%); clinical concern: 61/4269 (1.41%)). CONCLUSION: Children < 8 years who sustain trauma not from motor vehicle injury and have no LOC, displaced skull fracture, distracting injury or ventricular hemorrhage are at very low risk of a CSI. The absence of neck tenderness has little effect on the NPV. These data suggest that children who do not have these risk factors may not need radiographic imaging of their cervical spine.

5599. Varnamkhasti, M. and A. Thomas (2011). "Brain and facial trauma: A neuroradiology perspective." Trauma **13**(4): 317-333.

Traumatic head and facial injuries are common causes of emergency department admissions. Head trauma, in particular, is the commonest reason for emergency out of hours computed tomography (CT) performed. Most patients with traumatic brain injuries (TBIs) have mild head injuries, but up to 20% require hospitalisation or further management. The fixed size of the bony cranial cavity means that only small increases in volume within the intracranial compartment can be tolerated before pressure within the cavity increases dramatically leading to secondary brain injury, with potentially catastrophic consequences. Head and brain injuries are commonly associated with facial trauma, particularly of the upper face, and it is important to be aware of this because the treatment of the former injuries may need to take precedence over the facial injuries. This review aims to summarise the epidemiology of blunt trauma to the head and face and the various patterns of TBI. The role of CT, both in the acute setting and in follow-up these patients, is described.

5600. Vartanian, A. J. and A. Alvi (2000). "Bone-screw mandible fixation: an intraoperative alternative to arch bars." Otolaryngology--head and neck surgery : official journal of American Academy of Otolaryngology-Head and Neck Surgery **123**(6): 718-721.

OBJECTIVES: Bone-screw mandible fixation (BSMF) is evaluated as an alternative to intraoperative arch-bar maxillomandibular fixation before plating of mandibular fractures. BSMF is achieved by wire ligation of opposing bone-screws placed in the maxilla and mandible., METHODS: A retrospective evaluation of 23 patients with 40 mandibular fractures who underwent mandibular fracture repairs. BSMF was used instead of arch bars to ensure proper dental occlusion. All fractures were then plated, after which BSMF was removed before termination of anesthesia., RESULTS: Normal occlusion was observed in 21 patients (91.3%), Class II malocclusion was noted in 1 patient (4. 3%), and 1 patient was edentulous. No complications related to the use of BSMF were observed., CONCLUSION: BSMF can serve as a viable alternative to arch-bar maxillomandibular fixation for obtaining temporary intraoperative occlusion. BSMF produces acceptable malocclusion rates and offers the advantages of decreased intraoperative time, lower risk for percutaneous and mucosal wire punctures, and ease of use.

5601. Vascik, J. M. and J. M. Tew, Jr. (1982). "Foreign body embolization of the middle cerebral artery: review of the literature and guidelines for management." Neurosurgery **11**(4): 532-536.

Two cases of traumatic middle cerebral artery occlusion secondary to migratory intravascular metallic pellets are presented. Surgical removal of the occlusive pellet was achieved in one patient, and vessel patency was restored. One patient recovered from his neurological deficit without surgical intervention. Factors such as the availability of a microvascular surgeon, the status of the neurological deficit resulting from the embolus, the time interval from injury to the proposed operation, and the extent of ancillary injuries sustained concurrently all bear weight on the decision to explore surgically or treat by medical measures. We believe that in cases of trauma an attempt to remove intravascular emboli is warranted to prevent migration of the embolus and distal propagation of thrombus, to avoid chronic sepsis, to prevent arterial erosion, and to restore the integrity of the vascular tree.

5602. Vaudano, E., et al. (1995). "The effects of a lesion or a peripheral nerve graft on GAP-43 upregulation in the adult rat brain: an in situ hybridization and immunocytochemical study." The Journal of neuroscience : the official journal of the Society for Neuroscience **15**(5 Pt 1): 3594-3611.

We have sought to determine (1) if thalamic neurons upregulate the growth associated protein GAP-43 as a response to injury, or if a peripheral nerve graft is required to induce, enhance or sustain such a response, and (2) if thalamic neurons with different regenerative potentials also display different GAP-43 responses. Levels of GAP-43 protein (detected by LM and EM immunohistochemistry) and of GAP-43 mRNA (detected by in situ hybridization) were compared in the thalamus of adult rats between 1 d and 180 d after making a stab lesion or after implanting a peripheral nerve autograft. Stab injury is a sufficient stimulus to cause a transient upregulation in GAP-43 expression by neurons in the thalamus (both around the graft tip and in particular in the thalamic reticular nucleus) in the first week after injury but this response is both prolonged, and enhanced in the presence of a peripheral nerve graft. In addition, we demonstrate directly, by double labelling, that neurons of the thalamic reticular nucleus displaying high levels of the mRNA for GAP-43, have axons regenerating in the distal portion of the graft. These findings lend direct support to the hypothesis that upregulation of the GAP-43 gene is essential for prolonged regenerative axonal growth. We also demonstrate GAP-43 protein in graft Schwann cells and in brain astrocytes close to the site of graft implantation.

5603. Vayvada, H., et al. (2005). "Management of close-range, high-energy shotgun and rifle wounds to the face." The Journal of craniofacial surgery **16**(5): 794-804.

Close-range, high-energy shotgun wounds of the face are life-threatening and devastating traumas of the face. Suicidal attempts are the main reason in the great majority of the patients in civilian life. There is no consensus on the timing of reconstruction for bone and soft tissue defects resulting from high-energy shotgun wounds. The conventional method is primary repair as soon as possible and serial debridements and definitive reconstruction in the delayed stage. An alternative to this approach is the immediate definitive surgical reconstruction of the patient during the first operation for acute management of trauma. We had 15 patients with close-range, high-energy shotgun wounds in 10 years. Six of 15 patients referred to our center for definitive reconstruction after the acute management of the patients were performed in another center and the rest were all admitted in the acute period. Either conventional approach with delayed reconstruction for 10 patients or immediate definitive surgical reconstruction for 5 patients was used. Immediate reconstruction eliminated disadvantages of the conventional method such as high infection and scarring rate and deformities resulting from contraction of tissues. The emotional conditions of the patients were evaluated and major depression signs were determined. Functional evaluation showed that there was great correlation between facial appearance after reconstruction and social activity level.

5604. Vazirani, J., et al. (2016). "Autologous simple limbal epithelial transplantation for unilateral limbal stem cell deficiency: multicentre results." The British journal of ophthalmology **100**(10): 1416-1420.

PURPOSE: To report outcomes of autologous simple limbal epithelial transplantation (SLET) performed for unilateral limbal stem cell deficiency (LSCD) at multiple centres worldwide., METHODS: In this retrospective, multicentre, interventional case series, records of patients who had undergone autologous SLET for unilateral LSCD, with a minimum of 6 months of follow-up, were reviewed. The primary outcome measure was clinical success, defined as a completely epithelised, avascular corneal surface. Kaplan-Meier survival curves were constructed and survival probability was calculated. A Cox proportional hazards analysis was done to assess association of preoperative characteristics with risk

of failure. Secondary outcome measures included the percentage of eyes achieving visual acuity of 20/200 or better, percentage of eyes gaining two or more Snellen lines and complications encountered., RESULTS: 68 eyes of 68 patients underwent autologous SLET, performed across eight centres in three countries. Clinical success was achieved in 57 cases (83.8%). With a median follow-up of 12 months, survival probability exceeded 80%. Presence of symblepharon (HR 5.8) and simultaneous keratoplasty (HR 10.8) were found to be significantly associated with a risk of failure. 44 eyes (64.7%) achieved a visual acuity of 20/200 or better, and 44 eyes (64.7%) gained two or more Snellen lines. Focal recurrences of pannus were noted in 21 eyes (36.8%) with clinical success., CONCLUSION: Autologous SLET is an effective and safe modality for treatment of unilateral LSCD. Clinical success rates and visual acuity improvement are equal to or better than those reported with earlier techniques.

5605. Vega, L. G. and K. Brewer (2012). "Reconstruction of the severely atrophic maxilla or acquired maxillary defects using zygomatic implants: Outcome Study of 41 implants." Journal of oral and maxillofacial surgery **70**(9): e13-e14.

Dental rehabilitation is the ultimate goal of the reconstruction efforts for the severely atrophic maxilla or acquired maxillary defects. Multiple techniques dealing with these challenging reconstructions have been described in the literature. Most these techniques include bone grafting which has the disadvantage of prolonged the treatment plan, increased costs, and the potential of donor site morbidity. Zygoma implants are a graftless solution for the rehabilitation these patients. The purpose of this study was to evaluate indications, surgical problems and treatment outcomes related to the placement of zygoma implants and their prosthetic rehabilitation. Forty-one zygoma implants were placed in 11 consecutive patients (8 women, 3 men) between September 2007 and November 2011. The patient age range was 50 to 73 years with a mean age of 61.5 years. Six patients were treated due to severe maxillary atrophy and 5 were due to acquired maxillary defects. Three of the acquired defects were hemimaxillectomies due to cancer ablation, 1 was secondary to a gunshot wound, and 1 was a total maxillectomy secondary to a fungal infection. Three of the acquired maxillary defect patients underwent additional soft tissue reconstruction with a radial forearm free flap. Nine patients were reconstructed with 4 zygomatic implants, 1 was reconstructed with 3 zygo- matic implants and 1 had 2 zygoma implants placed. Five patients were reconstructed with a combination of zygomatic and conventional dental implants. A total of 10 dental implants were placed. Outcomes measures were zygomatic and conventional implants' survival rates, satisfaction with the prosthetic restoration as well as complications. Follow-up ranged from 10 months to 5 years with a mean of 30 months. No zygomatic implants were lost and minor complications occurred in 3 patients. Complications reported included less than ideal implant position, oral-antral communication and periimplantitis. Additionally 2 conventional implants were lost in two patients before loading. There were no reported cases of sinusitis, swelling, infection, or nerve damage. All patients were successfully restored with either a fixed or removable prosthesis. All patients reported high levels of satisfaction with the reconstruction. Within the limitations of the present study, the results suggest that reconstruction of the severely atrophic maxilla or acquired maxillary defects with zygomatic implants provides a viable and predictable treatment option with minimal complications.

5606. Vega, O. A. (2011). "A new device for alveolar bone transportation." International journal of oral and maxillofacial surgery **40**(10): 1036.

Purpose: To discuss a retrospective study of a new technique for alveolar bone transport by distraction osteogenesis, using a Hyrax modified device by the principal author (OAV). Patients and methods: There were treated seven patients: 5 male and 2 two female; five patients with cleft palate and lip diagnosis, one with a high-speed gunshot wound, and one patient with facial trauma sequel due to mandibular fracture. All of them were treated with an alveolar bone transportation technique (ABT) through the use of the modified Hyrax device (VEGAX). Before surgery bifocal distraction osteogenesis of adjacent alveolar bone was performed on four patients, while the trifocal type was performed on the other three patients. However, in one case, direct dental anchorage was not used, only orthodontic appliances. Results: In all the cases, new bone formation and gingival tissue around the defectwas obtained, closure of alveolar fistula, movement from posterior to anterior of the alveolar process; no complications were observed in any patient. In one case, two teeth involved in the disc of the ABT were extracted, due to a previous condition of periodontal disease. Conclusion: The alveolar bone transport by distraction osteognesis with the VEGAX device is an easy and accessible technique for almost every patient with alveolar defects due to diverse causes. In all the presented cases, predictability and success were demonstrated.

5607. Velasco, G. C. and G. M. C. Ambrocio (2021). "Bullet slug in the ethmoid sinus – A case report." Otolaryngology Case Reports **21**.

Objectives: To describe a case of a foreign body (bullet slug) lodged in the ethmoid sinus of an 8-year old female from a gunshot injury. Study design: Case report. Results: An 8-year-old female presented at the emergency room due to a gunshot wound on her right parietotemporal area. She was awake with stable vital signs and GCS 15, with no noted exit wound and no active bleeding on the injury site. CT scan revealed a 1.5cm × 1.5cm hyperdense foreign body with well-defined margins in her left anterior ethmoid sinus with no intracranial extension nor evident damage to vital structures. Endoscopic removal of the foreign body (bullet slug) was performed. The intraoperative findings verified the bullet slug lodged in the superoposterior part of the nasal septum, between the middle turbinates. The bullet slug was successfully extracted with no intraoperative and postoperative complications. Subsequent follow-up post-surgery with all involved services was uneventful. Conclusion: To prevent complications and improve patient outcomes, otolaryngologists should be aware of the presentation, diagnosis, and management of a bullet slug in the ethmoid sinuses. Important considerations should be given to pediatric patients due to the unique locations of their vital structures and their developing paranasal sinuses.

5608. Velioglu, Y., et al. (2018). "Gunshot Injury of Head and Neck Region with an Atypical Bullet Trajectory: The Importance of Whole Body Computed Tomography Scan." Journal of the College of Physicians and Surgeons--Pakistan : JCPSP **28**(9): S215-S216.

Nowadays, gunshot injuries have become a common medical-legal issue because of easy accessibility of firearms. Gunshot injuries of head and neck region are highly morbid and fatal, particularly when they affect vital organs. In rare cases, atypical tract lines resulting from such injuries can cause difficulties in the diagnosis and treatment. In this report, a high energy gunshot injury involving head and neck region with an atypical bullet trajectory is presented. A 24-year male soldier was brought to the emergency department on account of gunshot injury following a conflict. Although the entrance and exit holes of bullets were confined to head and neck region, the whole body computed tomography scan was carried out in spite of his borderline hemodynamics. Whole body computed tomography revealed massive hemopneumothorax, mediastinal shift, hepatic laceration, and foreign body (bullet) in the liver. The patient was operated successfully by a multidisciplinary surgical team on emergency basis. This report highlights the necessity and importance of whole body computed tomography scan in such cases.

5609. Vella, A. E., et al. (2006). "Predictors of fluid resuscitation in pediatric trauma patients." The Journal of emergency medicine **31**(2): 151-155.

Advanced Trauma Life Support (ATLS) is accepted as the standard for the first hours of trauma care. However, ATLS is designed primarily for adults. In children, vascular access can be difficult and time-consuming. Due to the differences in the epidemiology of children suffering traumatic injury, they may not require aggressive fluid resuscitation. The objective of the study was to establish predictors of fluid resuscitation, and to determine whether all pediatric Level I Trauma victims require two intravenous catheters. Medical charts of all patients aged < 18 years meeting Level I Trauma criteria who presented to Childrens Hospital Los Angeles (CHLA) between January 1 and December 31, 1999 were retrospectively reviewed. There were 152 patients reviewed with a median age of 6 years (range 4 months to 17 years); 64% were boys. The mechanism of injury was motor vehicle crash 49%, fall 37%, crush 8%, gunshot 5%, and knife 1%. Injuries included closed head 88%, penetrating abdomen/chest 6%, and other 6%. Vital signs over time showed no change in 59%, got better in 34%, and got worse in 7%. Fluid resuscitation included no bolus in 70%, 1 bolus in 20%, 2 boluses in 7%, > 2 boluses in 3%. The ICU admitted 23%, 12% were intubated, survival was 95%, and 59% received a prehospital i.v. The i.v. #1 site: antecubital 51%, hand 41%, foot 5%, femoral 1%. The i.v. #2 site: hand 30%, antecubital 20%, foot 2%, none 48%. T test showed no statistically significant differences in fluid resuscitation or second i.v. placement based on the mechanism of injury. T test for unequal variances showed a statistically significant difference in means with $p < 0.001$ for second i.v. placement as compared with only i.v. fluid amount, age, and Injury Severity Score (ISS). Revised Trauma Score was the only predictor of worsening of vital signs (logistic regression [LR], $p < 0.001$). Age was the only predictor of second i.v. placement (LR, $p < 0.03$). ISS was the only predictor of a bolus being given (LR, $p < 0.01$). In our study, blunt trauma occurred in 90% of children, with 10% requiring > 1 fluid bolus. ISS was the only predictor of the need for fluid resuscitation and is not likely to be helpful in the clinical setting. In our

population, nearly 50% had no second i.v. This preliminary review of the nature of pediatric trauma suggests that ATLS guidelines may not always be appropriate for the management of pediatric trauma.

5610. Vellimana, A. K., et al. (2021). "Endovascular Considerations in Traumatic Injury of the Carotid and Vertebral Arteries." Seminars in Interventional Radiology **38**(1): 53-63.

Cervical carotid and vertebral artery traumatic injuries can have a devastating natural history. This article reviews the epidemiology, mechanisms of injury, clinical presentation, and classification systems pertinent to consideration of endovascular treatment. The growing role of modern endovascular techniques for the treatment of these diseases is presented to equip endovascular surgeons with a framework for critically assessing patients presenting with traumatic cervical cerebrovascular injury.

5611. Velnar, T. and R. Pregelj (2014). "Craniocerebral trauma as a result of a compressor tube explosion: A case report." Brain injury **28**(5-6): 610.

Objectives: Traumatic brain injury is frequently encountered in neurosurgical practice. Although penetrating trauma is less common than closed injuries, it is more often lethal. Cavitation effect, vascular and neuronal damage, secondary brain injury and infection are the main causes of poor outcome. Methods: Clinical presentation of a 35-year old patient is described, who suffered explosion head injury. During the explosion of a construction machine, a foreign body (a part of a high-pressure compressor air tube, 6 cm in length, made of steel wires and plastic mantle) penetrated the basal parts of the frontal lobes through maxilla, medial orbit and ethmoid. It was embedded in the vessels of the anterior communicating complex, elevating it to the lower falx. At admission, GCS was rated at 14. No paresis was evident. Results: Through the inter-hemispheric approach, the foreign body was removed, debridement and reconstruction were done and all vessels were spared. The initial recovery was good and sedation was gradually discontinued. However, the patient's clinical condition deteriorated after 1 week due to vasospasm-induced brain infarction and meningitis and he died weeks later of infection and multi-organ failure. Conclusions: Penetrating injury to the brain has a poor prognosis and high disability among the survivors. Minimizing secondary insults to the brain tissue, strict adherence to the brain trauma guidelines and infection prevention are imperative. The deterioration may appear also late in the treatment course, after initial promising recovery.

5612. Velnar, T. and R. Pregelj (2016). "Compressor tube explosion causing severe craniocerebral trauma: A case report." Brain injury **30**(5-6): 559.

Objectives: Traumatic brain injury is frequently encountered in neurosurgical practice. Although penetrating trauma is less common than closed injuries, it is more often lethal. Cavitation effect, vascular and neuronal damage, secondary brain injury and infection are the main causes of poor outcome. Methods: Clinical presentation of a 35-year old patient is described, who suffered explosion head injury. Minimizing secondary insults to the brain tissue, strict adherence to the brain trauma guidelines and infection prevention are imperative. The deterioration may appear also late in the treatment course, after initial promising recovery.

5613. Venkata Naga, S. R., et al. (2020). "A case of T-cell ALL with remarkable recovery after treatment with an innovative induction chemotherapy regimen." Pediatrics **146**(1): 462-464.

Introduction Acute Lymphoblastic Leukemia (ALL) is the most common pediatric malignancy; most cases are derived from precursor B-cells; T-cell ALL comprises approximately 15% of cases. In the past, T-ALL has had lower cure rates than precursor-B ALL, often presenting with higher white blood cell (WBC) counts and extramedullar disease in the

mediastinum or central nervous system (CNS). In recent years cure rates for T-ALL have improved significantly with intensive chemotherapy regimens. Case report An 8-year old male with no significant medical history presented with a 2-week history of increasing lethargy, headaches, abdominal pain and episodes of emesis. On physical exam, he was poorly-responsive with a right gaze preference and his left arm and leg had increased tone. A complete blood count revealed WBC of 731.4 x 103/mcL, hemoglobin 5.8 gm/dL and platelet count 52 x 103/mcL. Flow cytometric analysis of peripheral blood was diagnostic of T-ALL MRI of the brain showed numerous foci of evolving intracranial hemorrhages without obvious mass lesions or leukemic infiltrates. Over an interval of hours, his mental status deteriorated further and a head CT showed enlarging lesions with evidence of uncal herniation. He was treated with dexamethasone, mannitol and underwent a decompressive right craniectomy. Once his clinical condition was stabilized, consideration was given to treatment of his T-ALL both systemically as well as in his CNS. Intrathecal chemotherapy was not considered feasible; therefore, an innovative regimen was devised, using chemotherapy medications active in T-ALL with significant penetration of the blood-brain barrier. This regimen included high-dose methotrexate and high-dose cytarabine as well as conventional drugs for ALL induction (vincristine and dexamethasone). He responded well to this modified induction regimen and was in remission four weeks after his initial diagnosis. Repeat MRI showed significant resolution of hemorrhagic brain lesions and surrounding edema, with no evidence of herniation. He then went on to receive standard T-ALL chemotherapy. His T-ALL has been in continuous remission for 2 years with negative minimal residual disease measurements. He has shown remarkable improvement in his neurologic function and is walking without difficulty and attending school. Discussion It is recognized that some T-ALL patients, like ours, present with hyperleukocytosis, organ infiltration and complications of tumor lysis and well as CNS involvement. However, cure rates for T-ALL approach 85% if solid remissions are achieved. Our patient's dramatic presentation with bulky CNS infiltration, hemorrhage and herniation was rare and typically would result in significant morbidity or mortality. His initial management posed unique problems which prevented the use of a standard chemotherapy approach. Our case demonstrates that potentially-devastating clinical scenarios can be overcome with the use of an individualized protocol which ultimately resulted in leukemia remission as well as restoration of his neurologic function.

5614. Ventruba, J. (2004). "Orbital roof fractures in children from the point of view of a neurosurgeon." Scripta Medica Facultatis Medicae Universitatis Brunensis Masarykianae **77**(4): 191-206.

Childhood is a highly risky age group in terms of orbital injuries. Injuries of the forehead in the presence of orbital ecchymosis, swelling and haematoma of the eyelids, infiltration and swelling of the surrounding tissues and the face must be carefully examined for a high level of suspicion of the presence of orbital fracture and exclusion of intracranial complications which may accompany orbital fractures (impressive fracture of the skull, epidural haematoma, pneumocephalus, dilaceration of dura mater, contusion or dilaceration of the brain, liquorrhoea, fronto-orbital encephalocele). An examination must be conducted by a traumatologist (surgeon, neurosurgeon), neurologist, and ophthalmologist. In the case of acute injuries, the most efficient radiological examination is CT, i.e. brain, orbit (with coronary projections as a minimum) and 3-D reconstruction of the skeleton. MR is performed when there is a suspicion of liquorrhoea and orbital encephalocele, and in very small children. The most frequent place of orbital trauma is the orbital roof. Orbital fractures without displaced bone fragments and with exclusion of intracranial complications are treated conservatively. Displaced fragments either in the orbit or the intracranial space indicate an operation. The aim of the operation is to remove displaced bone fragments, stop bleeding and evacuate blood clots, and to reconstruct the damaged bone cover. In the orbit, increased attention must be paid to complete liberation of the optic nerve, ophthalmogyric muscles, and other potential compressed structures. Parallel neurosurgical treatment of the intracranial trauma is obvious and, in many cases, of priority. The timing of the operation is within 24 hours after the injury unless the condition requires urgent operation (open injuries, epidural bleeding).

5615. Ventura, F., et al. (2002). "Suicide with the latest type of slaughterer's gun." The American journal of forensic medicine and pathology **23**(4): 326-328.

The authors describe a case of suicide by a single shot to the head from the latest type of captive bolt pistol (which has lateral instead of frontal gas outlets), with the aim of finding criteria to identify correctly the lesions caused by this type of weapon correctly and to distinguish them from those caused by typical firearms.

5616. Ventura, F., et al. (2011). "Suicide with "Florbert shotgun": case report." The American journal of forensic medicine and pathology **32**(4): 321-323.

The authors describe the case of a suicide with a shotgun charged with 9 caliber Flobert cartridge, that, if shot at a distance, generally does not cause mortal wounds. In the case in re, on the contrary, the mortal gunshot had been discharged in contact with the roof of the mouth causing not particularly destroying cranium-encephalic wounds. Consequently, there is description of the features of the entrance wound and of intracorporeal path, which can simulate distance wounds caused by handguns charged with classic small caliber cartridges.

5617. Verdaguer, J., et al. (2001). "Sliding osteotomies in mandibular reconstruction." Plastic and reconstructive surgery **107**(5): 1107-1114.

The aim of this article is to describe a few simple and atraumatic methods for mandibular reconstruction following the ablation of tumors or traumas. These reconstruction techniques are indicated for rebuilding short mandibular defects (less than 4 cm) or for patients in poor general condition with larger defects that cannot be remedied using longer and more complicated procedures. Five types of osteotomies were used: "C," single, double, bilateral sliding, and sagittal sliding. Osteotomies were performed on 14 patients, 13 with malignant tumors and one with a gunshot wound. Good results were obtained in 10 patients, total failure occurred in two, and complications without failure of the reconstruction arose in the other two.

5618. Verdonck, P., et al. (2016). "Penetrating and blunt trauma to the neck: clinical presentation, assessment and emergency management." B-ENT **Suppl 26**(2): 69-85.

Penetrating and blunt trauma to the neck: clinical presentation, assessment ana emergency management. In Belgium, and even in Western Europe, penetrating and blunt injury to the neck is relatively uncommon in both the civilian and military populations. Pre-hospital and emergency assessment and management will therefore always prove challenging, as individual exposure to this specific type of injury remains low. Historically, the neck has been divided into three anatomical zones with specific landmarks to guide the diagnostic and therapeutic approach to penetrating neck injuries. Most penetrating injuries need to be explored surgically, although with the advent of multi-detector computed tomographic angiography (MDCTA), which yields high diagnostic sensitivity, this inflexible approach has recently changed to a more targeted management, based on clinical, radiographic and, if deemed necessary, endoscopic findings. However, some authors have addressed their concern about this novel, 'no-zone' approach, since the risk of missing less apparent aerodigestive tract injuries may increase. It is recommended, therefore, that all patients with penetrating neck injuries be closely observed, irrespective of the initial findings. The incidence of blunt neck injury is much lower, and this makes risk assessment and management even more difficult in comparison with penetrating injuries. Again, MDCTA is most often the first diagnostic tool if a blunt neck injury is suspected, due to its good sensitivity for blunt cerebrovascular injuries (BCVI) as well as for aerodigestive tract injuries. Specific patterns of injury and unexpected neurological and neuro-radiological findings in trauma patients should always warrant further investigation. Despite ongoing debate, systemic anticoagulation is recommended for most BCVI, sometimes combined with endovascular treatment. Aerodigestive tract injuries may present dramatically, but are often more subtle, making the diagnosis more difficult than other types of neck injuries. Treatment may be conservative if damage is minimal, but surgery is warranted in all other cases.

5619. Verheggen, R., et al. (2005). "Experiences with LactoSorb™ miniplates and screws - Long-term follow-up data in paediatric patients and infant minipigs." Osteologie **14**(2): 101-110.

Perosseous intracranial translocation of metallic devices (Pit-effect) in the growing infant skull is caused by an appositional and resorptional bony remodelling process. We investigated the characteristics of a biodegradable fixation system (LactoSorb™) in cranial paediatric surgery with regard to clinical long-term results and analysed the histological changes and degradation process in an appropriate animal model. 23 children underwent either craniotomy and orbitotomy, repair of depressed skull fractures or fronto-orbital advancement and cranial vault remodelling. Fixation of bony flaps was obtained using LactoSorb™ devices. The stability and bone healing characteristics were extensively studied in infant minipigs. Following frontal craniotomy bone grafts were fastened by LactoSorb™ devices. After 3, 6, 9, 12 and 18 months the animals were sacrificed and the frontal sinus complex was resected to evaluate histomorphological changes. Radiographic examinations and clinical follow-up investigations were performed up to 34

months after surgery and revealed stability of the bony fragments without evidence of displacement or disturbed skull growth. Referring to the animal studies, histological investigations indicated complete resorption of the biopolymer after 18 months. The use of LactoSorb™ miniplates and screws led to a rigid fixation of cranial bone fragments. In growing skull, biodegradable devices are promising to avoid the Pit-effect. As greatest benefit, no further plate removal is necessary once the healing process has been finished. © 2005 by Verlag Hans Huber.

5621. Verhoff, M. A., et al. (2008). "Investigations on an isolated skull with gunshot wounds using flat-panel CT." International journal of legal medicine **122**(5): 441-445.

The use of computed tomography (CT) scanners is rapidly becoming established in forensic medicine. Current multislice CT (MSCT) scanners attain a resolution of 0.42 mm. An isolated skull with gunshot injuries was examined with a high-resolution eXplore Locus Ultra flat-panel CT (eLU-CT) and MSCT. Structures and minute fissures in the bone interior, which were neither visible macroscopically nor with the MSCT data, could be imaged with the eLU-CT data. In addition, a tiny interior impact defect from a retained missile could be detected by eLU-CT, which clearly aided the reconstruction of the gunshots in this case.

5622. Verlicchi, A., et al. (1998). "Civilian gunshot wounds to the head with brain stem localization. A case report." Journal of neurosurgical sciences **42**(4): 227-232.

The authors present a case of a patient wounded to the head and back by civilian firearm projectiles. The case peculiarity is that only one bullet reached the brain stem level causing significant neurological deficits. The final clinical picture is comparable to the "caudal pontine tegmentum syndrome". The authors describe both the bullet path and the intracranial localization taking into account ballistic details. The problems associated with prognosis, diagnosis, and treatment for gunshot wounds are discussed. In addition, the authors explain the main intracranial lesions and their mechanisms, the role of investigation, and the protocol of medical and surgical treatment. Lastly, a systematic approach for treating these types of gunshot wounds is outlined.

5623. Verma, A., et al. (2010). "Successful medical treatment of cerebral aspergillosis with voriconazole following liver transplantation." Liver Transplantation **16**: S200.

Background: Extension of invasive aspergillosis (IA) to the central nervous system (CNS) is associated with an exceedingly high mortality upto 100%. One major cause contributing to this devastating outcome is a poor penetration of frequently used antifungals into the CNS, such as amphotericin B. The best treatment strategy remains controversial. Voriconzole is a broad spectrum triazole proven to be a superior alternative to Amphotericin B in IA and readily penetrate the blood-brain barrier yielding fungicidal drug concentrations within the CNS. However because of its hepatotoxicity and interaction with immunosuppressive drugs, it's wide usage in post liver transplant recipients (PLTR) has been restricted. We report 3 cases of cerebral aspergillosis successfully treated with voriconazole. Patients and Results: The medical record of 3 LTR with proven cerebral aspergillosis were reviewed. Patients 1 & 2 were transplanted for drug induced acute liver failure (Female 50 yrs old; Male 33 yrs old) and patient 3 for primary biliry cirrhosis (Female 51 yrs old). Patient1&2 developed disease during the 3rd post LT week & in patient 3 detected on week 11. On CT scan all three patient had brain lesion and lung lesion in patient1&2. Aspergillus fumigatus was isolated in patient 1&2. Fungal were confirmed in brain aspirates in paitients1&2 and in eye aspirate in patient 2. Patient1&2 developed disseminated IA whilst on therapeutic does of Ambisome 3mg/ kg. Following diagnosis all three were treated with voriconazole and another antifungal was added caspofugin in patient 1&2 and Ambisome in patient 3 till improved clinically.Voriconazole was continued as single agent for 6-9 month in all three patients. Daily monitoiring of liver & renal function and immunosuppressive drug was done, there was no obvious side effects due to voriconazole. Patient 3 was in renal failure prior to onset and continues to have renal impairment. Patient 1died at 216 days PLT due to chronic rejection, whilst the others are currently alive at 221 and 610 days PLT respectively Conclusion: In our experience in cases of brain aspergillosis refractory to ambisome voriconazole is safe and effective in the successful management of cerebral aspergillosis in LTR.

5624. Verma, S. B., et al. (2008). "Late complication after tropic storm accident: subcutaneous and intracranial actinomycetoma." International wound journal **5**(5): 655-659.

We report a 53-year-old farmer who developed subcutaneous and cerebral masses 24 years after penetrating trauma during a tropic storm. Computed tomography scans, magnetic resonance imaging and histopathology disclosed actinomycetoma, a disease that rarely develops after trauma and is only occasionally seen with intracranial manifestation. Clinically, the cutaneous manifestation resembled acne keloidalis nuchae or dissecting folliculitis of the scalp. He was treated by neurosurgery and antibiosis.

5626. Veronezi, R. J. B., et al. (2018). "Epidemiological study of traumatic spinal cord injury in goiânia." Revista Brasileira de Neurologia e Psiquiatria **22**(1): 30-44.

Purpose: Spinal cord injuries are a growing cause of morbidity and mortality in the population. Studies on etiology and aggravation of this trauma are critical to subsidize health policies for this population. This study aimed to describe the epidemiological profile of patients with spinal cord injury in Goiânia, Goiás, Brazil. Methods: Epidemiological study with documental analysis of 265 cases of spinal cord injury treated at the Emergency Hospital of Goiania in 2013. Results: The trauma was prevalent in male young people. The main cause was traffic accidents. The thoracolumbar region was the most affected. Half of the patients showed no spinal cord injury, but 52.45% presented some motor deficit. Treatment was conservative in most cases. In 109 patients required surgery due to trauma associated with being the head trauma the most frequent. Mortality was 14% and the highest risk of death occurred in cases aged under 60 years, cervical spine trauma and complete spinal cord injury. The average hospital stay was 6 days and was higher in surgical patients. All patients were seen by the Unified Health System, generating a cost of R-756,449.37. Conclusion: These findings allow guidance on efficient allocation of resources for the management of these diseases and indicate the need to create targeted strategies to prevent this type of injury in this population.

5627. Verrett, A., et al. (2011). "Characterization of craniomaxillofacial injuries during operations enduring freedom and iraqi freedom - A 10 year review." Journal of oral and maxillofacial surgery **69**(9): e-95.

Statement of the Problem: 1. To expand and update past epidemiological studies on Craniomaxillofacial (CMF) injuries in Operations Iraqi Freedom, Enduring Freedom, and New Dawn (OIF/OEF/ OND), using 10 years of current wartime data from the Joint Theatre Trauma Registry (JTTR) a. To characterize and describe CMF battlefield injuries sustained by US services members in 10 years of OIF/OEF/OND b. Compare with previous studies regarding severity, classification and location of CMF injuries. Materials and Methods: 1. The JTTR was queried from October 19, 2001, to April 6, 2001, using ICD-9 codes. a. Non-battlefield injuries, killed in action and return to duty cases were excluded. b. Stratification of facial fractures rendered using ICD-9 codes. Results of Investigation: In a 10-year period, the total number of injured personnel was 42,913 of which 23,609 required level III echelon treatment. There were 11,951 unique patients with CMF injuries based on ICD-9 and Abbreviated Injury Score (AIS) codes. CMF injuries account for 24.4% (5,782/23,609) of all incidents. CMF fractures are responsible for 11.5% (2,709/ 23,609). The categorization of the fractures are as follows: nasal (26%), orbital (17%), malar/maxillary (28%), mandible (18%), and unclassified (29%). There is a prominent frequency of open fractures with ratio of open to closed fractures 1.34:1. Explosive devices and penetrating injuries were involved in most battlefield CMF injuries (45.8% and 40.8%). Other methods included gunshot wounds (3.4%), motor vehicle accidents (0.8%), and not documented/other (0.3%). The incidence of CMF injuries by branch of service was Army (74.1%), Marines (22.0%), Navy (2.1%), and Air Force (1.5%). Conclusion: Of the injured US serviced members, 24% had injuries to the CMF regions in Operations Iraqi Freedom/Enduring Freedom/New Dawn during a 10- year period. Multiple penetrating soft-tissue injuries and fractures by explosives were commonly seen. Advancing battlefield medicine, body armor, and use of explosives devices has likely elevated the relative frequency and incidence of CMF injuries. Further research is needed to characterize the severity of CMF battle injuries related to treatment outcome.

5628. Veselinovic, I., et al. (2019). "Suicide with an unusual home-manufactured firearm." Forensic science, medicine, and pathology **15**(2): 288-291.

A 22-year-old male with a medical history of depression was found lying on his right side with a pool of blood around his head. A pistol-shaped metal device was found next to the right hand of the deceased. Examination of the body revealed the presence of a gunshot wound to the head. The entrance wound was located in the right temporal area and was partially surrounded by a semicircular muzzle imprint. Analysis of the firearm revealed a home-manufactured device constructed from the posterior part of a captive bolt gun chamber containing a firing pin. The front part of an original captive bolt's cylinder was replaced with a conical iron tube, which could be detached from the chamber by an unscrewing action. The tube was unrifled and drilled in order to accept standard 9 mm ammunition. A hollow rectangular piece of metal was welded to the posterior part of the chamber perpendicularly and used as a grip. Cases of injuries caused by different types of captive bolt guns are well documented in the forensic literature. However, conversions of captive bolts in projectile-discharging devices or their use in the construction of zip guns, as well as the injuries produced by such types of firearms, are extremely rare in forensic and medico-legal practice.

We report a firearm wound of the brain which could not be analyzed by computed tomography because of induced artifacts. MRI study was remarkably after verifying the non-ferromagnetic nature of the projectiles.

5631. Vickers, K. L. (2020). "Impact of compensatory recommendations on consistency in adherence to behavioral regimens in traumatic brain injury." Dissertation abstracts international: section B: the sciences and engineering **81**(2-B): No.

Background: Adherence is the extent to which one's behavior aligns with prescribed healthcare recommendations and it has been found to be a mediating factor of rehabilitation success after traumatic brain injury (TBI). Individuals post- TBI are at risk due to executive dysfunction. Although methods of overcoming executive difficulties as they relate to adherence have been posited (e.g., compensatory strategies), there has been no systematic study of the relationship between adherence behaviors and executive functioning during an unstructured regimen in this population. Moreover, cognitively-mediated aspects of adherence, such as consistency, which may represent targetable mechanisms of non-adherence have not been explored.Objective: The current study aimed to investigate the relationship between compensatory recommendations, executive function, and adherence behaviors during a prescribed behavioral regimen. Primary aims were to investigate: 1) the impact of compensatory recommendations on consistency in adherence, 2) the impact of compensatory recommendations on overall adherence, and 3) the relationship between executive functioning and consistency in adherence. An exploratory aim investigated how relationship between compensatory strategy, executive function, and consistency in adherence changed over the course of the 4-weeks.Method: 13 adults with a history of non-penetrating head injury were recruited for the current study and randomized into two groups: one that received compensatory recommendations (n = 7; Mage = 43.71, SD = 12.16; 43% male) and one that received no strategy (n = 6; Mage = 46.00, SD = 7.13; 67% male). All participants completed cognitive testing before engaging in a 4-week online behavioral regimen. For each day of the regimen, three online cognitive activities were prescribed. Outcome measures included adherence (events completed of 84) and consistency in adherence (variability in timing of event completion). Participants also completed a follow-up survey.Results: A series of Pearson correlations and regression-based analyses revealed that presence of a compensatory strategy did not predict consistency in adherence, nor did it predict overall adherence after controlling for covariates. In supplementary analyses, individuals who received a compensatory strategy had better adherence for the CAT during week 1, but their adherence decreased to be equivalent to the no strategy group over the course of four weeks. Additionally, one measure of executive function (response inhibition) was significantly related to consistency in adherence. Upon further analyses, it was determined this relationship differed by group. Consistency in adherence followed a quadratic pattern

over time, such that all individuals were least consistent during the third week of the regimen, but were more consistent before and after that point.Conclusions: Consistency in adherence does not appear to be improved by the addition of a compensatory strategy. Although this component of adherence was related to executive function, this association appeared strongest among individuals who did not receive a strategy and who were more cognitively compromised. Adherence improved with the addition of a compensatory strategy initially, but declined over time to be equal to the no strategy group. Clinically, these findings suggest that compensatory strategies may need to be nuanced and target specific mechanisms of non-adherence. Moreover, the need for regular follow-up during a behavioral regimen to encourage continued motivation over time may be necessary to maximize adherence. Limitations include a small sample size, uneven groups with respect to cognitive function, and executive functioning measures which do not approximate real-world behaviors.

5632. Viel, G., et al. (2009). "Intersecting fractures of the skull and gunshot wounds. Case report and literature review." Forensic science, medicine, and pathology **5**(1): 22-27.

When two fracture lines of a solid surface (ice, glass, eggshell, etc.) intersect, it is always possible to tell which one has been made first. Indeed pre-existing damage of the surface arrests all the fracture lines produced by subsequent impacts. This well-known principle (established by Puppe in 1903) has been largely used in glass fracture analysis, but can be applied also to the examination of skull fractures. It can help sequencing blunt force or gunshot injuries determining the direction of fire and differentiating entrance from exit wounds in the absence of specific distinguishing features (i.e., internal/external beveling of the skull or overlying skin indicators). In this context, we report the case of a 76-year-old man who shot himself in the mouth with a Walther PPK 7.65 handgun and highlight the utility of the application of both Puppe's Rule and Multislice Computed Tomography (MSCT) in the examination of gunshot wounds to the skull.

5633. Viel, G., et al. (2009). "Planned complex suicide by penetrating captive-bolt gunshot and hanging: case study and review of the literature." Forensic science international **187**(1-3): e7-11.

Captive-bolt guns or slaughterer's guns are devices widely used in meat industry and private farmer households for slaughtering animal stocks. They consist of a simple cylindrical metal tube (barrel) with a metal bolt placed in their centre (around 9-15cm long and 1-1.5cm wide). The bolt is actuated by a trigger pull and is propelled forward by compressed air or by the discharge of a blank powder gun cartridge. Violent deaths inflicted by captive-bolt guns are rarely encountered in forensic practice and are predominantly suicidal events. We report an unusual complex suicide by hanging and self-shooting with a slaughterer's gun in a 21-year-old boy. The victim after putting a ceiling fixed rope around his neck shot himself in the head (occipital region) with a Kerner captive-bolt gun. He used two mirrors (a cosmetic mirror and a man-sized one) in order to properly visualize his back and to target the occipital region of his head. Radiological data (computed tomography with three dimensional reconstruction) and autopsy findings are discussed according to the clinical and forensic literature. A brief review on planned complex suicides is also given.

5634. Viero, A., et al. (2014). "An unusual case of "dyadic-death" with a single gunshot." Forensic science international **244**: e1-5.

The terms "dyadic death" or "murder-suicide" refer to an incident where an individual commits homicide and then takes his or her own life. These events are generally committed by men within the family network, using firearms or sharp force instruments, and make up a relatively small proportion of homicides overall. Herein, we present the application of post-mortem multislice computed tomography (CT) and micro-CT analysis to an unusual case of dyadic death, where a 38-year-old man fired a single gunshot to his own right temple, killing himself and his 50-year-old wife, lying on the bed beside him. The integration of radiological, autoptic and histological data allowed us to reconstruct the trajectory of the gunshot, the most probable dynamics of the event, and to classify the incident as a "suicide-homicide", because the female victim died a few minutes later than her husband and murderer.

5637. Vinuthinee, N., et al. (2015). "Gunshot-like wound caused by sling shot injury – A case report." International medical case reports journal **8**: 47-50.

We report a rare case of sling shot injury that presented with a gunshot-like wound with preseptal cellulitis, in a toddler. An 11-month-old Malay child presented with a gunshot-like wound over the forehead following sling shot injury. On examination, he had a deep circular laceration wound over the forehead, measuring 2.0 cm in diameter, with minimal bleeding. There was no obvious foreign body seen inside the wound and no palpable foreign body surrounding the wound. The gunshot-like wound was associated with left preseptal cellulitis. A skull X-ray showed a white opaque foreign body in the left frontal bone. Computed tomography (CT) scan of orbit and brain revealed a left comminuted fracture of the left orbital roof, and left frontal brain contusion with prelesional edema. Wound exploration was performed and revealed a 0.5 cm unshattered marble embedded in the left frontal bone. The marble and bone fragments were removed. The left preseptal cellulitis responded well to intravenous antibiotic and topical antibiotic.

5638. Viola, L., et al. (2004). "Suicide with a butcher's bolt." Journal of forensic sciences **49**(3): 595-597.

The captive bolt pistol is an atypical firearm exclusively produced and used for butchery of breeding animals, but in some rare cases, it has been used as a lethal weapon for committing suicide by butchers, breeders and other people who have access to such weapons during their professional activities. This study describes the suicide committed by a butcher in the province of Udine (N. Italy) in 2001 who shot himself with his own captive bolt pistol that produced in the right temporal region a circular wound and a bone lesion of the temporal squama with a groove involving the frontal lobe; he died five days later of the fatal consequences of the meningo-encephalic lesions. The medico-legal issues implicated in this case, seen in the light of the data reported in the international literature, illustrate the difficulties faced when diagnosing these types of lesions, bearing in mind their rarity and peculiar nature, and introduce elements of differential diagnosis regarding lesions produced by similar weapons that lead to ascertainment of the event as accidental, suicidal, or homicidal.

5639. Vitanovics, D., et al. (2014). "[Tailored cranioplasty using CAD-CAM technology]." Szemelyre szabott koponyacsontpotlasok CAD-CAM technologia felhasznalasaval. **67**(11-12): 390-396.

OBJECTIVE: The majority of cranial defects are results of surgical intervention. The defect must be covered within resonable period of time usually after 4-6 week given the fact that the replacement of bone improve the brain circulation. Number of surgical techniques and materials are available to perform cranioplasty. Due to favorable properties we chosed ultra high molecular weight polyethylene as material. In this paper the authors show a procedure which allows tailored artificial bone replacement using state of art medical and engineering techniques., METHODS: between 2004 and 2012, 19 patients were operated on cranial bone defect and a total of 22 3D custom-designed implants were implanted. The average age of patients was 35.4 years. In 12 patients we performed primary cranioplasty, while seven patients had the replacement at least once. Later the implants had to be removed due to infection or other causes (bone necrosis, fracture). All patients had native and bone-windowed 1 mm resolution CT. The 3D design was made using the original CT images and with design program. Computer controlled lathe was used to prepare a precise-fitting model. During surgery, the defect was exposed and the implant was fixed to normal bone using mini titanium plates and screws. All of our patients had control CT at 3, 6 and 12 months after surgery and at the same time neurological examination., RESULTS: Twenty-one polyethylene and one titanium implants were inserted. The average follow-up of the patients was 21.5 months, ranged from two to 96 months. We follow 12 patients (63.15%) more than one year. No intraoperative implant modifications had to be made. Each of the 22 implant exactly matched the bone defect proved by CT scan. No one of our patients reported aesthetic problems and we did not notice any kind of aesthetic complication. We had short term complication in three cases due to cranioplasty, subdural, epidural haemorrhage and skin defect., CONCLUSION: Polyethylene is in all respects suitable for primary and secondary

cranioplasty. Combined with 3D CAD- CAM method excellent aesthetic and functional result was achieved. In our study no case of infection occured. Proper preoperative preparation is important.

5640. Viteri, S., et al. (2020). "Activity of tepotinib in brain metastases (BM): Preclinical models and clinical data from patients (pts) with MET exon 14 (METex14) skipping NSCLC." Annals of Oncology **31**: S831.

Background: BM occur in 20–40% of NSCLC harboring METex14 skipping. We investigated the activity of the MET inhibitor tepotinib in BM in preclinical models and in pts from the VISION study (NCT02864992). Methods: Penetration of the blood–brain barrier was assessed in Wistar rats (n=3) at 3.66 mg/kg/h iv tepotinib by determining the unbound brain (fu br)-to-plasma (fu pl) concentration or exposure ratio (Kp u,u). Efficacy was assessed in two lung cancer patient-derived xenografts (PDX) from BM harboring high MET amplification (MET gain in copy number: LU5349 = 11, LU5406 = 24) grown in NOD-SCID mice. Subcutaneous PDX (n=5/group) or PDX orthotopically implanted into the brain (n=10/group) were treated with tepotinib 125 mg/kg or vehicle control orally once daily. Intracranial tumor growth was monitored by gadolinium-based MRI. In VISION Cohort A, pts with METex14 skipping NSCLC received tepotinib 500 mg once daily. Systemic objective response, as assessed per RECIST v1.1 by independent review committee (IRC) was a preplanned analysis in pts with baseline brain lesions identified by IRC (BM-IRC) or investigator assessment (BM-INV). Results: Preclinical data indicated high binding of tepotinib in the brain, with unbound tepotinib in brain tissue lower than in plasma (fu br = 0.4%, fu pl = 4%). Concentrations of unbound tepotinib in the brain were 25% of plasma (Kp u,u = 0.25).Tepotinib treatment resulted in tumor regression in both PDX models (mean % tumor volume: –84% in LU5349, –63% in LU5406). As of 1 Jan 2020, 22/152 pts enrolled in Cohort A had baseline BM, with similar baseline pt characteristics and comparable systemic response data (Table) as the overall population. [Formula presented] Conclusions: Tepotinib administration resulted in tumor regression in MET-driven lung cancer BM PDX models. Clinical activity in pts with NSCLC harboring METex14 skipping with baseline BM was consistent with the overall population in VISION. Cohort C aims to assess intracranial response. 5641. Vitkus, K. and M. Vitkus (1990). "Microsurgical reconstruction of shotgun-blast wounds to the face." Journal of reconstructive microsurgery **6**(3): 279-286.

Successful management of shotgun-blast injuries to the face with loss of composite tissue is discussed. While emphasis in the literature has generally been on weapons ballistics and their destructive effect on tissues, the most massive tissue destruction can be anticipated from close-range gun-barrel effects due to rapidly expanding gases. The authors stress uncommonly aggressive tissue transfer as the method of choice in reconstructing facial shotgun wounds. The surgeon must evaluate patient psychological readiness for step-by-step reconstruction. Fistulas are avoided by transplanting several small flaps, rather than one large flap. The dorsalis pedis flap is recommended as an excellent choice for contaminated intraoral reconstruction. A staged approach providing osteocutaneous composite tissue for repair of shotgun-blast facial wounds is presented. At subsequent stages, soft tissue defects are repaired and restoration of mandibular continuity is provided with the use of the scapular flap and other alternatives. Microsurgical management of facial gunshot wounds can provide satisfactory reconstruction and almost normal function.

5642. Viviano, S. L., et al. (2017). "Pediatric Facial Fractures: An Assessment of Airway Management." The Journal of craniofacial surgery **28**(8): 2004-2006.

Pediatric facial fractures present unique and challenging management considerations, especially with regards to airway management. Anatomical differences in children increase both airway resistance and the difficulty of intubation. A surgical airway may be required if intubation is unable to be performed. The purpose of this study was to examine a single center's experience with pediatric facial fractures to determine the frequency of advanced airway use, as well as the risk factors that may predispose a patient to requiring an advanced airway. A retrospective review of all facial fractures at a level 1 trauma center was performed from 2000 to 2012. Patients age 18 years and younger were included. Patient demographics were collected, as well as location of fractures, concomitant injuries, services consulted, and surgical management strategies. Information was collected regarding the need for an advanced airway, including intubation and the need for a surgical airway. A total of 285 patients met inclusion criteria. Of these, 57 patients (20%) required emergency intubation and 5 (1.8%) required a surgical airway. Intubation was significantly related to fractures of the midface, frontal sinuses, spine, skull, and pelvis, as well as depressed Glasgow coma scores and traumatic brain injury. The need for a surgical airway is extremely uncommon (1.8%), and tracheostomy was only needed in the setting of penetrating head trauma. Both emergent intubation and tracheostomy are associated with complications, but these complications must be weighed against the potentially life-saving measure of securing an airway.

5643. Vivien, B., et al. (2013). "An unexpected intracranial blade." Prehospital emergency care : official journal of the National Association of EMS Physicians and the National Association of State EMS Directors **17**(1): 95-97.

While self-mutilations with stab wounds are relatively common in psychiatric patients suffering from schizophrenia and personality disorders, they are rarely performed as suicidal attempts. Even in psychotic patients,

suicidal stab wounds of the skull are rare in the literature. We report the case of a 34-year-old schizophrenic man whom emergency medical services (EMS) providers cared for at his home because of a complete self-amputation of his right hand, without any other apparent wound than a facial laceration. The patient was transferred to the acute surgical ward for evaluation of the possibility reimplantation of the amputated hand. When his neurologic status rapidly declined after hospital admission, a whole-body computed tomography (CT) scan was performed for other injuries. Unexpectedly, cerebral CT scan showed the presence of an intracranial 11-cm-long blade, whose distal tip was located in the left temporal cerebral lobe. Given the nature of the cerebral injuries on CT scan and the major impairment of the neurologic status of the patient, the neurosurgeon considered surgical extraction of the blade to be futile, and the patient's condition rapidly deteriorated to brain death.

5644. Vláčil, O. and J. Kincl (2011). "Acute orbital cellulitis - diagnostics and treatment." Pediatrie pro Praxi **12**(5): 304-305.

Acute orbital cellulitis is the most common disease in childhood. In 85 % of cases arising from infection of the paranasal sinuses, the transfer from surrounding skin inflammation, after penetrating injury of the orbit or the hematogenous transfer is possible. The patient is threatened mainly temporary or permanent loss of visual acuity, intracranial spread of infection, usually by the cavernous sinus and the consequent risk of sepsis with an overall alteration of the state. The therapy is the overall administration of broad spectrum antibiotics. Although the results of early treatment are very good, preservation of visual acuity is not always obvious.

5645. Vladutiu, C., et al. (2009). "[The role of diagnostic imaging in pediatric ophthalmology]." Valoarea diagnosticului imagistic in oftalmopediatrie. **53**(3): 80-84.

The paper underlines the importance of the imagistic examination in the diagnosis and the therapeutical orientation in an orbital injury in a four-year-old child. The orbital injury ends with a foreign body (fragment of a pencil) in the orbit. The situation and the orientation of the foreign body was revealed by the computer tomography and the MIMICS program. Afterwards, the MRI exam ruled out a muscular injury and permitted a correct strabological diagnose and a correct strabismus surgery.

5646. Vlkova, E. and I. Slapak (1991). "[Injuries of the orbit caused by foreign body]." Verletzungen der Augenhohle durch Fremdkorper. **198**(2): 117-120.

Four cases of injury of the orbit by a big foreign body without damage to the bulbus are described. The bodies were extracted and the healing was without complications. Two of these bodies penetrated into the brain and in one case surgical intervention was necessary. In both instances vision was lost because of damage to the optic nerve.

5648. Vloka, C., et al. (2020). "Long term follow up after transorbital penetrating injury: A case report." American Journal of Ophthalmology Case Reports **19**.

Purpose: Traumatic brain injury is the leading cause of mortality and disability among young individuals. Unfortunately, there are few publications concerning long term follow up of patients with these types of injuries. We present a case of trans-orbital penetrating brain injury with an 18 year follow up. Observations: A 43-year-old, previously healthy, male was accidently impaled on a fencing foil resulting in a penetrating brain injury. Initial symptoms included diplopia, ophthalmoparesis, a non-reactive pupil, decreased visual acuity, decreased sensation across the cheek, dysphagia and dysarthria. CT scan taken on presentation showed a clear tract of the foil traversing the various structures of the brain. One week after the trauma, the patient developed a unique constellation of paroxysmal attacks of autonomic dysfunction consisting of profuse diaphoresis and decreased skin temperature on the left side of the body, as

well as dilation of the left pupil. Three months after the accident, the patient suddenly experienced severe constant pain affecting the left side of his body associated with thermal and tactile allodynia. On latest follow up, 18 years after the accident, the patient continues to have chronic pain, allodynia, and lack of temperature sensation throughout the left face, arm, and leg. He has a wide based, hemi-ataxic gait, with the left leg swinging out and around. EMG and nerve conduction studies have found no voluntary activity in the temporalis and masseter muscles resulting in atrophy and fibrosis. An MRI shows linear encephalomalacia along the path of the foil extending to the pons, involving the right spinothalamic tract, and cerebellum. Conclusions and Importance: Our case illustrates the importance of such a longitudinal follow up. It demonstrates the possible severity of the sequelae from these types of injuries including chronic pain and gait ataxia, as well as EOM and autonomic dysfunction. Due to the potential ongoing needs of such patients, it is important to plan a long-term, team-based approach that centers around physical therapy and improving long term quality of life.

5649. Vo, D. T., et al. (2017). "Novel Use of an Image-Guided Stereotactic Approach in Trauma for Localization of Transcranial Bullet." Cureus **9**(7): e1501.

Penetrating brain injuries from gunshot wounds can carry a poor prognosis and require an aggressive, multifaceted approach to obtain a good prognosis and outcome. An initial evaluation requires appropriate imaging studies followed by management and prophylaxis against increased intracranial pressure, infection, and seizures. Surgical management is then followed to ensure the watertight closure of any wounds, removal of any areas of hematoma, and removal of any potential areas of infection. In this paper, we report the case of a patient who presented with a self-inflicted gunshot wound to the head and then received aggressive medical and surgical management. This case presents that an image-guided stereotactic approach with suitable medical management should be used in patients with penetrating missile injuries to the head.

The authors report a case of a 22-year-old otherwise healthy female who presented following a head injury during a bar altercation, with no associated loss of consciousness and an unknown mechanism of injury. Examination revealed an isolated 1cm laceration on the right upper eyelid, superior to her medial canthus. She experienced diplopia on right horizontal gaze due to a left internuclear ophthalmoplegia (INO) with an associated left conjugate horizontal gaze palsy, collectively described as a left one-and-a-half syndrome. CT and MRI demonstrated evidence of a deep penetrating injury above the right medial canthus, traversing the ethmoid and sphenoid sinuses, the dorsum sella, narrowly missing the basilar artery, penetrating the pons, and extending to the floor of the contralateral fourth ventricle. The patient was diagnosed with multiple sinus fractures, lesions in her left paramedian pontine reticular formation (PPRF) and medial longitudinal fasciculus (MLF), and progressive pneumocephalus. She underwent a transsphenoidal endoscopic repair via a vascularized mucosal flap without complication. Postoperatively, the patient's pneumocephalus resolved and her conjugate gaze markedly improved; however, minimal diplopia remained. This case demonstrates the importance of the clinical exam, and its benefit in localizing imaging findings and guiding treatment.

5654. Volk, A. S., et al. (2019). "Facial Gunshot Wounds." Facial plastic surgery : FPS **35**(6): 578-583.

Craniomaxillofacial gunshot injuries, resulting from assault, suicide attempts, and accidental trauma, represent a major public health dilemma in the United States. Due to the extent of injury and resulting osseous and soft tissue loss, facial gunshot wounds pose a unique challenge to the reconstructive surgeon. Initial management should use advanced trauma life support principles with the goal of patient stabilization. Acute operative management should center around wound decontamination, debridement, and temporary closure. Historically, definitive surgical management focused on delayed reconstruction secondary to high rates of wound infections, necrosis, and ischemia. With improvements in imaging modalities, the advent of virtual surgical planning, and the popularization of microvascular free flaps, contemporary methods have shifted toward earlier more definitive reconstruction. Autologous free tissue transfer has resulted in a decrease in hospital stay and the number of overall surgeries. Importantly, due to the variability in injury pattern and complexity in reconstruction, a systematic approach toward intervention is needed to mitigate complications and optimize overall functional and aesthetic outcomes. 5656. von Arx, T., et al. (2014). "Perforation of the sinus membrane during sinus floor elevation: a retrospective study of frequency and possible risk factors." The International journal of oral & maxillofacial implants **29**(3): 718-726.

PURPOSE: To analyze the frequency of perforation of the sinus membrane during maxillary sinus floor elevation (SFE) and to assess possible risk factors., MATERIALS AND METHODS: Seventy-seven cases of SFE performed with a lateral window approach were evaluated retrospectively. Clinical and radiographic variables potentially influencing the risk of sinus membrane perforation were evaluated and divided into patient-related factors (age, sex, smoking habit); surgery-related factors (type of surgical approach, side, units, sites, and technique of osteotomy); and maxillary sinus-related factors (presence and height of septum, height of residual ridge, thickness of lateral sinus wall, width of antrum, and thickness and status of sinus membrane)., RESULTS: The following factors presented with at least a 10% difference in rates of perforations: smokers (46.2%) versus nonsmokers (23.4%), simultaneous (32%) versus staged (18.5%) approach, mixed premolar-molar sites (41.2%) versus premolar-only sites (16.7%) versus molar-only sites (26.2%), presence of septa (42.9%) versus no septa (23.8%), and minimum height of residual ridge <=4 mm (34.2%) versus > 4 mm (20.5%). These same parameters, except minimum height of residual ridge, also showed an odds ratio above 2. However, none of the comparisons reached statistical significance., CONCLUSION: The present study failed to demonstrate any factor that statistically significantly increased the risk of sinus membrane perforation during SFE using the lateral window approach.

5657. Von Hekkel, A. F., et al. (2022). "Successful Nonsurgical Management of a Traumatic Dens Fracture in a Cat with Clinical and Radiographic Resolution." Journal of the American Animal Hospital Association **58**(1): 48-53.

An adult domestic shorthair presented with obtundation, vestibular ataxia, head tilt, and visible evidence of facial injury following motor vehicle trauma. Plain radiographs and computed tomography imaging revealed a complete minimally displaced transverse fracture of the caudal aspect of the dens of the C2 vertebra and multiple minimally displaced cranial fractures. The dens fracture was managed with 8 wk of strict rest, followed by 4 wk of supervised activity at home. No external immobilization was performed. Neurological examinations at 8 days, 10 wk, and 9 mo following initial presentation were normal. Repeat radiographic and computed tomography examinations at 10 wk and 9 mo following the traumatic event demonstrated progressive and eventual complete osseous union of the fractured dens. To the authors' knowledge, this is the first report of successful nonsurgical management of a traumatic dens fracture in an adult cat with documented radiographic and clinical resolution. This report suggests that nonsurgical management can be considered in such cats and that complete resolution with osseous union is feasible.

5658. Von Oertzen, J. and C. E. Elger (2004). "Epileptic seizures and epilepsy secondary to brain injuries." Intensivmedizin und Notfallmedizin **41**(5): 331-336.

Up to 20% of epilepsies are caused posttraumatically. Posttraumatic seizures are subdivided into immediate seizures and delayed early seizures occurring during the first 24 hours or seven days after the injury, respectively, and

late seizures occurring after the first week. Posttraumatic epilepsy (PTE) is used to define the situation of recurring late seizures (more than 2). Early seizures are most often caused by the brain injury itself. Early seizures occurring after mild head injury may indicate more severe head injury and should lead to further diagnostics. This type of posttraumatic seizure should be treated precautionary with anticonvulsants as seizures may cause further brain damage to the vulnerable injured brain. This treatment will not affect the incidence of late seizures or PTE, which are both caused by a chronic epileptic focus. Treatment of PTE should be started after they have occurred as the incidence of PTE is not affected by prophylactic anticonvulsive treatment. High incidence of PTE is given after penetrating brain injuries or all kinds of brain injuries with (cortical) hemorrhage.

5659. Von Rahden, B. H. A., et al. (2004). "[Esophageal perforation by portions of a wild boar]." Osophagusperforation durch Wildschweinteile. **129**(4): 314-316.

We report a case of esophageal perforation by impacted portions of a wild boar. The 77-year-old patient was admitted 5 days after an opulent dinner. He complained of dysphagia and retrosternal pain and showed signs of severe sepsis. Endoscopy revealed meat and bone portions impacted in the esophagus. Surprisingly, impactation had not happened near any of the anatomical narrowings, but in the middle third. A CT scan showed penetration of the foreign body into the mediastinum and purulent mediastinitis. The patient underwent transthoracic esophagectomy and drainage of the severe, purulent mediastinal infection. Postoperative multi organ failure required a prolonged treatment in the intensive care unit. After recovery the gastrointestinal continuity was restored with gastric pull-up in the anterior mediastinum. The further course was uneventful.

5660. von See, C., et al. (2009). "Forensic imaging of projectiles using cone-beam computed tomography." Forensic science international **190**(1-3): 38-41.

In patients with gunshot injuries, it is easy to detect a projectile within the body due to the high-density of the object, but artefacts make it difficult to obtain information about the deformation and the exact location of the projectile in surrounding tissues. Cone-beam computed tomography (CBCT) is a new radiological imaging modality that allows radio-opaque objects to be localised and assessed in three dimensions. The full potential of the use of CBCT in forensic medicine has not yet been explored. In this study, three different modern projectiles were fired into the heads of pig cadavers (n=6) under standardised conditions. Tissue destruction and the location of the projectiles were analysed separately using CBCT and multi-slice computed tomography (MDCT). The projectiles had the same kinetic energy but showed considerable differences in deformation behaviour. Within the study groups, tissue destruction was reproducible. CBCT is less severely affected by metallic artefacts than MDCT. Therefore CBCT is superior in visualising bone destruction in the immediate vicinity of the projectile and projectile deformation, whereas MDCT allows soft tissue to be evaluated in more detail. CBCT is an improved diagnostic tool for the evaluation of gunshot injuries. In particular, it is superior to MDCT in detecting structural hard-tissue damage in the immediate vicinity of high-density metal projectiles and in identifying the precise location of a projectile in the body.

5662. Vonder Haar, C., et al. (2014). "Comparison of the effect of minocycline and simvastatin on functional recovery and gene expression in a rat traumatic brain injury model." Journal of neurotrauma **31**(10): 961-975.

The goal of this study was to compare the effects of minocycline and simvastatin on functional recovery and brain gene expression after a cortical contusion impact (CCI) injury. Dosage regimens were designed to provide serum concentrations in a rat model in the range obtained with clinically approved doses; minocycline 60 mg/kg q12h and simvastatin 10 mg/kg q12h for 72 h. Functional recovery was assessed using motor and spatial learning tasks and neuropathological measurements. Microarray-based transcriptional profiling was used to determine the effect on gene expression at 24 h, 72 h, and 7 days post-CCI. Gene Ontology analysis (GOA) was used to evaluate the effect on relevant biological pathways. Both minocycline and simvastatin improved fine motor function, but not gross motor or cognitive function. Minocycline modestly decreased lesion size with no effect of simvastatin. At 24 h post-CCI, GOA identified a significant effect of minocycline on chemotaxis, blood circulation, immune response, and cell to cell signaling pathways.

Inflammatory pathways were affected by minocycline only at the 72 h time point. There was a minimal effect of simvastatin on gene expression 24 h after injury, with increasing effects at 72 h and 7 days. GOA identified a significant effect of simvastatin on inflammatory response at 72 h and 7 days. In conclusion, treatment with minocycline and simvastatin resulted in significant effects on gene expression in the brain reflecting adequate brain penetration without producing significant neurorestorative effects.

5663. Vonnez, J. L., et al. (2013). "Asymptomatic dural venous sinus thrombosis after skull fracture." Swiss Medical Weekly **143**: 25S.

Introduction: Dural venous sinus thrombosis (DVST) is an uncommon finding in children head trauma. We report a case of asymptomatic marginal thrombosis of the sagittal sinus associated with a frontal bone fracture in a 3 year old child. Case report: A healthy 3 years old boy is admitted for cranio-cerebral trauma after falling from the roof of a camping car. He presents initial sleepiness, one episod of vomiting, but no loss of consciousness. Initial Glasgow coma score is 13/15 (E3, M5, V5). Native CT-scan of the skull shows a non displaced frontal bone fracture crossing the anterior part of the superior sagittal sinus. An angio-CT-scan performed two days later reveals a marginal, non-occlusive thrombosis of the sagittal sinus. The child receives enoxaparin 14 mg daily (1.2 mg/kg) subcutaneous for one month. Repeated MRI shows a complete radiologic resolution of the thrombosis. Interestingly, two months after the accident, the child presents with a two days history of headache, sunken eyes and facial swelling suggestive of relapse. A new MRI shows no sign of thrombosis or venous edema and the symptoms disappear spontaneously. Discussion: Radiologic studies in adults show that DSVT complicates up to 40% of skull fracture crossing dural sinuses [1]. Although rare after children head trauma (only 2% of cases [2]), sinus thrombosis should be excluded in all children with such skull fractures. Anticoagulation to prevent extension is probably beneficial, despite lack of specific clinical trials to support this therapy. Conclusion: Imaging to exclude DSVT should be performed on all children presenting with a skull fracture crossing a cranial venous sinus, because specific treatment can be indicated.

5664. Vora, N. A., et al. (2007). "Endovascular management of a traumatic ophthalmic artery aneurysm." The Journal of trauma **63**(1): 192-194.

5665. Vorrasi, J., et al. (2018). "What Factors Necessitate Removal of Retained Ballistic Fragments in the Head and Neck?" Journal of oral and maxillofacial surgery : official journal of the American Association of Oral and Maxillofacial Surgeons **76**(4): 819-825.

PURPOSE: The purpose of this study was to estimate the frequency of retained ballistic fragment (RBF) removal and to identify factors associated with an increased risk for RBF removal. To date, there are no studies focused on identifying factors associated with removal of RBFs localized to the maxillofacial region., MATERIALS AND METHODS: Using a retrospective cohort study design, the authors enrolled a sample composed of patients with RBFs localized to the maxillofacial region. The predictor variables included bullet size, location, involvement of bone, involvement of sinus, antibiotics, multiple antibiotics, and multiple locations. The primary outcome variable was RBF retrieval. The secondary outcome variables were timing of operative retrieval, fragment site infection, and migration of RBF. Appropriate uni- and bivariate statistics were computed and logistic regression modeling was used., RESULTS: The sample was composed of 20 patients (mean age, 30 yr; 80% male) and 55% (11 patients) required or desired object removal overall. The number of projectiles ranged from 1 to 19 (total, 48) in the 20 patients. The logistic model identified larger size, final location of bone, final location of soft tissue, and final location of sinus as having a higher probability of removal that was statistically significant ($P < .05$); however, size was the only variable with a substantial odds ratio (OR; 1.96; $P < .05$). There was no evidence of migration and a low rate (2.3%) of infection was noted at subsequent follow-up radiography and clinical examination., CONCLUSION: Size was the only statistically significant predictor variable with a substantial OR (1.96; 95% confidence interval, 1.31-3.40; $P < .05$). There was a low risk of infection even when considering oral pharyngeal contamination and low risk of migration. Further studies could focus on prudent antibiotic use and larger patient populations.

5666. Voss, J. O., et al. (2018). "Penetrating Foreign Bodies in Head and Neck Trauma: A Surgical Challenge." Craniomaxillofacial Trauma and Reconstruction **11**(3): 172-182.

Penetrating foreign bodies of different origins in the head and neck are rare and potentially dangerous injuries, which might pose problems for their detection, primary care, and final treatment. Depending on the severity of the underlying trauma, some injuries present a higher risk for the presence of foreign bodies. Minor wounds, including common lacerations, are likely to be contaminated with loose gravel debris or dental fragments, and need to be distinguished from severe wounds caused by impalement, shootings, stabbings, and explosions. Blast injuries resulting from terror attacks are challenging recent therapeutic concepts. Even though these injury patterns are uncommon, they carry the risk of impacted objects with dramatic consequences. Despite improving medical imaging techniques, detection remains a challenge as it is dependent on the material of the foreign body, the affected anatomical site, and the injury severity. Therefore, a detailed history of the circumstances leading to trauma is essential when foreign objects are not visible during clinical examination. Precise detection of the foreign body, its anatomical position, and the affected surrounding structures are vital, especially for impalement injuries of the head and neck area. Therefore, an interdisciplinary planning approach is essential prior to removal of the foreign object. Finally, tension-free anatomical adaptation of the corresponding structures is crucial for maintaining and restoring aesthetic and function. Here, we give an overview of the diagnosis and treatment of cases of foreign body injuries encountered in our department.

5667. Voss, M., et al. (1995). "Patients who reattend after head injury: a high risk group." BMJ (Clinical research ed.) **311**(7017): 1395-1398.

OBJECTIVE: To assess risk factors for important neurosurgical effects in patients who reattend after head injury., DESIGN: Retrospective study., SUBJECTS: 606 patients who reattended a trauma unit after minor head injury., MAIN OUTCOME MEASURES: Intracranial abnormality detected on computed tomography or the need for neurosurgical intervention., RESULTS: Five patients died: two from unrelated causes and three from raised intracranial pressure. On multiple regression analysis the only significant predictor for both abnormality on computed tomography (14.4% of reattenders) and the need for operation (5% of reattenders) was vault fracture seen on the skull radiograph ($P < 10(-6)$); predictors for abnormal computed tomogram were a Glasgow coma scale score < 15 at either first or second attendance ($P < 0.0001$) and convulsion at second attendance ($P < 0.05$); predictive for operation only was penetrating injury of the skull ($P < 10(-6)$). On contingency table analysis these associations were confirmed. In addition significant associations with both abnormality on computed tomography and operation were focal neurological abnormality, weakness, or speech disturbance. Amnesia or loss of consciousness at the time of initial injury, personality change, and seizures were significantly associated only with abnormality on computed tomography. Headache, dizziness, nausea, and vomiting were common in reattenders but were found to have no independent significance., CONCLUSIONS: All patients who reattend after head injury should undergo computed tomography as at least 14% of scans can be expected to yield positive results. Where this facility is not available patients with predictors for operation should be urgently referred for neurosurgical opinion. Other patients can be readmitted and need referral only if symptoms persist despite symptomatic treatment or there is neurological deterioration while under observation. These patients are a high risk group and should be treated seriously.

5668. Vrankovi, et al. (1992). "Management of missile wounds of the cerebral dura mater: experience with 69 cases." Neurochirurgia **35**(5): 150.

Over the period of seven months: from July 1991 to January 1992 sixty-nine patients with penetrating head war-injuries, were admitted in our hospital. Missile wounds of the dura mater require in most cases urgent operative management: watertight closure of the dura defects. However, a dilemma still exists as to the best material to be used to restore the missile dural defects. There are several possibilities: an autologous substitute as periosteum (pericranium) from surrounding, fascia of the temporalis muscle, fascia lata, or allograft transplant as lyophilised cerebral dura mater (lyodura). In the group of 69 patients, 7 were treated conservatively, 13 were treated surgically, but without closing the dural wounds because of their critical condition, and in 45 surgically treated patients the dural defects were covered with 53 transplants: with periosteum in 22 patients but 24 coverings, with fascia of temporalis muscle in 2 patients, with lyodura in 6 patients, with fascia lata in 15 patients but 21 coverings. In 4 patients the dura wounds were sutured by interrupted sutures. The best results were obtained in the fascia lata group.

5669. Vrankovic, D., et al. (1992). "Management of missile wounds of the cerebral dura mater: experience with 69 cases." Neurochirurgia **35**(5): 150-155.

5670. Vrankovic, D., et al. (1997). "[Therapeutic outcome in penetrating craniocerebral injuries in children. Personal experiences during war conditions]." Therapeutische Ergebnisse bei penetrierenden kraniozerebralen Verletzungen von Kindern. Unsere Erfahrungen unter Kriegsverhaltnissen. **100**(1): 13-16.

During the war period 1991-1992 in Croatia, ten wounded children (16 years of age or younger) with war injuries to the brain were admitted to the Division of Neurosurgery, Osijek Clinical Hospital. Six of them had been wounded by shrapnel and four by pistol or rifle bullets. All but one were managed surgically (i.e. by craniotomy). The outcome was: as follows three children had a good recovery, four retained a moderate neurological deficit, and three died (injured by shrapnel). Five of the wounded (four injured by shrapnel and one by bullets) had associated injuries (fractures of the leg bones, eye lesion, amputation of the right leg) which influenced morbidity, and in one case mortality. Children wounded with shrapnel had brain edema on admission to hospital. Our experience indicates that the thermal effect from heated shrapnel, as well as velocity, mass, size and shape of the shrapnel, could be an additional factor for the development of severe brain edema.

5671. Vrankovic, D., et al. (1998). "Self-inflicted gunshot wounds to the head during the war and post-war period." Injury **29**(5): 369-373.

Thirty-five patients with self-inflicted gunshot brain injury were admitted to our hospital during 1991-96. War conditions and availability of firearms influenced the increase in these injuries, nearly six times greater than in the previous 6-year peace time period (1985-90). Our management protocol consisted of radical debridement of the missile track and evacuation of haematomata. For in-driven bone fragments we followed a less radical approach, but, if a post-operative computed tomogram (CT) showed a cluster of retained bone fragments, we operated on this. Attention was paid to the development of intracranial infection performing in such cases a contrast enhanced brain computed tomography. Ten patients died early and 29 were managed operatively. Twelve survived, and were followed-up for up to 60 months. No case of suicide recidivism was noted. We conclude that patients with a Glasgow Coma score of 3 should not be considered for operation. Per-operatively ultrasonography was very helpful in localizing and extracting in-driven bone fragments. Post-operatively, a CT scan is needed to demonstrate retained bone fragments.

5672. Vrebos, J. and C. C. Dupuis (1998). "[The life of Maurice Virenque (1888-1946). From "Gueules Cassees" to cervicofacial facelift]." A la rencontre de Maurice Virenque (1888-1946). Des "Gueules cassees" au lifting cervico-facial. **43**(2): 169-174.

When going through the biography and bibliography of M. Virenque, one realizes that he was an outstanding maxillo-facial surgeon, who developed his knowledge mainly during the two world wars 1914-1918 and 1939-1945 and gave exceptional care to soldiers with severe face and skull injuries, the so-called "Gueules Cassees". Nevertheless, he did not disregard the importance of aesthetic surgery born between the two wars. Due to his large experience in maxillo-facial surgery and his broad knowledge of the anatomy of the face, he occupies a special place among the forerunners of facelifts by stressing on the importance of plication of the deep aponeurotic layers of the face, thus allowing the elaboration of a modified approach to the problems of the aging face.

5673. Vulekovic, P., et al. (1995). "[Treatment of penetrating craniocerebral injuries from the Vukovar conflict, 1991-1992. Analysis of a series]." Lecenje penetrantnih kraniocerebralnih povreda s Vukovarskog ratista, 1991-1992. Analiza serije. **48**(11-12): 421-424.

Throughout the course of Vukovar conflict from July, 1991, to May, 1992, there were 37 patients with war craniocerebral injuries evacuated to our Clinic. 29 patients suffered penetrating missile craniocerebral injuries, in 14 (48%) there were fragment wounds and in 15 (52%) gunshot wounds. The series was analyzed according to wounding agents, sites of head penetration, CT scan findings, neurological findings, operative and postoperative complications, and mortality. We have found significant difference in mortality between wounded who sustained fragment wounds (14%) and those with gunshot wounds (27%). Further we emphasize the necessity of CT scanning, concerning a high haematoma incidence of 27 percent. Presence of retained in-driven bone or metal fragments in our series had no influence on development of either seizure disorder or an infectious complication. This supports a thesis of a limited brain debridement as a correct approach in the treatment of penetrating missile injuries.

5675. Wade, C. E., et al. (2013). "Characterization of a swine model fo Penetrating Ballistic-like Brain Injury (PBBI)." Journal of neurotrauma **30**(15): A98.

Introduction Penetrating TBI only accounts for 10-12% of the patients with TBI. Penetrating TBI has a high rate of mortality accounting for 40% of TBI deaths. We developed a large animal model in swine using penetrating ballistic-like brain injury (PBBI) to determine the consequences of increasing magnitudes of injury. Methods Experiments were conducted on sexually mature male miniature swine randomly assigned to varying magnitudes of PBBI injury. Injury was induced employing the PBBI methods developed by Tortella et al in rodents. Following a craniectomy placement of an inflatable intracranial probe allowed creation of cavitational injuries of 0% (surgical control; n = 5), ~0.1 (probe only; n = 4), 2.5% (n = 4) and 5% (n = 3) of the estimated brain volume. Animals were instrumented and followed for 6 hours after injury. Physiological measurements were obtained throughout the experiment and blood samples taken at predetermined time intervals. The size of the cavitational injury was determined histologically and tissue damage by immumohistological staining only on animals surviving the experimental duration. Values are mean ± SEM and differences were determined by AVOVA, $p < 0.05$. Results In response to increasing injury ICP at 60min increased by 31± 18.2%, 199 ± 62% and 132 ± 31% for 0, 2.5 and 5% injuries, respectively. These increases did not persist for the duration of the experiment. There were no sustained differences in MAP, thus CPP was decreased with increasing injury. Cardiac output and heart rate were not significantly altered, nor were blood gases and chemistries. Body mass, brain mass and brain volume were not different between groups. With increasing PBBI total, cavitational and tissue injury volumes increased in a dose dependent manner. The total injury sizes were 38± 11.6, 57± 3.5, and 116 ± 16.7mm2. The cavitational injury progressively represented an increasing amount of the total injury, 29± 11.0, 37 ± 8.3 and 44± 5.8 %. With increasing injury there was a greater region proximal to the caviational injury containing dystrophic, silver-impregnated, neurons, and in glial activation based on GFAP immunopositive cells. Conclusions In a large animal swine model using PBBI we were able to induce injuries of increasing magnitude. These injuries acutely increased ICP, but failed to elicit alterations in cardiovascular hemodynamics. The initial increase in ICP resolved within hours. With increasing PBBI the total volume of injury rose. The contribution of the cavitational injury was increased as PBBI was increased. Thus, in the smaller penetrating wounds the majority of the injury is due to secondary injury and therefore amenable to early interventions to attenuate the volume of the total injury.

5676. Wagner, A., et al. (1996). "Image-guided surgery." International journal of oral and maxillofacial surgery **25**(2): 147-151.

Interventional video tomography (IVT), a new imaging modality, achieves virtual visualization of anatomic structures in three dimensions for intraoperative stereotactic navigation. Partial immersion into a virtual data space, which is orthotopically coregistered to the surgical field, enhances, by means of a see-through head-mounted display (HMD), the surgeon's visual perception and technique by providing visual access to nonvisual data of anatomy, physiology, and function. The presented cases document the potential of augmented reality environments in maxillofacial surgery.

5677. Wagner, A. K., et al. (2000). "Intentional traumatic brain injury: epidemiology, risk factors, and associations with injury severity and mortality." The Journal of trauma **49**(3): 404-410.

BACKGROUND: Intentional injury is associated with significant morbidity and mortality and has been associated with certain demographic and socioeconomic groups. Less is known about the relationship of intentional traumatic brain injury (TBI) to injury severity, mortality, and demographic and socioeconomic profile. The objective of this study was to delineate demographic and event-related factors associated with intentional TBI and to evaluate the predictive value of intentional TBI on injury severity and mortality., METHODS: Prospective data were obtained for 2,637 adults sustaining TBIs between January 1994 and September 1998. Descriptive, univariate, and multivariate analyses were conducted to determine the predictive value of intentional TBI on injury severity and mortality., RESULTS: Gender, minority status, age, substance abuse, and residence in a zipcode with low average income were associated with intentional TBI. Multivariate analysis found minority status and substance abuse to be predictive of intentional injury after adjusting for other demographic variables studied. Intentional TBI was predictive of mortality and anatomic severity of injury to the head. Penetrating intentional TBI was predictive of injury severity with all injury severity markers studied., CONCLUSION: Many demographic variables are risk factors for intentional TBI, and such injury is a risk factor for both injury severity and mortality. Future studies are needed to definitively link intentional TBI to disability and functional outcome.

5678. Wagner, M., et al. (1984). "[Gunshot injuries in peacetime and their therapy]." Schussverletzungen im Frieden und deren Therapie. **362**(4): 275-288.

Between 1976 and 1982 46 patients with gunshot injuries (43 m., 3 f.) were seen at the University of Heidelberg Department of Surgery. Frequent causes of injury in 42 adults (40 m., 2 f.) and 4 children (3 m., 1 f.) were suicide attempts (19) and carelessness in the handling of shotguns (11). Criminal offence was related to nine injuries; no retrospective classification of the event causing the injury was possible in further seven cases. Affected in descending order of frequency were brain and lung (10 each), soft tissue of thigh (9), intraabdominal organs (5), heart (4), liver and bone (3 each), blood vessels (2) and facial skull, penis, buttock, neck and mediastinum (1 each). Six patients suffered from combined injuries, in three cases a combined abdomino-thoracic injury was seen. Whilst suicidal injuries of the skull are related to poor prognosis, other peacetime gunshot wounds are less problematic when compared to military gunshot wounds due to the lower speed of the projectiles. Therapeutic procedures follow the general rules of open treatment of injuries including prophylaxis against tetanus and botulism as well as systemic antibiotic therapy. In general abdominal and abdomino-thoracic gunshot wounds as well as vascular injuries require immediate surgical procedure. In isolated thoracic injuries a conservative approach may be justified depending on the situation. The same rule applies to fractures caused by gunshots.

5679. Wagner, R., et al. (2020). "Pedestrian hit by a car impacted metal pole: reconstructing the head load." International journal of legal medicine **134**(4): 1403-1408.

Fatal head injuries are frequently seen in pedestrians hit by motorized vehicles. In our case, the pedestrian sustained a devastating head injury with skull splitting in the mediosagittal plane. A car collided with a traffic sign causing a bending of the pole. The metal pole hit a man standing close beside it; the man had a head injury severity that is more commonly due to falling objects than due to traffic accidents. Assuming a head mass of 5 kg, simplified calculations yield maximum contact forces of ca. 36 kN exceeding mean parietal fracture forces which are in the order of magnitude of 12.5 kN. The influences of the effective body mass and the horizontal distance between the pole and the pedestrian on maximum contact forces are investigated. High contact forces in our case can be mainly explained by the comparably high impact velocity and by a partial mass transfer of the total car mass to the pole.

5680. Wahid, F. I., et al. (2011). "Pattern of maxillofacial trauma seen at ENT department of a tertiary care hospital." Pakistan Journal of Medical Sciences **27**(5): 1042-1045.

Objective: To determine the pattern of maxillofacial trauma seen at Dept. of Ear, Nose and Throat Head and Neck Surgery of a tertiary care hospital. Methodology: This descriptive study was conducted at the Department of Ear, Nose, Throat (ENT), Head and Neck Surgery, Postgraduate Medical Institute, Lady Reading Hospital, Peshawar from June 2010 to Dec. 2010. It included 108 cases sustaining maxillofacial trauma. The patients of any age and either sex were

included while patients having trauma to other systems besides maxillofacial trauma were excluded from study. The universal rule of ABC (Airway, Breathing, circulation) regarding managing emergency was adopted for all the patients. After stabilizing the patient necessary surgical procedure was performed and concerned departments were consulted. Results: Our study included 108 cases of maxillofacial trauma constituting 97 male and 11 female, with male: female ratio of 8.8:1. The age of the patients ranged from 08-60 years with mean age of 30.55 + S.D 19.88 years. Most of the cases were from rural area (59.3%) and 75 cases (69.4%) were received in first 8 hours of incidence. Fire arm injuries 42% was on top followed by road traffic accidents 25% (n=27). Majority of cases (90.7%) were homicidal and mandiblular fracture was 49.07% followed by maxillary fractures. Conclusion: It is concluded that homicidal firearm injury is the commonest while road traffic accident is second most common causative factor for maxillofacial trauma. These can be minimized by proper implementation of traffic rules, free education of the people, free availability of essential primary health care, best tertiary care at hospital level and spread of weapon amongst public should be banned.

5681. Wahlig, J. B., et al. (1999). "The role of xenon-enhanced computed tomography in the management of a traumatic carotid-cavernous fistula: case report." The Journal of trauma **46**(1): 181-185.

5682. Wahyudi, et al. (2021). "An extremely rare case: Transorbital penetrating intracranial injury by wooden foreign body. Case report." Annals of Medicine and Surgery **71**.

Introduction and importance: Transorbital Penetrating Intracranial Injury (TOPI) is a rare case, but those caused by Wooden Foreign Body are even challenging that may pose unusual diagnostic and surgical challenges. Case presentation: we presented a TOPI following a wood penetrated to the left temporal fossa region via orbital roof due to struck the tree branches while got a motor vehicle accident. The patient was fully conscious with decreased visual acuity in the left eye and left ophthalmoplegia. Non-contrast CT scan showed the linear-shaped foreign body, air mimicking that penetrated medial orbit plane to the left temporal fossa. Clinical discussion: The surgery was performed with a temporobasal approach and revealed good results with only mild ophthalmologic complications without long-term fatal complications (1-year followed-up). Conclusion: early removal of wooden foreign body that penetrates to the intracranial via transorbital is mandatory and should be involved multidisciplinary approach to get the optimal result and avoid the fatal complication both neurologically or ophthalmologically.

5683. Walcott, B. P., et al. (2014). "Time interval to surgery and outcomes following the surgical treatment of acute traumatic subdural hematoma." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **21**(12): 2107-2111.

Although the pre-surgical management of patients with acute traumatic subdural hematoma prioritizes rapid transport to the operating room, there is conflicting evidence regarding the importance of time interval from injury to surgery with regards to outcomes. We sought to determine the association of surgical timing with outcomes for subdural hematoma. A retrospective review was performed of 522 consecutive patients admitted to a single center from 2006-2012 who underwent emergent craniectomy for acute subdural hematoma. After excluding patients with unknown time of injury, penetrating trauma, concurrent cerebrovascular injury, epidural hematoma, or intraparenchymal hemorrhage greater than 30 mL, there remained 45 patients identified for analysis. Using a multiple regression model, we examined the effect of surgical timing, in addition to other variables on in-hospital mortality (primary outcome), as well as the need for tracheostomy or gastrostomy (secondary outcome). We found that increasing injury severity score (odds ratio [OR] 1.146; 95% confidence interval [CI] 1.035-1.270; p=0.009) and age (OR1.066; 95%CI 1.006-1.129; p=0.031) were associated with in-hospital mortality in multivariate analysis. In this model, increasing time to surgery was not associated with mortality, and in fact had a significant effect in decreasing mortality (OR 0.984; 95%CI 0.971-0.997; p=0.018). Premorbid aspirin use was associated with a paradoxical decrease in mortality (OR 0.019; 95%CI 0.001-0.392; p=0.010). In this patient sample, shorter time interval from injury to surgery was not associated with better outcomes. While there are potential confounding factors, these findings support the evaluation of rigorous preoperative resuscitation as a priority in future study.

5684. Walcott, B. P., et al. (2012). "Bilateral hemicraniectomy in non-penetrating traumatic brain injury." Journal of neurotrauma **29**(10): 1879-1885.

Traumatic brain injury is a heterogeneous entity that encompasses both surgical and non-surgical conditions. Surgery may be indicated with traumatic lesions such as hemorrhage, fractures, or malignant cerebral edema. However, the neurological exam may be clouded by the effects of medications administered in the field, systemic injuries, and inaccuracies in hyperacute prognostication. Typically, neurological injury is considered irreversible if diffuse loss of grey/white matter differentiation or if brainstem hemorrhage (Duret hemorrhage) exists. We aim to characterize a cohort of patients undergoing bilateral hemicraniectomy for severe traumatic brain injury. A retrospective consecutive cohort of adult patients undergoing craniectomy for trauma was established between the dates of January 2008 and November 2011. The primary outcome of the study was in-hospital mortality. Secondary outcomes were ICU length of stay, surgical complications, and Glasgow Outcome Score at most recent follow-up. During the study period, 210 patients undergoing craniectomy for traumatic mass-occupying lesion (epidural hematoma, subdural hematoma, or parenchymal contusion) were analyzed. Of those, 9 met study criteria. In-hospital mortality was 67% (6 of 9 patients). The average ICU length of stay was 12 days. The GOS score was 3 in surviving patients. Bilateral hemicraniectomy is a heroic intervention for patients with severe TBI, but can be a life-saving procedure.

5685. Waldbaur, H. and P. Thierauf (1985). "[Intracranial late abscesses following injuries caused by grenade splinters]." Intrakranielle Spatabszesse nach Granatsplitterverletzungen. **46**(4): 354-359.

On the basis of 6 cases of late cerebral abscesses after lesions caused by shell-splinters treated by us, clinic, diagnostics and therapy of this complication are discussed in detail. In 3 patients there were no direct relations between the splinters and the abscesses so that further factors (age, vascular wall changes, and the like) must play a role in the formation of the abscesses; such vascular wall fibroses were found histologically in 3 of the examined abscess capsules. In 3 cases the bacteriological identification of the pathogens was possible. The treatment was carried out by employing puncture or extirpation or the combination of the two methods.

5686. Walder, B., et al. (2012). "Severe traumatic brain injury in a high income country: A population-based prospective cohort study." Intensive care medicine **38**: S14.

INTRODUCTION. In high income countries only few epidemiological studies on severe traumatic brain injury (TBI) are available, and these few studies have different designs. Severe traumatic brain injury is a high burden for society. OBJECTIVES. To describe characteristics and the outcome of patients with severe TBI in a national cohort of a high income country. METHODS. The study included adults sustaining severe traumatic brain injury (TBI) from blunt or penetrating trauma with an Abbreviated Injury Scale score of the head region (HAIS)>3 admitted to all eleven French and German speaking trauma centres in Switzerland. The follow-up lasted 1 year. Start of inclusion was May 2007; last follow-up was in April 2011. Outcome measures were Glasgow Coma Scale (GCS) at 14 days, mortality, Extended Glasgow Outcome Score (GOSE) and Neurobehavioral rating scale-revised (NBRS-R) at 3, 6 and 12 months. Descriptive statistics were performed. RESULTS. 1012 potential patients were screened for inclusion; 922 patients were included (74.1 % men). The incidence rate was 8.5 per 100,000 population. Median age was 55 years [inter quartile range 33, 71] with two age peaks (20-29.9, 60-69.9 years). Median GCS at scene was 9 [4, 14] and 5 [3, 14] in the emergency department. Both pupils were reactive in 73.7 % at scene and 72.3 % in the emergency department. Among all TBI, 95.7 % were blunt trauma. Injury Severity Score was 25 [20, 34], and 30.7 % of patients had multiple trauma. Falls were the mechanism in 52.6 %, road traffic accidents in 32.3 % (most were car divers, pedestrians and cyclists). Median arrival time (h:min) to the hospital for direct admission was 00:46 [00:35, 01:01], for indirect admission 3:12 [2:15, 4:20]; 44.1 % were intubated on scene. Hematoma evacuation was performed in 23.7 %, intraventricular drainage in 8.0 % and intracranial monitoring in 19.1 %. Median ICU stay was 9 days [4,20], hospital stay was 11 days [6, 21]; SAPS 2 Score 44 [29, 57]. Death rate was 30.3 %; median time to death was 2 days [1,6]; most deaths occurred during early ICU stay. Median GCS of survivors at 14 days was 15 [14, 15]. Median GOSE of survivors at 3 months was 5 [3, 7], at 6 months 6 [4, 8] and at 12 months 7 [5, 8]. Median NBRS-R of survivors at 3 months was 32 [29, 37], at 6 months 31 [28, 35], and at 12 months 30 [27, 35]. CONCLUSIONS. This population-based prospective cohort study included older patients and more falls compared to earlier studies in other European countries. High rates of cyclists and pedestrians with severe TBI were observed in the population with road traffic accidents. Most survivors were conscious at 14 days. GOSE increased slightly over a period of 1 year.

5687. Waldman, H. B. (1996). "Almost 19 million childhood injuries result in 11 thousand deaths." ASDC journal of dentistry for children **63**(1): 54-59.

Details are provided from a series of government and private agency reports on the accidents and related deaths of children and the effectiveness of efforts being made to reduce the incidence of these tragedies. In 1992 there were 83,000 accidental deaths and more than 17 million disabling injuries in the United States costing $399 billion. The death rate was down 10 percent from 1991, and also the lowest recorded in recent years. Included in these statistics are 19 million injured children and 11 thousand dead children. The leading cause of death of children less than ten years of age was an unintentional injury. The author presents details on the accidents and related deaths, as well as the effectiveness of efforts to reduce the incidence of these accidents. From the youngest ages to the teen years, a greater number of males than females are injured and die from accident-related causes. The number of accidental deaths of children, ages five to nine years, almost equalled the number of deaths from natural causes. For children ten to fourteen years old, the number of accidental deaths was one third greater than the number from natural causes. Statistics regarding death and injury from motor vehicles, firearms, consumer products, and poison are presented.

5688. Walid, M. S., et al. (2009). "Penetrating orbital trauma with internal carotid injury." Southern medical journal **102**(1): 116-117.

5689. Walker, M. L., et al. (1990). "Principles of management of shotgun wounds." Surgery, gynecology & obstetrics **170**(2): 97-105.

As an instrument of close range combat, the shotgun has no parallel. At short distances, its destructive capacity parallels that seen from high velocity missile injury. In this study, the history of the shotgun, wound ballistics, principles of initial therapy and special management problems related to shotgun wounds of specific sites are reviewed. An analysis of pooled data on abdominal shotgun wounds is presented. A subset of patients who do not require abdominal exploration exists. Specific problems encountered in defining this subset are enumerated. Three algorithms are presented that summarize our current management approach to shotgun wounds of the torso and extremities.

5690. Walker, P., et al. (2018). "Traumatic Brain Injury in Combat Casualties." Current Trauma Reports **4**(2): 149-159.

Purpose of Review: The purpose of this review is to give an overview of recent updates in the management of traumatic brain injury (TBI) in military settings. Recent Findings: Studies from the recent conflicts in Central and Southwest Asia have demonstrated that appropriate aggressive neurosurgical intervention in austere settings has been associated with improved outcomes. Summary: Modern management of military TBI has evolved from the era of Cushing in WWI to damage control and rapid aeromedical evacuation today. Aggressive management of severe injuries has been shown to increase survival. These interventions have included an emphasis on measures to reduce secondary brain injury—aggressive cranial decompression, addressing intracranial vascular injuries, and aeromedical evacuation to facilities with neurosurgical capability. Additionally, advances in the screening of mild TBI have led to increased awareness of the prevalence of this injury and potential associated long-term effects.

5691. Walker, P. F., et al. (2020). "Outcomes of tranexamic acid administration in military trauma patients with intracranial hemorrhage: a cohort study." BMC emergency medicine **20**(1): 39.

BACKGROUND: Tranexamic acid (TXA) may be a useful adjunct for military patients with severe traumatic brain injury (TBI). These patients are often treated in austere settings without immediate access to neurosurgical intervention. The purpose of this study was to evaluate any association between TXA use and progression of intracranial hemorrhage (ICH), neurologic outcomes, and venous thromboembolism (VTE) in TBI., METHODS: This was a retrospective cohort study of military casualties from October 2010 to December 2015 who were transferred to a military treatment facility (MTF) in the United States. Data collected included: demographics, types of injuries, initial and interval head computerized tomography (CT) scans, Glasgow Coma Scores (GCS), and six-month Glasgow Outcome Scores (GOS). Results were stratified based on TXA administration, progression of ICH, and VTE., RESULTS: Of the 687 active duty service members reviewed, 71 patients had ICH (10.3%). Most casualties were injured in a blast (80.3%), with 36 patients (50.7%) sustaining a penetrating TBI. Mean ISS was 28.2 +/- 12.3. Nine patients (12.7%) received a massive

transfusion within 24 h of injury, and TXA was administered to 14 (19.7%) casualties. Patients that received TXA had lower initial reported GCS (9.2 +/- 4.4 vs. 12.5 +/- 3.4, p = 0.003), similar discharge GCS (13.3 +/- 4.0 vs. 13.8 +/- 3.2, p = 0.58), and a larger improvement between initial and discharge GCS (3.7 +/- 3.9 vs. 1.3 +/- 3.1, p = 0.02). However, there was no difference in mortality (7.1% vs. 7.0%, p = 1.00), progression of ICH (45.5% vs. 14.7%, p = 0.09), frequency of cranial decompression (50.0% vs. 42.1%, p = 0.76), or mean GOS (3.5 +/- 0.9 vs. 3.8 +/- 1.0, p = 0.13). Patients administered TXA had a higher rate of VTE (35.7% vs. 7.0%, p = 0.01). On multivariate analysis, however, TXA was not independently associated with VTE., CONCLUSIONS: Patients that received TXA were associated with an improvement in GCS but not in progression of ICH or GOS. TXA was not independently associated with VTE, although this may be related to a paucity of patients receiving TXA. Decisions about TXA administration in military casualties with ICH should be considered in the context of the availability of neurosurgical intervention as well as severity of extracranial injuries and need for massive transfusion.

5692. Walker, W., et al. (2014). "The influence of penetrating vs closed type of traumatic brain injury on long-term global outcome." Brain injury **28**(5-6): 689.

Objectives: Well-validated predictors of poor global outcome after TBI include advanced age, low education, unemployment, long duration of post-traumatic amnesia (PTA) or coma (LOC) and longer hospitalization. Type of TBI, penetrating vs closed, is also believed important. Higher rates of early mortality, medical and neurologic complications are reported after penetrating TBI as are worse headache density and high seizure rates. However, information is lacking on the effect TBI type has on global long-term outcome. A recent review determined that nearly all studies of prognostic factors within civilian samples either exclude or under-represent patients with penetrating injuries. This study sought to understand the influence of injury type on TBI outcome within the NIDDR-funded TBI Model Systems (TBIMS) whose very large cohort size facilitates examining low frequency conditions. It was hypothesized that penetrating TBI increases the risk of poorer long-term global outcome when adjusting for known risk factors. Methods: Study design was a prospective multi-centre cohort study with retrospective data abstraction. All participants: (1) presented to the TBIMS acute care hospital within 72 hours of injury; (2) received both acute medical and acute rehabilitation care; (3) sustained TBI with at least admission Glasgow Coma Scale (GCS) score<13, LOC>30 minutes, PTA>24 hours or trauma-related intracranial abnormality on neuroimaging; and (4) age>15 years. Penetrating TBI was defined by either gun-shot wound injury mechanism and/or skull fragments on imaging. The final sample with complete data sets was 4982 patients. Outcome measure was the Glasgow Outcome Scale (GOS) 2 years post-injury. Dead and vegetative categories due to very low counts were collapsed into severe disability. A multiple cumulative logistic regression model was built using significant predictors identified on preliminary bivariate analyses. Manual backwards selection ($p<0.05$) was used to reduce the model and identify a parsimonious set of predictors for GOS. All two-way interactions were also considered. Results: Penetrating type TBI was 8.1% of the cohort. The final model identified the following predictors: injury type, age, sex, race/ ethnicity, pre-injury education level and employment, LOS and PTA duration. Injury type also had significant secondary interactions with employment and age. The odds of lower (worse) 2-year GOS were greater for individuals with penetrating TBI who were younger (45 or less) and employed pre-injury. A 20 year old individual employed preinjury is 2-times (95% CI=1.5, 2.8) more likely to have a lower GOS category; a 30 year old employed individual is 1.8-times (95% CI=1.4, 2.2) more likely. Conclusions: Global outcome 2 years after TBI is worse for penetrating compared to closed type, with the largest effect for younger persons employed pre-injury. Prognostication models and counselling should consider differing outcomes for type of TBI.

5693. Walker, W. C., et al. (2012). "Prediction of the functional impact of headache after traumatic brain injury: A longitudinal cohort analysis." PM and R **4**(10): S185.

Objective: Measure the functional impact of headache (HA) after moderate-severe traumatic brain injury (TBI), determine predictors, and assess for change over time. Design: Multicenter longitudinal cohort study. Setting: Subjects were enrolled during acute inpatient rehabilitation hospitalization following TBI. Participants: 450 participants with moderate-severe TBI consecutively enrolled at 7 participating TBI Model Systems (TBIMS) centers. Inclusion criteria were the same as for the TBIMS. Interventions: n/a. Main Outcome Measures:: Functional impact was a 5-level ordinal measure of the degree that HA interfered with activities of daily living (ADL). Results: Data was analyzed using a generalized linear mixed effects model. Sex was the only variable that showed a significant effect of change in ADL limitations from HA over time. At 3 months after TBI sex was not related to outcome, at 6 months there was a nonsignificant trend toward more HA related ADL impairment in females, whereas at 12 months females were

significantly more likely to have HA related ADL impairment (odds ratio 2.64 (P<.05, CI = 1.33, 5.24)). Multiple factors, including skull/facial fractures, penetrating TBI, female gender, and pre-injury HA, were significantly associated with ADL impairment from HA at various time points. However, severity of injury as measured by PTA duration was not predictive of outcome at any time point. Conclusions: These results corroborate past studies in showing that HA after TBI is both unrelated to severity of injury, and is more of a "problem" for females compared to males. Additionally, the current study showed that the influence sex had on ADL limitation from HA changed over time. At early time-points females and males were equally susceptible to having HA that limited ADLs. However, females become increasingly more susceptible to having HA that limits ADLs as the first post-injury year progresses.

5694. Walker, W. C., et al. (2015). "Global Outcome and Late Seizures After Penetrating Versus Closed Traumatic Brain Injury: A NIDRR TBI Model Systems Study." The Journal of head trauma rehabilitation **30**(4): 231-240.

BACKGROUND: If and how much dural penetration influences long-term outcome after traumatic brain injury (TBI) is understudied, especially within the civilian population., OBJECTIVES: Using the large TBI Model Systems cohort, this study assessed and compared penetrating TBI (PTBI) and closed TBI with respect to global outcome and late seizures 2 years after injury., METHODS: After performing unadjusted PTBI versus closed TBI comparisons, multivariate regression models were built and analyzed for both outcomes by including the following additional predictors: length of unconsciousness, posttraumatic amnesia duration, hospital length of stay, age, gender, race, marital status, education level, problem substance abuse, and preinjury employment status., RESULTS: The collapsed Glasgow Outcome Scale model (n = 6111) showed significant secondary effects of PTBI with employment status. When employed before injury, individuals with PTBI were 2.62 times more likely (95% confidence interval, 1.92-3.57) to have a lower Glasgow Outcome Scale category. The final model for late seizures (n = 6737) showed a significant main effect for PTBI. Adjusting for other predictors, individuals with PTBI were 2.78 times more likely (95% confidence interval, 1.93-3.99) than those with closed TBI to be rehospitalized for a seizure., CONCLUSION: This study empirically demonstrates that penetrating injury mechanism has important prognostic implications.

5695. Walker, W. C., et al. (2012). "Predictors of headache density after traumatic brain injury." Brain injury **26**(4-5): 740.

Objective: To determine if a specific set of variables are predictive of headache (HA) density at 3, 6, and/or 12 month post traumatic brain injury (TBI). Methods: Design was a prospective cohort study. The sample was 450 participants from the TBI Model System and HA Module Database admitted to inpatient rehabilitation between February 2008 and June 2009 and receiving a specially designed HA questionnaire. A HA frequency-duration index was created by multiplying frequency of HA and length of HA episode (using the midpoint of the response category) into hours of HA per time period. HA intensity (scale of 0-10) was split into 4 ordinal categories: (1,2), (3,4,5), (6,7,8), and (9,10), in addition to the category of no headache (0). The frequency-duration index was split into 4 ordinal categories and the 16 combinations of frequencyduration and HA intensity were assigned to one of six categories: none, minimal, mild, moderate, severe, and extreme. Thus, the primary outcome measure was the 6-level ordinal HA Density Index that simulated a pain diary summary rating. A generalized linear mixed-effects model was used to model the 6-level ordinal outcome as a function of time, sex, pre-injury history of HA (none, nonmigraine, migraine), limitations due to HA, type of TBI (penetrating, closed), evidence of any skull, spine, or face fractures, and time in post-traumatic amnesia (PTA). Results: At three months post-TBI, history of preinjury HA was the only significant predictor of HA density. The odds of more severe HAs post- TBI were greater for those with a pre-injury history of migraine HAs (odds ratio [OR]=10.38, 95% confidence interval [CI]=1.99, 54.02) or non-migraine HA (OR=4.12, 95% CI=1.62, 10.46) versus with no history of HA. At six months post-TBI, history of pre-injury HA, sex, and type of TBI were significant predictors of HA density. The odds of more severe HAs post-TBI were greater for females versus males (OR=2.59, 95% CI=1.31, 5.13), for those with a pre-injury history of migraine HA (OR=10.11, 95% CI=2.20, 46.54) or non-migraine HA (OR=3.20, 95% CI=1.25, 8.20) versus no history of HA, and for those with penetrating versus closed injuries (OR=4.14, 95% CI=1.13, 15.17). Finally, at twelve months post-TBI, the odds of a more severe HA post-TBI were greater for those with a pre-injury history of migraine HA versus no history of HA (OR=8.66, 95% CI=1.62, 45.96). Conclusion: Sex, pre-injury history of HAs, and TBI type were significant predictors of the severity of post-injury HA density. Females, those with preinjury HAs, and penetrating injuries were at the greatest risk for more severe HAs in the year following TBI.

5696. Walker, W. C., et al. (2013). "Prediction of headache severity (density and functional impact) after traumatic brain injury: A longitudinal multicenter study." Cephalalgia : an international journal of headache **33**(12): 998-1008.

BACKGROUND: Headache (HA) following traumatic brain injury (TBI) is common, but predictors and time course are not well established, particularly after moderate to severe TBI., METHODS: A prospective, longitudinal cohort study of HA severity post-TBI was conducted on 450 participants at seven participating rehabilitation centers. Generalized linear mixed-effects models (GLMMs) were used to model repeated measures (months 3, 6, and 12 post-TBI) of two outcomes: HA density (a composite of frequency, duration, and intensity) and HA disruptions to activities of daily living (ADL)., RESULTS: Although HA density and ADL disruptions were nominally highest during the first three months post-TBI, neither showed significant changes over time. At all time points, history of pre-injury migraine was by far the strongest predictor of both HA density and ADL disruptions (odds ratio (OR) = 8.0 and OR = 7.2, averaged across time points, respectively). Furthermore, pre-injury non-migraine HA (at three and six months post-TBI), penetrating-type TBI (at six months post-TBI), and female sex (at six and 12 months post-TBI) were each associated with an increase in the odds of a more severe HA density. Severity of TBI (post-traumatic amnesia (PTA) duration) was not associated with either outcome., CONCLUSION: Individuals with HA at three months after moderate-severe TBI do not improve over the ensuing nine months with respect to HA density or ADL disruptions. Those with pre-injury HA, particularly of migraine type, are at greatest risk for HA post-TBI. Other independent risk factors are penetrating-type TBI and, to a lesser degree and post-acutely only, female sex. Individuals with these risk factors should be monitored and considered for aggressive early intervention.

5697. Wallace, et al. (2017). "Safety and effectiveness of preoperative endovascular vertebral artery sacrifice." Journal of neurointerventional surgery **9**: A45.

Background and Purpose Endovascular vertebral artery sacrifice is performed to facilitate surgical resection of cervical spine tumors that encase or are in close proximity the vertebral artery, other surgeries that necessitate vertebral artery transection active extravasation or delayed pseudoaneurysm secondary to penetrating trauma or deceleration injury. Herein, we report our experience with this procedure. Materials and Methods Institutional review board approval was obtained to retrospectively review the neurointerventional databases of a tertiary medical center for all cases of endovascular vertebral artery sacrifice performed between January 2003 and December 2016. Demographic information, clinical history, and outcomes were collected from electronic medical records. Procedural details and periprocedural complications were collected from operative reports. Preoperative digital subtraction angiography (DSA) was reviewed for details of vertebral artery anatomy. Results During the study period, 15 unilateral endovascular vertebral artery occlusions were performed. The cohort included 10 men and 5 women with a mean age of 55 years (range, 18-82 years). Indications for the procedure included preoperative vertebral artery sacrifice prior to cervical tumor resection (80%; 12/15), surgical fixation of a C4-C5 fracture subluxation associated with an occlusive vertebral artery dissection, surgical removal of a misplaced central line, and delayed pseudoaneurysm after gunshot trauma. The vertebral arteries were codominant in 73% (11/15) of cases. The non-dominant vertebral artery was occluded in 20% (3/15) of cases. The dominant vertebral artery was occluded in one case in which the contralateral vertebral artery measured 3 mm in maximum diameter. Prior to endovascular occlusion, the vertebral arteries were patent and normal caliber (47%; 7/15), patent but narrowed (47%; 7/15), and occluded in 1 case. Successful endovascular occlusion was achieved in 93% (13/14) of cases performed prior to surgical transection of the target artery. The mean diameter of the occluded vertebral artery segment was 3.3 mm (range, 1.7-5.7 mm). The vertebral arteries were most commonly occluded using coils (53%; 8/15) or a combination of coils and Micro Vascular Plugs (33%; 5/15; Medtronic; Plymouth, MN). One vertebral artery was occluded with a combination of coils and an Amplatzer Vascular Plug (Medtronic; Plymouth, MN) and 42 coils (patient 11), and one was occluded with 5 Micro Vascular Plugs (patient 13). The mean numbers of coils used without and with vascular plugs were 23 (range, 6-33) and 9 (range, 4-13), respectively. The mean number of Micro Vascular Plugs used in combination with coils was 2.9 (range, 1-5). Antecedent temporary balloon occlusion testing to confirm filling of the basilar artery and ipsilateral posterior inferior cerebellar artery from the contralateral vertebral artery was performed in four cases using a 7 × 7 mm (3 cases) or 4 × 7 mm (1 case) HyperForm balloon. In each of these cases the balloon was also used to arrest antegrade flow during occlusion. Five patients (33%; 5/15) received aspirin postoperatively. There were no procedure-related complications. Conclusion Endovascular vertebral artery sacrifice is a safe and effective treatment for minimizing blood loss during surgeries that involve transection of the vertebral artery.

5698. Wallace, M. N. and S. K. Bisland (1994). "NADPH-diaphorase activity in activated astrocytes represents inducible nitric oxide synthase." Neuroscience **59**(4): 905-919.

In paraformaldehyde-fixed sections of healthy brain, glial cells at the light-microscope level do not contain measurable levels of NADPH-diaphorase. However, after a variety of lesions in the mouse brain, some reactive astrocytes express varying amounts of this enzyme. Following stab wounds, activated astrocytes or related glial cells surrounding the lesion, contained moderate to high levels of NADPH-diaphorase in the cerebellum, midbrain, thalamus, striatum, hippocampal formation and neocortex. Double-labelling experiments confirmed that this corresponds to an inducible form of nitric oxide synthase, similar to that found in activated macrophages. Within the lesion there were large numbers of macrophages which also contained NADPH-diaphorase. After 10 min of global hypoxic ischaemia, some reactive astrocytes also contained NADPH-diaphorase. These cells were confined to the dorsal part of the hippocampal formation (the dentate fascia and CA1 areas) and to the anterolateral striatum. More focal ischaemic damage, produced by dividing an arterial branch, also produced a rim of reactive astrocytes containing NADPH-diaphorase, that surrounded the area of necrosis. Low levels of NADPH-diaphorase were induced within one day of a stab wound and the enzyme activity reached near maximal levels by two days postlesion. Moderate NADPH-diaphorase activity was still present at 63 days postlesion, but only a small number of astrocytes were stained in the immediate vicinity of the lesion. These experiments confirm that NADPH-diaphorase activity represents inducible nitric oxide synthase in activated astrocytes and probably in inflammatory macrophages. We conclude that a high proportion of activated astrocytes and a small proportion of invading macrophages are induced to express moderate to high levels of nitric oxide synthase following neuronal damage. Our results indicate that following a variety of lesions reactive astrocytes are synthesizing significant levels of nitric oxide within 24 h. This nitric oxide may be involved in modulating the likelihood of epileptic seizures.

5699. Wallace, P. B. and A. M. Meirowsky (1960). "The repair of dural defects by graft. An analysis of 540 penetrating wounds of the brain incurred in the Korean War." Annals of surgery **151**: 174-180.

5700. Waller, J. A., et al. (1993). "Potential availability of transplantable organs and tissues in fatalities from injury and nontraumatic intracranial hemorrhage." Transplantation **55**(3): 542-546.

Study of all Vermont and urban Rhode Island trauma fatalities for 1987, and all fatalities in these states from nontraumatic intracranial hemorrhage for 1986 and 1987, identified few potential donors for asystole-sensitive organs, such as heart, lungs, liver, pancreas, and kidneys. It is estimated that nationally there is a maximum potential of about 5000 cadavers per year from these two sources that meet screening criteria for age, duration of survival after event, brain death, and absence of organ damage or important disease. This would yield up to 5000 hearts, livers, and pancreases, perhaps 5-6000 lungs, and up to 10,000 kidneys. However, for tissues that have longer postdeath viability it is estimated that annually at least 60,000 eyes, 22,000 heart valve sets, 29,000 donations of 2 or more long bones per cadaver, and 36,000 skin donations are potentially available from these sources.

5701. Waller, S. G., et al. (1993). "Retrobulbar anesthesia risk. Do sharp needles really perforate the eye more easily than blunt needles?" Ophthalmology **100**(4): 506-510.

PURPOSE: Conventional wisdom in ophthalmology is that the force required to perforate an eye during retrobulbar injection is noticeably greater with a specially designed blunt needle than with a standard hypodermic needle. A search of the literature showed no measurements of scleral perforation pressure with specific needle tips. The authors investigated this concept., METHODS: A computerized search for eye perforations of the surgical records over a 5-year period at Wilford Hall United States Air Force Medical Center was conducted. A double-masked trial by experienced ophthalmologists, using preserved eye bank eyes and several commercially available needles, subjectively assessed the force required to perforate the globe. The authors designed and built a portable transducer system to objectively measure the perforation pressure of human globes with the needles. Measurements were done with preserved and unpreserved human cadaver eyes., RESULTS: No globe penetrations or perforations were found in this consecutive series of over 4000 retrobulbar anesthesia procedures. A subjective difference between the hypodermic and blunt needles was detected. Objective measurements showed a significant difference between the hypodermic and blunt needles, and between types of blunt needles. The difference was present with both eye bank eyes and fresh cadaver eyes., CONCLUSIONS: Blunt-tipped needles do require greater force to penetrate the eye. The noncutting edge, blunt-tipped needles have higher scleral perforation pressures than those with cutting edges.

5702. Walter, A., et al. (2022). "Association of White Matter Microstructural Integrity and Short-Term Outcomes After Traumatic Brain Injury." Brain injury **36**(SUPPL 1): 95.

Objectives: Traumatic brain injury (TBI) is a heterogenous disease that can have a wide range of outcomes post-injury. These outcomes can vary both in their presentation and temporal pattern, making effective treatment and rehabilitation challenging. Diffusion tensor imaging (DTI) can characterize the microstructural properties of white matter post-injury however, the precise relationship between DTI abnormalities and outcomes is not fully understood. The aim of this analysis was to identify microstructural abnormalities in neuroanatomically defined brain regions that are most contributing to cognitive and functional outcomes. Methods: Forty-four patients with non-penetrating TBI (mean [SD] age: 35.6 [16.6] years, 80% male, 52% white, median GCS: 15 (IQR: 14-15)) were enrolled within 24 hours of admission to our Level 1 Trauma Center. Participants underwent a research 3 T MRI that included a DTI sequence and symptom and neuropsychological assessment (Glasgow Outcome Scale - Extended (GOSE); Rivermead Post-Concussion Symptom Questionnaire (RPQ); Rey Auditory Verbal Learning Test (RAVLT); Trail Making Test (TMT) A&B) at 14 ± 2 days postinjury. Diffusion weighted images were preprocessed and registered to the JHU-MNI-ss (Eve) atlas. Mean fractional anisotropy (FA), mean diffusivity (MD), radial diffusivity (RD), and axial diffusivity (AD) were calculated in each region of interest (ROI) and 92 white matter ROIs were then grouped into five neuroanatomical categories: Association, Cerebellar, Commissural, Projection, and Superficial White Matter. Least Absolute Shrinkage and Selection Operator (Lasso) regressions, using cross validation and with sex and age a priori selected into the model, were run to identify which region and corresponding DTI metric most contributed to an outcome of interest. Results: Lasso regressions revealed that for functional rating scale outcomes, GOSE was most explained by AD Cerebellar and FA Projection (MSE = 1.151, R2 = 0.141) while RPQ was most explained by FA Projection, AD Superficial White Matter, and AD Cerebellar (MSE = 100.805, R2 = 0.256). For cognitive outcomes, RAVLT was most explained by FA Cerebellar, AD Commissural, and AD Superficial White Matter (MSE = 114.717, R2 = 0.267), TMT-A was most explained by MD Cerebellar, AD Projection, FA Association, and AD Projection (MSE = 115.427, R2 = 0.549), and TMT-B was most explained by FA Cerebellar, RD Cerebellum, and FA Association (MSE = 1905.616, R2 = 0.503). Conclusions: As TBI can lead to variable symptoms and objective deficits in somatic, affective, and cognitive function, a better insight into the underlying physiology of these outcomes is needed. These findings begin to identify regions of the brain that may contribute to distinct negative outcome patterns post-injury. Additionally, the data suggest cognitive outcomes are more explained by microstructural integrity in distinct white matter regions and that microstructural measures beyond FA and MD may be useful in explaining these outcome patterns. Additional work is needed to further elucidate the relationship between regional white matter damage, specific outcome domains, and the temporal evolution of these abnormalities.

5703. Walter, T., et al. (2016). "Positive outcome after a small-caliber gunshot fracture of the upper cervical spine without neurovascular damage." Polish Journal of Radiology **81**: 134-137.

Background: Gunshot wounds to the cervical spine most frequently concur with serious injuries to the spinal cord and cervical vessels and often have a fatal outcome. Case Report: We describe the case of a 35-year-old male with a complex fracture of the C2 vertebra body and a mandibular fracture after a penetration gunshot to the cervical spine. Computed tomography (CT) at admission revealed the exact extent of the fractures and the small caliber bullet lodged next to the C2 vertebra. In this rare and extremely lucky case no collateral vascular or neurological damage was detected. Eighteen months after surgical bullet removal and posterior C1–C3 fusion complete bone healing of the C2 vertebra was achieved and there were no secondary neurovascular deficits. Conclusions: Immediate surgical C1–C3 fixation resulted in an excellent outcome without secondary neurovascular deficits in this rare case of traumatic complex C2 vertebral fracture caused by a gunshot injury.

5704. Walton, D. N. (1981). "Epistemology of brain death determination." Metamedicine **2**(3): 259-274.

5705. Wan, Y., et al. (2019). "Neurosurgical Care of Nonpowder Firearm Injuries: A Narrative Review of the Literature." Emergency medicine international **2019**.

Background. Nonpowder firearms discharge a projectile using compressed gases. Unlike traditional firearms, there is a perception that nonpowder guns do not cause serious injury. However, intracranial injury disproportionally

affects children and can cause significant neurological disabilities and mortality. Management of nonpowder firearm injuries has received little attention in the literature and presents unique surgical challenges. Materials and Methods. We conducted a narrative review of the literature of the management of nonpowder firearm injuries with particular emphasis on intracranial injury. Results. Modern nonpowder firearms have muzzle velocities which are capable of penetrating the skin, eyes, and bone. Direct intracranial injury commonly results from entrance of projectile through thinner portions of the skull. Operative intervention is needed to debride and safely explore the trajectory to remove fragments which can easily cause neurovascular injury. Conclusions. Neurosurgeons play a crucial role in managing serious nonpowder firearm injuries. A multidisciplinary team is needed to manage the direct results of penetrating injury and long-term sequalae.

5706. Wang, A., et al. (2019). "Orbital and intracranial Nocardia farcinica infection caused by trauma to the orbit: a case report." BMC infectious diseases **19**(1): 953.

BACKGROUND: Localized `and disseminated Nocardia farcinica infection is frequently reported in immunocompromised patients. However, orbital nocardiosis is rare, and, to our knowledge, traumatic orbital nocardiosis that affects the brain has never been described. Here, we report a case of traumatic orbital and intracranial N. farcinica infection in an immunocompetent patient., CASE PRESENTATION: A 35-year-old man, who was immunocompetent, to the best of our knowledge and as per the absence of immunodeficiency symptoms, with orbital trauma caused by the penetration of a rotten bamboo branch developed lesions in the orbit and brain. Subsequently, he underwent debridement and received broad-spectrum antibiotic therapy, but orbital infection occurred, with drainage of pus through the sinus tract. The patient then underwent endoscope-assisted local debridement. Bacterial culture of the sinusal pus was positive for N. farcinica, and a combined intracranial infection had developed. The disease was treated effectively by trimethoprim-sulfamethoxazole and ceftriaxone sodium therapy. The patient remained infection free and without complications at the 14-month follow-up., CONCLUSIONS: Traumatic orbital and intracranial infection caused by N. farcinica is a rare infectious disease, and atypical presentations easily lead to misdiagnosis. When a patient presents with an atypical orbital infection that is unresponsive to empirical broad-spectrum antibiotics, along with suspicious neurologic symptoms, Nocardia infection should be considered. Identification by bacterial culture is the gold standard. Complete local debridement and appropriate antibiotic treatment are keys to the treatment of the disease.

5707. Wang, A.-L., et al. (2020). "Bromide Ions Triggered Synthesis of Noble Metal-Based Intermetallic Nanocrystals." Small (Weinheim an der Bergstrasse, Germany) **16**(40): e2003782.

Ordered intermetallic nanomaterials with a well-defined crystal structure and fixed stoichiometry facilitate the predictable control of their electronic structure and catalytic performance. To obtain the thermodynamically stable intermetallic structures, the conventional approaches with high-temperature annealing are still far from satisfactory, because of annealing-induced aggregation and sintering of nanomaterials. Herein, a general wet-chemical method is developed to synthesize a series of noble metal-based intermetallic nanocrystals, including hexagonal close-packed (hcp) PtBi nanoplates, face-centered cubic (fcc) Pd3 Pb nanocubes, and hcp Pd2.5 Bi1.5 nanoparticles. During the synthetic process, Br- ions play two important roles for the formation of ordered intermetallic structures: i) Br- ions can coordinate with the metal ions to decrease their reduction potentials thus slowing down the reduction kinetics. ii) Br- ions can combine with molecular oxygen to generate an oxidative etching effect, hence reconstructing the atom arrangement, which is beneficial for the formation of the intermetallic structure. As a proof-of-concept application, Pd3 Pb nanocubes are used as electrocatalysts for ethanol and methanol oxidation reactions, which exhibit significantly improved electrochemical performance compared with the commercial Pd black catalyst.

5708. Wang, F., et al. (2004). "[Effect of L-arginine on the changes of cerebral microcirculation following craniocerebral missile wound at early stage in cats]." Sichuan da xue xue bao. Yi xue ban = Journal of Sichuan University. Medical science edition **35**(3): 402-405.

OBJECTIVE: To study the alterations of cerebral microcirculation and the effect of L-Arginine after craniocerebral missile wound (CMW) at early stage in cats., METHODS: The CMW animal model in cat was constructed by Carey method. Altogether 12 mongrel cats with either sex were divided into the CMW group and the L-Arginine treatment group. The caliber (D), velocity (V) and blood flow (Q) of pial microvessels and pathological examination of brain tissue at

10 min before CMW and from 5 min to 5 h after CMW were evaluated in each group., RESULTS: 1. In CMW group, although the Da, Va and Qa of pial arteriole decreased from 5 to 20 minutes, Da and Qa elevated at 90 minutes after CMW. There were no significant changes in the Dv of pial venule, but the levels of Vv and Qv were lower at 5 min and 20 min after CMW. Qv increased from 45 min to 3 h after CMW. The pial venules were in congestion situation. 2. In the L-Arginine treatment group, the pial aterioles persistently dilated after CMW. The blood flow of pial aterioles increased at 20 min after CMW and the higher level lasted 5 h. Similarly, the dilation of pial venules was observed, and the blood flow increased at 20 min after the injury, followed by venules constriction temporarily. 3. Petechial hemorrhage, microthrombosis and nerve cell swelling were found in the cortex on the opposite side of the trauma area. The pathological changes were less severe in the L-Arginine treatment group than those in the CMW group., CONCLUSION: At the early stage after CMW, there are obstructions to cerebral microcirculation, which induce brain ischemia, hypoxia and secondary failure of cerebral function. The mechanism by which L-Arginine alleviates the impaired cerebral microcirculation may lie in the vascular activation of L-Arginine-NO system.

5709. Wang, F., et al. (2004). "[Early-stage changes of caliber and blood flow of cat pial microvessels following craniocerebral missile wound]." Di 1 jun yi da xue xue bao = Academic journal of the first medical college of PLA **24**(8): 888-891.

OBJECTIVE: To investigate the early-stage changes of cerebral microcirculation after craniocerebral missile wound (CMW) in cats., METHODS: Twelve mongrel cats of either sex were used for measuring the caliber (D), velocity (V) and blood flow (Q) of the pial microvessels and observing the vital signs 10 min before CMW and from 5 min to 5 h after CMW. The pathological changes of the brain tissue were also examined., RESULTS: After CMW, the D, V and Q of the pial arteriole decreased within the initial 5 to 20 min, followed by elevation of Da and Qa at 90 min. No significant changes were noted in the Dv of the pial venule but its Vv and Qv remained at low levels., CONCLUSION: After CMW, the Q of microvessels may increase progressively in the areas of concussion, contusion and laceration injuries to induce reperfusion injury following ischemia and hypoxia of the brain tissue resulting from microcirculation disorder caused by the wound.

5710. Wang, H. (2021). "1369TiP A dose exploration study of almonertinib for epidermal growth factor receptor (EGFR)-mutant non-small cell lung cancer (NSCLC) patients with newly diagnosed or recurrent brain/leptomeningeal metastasis (ARTISTRY)." Annals of Oncology **32**: S1038.

Background: Approximately 25 to 40% of patients with NSCLC have brain metastases (BM) and 3% to 4% develop leptomeningeal metastases (LM). Prognosis for patients with NSCLC and BM or LM is dismal, which seriously affects the quality of life and survival of patients. Several therapeutic options have been applied to manage BM or LM. However, the efficacy is limited. More recently, EGFR-TKIs have shown potential as a treatment option for BM or LM NSCLC patients. Almonertinib (HS-10296), a third-generation EGFR tyrosine kinase inhibitor (TKI), efficiently penetrates the blood brain barrier. This study aims to explore the efficacy and safety of different doses of almonertinib in the first-line and second-line treatment of BM or LM NSCLC patients. Trial design: The ARTISTRY study (NCT04778800) was a single-arm, three cohort study. NSCLC patients with EGFR mutations who developed CNS progression are eligible for this study. This trial prepared to enroll approximately 60 patients. For cohort 1, the patients had to have measurable brain lesions and undergone no previous treatment with EGFR-TKI or radiotherapy for brain metastases(n=30). And they will receive oral almonertinib 110 mg/d first and receive 160 mg/d with disease progression in the central nervous system for this group. For cohort 2, the patients had to have LMs confirmed by either CSF cytology or brain MRI and have undergone no previous treatment with EGFR-TKI or radiotherapy for brain metastases(n=10). For cohort 3, the patients have measurable brain lesions whose disease had progressed on first or second-generation EGFR-TKI therapy. For cohort 2 and 3, patients will receive almonertinib 110/160/220 mg/d once daily with a dose-escalation phase if no disease progression was observed in twice consecutive assessments. The primary endpoint is intracranial progression-free survival. Secondary endpoints are progression-free survival, overall survival, intracranial objective response rate, disease control rate, intracranial disease control rate, safety and tolerability. Clinical trial identification: NCT04778800; 3 March 2021. Legal entity responsible for the study: Henan Cancer Hospital. Funding: Jiangsu Hansoh Pharmaceutical Co., Ltd. Disclosure: The author has declared no conflicts of interest.

5711. Wang, H., et al. (2008). "Electrocatalytic mechanism and kinetics of SOMs oxidation on ordered PtPb and PtBi intermetallic compounds: DEMS and FTIRS study." Physical chemistry chemical physics : PCCP **10**(25): 3739-3751.

The electrocatalytic activities and mechanisms of PtPb and PtBi ordered intermetallic phases towards formic acid, formaldehyde and methanol oxidation have been studied by DEMS and FTIRS, and the results compared to those for a pure polycrystalline platinum electrode. While PtPb exhibits an enhanced electrocatalytic activity for the oxidation of all three organic molecules when compared to a Pt electrode, PtBi exhibits an enhanced catalytic activity towards formic acid and formaldehyde oxidation, but not methanol. FTIRS data indicate that adsorbed CO does not form on PtPb or PtBi intermetallic compounds during the oxidation of formic acid, formaldehyde and methanol, and therefore their oxidation on both PtPb and PtBi intermetallic compounds proceeds via a non-CO(ads) pathway. Quantitative DEMS measurements indicate that only CO(2) was detected as a final product during formic acid oxidation on Pt, PtPb and PtBi electrodes. At a smooth polycrystalline platinum electrode, the oxidation of formaldehyde and methanol produces mainly intermediates (formaldehyde and formic acid), while CO(2) is a minor product. In contrast, CO(2) is the major product for formaldehyde and methanol oxidation at a PtPb electrode. The high current efficiency of CO(2) formation for methanol and formaldehyde oxidation at a PtPb electrode can be ascribed to the complete dehydrogenation of formaldehyde and formic acid due to electronic effects. The low onset potential, high current density and high CO(2) yield make PtPb one of the most promising electrocatalysts for fuel cell applications using small organic molecules as fuels.

5712. Wang, H.-f., et al. (2013). "Transoral penetrating craniocerebral injury by a bamboo chopstick in a child." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **20**(5): 746-748.

We present a 3-year-old girl with a transoral injury by a bamboo chopstick penetrating the middle skull base. The features of imaging are described and the management is discussed. The potential for injury to the cavernous sinus is emphasized, even if no there is no hemorrhage on the initial CT scan. Early intracranial infection in relation to penetrating injuries is a factor in planning treatment by craniotomy.

5713. Wang, I. K., et al. (2015). "Comparison of Subdural Hematoma Risk between Hemodialysis and Peritoneal Dialysis Patients with ESRD." Clinical journal of the American Society of Nephrology : CJASN **10**(6): 994-1001.

BACKGROUND AND OBJECTIVES: This study compared the risk of subdural hematoma (SDH) and subsequent mortality in hemodialysis (HD) and peritoneal dialysis (PD) patients with ESRD., DESIGN, SETTING, PARTICIPANTS, & MEASUREMENTS: Claims data were obtained from the National Health Insurance Administration Research Database in Taiwan. This retrospective cohort study comprised 10,136 PD patients and 10,136 HD patients with newly diagnosed ESRD from 1998 to 2010. Patients were matched by propensity score and year of dialysis initiation. Incidence rates and hazard ratios of SDH as well as odds ratios of subsequent 30-day deaths from SDH were evaluated from the date of the first dialysis session to the date when SDH was diagnosed, or the date of renal transplantation, death, withdraw from insurance, or the end of the follow-up period (December 31, 2011)., RESULTS: Median (25th percentile, 75th percentile) follow-up times for SDH events were 3.61 years (1.91, 6.33) and 3.33 years (1.83, 5.66) in the HD and PD cohorts, respectively. The overall SDH incidence rate (95% confidence interval [95% CI]) was 61.4% higher in the HD cohort than in the PD cohort (34.7 [95% CI, 31.4 to 35.4] versus 21.5 [95% CI, 20.2 to 22.9] per 10,000 person-years, with an adjusted hazard ratio of 1.62 [95% CI, 1.17 to 2.33]). Approximately 152 of 253 (60%) of SDH events were associated with trauma. Subsequent 30-day SDH-related mortality was not statistically higher in HD patients than in PD patients (29.1% versus 25.3%; adjusted odds ratio, 1.30; 95% CI, 0.70 to 2.41)., CONCLUSIONS: HD patients have a higher risk of developing SDH than PD patients. Both patient groups have a high risk of mortality. Routine education on fall prevention is needed for dialysis patients.

5714. Wang, J. and H. M. Bartkowski (1997). "Early onset of leptomeningeal cyst with severe brain herniation: report of two cases." Neuropediatrics **28**(3): 184-188.

Leptomeningeal cyst as a rare complication of skull fracture in children is well documented. Most cases occur months or years after the original skull fracture, with characteristic roentgenogram findings. The authors report two cases of leptomeningeal cysts in children less than two years old. The association of hygroma, severe brain injury, increased ICP, and early development of leptomeningeal cyst are discussed. Both patients sustained parietal diastatic skull fracture and developed external brain herniation within 10 days after motor vehicle accidents. Clinically they

presented with seizure, hemiparesis, and an enlarging subgaleal mass over the skull fracture. MRI demonstrated severe underlying brain contusion, hygroma around the fracture site, and brain herniation through the skull fracture. Surgical repair of dural laceration and cranioplasty produced good results. The development of hygroma and increased intracranial pressure might account for the early development of leptomeningeal cysts in these two cases.

5715. Wang, J., et al. (2019). "Virtual reality and integrated crime scene scanning for immersive and heterogeneous crime scene reconstruction." Forensic science international **303**: 109943.

Crime scene reconstruction plays a significant role in crime solving by helping to determine the course of events. Non-invasive, high-resolution measurement and increased insight are always the goal of forensic crime scene documentation. However, entire crime scenes cannot be effectively reconstructed with traditional methods. In this study, we present a portable system that consists of a laser scanner, two hand-held structured light scanners and a low-cost virtual reality (VR) headset with a mobile power supply to conduct multi-angle and omnidirectional three-dimensional spatial data collection of crime scenes. To demonstrate practical use, a real case has been analysed to verify the feasibility and effectiveness of the system. The system accurately obtains information on decedent injuries, possible injury-inflicting tools and on-site traces. Various types of evidence from the crime scene can be jointly studied by three-dimensional visualization to develop a cohesive story. The data are presented via immersive VR rather than displayed on computer screens. The relationship between evidence chains enables us to achieve a complete crime scene reconstruction, using the specialized knowledge of experts and computer-aided forensic tools to analyse the causes of damage and identify suspects. The use of three- dimensional imaging techniques allows a more insightful survey and several useful analyses, such as accurate measurement, relative blood source location determination and injury-inflicting tool comparison.

5716. Wang, J., et al. (2013). "Introducing newtechniques for imaging of metal in gunshotwounds with cranial facial injuries-howdoes it affect management?" Emergency radiology **20**(5): 347.

Purpose/Aim: 1. Review the various imaging modalities used to evaluate gunshot wounds (GSW) with cranial facial injuries 2. Review common patterns of injury, with particular attention to bone fracture patterns in exit and entry wounds 3. Review essential CT findings for a surgeon's knowledge prior to surgery (i.e. ballistic wound path and angles) Background: Firearm-related injuries are the second leading cause of injuryrelated deaths in United States. Fourteen percent of all gunshot-related assaults will result inmaxillofacial injuries. Unfortunately, there has been an increase in the incidence of gunshot wounds to the face. Although gunshot-related craniofacial injuries are still not as common as those to other regions of the body, the incidence rate has been increasing, and thus if the trend continues, mortality rate related to fire arms will exceed the mortality associated with motor vehicle collisions (MVC). Currently MVC are the most common cause of death for maxillofacial injury. Thus, it is critical to recognize maxillofacial injuries early to help expedite management efficiently and effectively. Content Organization: -Parameters used in clinical assessment of GSWwith cranial facial injuries -Review imaging modalities available for assessment including radiographs, ultrasound, MRI and angiography with emphasis on MDCT as exam of choice -Characteristic findings on MDCT in the setting of GSW with focus on location of bullet and bone fragments within the skull, intracranial course of the bullet and skull fractures associated with the GSWImaging examples of various patterns of injury of GSW -Examples of new techniques to reduce artifacts from metal on CT (i.e. Iterative reconstruction, Mono-energetic spectral imaging) -Usefulness and limitations ofMDCT in the setting of determining management and the need for surgical exploration Summary/Conclusion: Major teaching points: -There are characteristic patterns of injuries of GSW with cranial facial injuries -New techniques can help to minimize artifacts from metal foreign bodies -MDCT is the imaging modality of choice for determining appropriate surgical interventions.

5717. Wang, J., et al. (2012). "Direct repair of displaced anterior arch fracture of the atlas under microendoscopy: experience with seven patients." European spine journal : official publication of the European Spine Society, the European Spinal Deformity Society, and the European Section of the Cervical Spine Research Society **21**(2): 347-351.

INTRODUCTION: In general, bony injuries heal well with immobilization when the fractured segments are well apposed in the cases of stable atlas fracture. Osseous nonunion of the displaced anterior arch fracture of the atlas has been reported in the literature. However, there have been no reports published on the treatment of nonunion of the atlas fractures., OBJECTIVE: The objective of this study is to describe a new technique for direct repair of the displaced

anterior arch fracture of the atlas in a minimally invasive manner., METHODS: Seven patients with the atlas fracture were treated by a minimally invasive approach. Reduction of anterior arch fractures was not performed by skull traction and the displacement of fractures was more than 5 mm. Direct autograft was performed under microendoscope to improve union of the anterior arch fractures. Radiographic and CT evaluation of the atlas fractures were performed at 3, 6 and 12 months postoperatively., RESULTS: Seven cases of the atlas fractures (one old and six new fractures) underwent the surgical procedure smoothly without major complications. Total average displacement of the anterior arch fracture was 5.7 mm (range 5-8 mm) before surgery. Of the seven patients, bony union of the fracture developed in six. At latest follow-up, two patients had neck pain associated with movement and limited range of rotational motion., CONCLUSION: Direct repair under microendoscope is a new technique that improves bony union of displaced anterior arch of the atlas fractures.

5718. Wang, M. L., et al. (1992). "A comparison of visual outcome in open-globe repair: succinylcholine with D-tubocurarine vs nondepolarizing agents." Ophthalmic surgery **23**(11): 746-751.

We compared the visual outcome in patients with ocular perforations who received succinylcholine with d-tubocurarine during anesthesia induction, with the visual outcome of those who did not. No statistically significant differences in visual outcome were detected. No extrusion of intraocular contents occurred during induction in either group.

5719. Wang, P., et al. (2022). "PRELIMINARY PHARMACOKINETIC AND PHARMACODYNAMICS (PK/PD) PROFILE OF PERIPHERALLY ADMINISTRATED ANTI-CD47 ANTIBODIES IN A RAT MODEL OF PTBI." Journal of neurotrauma **39**(11-12): A57.

There remains a lack of therapeutic options for traumatic brain injury (TBI)-induced intracerebral hematoma clearance. CD47 is an antiphagocytic cell surface protein involved in hematoma stability. Preclinical stroke models have demonstrated potential for anti-CD47 antibodies in augmenting hematoma clearance. The objective of this study was to evaluate the pharmacokinetic and pharmacodynamics profile of intravenously (i.v.) administrated anti-CD47 antibody following TBI, and potential neuroprotective effects. Anti-CD47 antibody therapy was administered at varying doses intravenously. Blood, urinalysis and extensive diagnostic necropsy were used to evaluate the safety of this antibody. Anti-CD47 antibody concentration in blood and brain lysates was detected using a customized fluorescence-based spectrophotometric assay. Neurological assessment, cerebral edema measurement and immunohistochemistry were used to determine efficacy on mitigating TBIinduced neuropathology. At 2 hrs post-injury, preliminary results showed that anti-CD47 antibody was detected in plasma at 10.37±0.36 ug/ml and was still present in plasma at 72 hrs post-injury at a concentration of 2.41± 0.52 ug/ml. In addition, 32 ng/ml (contralateral) and 55 ng/ml (ipsilateral) were detected in brain lysates. Neurological assessment revealed no change in neurological deficits following anti-CD47 antibody treatment. Blood test and initial necropsy analysis has demonstrated no severe adverse events but additional evaluation is ongoing. These results provide preliminary evidence that peripherally administrated anti-CD47 antibodies following pTBI did not cause severe adverse events and iswell tolerated. While no improvement of neurological deficits was observed, continued analysis of neuropathology will evaluate potential neuroprotective effects and hematoma clearance.

5720. Wang, P., et al. (2014). "Immunotherapeutic efficacy of recombinant Mycobacterium smegmatis expressing Ag85B-ESAT6 fusion protein against persistent tuberculosis infection in mice." Human vaccines & immunotherapeutics **10**(1): 150-158.

The application of immunotherapy in combination with chemotherapy is considered an effective treatment strategy against persistent Mycobacterium tuberculosis (Mtb) infection. In this study, we constructed a novel recombinant Mycobacterium smegmatis (rMS) strain that expresses Ag85B and ESAT6 fusion protein (AE-rMS). Immunization of C57BL/6 mice with AE-rMS generated mainly Th1-type immune responses by strongly stimulating IFN-gamma- and IL-2-producing splenocytes and increasing antigen-specific cytotoxic T lymphocyte (CTL) activity. To test the immunotherapeutic efficacy of AE-rMS, a persistent tuberculosis infection (PTBI) model was established via tail-vein injection of C57BL/6 mice with 1x10(4) colony forming units (CFU) of Mtb strain H37Rv in combination with concurrent chemotherapy drugs isoniazid (INH) and pyrazinamide (PZA). PTBI mice immunized with AE-rMS showed high levels of IFN-gamma secreted by splenocytes and decreased bacteria loads in lung. Treatment with only the anti-tuberculosis

(anti-TB) drugs RFP and INH (RI), decreased bacteria loads to low levels, with the Th1-type immune response further attenuated. Moreover, AE-rMS, when combined with RI treatment, further reduced the bacteria load as well as the pathological tissue damage in lung. Together, these results demonstrated the essential roles of AE-rMS-induced Th1-type responses, providing an effective treatment strategy by combining AE-rMS and RI for persistent TB.

5721. Wang, Q., et al. (2010). "Fatal facial-intracranial impalement injury in an accidental fall from a height: an autopsy case report with a review of the literature." Forensic science international **200**(1-3): e21-24.

Impalement injury to the face and head is of clinical and forensic pathological significance because of its diagnostic pitfalls. This injury often penetrates the orbital, nasal or oral cavity into the skull, but impaling other sites of facial bone is rare. The present case was a rare type of facial-intracranial impalement injury with a direct cerebral arterial laceration. The victim was a 44-year-old man who fell from a height of about 2.5m onto a broken chair and died 6 days later despite surgical treatment. The clinical diagnosis was a 'small abrasion' of the face and 'traumatic intracerebral hemorrhage with intraventricular and subarachnoid hemorrhages' on computed tomography (CT). At autopsy, a small crescent laceration was seen below the right zygomatic region. Intracranial lesions comprised a perforating skull-base fracture, a subarachnoid hemorrhage with laceration of the posterior communication artery, and a massive intraventricular hematoma that involved cerebral injury connected with the skull-base fracture, which were consistent with penetration by a steel tube from the chair. A review of the literature suggested that such severe intracranial-facial impalement injuries are caused by traffic accidents or falls, and the prognosis was poor due to an injury around the brainstem despite an appropriate clinical diagnosis. Furthermore, the present case suggested the difficulty of clinical diagnosis even using CT; thus, a forensic autopsy was necessary to determine the manner and cause of death.

5722. Wang, Q., et al. (2004). "Alterations of myelin basic protein and ultrastructure in the limbic system at the early stage of trauma-related stress disorder in dogs." The Journal of trauma **56**(3): 604-610.

BACKGROUND: The secondary injury and related complications after trauma are still the focus of trauma research. However, whether the remote effects on the central nervous system could be induced by high-energy missile extremity impact remains unclear. Also, the possible biomarker for brain damage in traumatic stress disorder has not been determined., METHODS: Forty-two healthy adult dogs were divided into three groups: the control group (n = 12), the high-speed trauma group (n = 15), and the low-speed trauma group (n = 15). Bilateral thighs of dogs were wounded with a smoothbore 6.2-mm rifle at a speed of 1,368 m/s (1.03-g steel bullet) for the high-speed trauma group and 625 m/s for the low-speed trauma group. The expression of myelin basic protein (MBP) in cerebrospinal fluid (CSF), hypothalamus and hippocampus of the limbic system, and temporoparietal cortex was investigated by enzyme-linked immunosorbent assay and dot-blot analysis. Also, the ultrastructure of the above areas was observed with light and electron microscopy., RESULTS: Neuronal degeneration and nerve fiber demyelination were seen in the hypothalamus and hippocampus in the high-speed trauma group at 8 hours after impact. The MBP level was markedly increased in the CSF ($p < 0.01$) in the two trauma groups, in the hypothalamus of the low-speed trauma group ($p < 0.05$), and in both the hypothalamus and the hippocampus of the high-speed trauma group ($p < 0.01$). The expression of MBP mRNA was also significantly enhanced in these areas at the same time. The increase of MBP content in the CSF was positively correlated with the elevation of MBP concentration in the hypothalamus and hippocampus., CONCLUSION: The hypothalamus and hippocampus of the limbic system in the central nervous system are vulnerable to damage after high-energy missile extremity impact, indicating that it might be one of the important pathologic bases involved in the development of trauma-related complications. Meanwhile, the MBP level in the CSF may be a sensitive biological indicator for brain damage at the early stage of trauma-related stress disorder.

5723. Wang, S.-H., et al. (2021). "Survival after multiple nail gun injuries to the brain, lung, and heart: a case report and a review of the literature." The Journal of international medical research **49**(10): 3000605211049923.

Most nail gun injuries involve the extremities and result from work-related accidents. Injuries to the brain or thorax are relatively rare, and cases with injuries to both regions are even rarer and often lethal. Initial evaluation, resuscitation, and surgical planning can be challenging for emergency physicians and surgeons. We present the details of a man with multiple nail gun injuries to the brain, lung, and heart following a suicide attempt. The patient presented to the emergency department in shock. After immediate resuscitation, emergent sternotomy, and subsequent craniotomy,

he was discharged without significant morbidity. According to the literature, this is the only reported case involving multiple nail gun injuries to the brain, lungs, and heart. The mortality rate of multiple nail gun injuries involving the head and chest is approximately 20%. Rapid evaluation, immediate resuscitation, and appropriate imaging and surgery are crucial for increasing survival and achieving a good prognosis. Emergency sternotomy for cardiac injury is the foremost priority, and the timing of craniotomy depends on the patient's vital sign status and whether brain injury is evident.A preprint of this article is available online: DOI: 10.21203/rs.3.rs-35448/v1.

5724. Wang, T. C., et al. (2020). "Noise induced hearing loss and tinnitus—new research developments and remaining gaps in disease assessment, treatment, and prevention." Brain Sciences **10**(10): 1-11.

Long-term noise exposure often results in noise induced hearing loss (NIHL). Tinnitus, the generation of phantom sounds, can also result from noise exposure, although understanding of its underlying mechanisms are limited. Recent studies, however, are shedding light on the neural processes involved in NIHL and tinnitus, leading to potential new and innovative treatments. This review focuses on the assessment of NIHL, available treatments, and development of new pharmacologic and non-pharmacologic treatments based on recent studies of central auditory plasticity and adaptive changes in hearing. We discuss the mechanisms and maladaptive plasticity of NIHL, neuronal aspects of tinnitus triggers, and mechanisms such as tinnitus-associated neural changes at the cochlear nucleus underlying the generation of tinnitus after noise-induced deafferentation. We include observations from recent studies, including our own studies on associated risks and emerging treatments for tinnitus. Increasing knowledge of neural plasticity and adaptive changes in the central auditory system suggest that NIHL is preventable and transient abnormalities may be reversable, although ongoing research in assessment and early detection of hearing difficulties is still urgently needed. Since no treatment can yet reverse noise-related damage completely, preventative strategies and increased awareness of hearing health are essential.

5725. Wang, W., et al. (2015). "Complex reconstruction of facial deformity and function after severe gunshot injury: One case report." International Journal of Clinical and Experimental Medicine **8**(1): 1427-1433.

In this report, we described clinical outcomes of a multi-stage surgery integrating multiple techniques in restoration of facial morphology and function of a 17-year-old boy with severe gunshot injuries. This multi-stage surgery was applied in treatment of one rare case of gunshot-caused complicated facial deformities involving most parts of the face (labrum, left nose wing, nasal columella, nasal septum, maxillary alveolar process, hard palate, soft palate, bilateral maxillary bones, left zygoma, suborbital bone defects) and clinical efficacy upon restoring facial form and function were retrospectively evaluated. The patient was diagnosed with massive facial defects and deformities caused by gunshot, which led to feeding difficulty, severe articulation disorders and serious facial disfigurement. To reconstruct facial form and restore functions of mastication and articulation, multiple examinations and surgical procedures including mirror imaging, rapid prototyping technique, porous titanium implants, microscopic surgical technique, dental implants, osteomyocutaneous flap, muscular flap, shifting and repairing of adjacent tissue flaps and free bone graft reconstruction were undertaken. Postoperatively, reconstruction of severe facial disfigurement and restoring basic functions including articulation and feeding for the first time and relatively sound clinical outcomes have been obtained, which may add clinical evidence to the treatment of similar cases of severe facial deformities.

5726. Wang, W., et al. (2018). "Free bone segments preservation in the treatment of mandibular fracture caused by gunshot wound: A report of two clinical cases." Journal of Biomaterials and Tissue Engineering **8**(3): 363-365.

Mandibular gunshot wounds can cause serious complications and it’s important to select adequate methods to fix and reconstruct the mandible. Proper debridement and preservation of the scattered bone segments may be a good choice for preventing the bone defect. Here, two cases were reported to share our successful experiences of free bone preservation in the treatment of mandibular fracture due to the gunshot.

5727. Wang, W., et al. (2017). "Long-Term Follow-Up of Flap Prefabrication in Facial Reconstruction." Annals of plastic surgery **79**(1): 17-23.

BACKGROUND: Flap prefabrication is to turn a random flap into an axial flap by transferring a vascular pedicle., METHODS: In the past 13 years, we have prefabricated 20 flaps in 20 patients by the superficial temporal artery and its

concomitant veins. Typically, a 50- to 800-mL tissue expander was implanted in the donor site. After flap maturation, the prefabricated flap was raised and transferred locally to cover the large defect on the face. All the cases were followed up regularly., RESULTS: The patients' age were between 3 and 27 years, the size of the flaps were between 3.5 x 5.5 cm and 13 x 15 cm, the superficial temporal artery length was between 10 and 15 cm. All flaps were transferred successfully: 10 of the flaps had venous congestion, partial epidermis exfoliation and flap necrosis occurred in 4 flaps. All cases were followed up for at least 1 year, the longest follow-up period was 9 years. Long-term follow-up results showed the prefabricated flap survived in good condition and had a satisfactory outcome., CONCLUSIONS: Because flap prefabrication is practical, and long-term follow-ups have proved its preferable characters and stability, it is a fine method for large area facial reconstructions.

5728. Wang, X., et al. (2017). "Systemic antimiR-337-3p delivery inhibits cerebral ischemia-mediated injury." Neurobiology of disease **105**: 156-163.

Modulation of miRNA expression has been shown to be beneficial in the context of multiple diseases. The purpose of this study was to determine if an inhibitor of miR-337-3p is neuroprotective for hypoxic injury after tail vein injection. We evaluated miR-337-3p expression levels and in brain tissue in vivo before and after permanent middle cerebral artery occlusion (pMCAO) in mice. Subsequently, a custom locked nucleic acid (LNA) antimir-337-3p oligonucleotide was developed and tested in vitro after induction of oxygen glucose-deprivation (OGD) and in vivo by injection into the mouse tail vein for 3 consecutive days before pMCAO. Ischemic lesion volume was measured by TTC staining. We show that systemically administered LNA antimir-337-3p crosses the blood brain-brain-barrier (BBB), penetrates into neurosn, downregulates endogenous miR-337-3p expression and reduces ischemic brain injury. The findings support the use of similar antimir-LNA constructs as novel therapies in neurological disease. Copyright © 2017. Published by Elsevier Inc.

5729. Wang, X., et al. (2013). "Orbital trauma with a large plant foreign body: a case report." Eye science **28**(1): 44-47.

We report a case of a large plant foreign body in the orbit. A 30-year-old male presented to our hospital 6 h after a penetrating orbital injury in his left superior eyelid when he skidded from his motorcycle while riding. When the patient reported to us, he already had an inability to open his left eye and a continuous pain in the left orbit. On examination, there was a large plant foreign body penetrating the nasal orbit through the left upper eyelid. Orbital CT revealed a low density linear foreign body measuring 3.6 x 0.5 cm in the left orbit. An emergency operation was performed to remove the foreign body. The patient's visual acuity did not recover satisfactorily due to optic nerve injury. This case highlights the fact that careful surgical removal of foreign bodies is the treatment of choice and that all patients should receive post-operative antibiotic therapy because of the high incidence of secondary orbital infections. The final outcome and prognosis depend greatly upon the composition and location of the foreign body and whether there are serious complications.

5730. Wang, Y., et al. (2008). "Delayed presentation of grease-gun injury to the orbit." Ophthalmic plastic and reconstructive surgery **24**(2): 154-156.

A 44-year-old man was examined for marked edema and ptosis of the right upper eyelid after grease from high-pressure hydraulic machinery penetrated his right orbit 20 days earlier. The diagnosis of residual grease in the injured orbit was confirmed by CT and MRI, and the clinical presentation. During orbital exploration, the grease was removed completely. Among the wide variety of orbital foreign bodies, grease is rarely reported. We present the sixth case of grease-gun injury to the orbit to be reported in the English language literature since 1964.

5731. Wang, Y., et al. (2014). "The surgical treatment of reinforced steel bar injury penetrating the skull base and maxilla-mandibular area." The Journal of craniofacial surgery **25**(6): e521-523.

Penetrating injuries with reinforced screwed steel bar in the skull base represent a unique challenge for oral maxillofacial surgeons. Management of these injuries is complicated by associated injuries and the proximity to vital neurovascular structures. A 35-year-old man was admitted to our hospital because of injury due to a downward fall upon a reinforced steel rod. Radiologic studies of the skull base revealed that the steel bar traversed the temporomandibular space between the left cervical spine and the mastoid process to the space between the inner side

of the left mandibular ramus and the maxilla. We performed osteotomy of the left mastoid process tip and the left mandibular ramus to take out the steel bar from the maxilla and repaired the left mandible with internal fixation. Appropriate preoperative planning, including three-dimensional computed tomographic images, is integral in the surgical approach for the safe removal of such objects.

5732. Wang, Y., et al. (2022). "Lycopene attenuates oxidative stress, inflammation, and apoptosis by modulating Nrf2/NF-kappaB balance in sulfamethoxazole-induced neurotoxicity in grass carp (Ctenopharyngodon Idella)." Fish & shellfish immunology **121**: 322-331.

All drugs that can penetrate the blood-brain barrier (BBB) may lead to mental state changes, including the widely used anti-infective drug sulfamethoxazole (SMZ). Herein, we investigated whether lycopene (LYC) could ameliorate SMZ-induced brain injury and the postulated mechanisms involved. A total of 120 grass carps were exposed under SMZ (0.3 mug/L, waterborne) or LYC (10 mg/kg fish weight, diet) or their combination for 30 days. Firstly, brain injury induced by SMZ exposure was suggested by the damage of BBB (decreases of Claudins, Occludin and Zonula Occludens), and the decrease of neurotransmitter activity (AChE). Through inducing oxidative stress (elevations of malondialdehyde and 8-hydroxy-2 deoxyguanosine, inhibition of glutathione), SMZ increased the intra-nuclear level of NF-kappaB and its target genes (TNF-alpha and interleukins), creating an inflammatory microenvironment. As a positive feed-back mechanism, apoptosis begins with activation of pro-death proteins (Bax/Bcl-2) and activation of caspases (caspase-9 and caspase-3). Meanwhile, a compensatory upregulation of constitutive Nrf2 and its downstream antioxidative gene expression (NAD(P)H Quinone Dehydrogenase 1 and Heme oxygenase 1) and accelerated autophagy (increases of autophagy-related genes and p62 inhibition) were activated as a defense mechanism. Intriguingly, under SMZ stress, LYC co-administration decreased NF-kappaB/apoptosis cascades and restored Nrf2/autophagy levels. The neuroprotective roles of LYC make this natural compound a valuable agent for prevention SMZ stress in environment. This study suggests that LYC might be developed as a potential candidate for alleviating environmental SMZ stress in aquaculture.

5733. Wang, Y.-x., et al. (2003). "[Restoration of deformities caused by complex fracture of the orbit region and adjacent cranio-maxillofacial fracture]." Zhonghua kou qiang yi xue za zhi = Zhonghua kouqiang yixue zazhi = Chinese journal of stomatology **38**(6): 450-451.

OBJECTIVE: In order to improve the diagnosis and treatment of the complex fracture of the orbit region and adjacent cranio-maxillofacial fracture., METHODS: 73 cases with blowout fracture of the orbit and adjacent cranio-maxillofacial fracture in recent years were retrospectively analyzed and compared with different methods of treatment. All cases had undertaken CT examinations., RESULTS: The positive rate of the CT examinations with blowout fracture of the orbit and adjacent cranio-maxillofacial region were 100%. Operating repositioning, rigid fixation and artificial material placement were used to treat this kind of deformities., CONCLUSIONS: With the progress of modern photographic methods, blowout fracture of the orbit and adjacent cranio-maxillofacial fracture can be diagnosed clearly and help the operation procedure. Operations with reduction, rigid fixation and filling materials can be used to restore this kind of fracture and appearance.

5734. Wani, A. A., et al. (2012). "Management dilemma in penetrating head injuries in comatose patients: Scenario in underdeveloped countries." Surgical neurology international **3**: 89.

BACKGROUND: The optimal management of patients with minimal injury to brain has been a matter of controversy and this is especially intensified when the patient has a poor neurological status. This is important in the regions where neurosurgical services are limited and patient turnover is disproportionate to the available resources. We aimed to determine the effectiveness of aggressive management in coma patients after penetrating missile injuries of the brain., METHODS: All the patients of gunshots or blast injuries were included if they had a Glasgow Coma Scale score of less than 8 after initial resuscitation and had no other injury that could explain their poor neurological status. The indication for emergency surgery was evidence of a mass lesion causing a significant mass effect; otherwise, debridement was done in a delayed fashion. The patients who were not operated were those with irreversible shock or having small intracranial pellets with no significant scalp wounds. The patients who had a Glasgow outcome score of 1, 2, or 3 were classified as having an unfavorable outcome (UO) and those with scores 4 and 5 were classified as having a favorable outcome (FO)., RESULTS: We operated 13 patients and the rest 13 were managed conservatively. The

characteristics of the patients having a favorable outcome were young age (OR = 28, P = 0 .031), normal hemodynamic status (OR = 18, P = 0.08), presence of pupillary reaction (OR = 9.7, P = 0.1), and injury restricted to one hemisphere only (OR = 15, P = 0.07). All of the patients who were in shock after resuscitation died while 25% of the patients with a normal hemodynamic status had a favorable outcome., CONCLUSIONS: In developing countries with limited resources, the patients who are in a comatose condition after sustaining penetrating missile injuries should not be managed aggressively if associated with bihemispheric damage, irreversible shock, or bilateral dilated nonreacting pupils. This is especially important in the event of receiving numerous patients with the same kind of injuries.

5735. Wani, A. A., et al. (2011). "Missile injury to the pediatric brain in conflict zones." Journal of neurosurgery. Pediatrics **7**(3): 276-281.

OBJECT: This study was conducted both prospectively and retrospectively at one center over a period of 8 years. The population consisted of all patients with both an age 18 years or younger and a diagnosed penetrating missile injury (PMI) during the study interval. The authors analyzed factors determining outcome and demographic trends in this population, and they compared them with those in the more developed world., METHODS: Fifty-one patients were the victims of armed conflict, although no one was directly a party to any battle. This mechanism of injury is in strong opposition to data in the literature from developed countries, in which most missile injuries are the result of suicide or homicide or are even sports related. Moreover, all previous studies on the pediatric population have considered only injuries from gunshots, but authors of the current study have included injuries from other penetrating missiles as well., RESULTS: On cross tabulation analysis using the chi-square test, the factors shown to correlate with outcome included the Glasgow Coma Scale (GCS) score, pupillary abnormalities, patient age, hemodynamic status, and bihemispheric damage. On multinomial regression analysis, the two strongest predictors of death were GCS score and pupillary abnormalities. The GCS score and hemodynamic status were the strongest predictors of disability., CONCLUSIONS: There was no difference in the prognostic factors for PMI between developing or more developed countries. Glasgow Coma Scale score, pupillary abnormalities, and hemodynamic status were the strongest predictors of outcome. In conflict zones in developing countries the victims were mostly innocent bystanders, whereas in the more developed countries homicides and suicides were the leading etiological factors.

5736. Wani, A. A., et al. (2011). "Delayed intracerebral hematoma after a bullet injury to brain leading to secondary pulmonary edema." Neurosurgery Quarterly **21**(4): 252-254.

The outcome of brain trauma is determined by the initial injury and the development of secondary problems, such as hematomas, edema, herniation, infections, cerebrospinal fluid leaks, and seizures. The DICH can cause rapid clinical deterioration of the patient and can even lead to fatal outcome. The problem is unusual but not rare. Although first reported in 1895 by Guibert, traumatic intracranial aneurysms (TICA) have received little attention in the literature. Missile TICA's are often seen on a secondary branch of middle cerebral artery and are usually accompanied by a intracerebral hematoma (80%) or by an acute subdural hematoma (26%). TICAs may enlarge in time, and seemingly inoffensive, may rupture and may lead to death. Depending on the patient's status and level of consciousness, angiography followed by the trapping of aneurysm is the treatment of choice. Our case has developed delayed posttraumatic intracerebral hematoma associated with pulmonary edema and subsequent death of the patient.

5737. Wani, A. A., et al. (2017). "Pediatric head injury: A study of 403 cases in a tertiary care hospital in a developing country." Journal of pediatric neurosciences **12**(4): 332-337.

Introduction: Traumatic brain injury (TBI) in children is a significant cause of morbidity and mortality worldwide. Falls are the most common type of injury, followed by motor vehicle-related accidents and child abuse. Aims and Objectives: The aim and objective of this study was to elucidate the various modes of injury, prognostic factors, complications, incidence of various modes of injury, and outcome in TBI in pediatric population. Materials and Methods: Patients with TBI, 18 years or less in age, managed in our Department of Neurosurgery, over a period of 2 years, were studied prospectively. Detailed history, general physical examination, systemic examination, and central nervous system examination including assessment of Glasgow Coma Scale score (GCS) and pupillary size and reaction were noted in every patient. Based on GCS, patients were divided into mild head injury (GCS 13-15), moderate head injury (GCS 9-12), and severe head injury (GCS ≤8) categories. All the patients were subjected to plain computed tomography (CT) scan

head, and CT findings were noted. Patients were managed conservatively or surgically as per the standard indications. The outcome of all these patients was assessed by Glasgow outcome scale and divided into good (normal, moderate disability) and poor (severe, vegetative, dead) outcome. Outcome was assessed in relation to age, sex, GCS, pupil size and reaction, CT scan features, intervention, and associated injuries. Results: A total of 403 patients aged between 1 day and 18 years were included in the study comprising 252 males (63%) and 151 females (37.75%). The common modes of injury were fall 228 (56.6%) followed by road traffic accidents 138 (34.2%), assault 10 (2.5%), and others 27 (6.7%) which include sports injury, hit by some object on head, and firearm injury. Majority of our patients had a GCS of 13-15 (mild head injury), 229 (57.3%), followed by 9-12 (moderate head injury) 119 (29.8%), followed by 8 or less (severe head injury) 52 (13%). In group of patients in the category of GCS ≤ 8, poor outcome was seen in 65.3%, followed by patients in group GCS 9-12 at 2.45% succeeded by group of patients with GCS 13-15 at 2.6%, which was statistically significant (P 0.0001). A total of 354 (87.8%) patients had normal pupils, 37 (9.2%) had anisocoria, and 12 (3%) patients had fixed dilated pupils. Fixed dilated pupil had poor outcome (100%) followed by anisocoria (40.5%) and normal pupils (16%), which was statistically significant (P 0.0001). Conclusion: Majority of children who suffer from TBI do well although it still continues to be a significant cause of morbidity and mortality in them. The outcome is directly related to the neurological status in which they present to the hospital.

5738. Wani, N. A. and A. Q. Khan (2010). "Foreign body within sphenoid sinus: multidetector-row computed tomography (MDCT) demonstration." Turkish neurosurgery **20**(4): 547-549.

Trans-nasal sphenoid sinus foreign body is a rare condition. We report a case of trans-nasal gun bullet within the sphenoid sinus with breach of the floor of the sella turcica. A 42-year-old soldier presented a few weeks after a gun battle with a history of headache. The skull x-ray demonstrated a foreign body in the region of sphenoid sinus and sella. Multidetector-row CT with multiplanar reformats demonstrated a bullet within the sphenoid sinus with its tip penetrating into the sella turcica. A few days later the patient coughed up the bullet as it came out spontaneously without any intervention. This is perhaps the unique occurrence of such a foreign body.

5739. Wankhede, A. G. (2008). "Patterned injuries caused by wooden plank." Journal of forensic and legal medicine **15**(2): 118-123.

Wooden planks of different dimensions are commonly used in construction of buildings, fence of houses, bullock-carts and walls of huts. There is plenty of opportunity for wooden plants to be used as assault implements. Three cases of homicide are reported. In each case a wooden plank was the weapon of offence. The causes of death were respectively anal impalement injury, liver rupture and head injury. Case 1: A 30-year-old man who was beaten by a wooden plank and had it inserted per anum was found alive by a police officer after approximately 48 h. He sustained multiple patterned contused abrasions and death was attributed to purulent peritonitis due to perforation of small intestine by the wooden plank. Case 2: A 50-year-old man working as a security guard at a building construction site was killed by his 21-year-old son by beating him with a wooden plank found around the construction site. The deceased sustained multiple contusions, abrasions, typical patterned contused abrasions and lacerations externally. Death was attributed to shock due to ruptured liver. Case 3: A 13-year-old female was killed by her 19-year-old male paternal cousin with one stroke of a wooden plank over head. At autopsy she was having a lacerated wound to forehead below which there was a patterned fracture of skull. Death was attributed to sub-arachnoid hemorrhage following head injury. We have recorded peculiar patterned abrasions, patterned fracture with wooden fragment and part of impaled wooden plank in abdominal cavity. These types of injuries are rare. The cases emphasise the need for accurate description of these injuries with photographs in order to achieve effective evaluation and recognition of this type of patterned wounds as they correspond to specific weapons.

5740. Wannatoop, T. and W. Slisatkorn (2022). "Endovascular treatment of concomitant innominate and subclavian artery injury with pseudoaneurysms from a gunshot wound in a polytrauma patient." Trauma (United Kingdom) **24**(1): 72-76.

Introduction: Injury of the innominate artery (IA) is associated with high mortality and morbidity, such as a major neurologic event. The aim of this case report was to describe an example of prioritization in polytrauma management by applying endovascular intervention in a difficult case with impending uncal herniation, extensive cerebral infarction, and large pseudoaneurysm from concomitant innominate and right subclavian artery injuries. Case

Report: A 34-year-old woman sustained a gunshot wound to her upper chest that lodged in the anterior triangle of her neck and presented with tension pneumothorax and cardiac arrest, which was successfully resuscitated. Subsequently she developed drowsiness and left hemiparesis, and computerized tomography demonstrated a large right cerebral hemisphere and left cerebellar region infarction with impending uncal herniation and pseudoaneurysms from the IA and proximal right subclavian artery. After emergency craniectomy to avert herniation, endovascular treatment was performed to facilitate vessel repair due to anatomical difficulty and the patient's unstable condition. She was discharged home 3 weeks after operation, and 2 months postoperatively, she was neurologically intact with no evidence of endoleakage or pseudoaneurysm. Conclusion: In such a complex polytrauma case, correct prioritization of interventions is crucial to obtaining the best outcomes, and the Endovascular Resuscitation and Trauma Management protocol can be applied as an alternative treatment protocol with good results.

5741. Ward, J. D., et al. (1994). "Penetrating head injury." Critical care nursing quarterly **17**(1): 79-89.

Penetrating head injuries are a significant public health problem in the United States, with an estimated 33,000 gun-related deaths and many more nonfatal shootings per year. Initial treatment for a penetrating head injury is similar to that of a closed head injury. That is, all efforts must be made to prevent any secondary insults, hypoxia, or ischemia. This translates into the standard methodology of care of the trauma patient. The basic neurologic examination consists of using the Glasgow Coma Score and estimation of pupillary function and some estimation of brain stem function and motor power. The radiologic test of choice for a penetrating head injury is the computed tomography scan. There are several indications for surgery: the patient's condition will be improved or significant neurologic sequelae will be averted; the patient is sufficiently stabilized from any other injuries such that he or she can tolerate surgery; the condition of the patient is not so poor that surgery will have no effect; and the area of penetration is reasonably accessible to surgical intervention. Three main goals of medical management of a penetrating head injury include (1) control of hypertension, (2) maintenance of adequate cerebral circulation oxygenation, and (3) prevention of secondary complications. Outcome after a penetrating head injury is related to the extent of brain tissue damage caused either directly or indirectly by the missile as well as any indirect insults. The most significant indicator, particularly in terms of survival versus death, has consistently been the patient's presenting neurologic status. Some investigators have recommended that a patient presenting with a Glasgow Coma Scale Score of > 5 should not be treated. Others have said that patients with a low coma score and transventricular gunshot wounds should not be treated because of the high mortality. If the patient survives a penetrating head injury, he or she generally goes on to experience a relatively good functional outcome. Only if all components of a good treatment regimen are in place will patients and their families obtain the best possible outcome.

5742. Warden, D. (2006). "Military TBI during the Iraq and Afghanistan wars." The Journal of head trauma rehabilitation **21**(5): 398-402.

Traumatic brain injury (TBI) is an important source of morbidity in the Iraq and Afghanistan wars. Although penetrating brain injuries are more readily identified, closed brain injuries occur more commonly. Explosion or blast injury is the most common cause of war injuries. The contribution of the primary blast wave (primary blast injury) in brain injury is an area of active research. Lessons learned from the sports concussion and civilian mild TBI literature are useful. Individuals with TBI and posttraumatic stress disorder require treatment of both conditions. Families and communities need to be cognizant of the needs of these returning veterans.

5743. Warpeha, R. L. (1981). "Resurfacing the burned face." Clinics in plastic surgery **8**(2): 255-267.

Facial burns cause deformities through the permanent effects of wound contracture and scar hypertrophy; they are related to the depth of the burn. The depth of an acute burn can be accurately ascertained only by observation over a period of time. Facial skin burns that do not heal by three weeks are subject to increasingly permanent deformity with the passage of time. The best defense against wound contraction and hypertrophic scar is early and complete wound closure. Early and late grafting must be completely successful in "take" to avoid unsightly irregular scarring; therefore, the receptor bed must be meticulously prepared for optimal take. Both early and late grafts are patches that flatten normal contour. However, if the skin graft conforms to a position in the facial mosaic (aesthetic unit of the face), or some subunit that is harmonious with normal facial lines, the patch of proper color can give a more aesthetic result. Nonreproducible anatomical structures such as the margins of the lids, lips, and nostrils should be preserved whenever

found to be normal or only partially destroyed. To minimize the distorting effects of wound contracture, pressure therapy of the face and neck, as well as the positional splinting of the neck, must be maintained for many months following grafting and epithelialization until the deleterious wound forces abate. Burns of mobile structures, such as lids and lips, do not lend themselves to control by pressure, and frequently must be managed secondarily by first totally removing scarred tissues and then applying thick skin grafts of the best color match.

5744. Wasicek, P. J., et al. (2021). "Survival Following Self-Inflicted Gunshot Injuries to the Face Using the National Trauma Data Bank." The Journal of craniofacial surgery **32**(6): 2064-2067.

INTRODUCTION: Self-inflicted gunshot wounds to the face frequently result in devastating injuries; however, there is a paucity of large experiences describing determinants of mortality and outcomes., METHODS: Using the National Trauma Databank from 2007 to 2015, patients suffering self-inflicted firearm facial injuries were included., RESULTS: Over 9 years 7869 patients were included: 87.7% were male, 46.4% suffered traumatic brain injury (TBI) and overall in-hospital mortality was 44.7%. The majority (67.8%) of in-hospital mortality occurred within the first 24 hours. Using multiple regression, advanced age (>65 years), presence of TBI, admission hypotension, and decreased Glasgow coma score were each independently associated with increased odds of mortality (all $P < 0.001$). Mandible or combined mandible/midface fracture injury patterns were most likely to survive ($P < 0.001$). Of those surviving to hospital discharge, the median [interquartile range] length of stay was 13 [6, 23] days, 86.6% required an intensive care unit stay with 67% requiring intubation and 42.5% tracheostomy. Among survivors, the combined mandible and midface fracture pattern resulted in the highest rates of tracheostomy (70.5%), gastrostomy tube placement (50.5%), and facial operations (87.0%) with a median [interquartile range] of 5 [3, 7] operative trips (all $P < 0.001$)., CONCLUSIONS: Self-inflicted facial firearm injuries are highly morbid injuries with the majority of in-hospital deaths occurring the first hospital day. Differences including concomitant TBI, facial injury pattern, neurologic status, and presence of hypotension on admission were independently associated with survival/death. More extensive facial injuries (combined mandible and midface fracture patterns) were more likely to survive and required more intensive interventions.

5747. Waters, J. B., et al. (1999). "Development and implementation of clinical pathways for the management of four trauma diagnoses." Journal for healthcare quality : official publication of the National Association for Healthcare Quality **21**(3): 4-11.

Clinical pathways are similar to the production algorithms developed by industry. They are being adapted for use in healthcare to reduce resource utilization, decrease variability, and control expenditures. At Boston Medical Center we identified four trauma diagnoses that we believed to be amenable to the design and implementation of clinical pathways: closed head injury, penetrating wound to the abdomen, penetrating wound to the chest, and penetrating wound to an extremity. Upon implementation of these pathways, appropriate nonoperative, single-system, short-stay trauma patients were enrolled in them. This article details the process by which the four diagnoses were identified and the pathways designed, implemented, and evaluated. Preliminary data demonstrate a significant decrease in resource utilization following implementation of the pathways, without an adverse impact on readmission rates, length of stay, or mortality.

5750. Watts, A. C. and N. Mel (2019). "Acanthamoeba encephalitis in HIV-infected male presenting with headache and tonic-clonic seizures: A case report." Journal of General Internal Medicine **34**(2): S464.

Learning Objective #1: Recognize the radiographic and pathologic features of Acanthamoeba encephalitis Learning Objective #2: Formulate a differential diagnosis for space-occupying brain lesions in immunocompromised patients CASE: A 27-year-old man with Acquired Immune Deficiency Syndrome (with a CD4+ cell count of 5 cells/mm3) presented with tonic-clonic seizures and headache. Physical exam on admission did not reveal focal neurological deficits. Laboratory studies showed a WBC of 4.6 K/mcL (12.7% eosinophils). Magnetic resonance imaging (MRI) demonstrated a right frontoparietal peripherally enhancing lesion with mild surrounding edema and associated mass effect. Cerebrospinal fluid studies demonstrated neutrophil-predominant pleocytosis (WBC 147/mcL with 50% neutrophils) with normal protein and glucose. Broad-spectrum therapy for potential bacterial, viral, and fungal infections was initiated; nonetheless, the patient developed increasing somnolence and new focal neurological deficits. Repeat MRI six days after admission demonstrated new, enlarging edema-tous and peripherally enhancing lesions favored to represent multifocal cerebritis. Craniotomy and open brain biopsy with resection of dura was performed ten days after admission. Pathology revealed lymphohistiocytic inflammation with amoebic necrotizing abscesses. Immunohistochemical and PCR testing confirmed Acanthamoeba infection. Despite multidrug treatment (with miltifosine, flucytosine, pentaminidine, sulfdiazine, flucon-azole, and azithromycin), the patient expired on hospital day 16. IMPACT/DISCUSSION: Acanthamoeba is a pervasive protozoal species found in soil, water, air, and dust; the organism has been associated with three infectious syndromes in humans: amoebic encephalitis, disseminated granulomatous amebic disease, and keratitis (especially in contact lense users). Unlike the fulminant infection caused by Naegleria fowleri, Acanthamoeba causes a subacute encephalitis that progresses over days to months. Acanthamoeba likely causes central nervous system infection in immunocompromised hosts through hematogenous spread after initial pulmonary or skin inoculation and subsequent penetration of the blood-brain barrier. Investigational therapies for Acanthamoeba encephalitis include surgical resection of lesions and combination drug therapy. Conclusion: Amoebic encephalitis is an exceedingly rare cause of central nervous system infection with a mortality exceeding 90%. Various protozoa have been implicated in central nervous system disease, including Naegleria fowleri, Balamuthia mandrillaris, and multiple species of Acanthamoeba. Little data exists regarding the clinical characteristics, radiographic findings, and treatment of Acanthamoeba encephalitis, as fewer than 150 cases have been reported globally since the condition was first described in the 1960s. Acanthamoeba encephalitis should be considered in immunocompromised patients presenting with central nervous system infection, as delayed recognition and treatment contribute to the condition's grave prognosis.

5751. Wearne, M. J., et al. (1998). "Vitreoretinal surgery after inadvertent globe penetration during local ocular anesthesia." Ophthalmology **105**(2): 371-376.

OBJECTIVE: This study aimed to review visual morbidity resulting from inadvertent globe penetration during administration of local anesthetic and to identify the most appropriate management., DESIGN: The records of 20 consecutive patients referred to a specialist vitreoretinal unit over a 2-year period were reviewed., PARTICIPANTS: Twenty eyes of 20 consecutive patients were included., INTERVENTION: Observations included type of local anesthetic administered (e.g., retrobulbar or peribulbar), level of training of person administering the block, type of needle used for the block, and findings at presentation to the vitreoretinal unit. The authors also observed results of B-scan ultrasound evaluation of the retina, interval between the recognition of the complication and referral, as well as nature and timing of subsequent surgical intervention., MAIN OUTCOME MEASURES: Final visual acuity and retinal status (attached versus detached) were measured., RESULTS: The most common presentation was vitreous hemorrhage observed from the first postoperative day. Ten eyes were found to have an associated retinal detachment on initial assessment in the vitreoretinal unit. These eyes generally had a poor visual outcome despite vitrectomy with long-acting gas or silicone oil tamponade. Seven (70%) of the remaining eyes with attached retina at the time of presentation achieved good visual recovery after vitrectomy., CONCLUSIONS: The authors recommend prompt referral for consideration of early vitrectomy in eyes with dense vitreous hemorrhage after inadvertent globe penetration. This management may improve the overall visual prognosis by preventing subsequent retinal detachment.

5752. Weber, J. and A. Czarnetzki (2001). "Brief communication: neurotraumatological aspects of head injuries resulting from sharp and blunt force in the early medieval period of southwestern Germany." American journal of physical anthropology **114**(4): 352-356.

Approximately 10% (33 of 304) of the predominantly male skulls from the 6th through 8th centuries in southwestern Germany exhibit cranial fractures derived from blunt or sharp force trauma. No evidence of fracture healing characterizes 24% (n = 8) of these individuals. All nonhealed fractures were caused by sharp force, and four of these wounds cross the sagittal sinus. The lengths of these straight-edged wounds, produced exclusively by sword blows, measure around 8.0 cm for fatal, and about 5.0 cm for nonfatal wounds. Seventy-six percent (n = 25) of these skulls exhibit some healing, which indicates that these injuries did not lead to immediate death. In this group are all depressed fractures resulting from blunt force blows. Two thirds of the 45 cranial injuries noted on these 33 skulls are located on the left side of these individuals, with a concentration in the frontoparietal region. Bony indications of wound infection occur in four cases (12%). Three crania exhibit circular trepanations in association with fractures. These phenomena are discussed in the context of modern neurotraumatological knowledge. Copyright 2001 Wiley-Liss, Inc.

5753. Weber, M., et al. (2021). "Sharp force trauma with two katana swords: identifying the murder weapon by comparing tool marks on the skull bone." International journal of legal medicine **135**(1): 313-322.

This paper describes the variety of information that a tool mark analysis on human tissue can provide based on a case of multiple sharp violence. The perpetrator attacked the victim with a sharp-edged weapon against the head, leaving several deep wounds on the back of the skull bone. Three of those marks on the skull bone could be used for a forensic tool mark examination. Silicone casts of the marks were compared by light microscopy with casts of test marks of Japanese katana swords found at the crime scene. One of the swords could be identified as the one responsible for the marks. In addition, the marks and the test marks were scanned in 3D and examined in a visual on-screen comparison confirming the results from the light microscopic examination. Furthermore, a mathematical approach in which the signatures of the marks from the skull bone and the test marks from the sword were compared by cross correlation confirms those findings. In addition, the aforementioned results were used to determine the orientation of the sword in relation to the cranial bone at the time of the respective impact.

The case report of a 54-year-old patient with a right frontal intracerebral abscess 48 years after a missile injury is presented. Treatment included surgical evacuation and antibiotic therapy. The patient was discharged without neurological deficit.

5758. Wehrmann, D., et al. (2017). "Penetrating Ocular Trauma from a Bean Bag Gun: A Case Report and Review of Less-Lethal Force and Their Consequences." Missouri medicine **114**(4): 308-310.

Although bean bag guns are considered a "less-lethal" form of law enforcement, these blunt projectiles have risk. The purpose of this study was to perform a literature review of morbidity and mortality associated with less-lethal munitions and present a case report of a bean bag injury leading to a traumatic globe evisceration and skull base fracture. Patients presenting with bean bag gun associated injuries warrant a high clinical suspicion for injury to deeper structures.

5759. Wei, G., et al. (2010). "Intracranial pressure following penetrating ballistic-like brain injury in rats." Journal of neurotrauma **27**(9): 1635-1641.

Penetrating ballistic brain injury involves a leading shockwave producing a temporary cavity causing substantial secondary injury. In response to the prevalence of this type of brain trauma in the military, a rat model of penetrating ballistic-like brain injury (PBBI) was established. This study focuses on cerebral physiological responses resulting from a PBBI, specifically the immediate and delayed changes in intracranial pressure (ICP) and cerebral perfusion pressure (CPP). ICP/CPP was measured continuously in rats subjected to PBBI, probe insertion alone, or sham injury. Immediately following the PBBI, a transient (<0.1 sec) and dramatic elevation of ICP reaching 280.0 +/- 86.0 mm Hg occurred, accompanied by a profound decrease in CPP to -180.2 +/- 90.1 mm Hg. This emergent ICP/CPP response resolved spontaneously within seconds, but was followed by a slowly-developing and sustained secondary phase, which peaked at 24 h post-injury, reaching 37.2 +/- 10.4 mm Hg, and remained elevated until 72 h post-injury. The measured decrease in CPP reached 85.3 +/- 17.2 mm Hg at 3 h post-injury. By comparison, probe insertion alone did not produce the immediate ICP crisis (28.6 +/- 9.1 mm Hg), and only a mild and sustained increase in ICP (13.5 +/- 2.1 mm Hg) was observed in the following 3 h post-injury. Injury severity, as measured by lesion volume, brain swelling, and neurological deficits at 1, 3, and 7 days post-injury, also reflected the distinctive differences between the dynamics of the PBBI versus controls. These results not only reinforced the severe nature of this model in mimicking the ballistic effect of PBBI, but also established cerebral pathophysiological targets for neuroprotective therapies.

5760. Wei, H. H., et al. (2009). "NNZ-2566 treatment inhibits neuroinflammation and pro-inflammatory cytokine expression induced by experimental penetrating ballistic-like brain injury in rats." Journal of neuroinflammation **6**: 19.

BACKGROUND: Inflammatory cytokines play a crucial role in the pathophysiology of traumatic brain injury (TBI), exerting either deleterious effects on the progression of tissue damage or beneficial roles during recovery and repair. NNZ-2566, a synthetic analogue of the neuroprotective tripeptide Glypromate, has been shown to be neuroprotective in animal models of brain injury. The goal of this study was to determine the effects of NNZ-2566 on inflammatory cytokine expression and neuroinflammation induced by penetrating ballistic-like brain injury (PBBI) in rats., METHODS: NNZ-2566 or vehicle (saline) was administered intravenously as a bolus injection (10 mg/kg) at 30 min post-injury, immediately followed by a continuous infusion of NNZ-2566 (3 mg/kg/h), or equal volume of vehicle, for various durations. Inflammatory cytokine gene expression from the brain tissue of rats exposed to PBBI was evaluated using microarray, quantitative real time PCR (QRT-PCR), and enzyme-linked immunosorbent assay (ELISA) array. Histopathology of the injured brains was examined using hematoxylin and eosin (H&E) and immunocytochemistry of inflammatory cytokine IL-1beta., RESULTS: NNZ-2566 treatment significantly reduced injury-mediated up-regulation of IL-1beta, TNF-alpha, E-selectin and IL-6 mRNA during the acute injury phase. ELISA cytokine array showed that NZ-2566 treatment significantly reduced levels of the pro-inflammatory cytokines IL-1beta, TNF-alpha and IFN-gamma in the injured brain, but did not affect anti-inflammatory cytokine IL-6 levels., CONCLUSION: Collectively, these results suggest that the neuroprotective effects of NNZ-2566 may, in part, be functionally attributed to the compound's ability to modulate expression of multiple neuroinflammatory mediators in the injured brain.

5761. Wei, L. A., et al. (2016). "Traumatic orbital encephalocele: Presentation and imaging." Orbit (Amsterdam, Netherlands) **35**(2): 72-77.

OBJECTIVE: Traumatic orbital encephalocele is a rare but severe complication of orbital roof fractures. We describe 3 cases of orbital encephalocele due to trauma in children., METHODS: Retrospective case series from the University of Wisconsin - Madison and Medical College of Wisconsin., RESULTS: Three cases of traumatic orbital encephalocele in pediatric patients were found. The mechanism of injury was motor vehicle accident in 2 patients and accidental self-inflicted gunshot wound in 1 patient. All 3 patients sustained orbital roof fractures (4 mm to 19 mm in width) and frontal lobe contusions with high intracranial pressure. A key finding in all 3 cases was progression of

proptosis and globe displacement 4 to 11 days after initial injury. On initial CT, all were diagnosed with extraconal hemorrhage adjacent to the roof fractures, with subsequent enlargement of the mass and eventual diagnosis of encephalocele., CONCLUSION: Orbital encephalocele is a severe and sight-threatening complication of orbital roof fractures. Post-traumatic orbital encephalocele can be challenging to diagnose on CT as patients with this condition often have associated orbital and intracranial hematoma, which can be difficult to distinguish from herniated brain tissue. When there is a high index of suspicion for encephalocele, an MRI of the orbits and brain with contrast should be obtained for additional characterization. Imaging signs that should raise suspicion for traumatic orbital encephalocele include an enlarging heterogeneous orbital mass in conjunction with a roof fracture and/or widening fracture segments.

5762. Wei, L.-F., et al. (2013). "Surgical therapy for craniocerebral firearm injury." Turkish neurosurgery **23**(4): 491-497.

AIM: The current study aims to explore the clinical characteristics of craniocerebral firearm injury and to improve the diagnosis and treatment of this condition., MATERIAL AND METHODS: Data from 56 patients with craniocerebral firearm injury were analyzed retrospectively for projectile types, traumatic conditions, and treatment approaches., RESULTS: 43 patients exhibited intracranial foreign body residence. Of them, 40 were subjected to complete foreign body removal and 2 to partial removal, leaving 1 without receiving removal treatment. 54 patients (96.4%) survived and 2 (3.6%) died. Of the survivors, 36 (64.3%) recovered well, 15 (26.8%) were moderately disabled, 2 (3.6%) were severely disabled, and 1 (1.8%) lapsed into vegetative state. Patients receiving debridement within 8 h after injury had a significantly higher recovery rate than those receiving such treatment after 8 h (82.1% vs. 26.7%; $P < 0.001$)., CONCLUSION: Craniocerebral firearm injury is characterized by rapid traumatic condition development as well as serious trauma and contamination. Accurately judging the traumatic condition and the ballistic tract, performing complete debridement as early as possible, reasonably deciding on the operative mode and approach for intracranial residing foreign body removal, and increasing vigilance regarding concomitant injuries are the keys to the improvement of the overall treatment of craniocerebral firearm injury.

5763. Wei, R., et al. (2010). "Removal of a foreign body from the skull base using a customized computer-designed guide bar." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **38**(4): 279-283.

BACKGROUND: Foreign bodies located at the base of the skull pose a surgical challenge. Here, a customized computer-designed surgical guide bar was designed to facilitate removal of a skull base foreign body., METHODS: Within 24h of the patient's presentation, a guide bar and mounting platform were designed to remove a foreign body located adjacent to the transverse process of the atlas and pressing against the internal carotid artery., RESULTS: The foreign body was successfully located and removed using the custom designed guide bar and computer operative planning. Ten months postoperatively the patient was free of complaints and lacked any complications such as restricted opening of the mouth or false aneurysm. The inferior alveolar nerve damage noted immediately postoperatively (a consequence of mandibular osteotomy) was slightly reduced at follow-up, but labial numbness persisted., CONCLUSIONS: The navigation tools described herein were successfully employed to aid foreign body removal from the skull base.

5764. Weichel, E. D., et al. (2009). "Traumatic brain injury associated with combat ocular trauma." The Journal of head trauma rehabilitation **24**(1): 41-50.

PURPOSE: To determine the impact of traumatic brain injury (TBI) on visual outcomes in combat ocular trauma (COT) and determine the association between TBI severity and types of ocular injuries., PARTICIPANTS: One hundred fifty-two US casualties sustained 207 globe/oculoplastic combat injuries., METHODS: Retrospective, hospital-based cross-sectional study of US service members injured during Operations Iraqi Freedom and Enduring Freedom were treated by the Ophthalmology Service at Walter Reed Army Medical Center and screened for TBI by the Defense and Veterans Brain Injury Center from August 2004 to October 2006., MAIN OUTCOME MEASURES: The main outcome measure was best-corrected visual acuity (BCVA). Secondary outcome measures included the severity and frequency of TBI with globe, oculoplastic, and/or neuro-ophthalmic injury., RESULTS: The frequency of COT with positive TBI screening was 101 of 152 cases (66%) in comparison with negative TBI screening, which was 51 of 152 (34%) cases. The Defense and Veterans Brain Injury Center found TBI with concomitant ocular trauma in 101 of 474 (21%) consecutive casualties. Explosive fragmentary munitions accounted for 79% of TBI-associated COT. The median follow-up was 185

days. Traumatic brain injury severity did not correlate with worse final BCVA (Spearman coefficient, r = 0.12). The odds that BCVA worse than 20/200 was present with TBI was not statistically significant (OR: 1.5; 95% CI, 0.9-2.6; P = .10). The presence of TBI in COT was not associated with worse visual outcome (Mann-Whitney U test, P = .10). Globe injuries were more common than oculoplastic or neuro-ophthalmic injury. Closed-globe injuries were more likely to have TBI than open-globe injuries (OR: 2.17; 95% CI, 1.12-4.21; P = .03). Traumatic brain injury severity associated with COT included mild TBI (31%), moderate TBI (30%), severe TBI (25%), and penetrating TBI (14%). Severe TBI is more frequently associated with COT., CONCLUSION: Traumatic brain injury occurs in two thirds of all COT and ocular trauma is a common finding in all TBI cases. Closed-globe injuries are at highest risk for TBI while TBI does not appear to lead to poorer visual outcomes. Every patient with COT needs TBI screening. Those service members who are screened TBI positive need a referral to a TBI rehabilitation specialist.

5766. Weinacht, S., et al. (1998). "Optic atrophy induced by an intraorbital wooden foreign body: the role of CT and MRI." Journal of pediatric ophthalmology and strabismus **35**(3): 179-181.

5767. Weisbrod, A. B., et al. (2012). "Long-term outcomes of combat casualties sustaining penetrating traumatic brain injury." The journal of trauma and acute care surgery **73**(6): 1525-1530.

BACKGROUND: Previous studies have documented short-term functional outcomes for patients sustaining penetrating brain injuries (PBIs). However, little is known regarding the long-term functional outcome in this patient population. Therefore, we sought to describe the long-term functional outcomes of combat casualties sustaining PBI., METHODS: Prospective data were collected from 2,443 patients admitted to a single military institution during an 8-year period from 2003 to 2011. PBI was identified in 137 patients and constitute the study cohort. Patients were stratified by age, Injury Severity Score (ISS) and admission Glasgow Coma Scale (aGCS) score. Glasgow Outcome Scale (GOS) scores were calculated at discharge, 6 months, 1 year and 2 years. Patients with a GOS score of 4 or greater were considered to have attained functional independence (FI)., RESULTS: The mean (SD) age of the cohort was 25 (7) years, mean (SD) ISS was 28 (9), and mean (SD) aGCS score was 8.8 (4.0). PBI mechanisms included gunshot wounds (31%) and blast injuries (69%). Invasive intracranial monitoring was used in 80% of patients, and 86.9% of the study cohort underwent neurosurgical intervention. Complications included cerebrospinal fluid leak (8.3%), venous thromboembolic events (15.3%), meningitis (24.8%), systemic infection (27.0%), and mortality (5.8%). The cohort was stratified by aGCS score and showed significant improvement in functional status when mean discharge GOS score was compared with mean GOS score at 2 years. For those with aGCS score of 3 to 5 (2.3 [0.9] vs. 2.9 [1.4], $p < 0.01$), 32% progressed to FI. For those with aGCS score of 6 to 8 (3.1 [0.7] vs. 4.0 [1.2], $p < 0.0001$), 63% progressed to FI. For those with aGCS score of 9 to 11 (3.3 [0.5] vs. 4.3 [0.8], $p < 0.0001$), 74% progressed to FI. For those with aGCS score of 12 to 15 (3.9 [0.7] vs. 4.8 [0.4], $p < 0.00001$), 100% progressed to FI., CONCLUSION: Combat casualties with PBI demonstrated significant improvement in functional status up to 2 years from discharge, and a large proportion of patients sustaining severe PBI attained FI., LEVEL OF EVIDENCE: Epidemiologic study, level III.

5768. Weisman, R. A., et al. (1983). "Computed tomography in penetrating wounds of the orbit with retained foreign bodies." Archives of otolaryngology (Chicago, Ill. : 1960) **109**(4): 265-268.

Penetrating wounds of the orbit can have serious immediate and delayed effects on the eye and the CNS. Infection, vessel erosion, or interference with ocular function necessitates removal of the foreign object. Precise localization of the retained material and its relationship to the globe, extraocular muscles, optic nerve, and brain is essential, when surgery is contemplated. We describe two children with retained foreign bodies that required removal. Computed tomography (CT) was essential in one instance in planning the surgical approach. In the other patient, the retained foreign body and an associated brain abscess were recognized only by CT. The contribution of CT to the assessment of retained foreign bodies is discussed and its present limits are defined. Computed tomography is highly recommended as the single most informative diagnostic modality for this type of injury.

5769. Weisner, Z., et al. (2020). "Association of prehospital hypocarbia and hypercarbia with outcomes with severe traumatic brain injury patients." Critical Care **24**.

Introduction: Hypocarbia and hypercarbia alter cerebral blood flow and intracranial pressure. Both might cause secondary brain injury after traumatic brain injury (TBI). Methods: We performed a retrospective observational study from Jan 2012 to Dec 2017 including adult blunt trauma patients with initial Glasgow Coma Scale (GCS) ≤ 14, clinical suspicion for TBI, endotracheal intubation and continuous capnography. We excluded interfacility transfers, penetrating TBI and cases treated for herniation (management includes hyperventilation). All patients were treated by a single air medical transport service in southwest Pennsylvania. Our primary exposure was depth-duration of EtCO2 <35mmHg (hypocarbia). Secondary outcomes were depth-duration of hypercarbia >45mmHg, and maximum depths of hypocarbia and hypercarbia. Our primary outcome was survival to discharge. Covariates were age, sex, initial GCS, shock index and first prehospital serum lactate. We performed unadjusted and adjusted logistic regression testing relationships between EtCO2 and outcome. Results: Overall, 148 patients were included and 113 (76%) survived. Overall, 104 (70%) were hypocarbic at least once. Median hypocarbia depth was 26 [IQR 18-30] mmHg, median hypocarbia duration was 15 [4 - 28] min, and median depth-duration was 60 [14 - 141] mmHg∗min. Hypercarbia occurred in 56 (38%) patients. Median duration of hypercarbia short (0.5 [0 - 5] min) and median depth duration was only 2 [IQR 0 - 18] mmHg∗min. Neither hypocarbia nor hypercarbia (maximum, duration or depth-duration) were associated with outcome in unadjusted or adjusted models. Age [OR; 0.96, 95% CI 0.94-0.98], initial GCS scores [OR; 1.12, 95% CI 1.01 to 1.25] and shock index [OR; 0.41 95% CI 0.19 to 0.88] were independent predictors of mortality. Conclusions: Among intubated blunt TBI patients, prehospital hyper- and hypoventilation do not appear to worsen outcomes.

5770. Weisner, Z. M., et al. (2020). "Association of prehospital hypocarbia and hypercarbia with outcomes with severe traumatic brain injury patients." Academic emergency medicine **27**: S265-S266.

Background and Objectives: Hypocarbia causes cerebral vasoconstriction and decreases cerebral blood flow. Hypercarbia causes cerebral vasodilation and may increase intracranial pressure. Both may result in secondary brain injury and therefore worsen outcomes after traumatic brain injury (TBI). Methods: We performed a retrospective observational study from January 2012 to December 2017 including adult blunt trauma patients with initial Glasgow Coma Scale (GCS) ≤ 14, documented clinical suspicion for TBI, endotracheal intubation and continuous waveform capnography data available. We excluded interfacility transfers, penetrating TBI and cases treated for herniation (protocol includes deliberate hyperventilation). All patients were treated by a single critical care air medical transport service and transported to a Level 1 trauma center in southwest Pennsylvania. Our primary exposure of interest was depth-duration of EtCO2 45mmHg, maximum depth of hypocarbia and maximum depth of hypercarbia. Our primary outcome of interest was survival to hospital discharge. Covariates were age, sex, initial GCS, shock index and first prehospital serum lactate. We performed unadjusted and adjusted logistic regression testing the relationship between EtCO2 and outcome. Results: Overall, 148 patients were included of whom 113 (76%) survived. Among all patients, 104 (70%) were hypocarbic at least once. Median depth of hypocarbia was 26 [IQR 18-30] mmHg, median duration of hypocarbia was 15 [4 - 28] min, and median depth-duration was 60 [14 - 141] mmHg∗min. Hypercarbia was less common, with 56 (38%) patients hypercarbia at least once. Median duration of hypercarbia exposure was 0.5 min [0 - 5] min and median depth duration was 2 [IQR 0 - 18] mmHg∗min. Neither hypocarbia nor hypercarbia (maximum, duration or depth-duration) were associated with outcome in unadjusted or adjusted models. Age [OR; 0.96, 95% CI 0.94-0.98], initial GCS scores [OR; 1.12, 95% CI 1.01 to 1.25] and shock index [OR; 0.41 95% CI 0.19 to 0.88] were independent predictors of mortality. Conclusion: Among adult intubated patients with blunt TBI, prehospital hyper- and hypo-ventilation may not cause clinically significant secondary brain injury.

5771. Weiss, G. H., et al. (1986). "Predicting posttraumatic epilepsy in penetrating head injury." Archives of neurology **43**(8): 771-773.

Using data derived from a 15-year follow-up study of 520 veterans surviving penetrating brain wounds received in the Vietnam war, we have developed a predictive formula and tables for posttraumatic epilepsy based on time elapsed postinjury and presence of specific clinical and computed tomographic scan risk factors. Such patients remain at some increased risk for epilepsy even ten to 15 years postinjury, although most can be 95% certain of avoiding epilepsy if they have been seizure free for three years posttrauma. Epilepsy onset latency was independent of any risk factors identified.

5772. Weiss, R., et al. (2019). "Patterns of Pediatric Firearm-Related Ocular Trauma in the United States." JAMA ophthalmology **137**(12): 1363-1370.

Importance: Gun violence represents a substantial public health issue, and firearm-related injuries rank second among the causes of injury-related deaths in children aged 0 to 17 years in the United States. Ocular trauma from firearm-related injuries can lead to devastating vision loss, but little is known to date about the specific demographics and characteristics of such injuries in children., Objective: To evaluate the epidemiologic pattern of pediatric firearm-related ocular injuries., Design, Setting, and Participants: This retrospective analysis used deidentified data from the National Trauma Data Bank, the largest national registry of hospitalized trauma cases in the United States. The firearm-related ocular injuries (n = 1972) of pediatric patients (defined as those younger than 21 years) hospitalized between January 1, 2008, and December 31, 2014, were analyzed. Statistical analyses were conducted from July 15, 2017, to June 15, 2019., Exposure: Firearm-related ocular trauma., Main Outcomes and Measures: Pediatric patients with firearm-related ocular injuries were identified using International Classification of Diseases, Ninth Revision, Clinical Modification codes and external causes of injury codes. Patient demographics (age, sex, and race/ethnicity), type of ocular injury, injury intent, geographic location, length of hospital admission, health insurance status, disposition at discharge, Injury Severity Score (ISS), and Glasgow Coma Scale (GCS) score were collected., Results: A total of 8715 firearm-related ocular injuries were identified. Of these injuries, 1972 (22.6%) occurred in pediatric patients, most of whom were male (1678 [85.1%]) and adolescents (1037 [52.6%]), with a mean (SD) age of 15.2 (5) years. Common locations of injury were home (761 [38.6%]) and street (490 [24.8%]). Mean (SD) hospital length of stay was 7.6 (12) days, ISS was 16 (13.1), and GCS score was 11 (5.1). The most common types of firearm-related ocular injuries were open wound of the eyeball (820 [41.6%]) and ocular adnexa (502 [25.5%]), orbital injuries or fractures (591 [30.0%]), and contusion of the eye or adnexa (417 [21.1%]). Patients aged 0 to 3 years had greater odds of unintentional injuries (odds ratio [OR], 4.41; 95% CI, 2.51-7.75; P < .001) and injuries occurring at home (OR, 5.39; 95% CI, 2.81-10.38; P < .001), and those aged 19 to 21 years had greater odds of assault injuries (OR, 2.17; 95% CI, 1.77-2.66; P < .001) and injuries occurring on the street (OR, 1.61; 95% CI, 1.3-1.98; P < .001). Black patients had the greatest odds of having injuries with assault intention (OR, 4.53; 95% CI, 3.68-5.59; P < .001), and white patients had the greatest likelihood for self-inflicted injury (OR, 7.1; 95% CI, 5.92-9.51; P < .001). Traumatic brain injury resulted mostly from self-inflicted trauma (OR, 5.99; 95% CI, 4.16-8.63; P < .001), as did visual pathway injuries (OR, 2.86; 95% CI, 1.95-4.20; P < .001). The inpatient mortality rate was 12.2%., Conclusions and Relevance: This study found that pediatric firearm-related ocular injuries from 2008 through 2014 were predominantly sight-threatening and associated with traumatic brain injury. If the possible risk factors, including sex, age, race/ethnicity, and injury intention, can be confirmed for 2015 through 2019, these findings may be useful in developing strategies to prevent pediatric firearm-related ocular injuries.

5773. Weissman, M. N., et al. (1984). "In-utero gunshot wound to the head. Use of intraoperative ultrasonography for localization of an intracerebral projectile." Surgical neurology **21**(4): 347-350.

Approaching full gestational age, a 1700-g male fetus sustained a penetrating gunshot wound to the left parietal region of the head while in utero. The child was delivered by emergency caesarean section. Initially in profound fetal shock and with almost no neurological function, the child was eventually stabilized. A posttraumatic intracerebral porencephalic cyst developed, with the projectile moving freely within the confines of the cyst cavity. Six weeks after the initial injury, the patient underwent an operation for extraction of the projectile. The Neuro SectOR ATL ultrasound probe was used intraoperatively and was instrumental in determining the exact position of the intracerebral projectile.

5774. Weithoener, D. and U. Klages (1974). "[Determination of the mineral contents of human skulls by x-ray analysis with regard to projectile perforation (author's transl)]." Eine Bestimmung des Mineralgehaltes von menschlichen Schadelknochen aus dem Rontgenbild in Beziehung zu perforierenden Schussverletzungen **75**(3): 171-178.

5775. Welch, R. D. (2001). "Management of traumatically injured patients in the emergency department observation unit." Emergency medicine clinics of North America **19**(1): 137-154.

An EDOU may be an ideal setting for the short-term monitoring and treatment of certain acutely injured patients. The patients choosen for observation, and the diagnostic studies used, will be specific to a particular

institution's availability and expertise. Pathways should be developed in conjunction with all services caring for these patients.

5776. Wellwood, J., et al. (2002). "Neurotrauma: the role of CT angiogram." Neurological research **24 Suppl 1**: S13-16.

Cerebrovascular injuries can occur in blunt or penetrating head and neck trauma. A high index of suspicion based on mechanism of injury and clinical assessment warrants screening for intracranial and extracranial vascular lesions. Conventional angiogram has been and remains the gold standard for diagnosis of these injuries, but computerized tomography angiography offers a fast, noninvasive method of imaging for neurotrauma patients. Advantages and disadvantages of each modality are discussed.

5777. Welter, S. (2014). "Repair of tracheobronchial injuries." Thoracic surgery clinics **24**(1): 41-50.

Tracheobronchial injuries (TBIs) are caused by blunt, penetrating injury or by iatrogenic damage. Most injuries are life threatening and need early and skillful airway management. Bronchoscopy remains the gold standard of diagnosis. Penetrating TBI always needs blunt trauma, and iatrogenic TBI sometimes needs surgical exploration and reconstruction, which is performed after sparing debridement with primary repair and wound closure. Prognosis mainly depends on associated injuries and comorbidities in terms of tracheal membrane laceration.

5778. Welter, S. and W. Essaleh (2020). "Management of tracheobronchial injuries." Journal of Thoracic Disease **12**(10): 6143-6151.

Tracheobronchial injuries (TBI) are a heterogenous group of sometimes life-threatening traumas with different management approaches. Symptoms are mediastinal and subcutaneous emphysema, bloody secretions from the airway or haemoptysis in alert patients, and high air leakage along the cuff or increased ventilatory resistance may be signs for TBI in intubated patients. The necessity of immediate clinical evaluation, CT-scan and bronchoscopic evaluation are essential for prompt diagnosis and classification as well as experienced air way management and treatment, these patients are best managed from interdisciplinary teams including thoracic surgeons. While iatrogenic tracheal membrane laceration from intubation can be treated by lesion bridging with ventilation tube, stent application, open operative repair or endoluminal repair, intraoperative accidental cuts should be repaired by direct suture or with vital tissue coverage in case of local ischemia. The management of blunt or penetrating injury is sequential and needs immediate establishment and maintenance of a secure patent airway to provide adequate oxygenation. The next step is the treatment of life-threatening collateral injuries like major hemorrhage, cranial trauma or major organ damage arranged in the trauma team. The treatment of penetrating injuries to the airway need operative exploration in almost every case with minimal local dissection and debridement followed by direct repair. Muscle flap coverage is useful in case of combined esophageal injury. Damage of the tracheobronchial tree after blunt trauma must be repaired by direct suture or local tissue sparing resection and anastomosis. These lesions can be missed in the initial phase and may become prominent with scar tissue formation, stenosis and atelectasis in the later phases.

5779. Wen, P. Y., et al. (2015). "Ceritinib in ALK1 NSCLC metastatic to brain and/or leptomeninges: The ASCEND-7 study." Neuro-Oncology **17**: v52.

BACKGROUND: The anaplastic lymphomakinase inhibitor (ALKi) crizotinibachieves high responses in patients with ALK-rearranged (ALK+) non-small cell lung cancer (NSCLC). However, disease progression can occur within 1 year and the brain/central nervous system (CNS) is a common site of progression/relapse. Ceritinib is a novel oral ALKi with 20-fold greater potency than crizotinib in enzymatic assays and crosses the blood-brain barrier with good CNS penetration in preclinical studies. In phase 1 and 2 studies, ceritinib was highly active in ALK+ NSCLC patients (regardless of prior crizotinib exposure) and achieved intracranial responses in 31-59% of patients with measurable baseline brain lesions. METHODS: This international, prospective, phase 2, open-label study will evaluate the antitumor activity of ceritinib in patients with ALK+ NSCLC and active brain metastases (BM) or leptomeningeal carcinomatosis (LC), either with or without prior whole brain radiotherapy (WBRT) (ASCEND-7;NCT02336451). Eligible patients must have ALK+ (centrally assessed) NSCLC with active CNS metastases and ≥1 extracranial measurable lesion using Response Evaluation Criteria in Solid Tumors (RECIST) v1.1. Patients must be neurologically stable prior to study drug administration and will

be allocated to 1 of 5 arms: active BM without LC, with prior ALKi exposure, with or without prior WBRT (Arms 1 and 2, respectively); active BM without LC, with no prior ALKi exposure, with or without prior WBRT (Arms 3 and 4, respectively); LC with or without evidence of active lesion at baseline (Arm 5). Oral ceritinib 750 mg/day will be dosed on a continuous schedule. The primary and key secondary objectives are to evaluate overall response rate and disease control rate, respectively. Other secondary objectives include assessment of intracranial and extracranial response for all patients and overall survival and safety for all patients in arms 1-4, including pharmacokinetics for each of arms 1-5. Enrollment is ongoing.

5780. Wendling-Keim, D. S., et al. (2021). "Trauma Scores and Their Prognostic Value for the Outcome Following Pediatric Polytrauma." Frontiers in Pediatrics **9**.

Purpose: The management and prognostic assessment of pediatric polytrauma patients can pose substantial challenges. Trauma scores developed for adults are not universally applicable in children. An accurate prediction of the severity of trauma and correct assessment of the necessity of surgical procedures are important for optimal treatment. Several trauma scores are currently available, but the advantages and drawbacks for use in pediatric patients are unclear. This study examines the value of the trauma scores Injury Severity Score (ISS), Pediatric Trauma Score (PTS), National Advisory Committee for Aeronautics (NACA), and Glasgow Coma Score (GCS) for the assessment of the polytraumatized child. Methods: In a retrospective study, 97 patients aged 0–17 years who presented with polytrauma and an ISS ≥16 in the trauma bay were included in the study. Patient records including radiological studies were analyzed. Pathological imaging findings and emergency surgery were assessed as outcome variables and the predictive value of the trauma scores were analyzed using receiver operator characteristic (ROC) curves. Statistical significance was set at an alpha level of $P \leq 0.05$. Results: In this study, 35 of the 97 studied children had pathological cranial computed findings. These either underwent craniectomy or trepanation or a parenchymal catheter was placed for intracranial pressure monitoring. Abdominal trauma was present in 45 patients, 16 of which were treated surgically. Forty-three patients arrived with thoracic injuries, 10 of which received a thoracic drainage. One child underwent an emergency thoracotomy. Predictive accuracy for emergency surgery calculated using receiver-operator characteristic (ROC) curves was highest for ISS and NACA scores (0,732 and 0.683, respectively), and lower for GCS (0.246) and PTS (0.261). Conclusion: In our study cohort, initial ISS and NACA scores better predicted operative interventions and outcome than PTS or GCS for polytraumatized pediatric patients.

5781. Weppner, J. and H. Asthagiri (2017). "Hyponatraemia in patients with moderate and severe traumatic brain injury: risk factors, prevalence and short-term consequences." Brain injury. Conference: 12th world congress on brain injury of the international brain injury association. United states **31**(6-7): 793.

Objectives: Hyponatraemia, a common electrolyte disorder associated with traumatic brain injuries (TBIs), has been associated with high morbidity and mortality rates. In addition, hyponatraemia is one of the main causes of disability in TBI patients. Mild symptoms of hyponatraemia include irritability, headaches, nausea and poor balance with severe symptoms that include confusion, seizures, coma and even death. The pathophysiology of hyponatraemia in TBI is not completely understood, but in large part is explained by the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and cerebral salt wasting (CSW). Despite the importance of sodium disorders in TBI, the incidence has been little studied. The aim of this study is to identify the incidence of and risk factors for hyponatraemia in adult persons with moderate-to-severe TBI. Methods: Patients who were admitted to our level one trauma centre with moderate or severe TBI between May 2011 and May 2016 were retrospectively reviewed. Patients admitted with spinal cord injury and TBI were excluded as spinal cord injury could confound the cause of hyponatraemia. The relationships between the occurrence of hyponatraemia and age, sex, type of injury, Glasgow Coma Scale (GCS) score, Glasgow Outcome Scale score at discharge, whether the patient underwent surgery, the presence of cerebral oedema, skull fracture, and intracranial injury were analysed statistically using a chi2 test and multivariate logistic regression analysis. Results: Out of the 3460 subjects retrospectively reviewed for the study (2145 males and 1315 females; age of 45 +/- 13 years), 1214 (35%) suffered from hyponatraemia, which was defined as a serum sodium level <135 mmol/L. Hyponatraemia was associated with longer hospital stay ($p < .001$) and bad outcome, which was defined as a Glasgow Outcome Scale score of severe disability or higher on discharge ($p < .05$). Multivariate analysis indicated that hyponatraemia following TBI was not related to age ($p > 0.05$), sex ($p > 0.05$), or surgical history ($p > 0.05$), but that it was related to the intracranial haemorrhage (odds ratio = 3.11, $p < 0.05$), a GCS score <=8 (odds ratio = 4.25, $p < 0.001$), penetrating head trauma (odd ratio = 5.83, $p < 0.001$), the presence of cerebral oedema (odd ratio = 6.85, $p < 0.001$),

and skull fracture (odds ratio = 5.91, p < 0.001). Conclusions: To increase the understanding of hyponatraemia in persons with TBI, the present study investigated the prevalence and aetiology of hyponatraemia in the setting of TBI. The prevalence of hyponatraemia following TBI was not associated with age, sex, or whether the patient underwent surgery. TBI patients with intracranial haemorrhage, GCS score <=8, presence of cerebral oedema, penetrating head trauma and skull fracture are particularly prone to developing hyponatraemia. These patients require close monitoring of sodium and prompt treatment of hyponatraemia to normalize serum sodium levels to prevent deterioration of their condition.

5782. Wesley, R. E., et al. (1987). "Management of orbital-cranial trauma." Advances in ophthalmic plastic and reconstructive surgery **7**: 3-26.

Orbital-cranial injuries have the greatest potential for death and disability of any condition treated by the ophthalmologist. An object that penetrates through the orbit into the brain may leave only a small entrance wound. Patients can have normal vision, neurologic exam, and plain x-rays despite trauma that may lead to meningitis, brain abscess, or pneumocephalus. The CT scan greatly aids in both the early and late management of blunt and penetrating orbital-cranial trauma. The detection of pneumocephalus may be the only clue that intracranial penetration has occurred. Blunt trauma can cause vision loss, ophthalmoplegia, ptosis, and intracranial injury. Management of orbital-cranial trauma frequently requires a team approach by the ophthalmologist and neurosurgeon due to the complexity of these injuries.

_____

5783. Wesley, R. E. and C. D. McCord (1982). "Tension pneumocephalus from orbital roof fracture." Annals of ophthalmology **14**(2): 184-190.

Despite the detection and treatment of an extensive orbitocranial fracture in an 18-year-old man following a motor vehicle injury, the persistent leakage of CSF and trapping of air within the intracranial cavity resulted in fulminant neurologic deterioration due to the mass effect of air when tension pneumocephalus developed. The ethmoidal defect closed spontaneously, and the patient recovered neurologically when the tension pneumocephalus was relieved with a ventriculoatrial shunt. Orbitocranial injuries, which may be unsuspected despite careful orbital, neurologic, and conventional roentgenographic examination, have a considerable mortality. The presence of intracranial penetration. The CT scans, which detect as little as 0.5 mL of intracranial air, can be used to document serial changes in amount or position of air and detect shifts of the brain. tension pneumocephalus following orbitocranial injury and management with ventriculoatrial shunting have not been previously reported.

5785. Wessely, P. (1977). "[Epileptic manifestations following head injury (author's transl)]." Epileptische Manifestationen nach Schadelhirntraumen **64**: 1-43.

An analysis is presented of the findings in a group of 300 patients with head injury, aged 15 years or over at the time of the accident, who subsequently developed epileptic manifestations. Early fits (including one case of immediate onset) were found in 33% of the cases (99 patients). In contrast to post-traumatic late epilepsy (PTE), which is a manifestation of a static process, early fits are triggered off by a dynamic process (brain oedema, haemorrhage) and are a sign of cerebral irritation, but do not represent a true form of epilepsy. Early fits are related to the acute traumatic state; the time limit is flexible, but lies in the region of 4 weeks following injury. Conversion of early fits to PTE (with or without a latent interval) occurred in 72% of the cases. This percentage is higher than the average incidence quoted in the literature and presumably arises partly from the selection criteria applied in this study. The time of appearance of early fits following injury is one factor which determines the prognosis. Fits appearing on the first day carry a relatively favourable prognosis and do not proceed to PTE in 41% of the cases, whereas this percentage shrinks to 15% in the case of fits appearing from the second week onwards. Early fits are an isolated occurrence in one third of the cases; progression to PTE is less frequent in these patients than following frequent, repeated convulsions. Furthermore, the

incidence of early fits is dependent, to a large extent, on traumatological and clinical factors: the combination of unconsciousness of over three hours' duration, neurological signs referable to the central nervous system, persistent organic psychotic syndrome and intracranial bleeding leads to a significantly higher incidence of early fits than unconsciousness of less than three hours' duration and absence of neurological signs in patients who, moreover, do not display features of the psychotic syndrome, and shows a greater tendency to early fits even than the combination of depressed fracture of the skull with penetration of the dura. Should, however, early fits occur in spite of a favourable assessment of the traumatological factors involved, then progression to PTE occurs in a higher percentage of such cases than in patients displaying signs of a serious import following injury. The transition to PTE is markedly higher following diffuse cerebral contusion (75% of cases) than in cases displaying signs of local contusion....

5786. Westenbroek, R. E., et al. (1998). "Upregulation of L-type Ca2+ channels in reactive astrocytes after brain injury, hypomyelination, and ischemia." The Journal of neuroscience : the official journal of the Society for Neuroscience **18**(7): 2321-2334.

Anti-peptide antibodies that specifically recognize the alpha1 subunit of class A-D voltage-gated Ca2+ channels and a monoclonal antibody (MANC-1) to the alpha2 subunit of L-type Ca2+ channels were used to investigate the distribution of these Ca2+ channel subtypes in neurons and glia in models of brain injury, including kainic acid-induced epilepsy in the hippocampus, mechanical and thermal lesions in the forebrain, hypomyelination in white matter, and ischemia. Immunostaining of the alpha2 subunit of L-type Ca2+ channels by the MANC-1 antibody was increased in reactive astrocytes in each of these forms of brain injury. The alpha1C subunits of class C L-type Ca2+ channels were upregulated in reactive astrocytes located in the affected regions in each of these models of brain injury, although staining for the alpha1 subunits of class D L-type, class A P/Q-type, and class B N-type Ca2+ channels did not change from patterns normally observed in control animals. In all of these models of brain injury, there was no apparent redistribution or upregulation of the voltage-gated Ca2+ channels in neurons. The upregulation of L-type Ca2+ channels in reactive astrocytes may contribute to the maintenance of ionic homeostasis in injured brain regions, enhance the release of neurotrophic agents to promote neuronal survival and differentiation, and/or enhance signaling in astrocytic networks in response to injury.

5787. Westergren, H., et al. (1991). "Traumatic occlusion of the internal carotid artery in a healthy young male: effects on the regional cerebral blood flow." Acta neurochirurgica **113**(1-2): 91-95.

The effects of acute right internal carotid artery occlusion in a previously healthy young male, was studied over a period of 10 months, with angiography, TransCranial Doppler ultrasonography (TCD) and SPECT-rCBF. A clinically observed inability to meet increased metabolic demand in the right hemisphere was concommitant to a decreased Pulsatility Index (PI) in the right middle cerebral artery (MCA). Autoregulation studies showed almost dilatation of the resistance vessels in the right middle cerebral artery territory, at rest. A decreased blood flow velocity, in the right middle cerebral artery 7 months after the accident, suggesting a decreased rCBF, could not be confirmed by SPECT-rCBF studies. This finding strongly cautions against interpretation of chronical blood flow velocity changes in terms of changes in regional blood flow. The present study shows the benefits in the combined use of angiography, SPECT-rCBF, and TCD.

5788. Whitaker, T. E., et al. (1999). "Orbital 'shanking': A unique prison injury." Orbit **18**(4): 273-279.

The purpose of this paper is to describe orbitocranial penetration due to 'shanking', a common mode of assault in prison facilities. We report the case of a prisoner who presented with orbital apex syndrome 5 days after an assault. He died 9 days after surgical removal of the 'shank' due to a presumed ruptured traumatic aneurysm. Physicians who evaluate prisoners must maintain a high index of suspicion for penetrating injuries. The entrance site is often inconspicuous and the history may be limited in this unique population.

5789. White, M. M. and M. R. Lofwall (2015). "Challenges of the capacity evaluation for the consultation-liaison psychiatrist." Journal of psychiatric practice **21**(2): 160-170.

Assessing medical decision-making capacity is a clinical skill required of all medical professionals, but it is particularly essential for consultation- liaison psychiatrists. Medical decision-making capacity, often confused with competency, is evaluated by assessing 4 standards, which include whether a patient (1) can understand his or her

medical situation, (2) can manipulate the information, (3) can evidence a choice about the proposed treatment, and (4) can appreciate the situation and its consequences. Multiple myths and pitfalls may be encountered during capacity evaluations; many of these can be avoided by proper education and training. We discuss the case of a 71-year-old man who presented to the emergency department by ambulance and was refusing non-emergent neurosurgery after a self-inflicted gunshot wound to the head. He was evaluated for medical decision-making capacity, specifically on whether he had the capacity to refuse neurosurgery and accept intravenous antibiotic treatment. In discussing this case, which illustrates the elements, challenges, and ethical dilemmas of the capacity evaluation, we review several mental illnesses that may prevent individuals from having medical decision-making capacity. Myths and pitfalls of capacity evaluations and possible methods for avoiding them are proposed. Specifically, we emphasize the importance of communication between the primary team and the consultationliaison psychiatry service and describe possible solutions to common communication problems that may arise between services. It is hoped that this case presentation and review will help educate psychiatry residents and other physicians so that they are well prepared to perform a medical decision-making capacity evaluation.

5791. Whitlock, R. I. and J. M. Gorman (1978). "Some missile injuries due to civil unrest in Northern Ireland." International journal of oral surgery **7**(4): 240-245.

Some missile injuries are reviewed after nearly 8 years of continuous warfare. A feature of many of these injuries is the early admission to hospital which has had a profound effect on the survival rate and the recovery period. Some examples are given of injuries inflicted by rubber bullets. The effects of wounding by low and high velocity missiles are described and examples given. An injury caused by a missile incorporated in a bomb is also shown.

5792. Widodo, D., et al. (2022). "Combined transcranial and transnasal endoscopic approach in transnasal-penetrating intracranial injury: A rare case report." International journal of surgery case reports **97**: 107422.

INTRODUCTION: Transnasal-penetrating intracranial injuries are rare traumatic brain injuries that can cause serious and fatal brain damage and a high mortality rate and necessitate immediate multidisciplinary surgical management. We describe an uncommon case whereby a patient who presented with an accidental penetrating injury of the brain was found to have a wooden transnasal-penetrating intracranial object., CASE PRESENTATION: A 28-year-old man consulted an ear, nose, and throat (ENT) surgeon after complaints of headache for two days, a history of epistaxis, and vomitus. The right side of the nose had been punctured by wood as a result of falling from a motorcycle. A computed tomography (CT) scan led to diagnosis of a transnasal penetrating intracranial injury. Removal of the transcranial foreign body was carried out jointly by a neurosurgeon and ENT surgeon. Postoperatively, antibiotics were given for 14 days, and the patient was discharged without neurological deficit., CLINICAL DISCUSSION: Early diagnostic procedures, such as CT scan of the skull to assess trajectory and extent of vascular and brain tissue injury, are required for appropriate surgical planning and post-operative treatment of such patients. Surgery was performed by combined transcranial and transnasal endoscopy to identify the skull base, dura mater defect, and brain tissue damage. Removal of the corpus alienum by transnasal endoscopy yielded a good outcome., CONCLUSION: Combined transcranial and transnasal endoscopic approach showed better result than transcranial approach only. The wooden foreign body can be completely eliminated transnasally without active bleeding using this approach. The patient was discharged with good outcome.

5793. Wieck, M. M., et al. (2018). "Direct to operating room trauma resuscitation decreases mortality among severely injured children." The journal of trauma and acute care surgery **85**(4): 659-664.

BACKGROUND: Expediting evaluation and intervention for severely injured patients has remained a mainstay of advanced trauma care. One technique, direct to operating room (DOR) resuscitation, for selective adult patients has demonstrated decreased mortality. We sought to investigate the application of this protocol in children., METHODS: All DOR pediatric patients from 2009 to 2016 at a pediatric Level I trauma center were identified. Direct to OR criteria included penetrating injury, chest injuries, amputations, significant blood loss, cardiopulmonary resuscitation, and surgeon discretion. Demographics, injury patterns, interventions, and outcomes were analyzed. Observed mortality was

compared with expected mortality, calculated using Trauma Injury Severity Score methodology, with two-tailed t tests, and a p value less than 0.5 was considered significant., RESULTS: Of 2,956 total pediatric trauma activations, 82 (2.8%) patients (age range, 1 month to 17 years) received DOR resuscitation during the study period. The most common indications for DOR were penetrating injuries (62%) and chest injuries (32%). Forty-four percent had Injury Severity Score (ISS) greater than 15, 33% had Glasgow Coma Scale (GCS) score of 8 or less, and 9% were hypotensive. The most commonly injured body regions were external (66%), head (34%), chest (30%), and abdomen (27%). Sixty-seven (82%) patients required emergent procedural intervention, most commonly wound exploration/repair (35%), central venous access (22%), tube thoracostomy (19%), and laparotomy (18%). Predictors of intervention were ISS greater than 15 (odds ratio, 14; p = 0.013) and GCS < 9 (odds ratio = 8.5, p = 0.044). The survival rate to discharge for DOR patients was 84% compared with an expected survival of 79% (Trauma Injury Severity Score) (p = 0.4). The greatest improvement relative to expected mortality was seen in the subgroup with penetrating trauma (84.5% vs 74.4%; p = 0.002)., CONCLUSION: A selective policy of resuscitating the most severely injured children in the OR can decrease mortality. Patients suffering penetrating trauma with the highest ISS, and diminished GCS scores have the greatest benefit. Trauma centers with appropriate resources should evaluate implementing similar policies., LEVEL OF EVIDENCE: Diagnostic tests or criteria, level II.

5794. Wiedemayer, H., et al. (2002). "Early seizures following non-penetrating traumatic brain injury in adults: risk factors and clinical significance." Brain injury **16**(4): 323-330.

BACKGROUND: In the literature dissenting data are obtained about risk factors for early post-traumatic seizures and their impact on outcome. This study was conducted to obtain more information about the clinical significance of early seizures and their possible impact on the treatment of traumatic brain injury., METHODS AND RESULTS: A consecutive series of 1868 adult patients with head injury were analysed retrospectively. Demographic data of the patients, characteristics of the injury, and findings on CT scan were recorded. Risk factors for early post-traumatic seizures were identified using univariate statistics. A multivariate logistic regression was performed to look for interaction of different variables. The impact of early post-traumatic seizures on outcome was examined in an analogous way. Chronic alcohol abuse, subdural haematoma and brain contusion were identified as independent risk factors for early post-traumatic seizures. A significant association of early post-traumatic seizures with an unfavourable outcome was observed, but this effect was small compared to other variables., CONCLUSIONS: Early post-traumatic seizures appear to be an acute reaction of the brain to cortical damage with little independent impact on the management of head injury.

5795. Wienand, P., et al. (1992). "Donor conditions and graft survival--a retrospective study." Transplant international : official journal of the European Society for Organ Transplantation **5 Suppl 1**: S151-152.

In a retrospective study (one centre) the influence of donor and recipient factors were evaluated (n = 308). Head injury as the cause of death and anastomotic time less than 35 min were associated with a significantly better graft survival rate (P < 0.05). Although some of the donor factors influence graft survival, a stricter selection of grafts is not advisable, firstly because fewer kidneys would then be offered, and secondly because even comparatively bad graft survival rates are still better than dialysis.

5796. Wigginton, J. G., et al. (2011). "Advances in resuscitative trauma care." Minerva anestesiologica **77**(10): 993-1002.

Over the last two decades, experimental and clinical data have begun to shape a more discriminating approach to intravascular (IV) fluid infusions in the resuscitation of trauma patients with presumed internal hemorrhage. This approach takes into account the presence of potentially uncontrollable hemorrhage (e.g., deep intra-abdominal or intra-thoracic injury) versus a controllable source (e.g. distal extremity wound). This limitation on fluid resuscitation is particularly applicable in the case of patients with penetrating truncal injury being transported rapidly to a nearby definitive care center. Meanwhile, longstanding debates over the type of fluid that should be infused remain largely unresolved and further complicated by recent clinical trials that did not demonstrate support for either hemoglobin-based oxygen carriers or hypertonic saline. However, there is also growing evidence that does support the increased use of fresh frozen plasma as well as tourniquets, and intra-osseous devices. While a more discriminating approach to fluid infusions have evolved, it has also become clear that positive pressure ventilatory support should be limited in the face of potential severe hemorrhage due to the accompanying reductions in venous return. Controversies over prehospital

endotracheal tube placement are confounded by this factor as well as the effects of paramedic deployment strategies and related skills usage. Beyond these traditional areas of focus, a number of very compelling clinical observations and an extensive body of experimental data has generated a very persuasive argument that intravenous estrogen and progesterone may be of value in trauma management, particularly severe traumatic brain injury and burns.

5797. Wijdicks, E. F. M. and E. A. Pfeifer (2008). "Neuropathology of brain death in the modern transplant era." Neurology **70**(15): 1234-1237.

BACKGROUND: Autopsy studies in patients who have been declared brain dead are rare. Total brain necrosis ("respirator brain") has been a common finding in the distant past. The time to brain fixation has been shortened as a result of timely organ transplant protocols, therefore the neuropathologic findings may be different than previously described., METHODS: We reviewed macroscopic and microscopic brain pathology for ischemic neuronal damage in 41 patients who fulfilled the clinical criteria of brain death. Hematoxylin and eosin stained brain tissue slides were retrieved and available wet tissue was additionally stained to complete a series of samples of the hemispheres, brainstem, and cerebellum for each patient. Neuronal ischemic change was semiquantitatively graded for severity (mild 0 to 5%, moderate >5 to 75%, and severe >75%)., RESULTS: After the clinical diagnosis of brain death and terminal cardiac arrest, 12 brains were fixated in less than 12 hours and 29 brains were fixated between 12 and 36 hours. The frontal lobe, temporal lobe, parietal lobe, occipital lobe, and basal ganglia showed moderate to severe ischemic change in 53 to 68% of the cases. Moderate to severe neuronal ischemic change was found in the thalamus in 34%, midbrain in 37%, pons in 41%, medulla in 40%, and cerebellum in 52% of the cases., CONCLUSIONS: No distinctive neuropathologic features were apparent in our series of patients with brain death. Neuronal ischemic changes were frequently profound, but mild changes were present in a third of the examined hemispheres and in half of the brainstems. Respirator brain with extensive ischemic neuronal loss and tissue fragmentation was not observed. Neuropathologic examination is therefore not diagnostic of brain death.

5798. Wilberger, J. E., Jr. and D. Pang (1983). "Craniocerebral injuries from dog bites." JAMA **249**(19): 2685-2688.

Dog bites are a common cause of injury in infants and children, with the face and head frequently involved. While scalp injuries may be extensive and severe, only five cases of compound depressed skull fractures caused by dog bites have been reported, to our knowledge. Four cases are presented to point out the potential risks of cranial penetration and underlying brain injury when infants and children suffer dog bites to the head. The principles for management of these injuries are outlined.

5799. Wilgus, J. and B. Wilgus (2009). "Face to face with Phineas Gage." Journal of the history of the neurosciences **18**(3): 340-345.

We present here a reproduction of a daguerreotype of Phineas Gage that came into our possession more than 30 years ago. It is, as far as we know, the only image of this famous patient. We describe how we identified the subject in the image, describe how daguerreotypes are made and set out our comparisons of the image with the Phineas Gage life mask and tamping iron held in the Warren Anatomical Museum, Francis A. Countway Library of Medicine.

5801. Will, M. J., et al. (2005). "Oral and maxillofacial injuries experienced in support of operation Iraqi Freedom I and II." Oral and maxillofacial surgery clinics of North America **17**(3 SPEC. ISS.): 331-339.

Penetrating, perforating, and avulsive fragmentation injuries present a unique surgical challenge for oral and maxillofacial surgeons in the Iraqi theater of operation. Maxillofacial injuries encountered in Operation Iraqi Freedom I and Operation Iraqi Freedom II have presented injury patterns not encountered previously in other large-scale armed conflicts. Current literature in the field of oral and maxillofacial surgery does not cover adequately the concerns that are inherent to care and treatment planning at an echelon III facility. This article addresses clinical and surgical practice

guidelines that were developed by oral surgeons in theater and from feedback they received from higher echelons of care.

5802. Williams, A. J., et al. (2006). "Penetrating ballistic-like brain injury in the rat: differential time courses of hemorrhage, cell death, inflammation, and remote degeneration." Journal of neurotrauma **23**(12): 1828-1846.

Acute and delayed cerebral injury was assessed in a recently developed rat model of a penetrating ballistic-like brain injury (PBBI). A unilateral right frontal PBBI trajectory was used to induce survivable injuries to the frontal cortex and striatum. Three distinct phases of injury progression were observed. Phase I (primary injury, 0-6 h) began with immediate (<5 min) intracerebral hemorrhage (ICH) that reached maximal volumetric size at 6 h (27.0 +/- 2.9 mm(3)). During Phase II (secondary injury, 6-72 h), a core lesion of degenerate neurons surrounding the injury track expanded into peri-lesional areas to reach a maximal volume of 69.9 +/- 6.1 mm(3) at 24 h. The core lesion consisted of predominately necrotic cell death and included marked infiltration of both neutrophils (24 h) and macrophages (72 h). Phase III (delayed degeneration, 3-7 days) involved the degeneration of neurons and fiber tracts remote from the core lesion including the thalamus, internal capsule, external capsule, and cerebral peduncle. Overall, different time courses of hemorrhage, lesion evolution, and inflammation were consistent with complementary roles in injury development and repair, providing key information about these mediators of primary, secondary, and delayed brain injury development. The similarities/differences of PBBI to other focal brain injury models are discussed.

5803. Williams, A. J., et al. (2006). "Severity level and injury track determine outcome following a penetrating ballistic-like brain injury in the rat." Neuroscience letters **408**(3): 183-188.

Penetrating ballistic brain injury (PBBI) is a high-energy transfer wound causing direct damage to the cerebrum. Outcome is directly related to the ballistic's anatomical path and degree of energy transfer. In this study we evaluated differences in outcome induced by altering the 'projectile' paths and severity levels of a simulated bullet wound using a newly characterized rat model of PBBI. Severity levels (5, 10, and 15%) were compared across three distinct injury paths: (1) unilateral 'frontal', (2) 'bilateral' hemispheric, and (3) unilateral 'caudal' (including cerebellum/midbrain). Outcome was assessed by differences in mortality rate and motor dysfunction (e.g. neurological and balance beam deficits). Results indicated that outcome was dependent not only on the severity level of PBBI ($P<0.001$, $r=0.535$) but also brain regions injured ($P<0.001$, $r=0.398$). A unilateral caudal injury was associated with the highest degree of mortality (up to 100%) and motor dysfunction (64-100% disability). Bilateral hemispheric injuries were also potentially fatal, while the best outcomes were associated with a unilateral frontal injury (no mortality and 14-39% motor disability). These data closely resemble clinical reports of ballistic wounds to the head and further validate the rat PBBI model with the ultimate intent to investigate novel therapeutic approaches for diagnosis and treatment of the neuropathological damage associated with PBBI.

5804. Williams, A. J., et al. (2007). "Acute and delayed neuroinflammatory response following experimental penetrating ballistic brain injury in the rat." Journal of neuroinflammation **4**: 17.

BACKGROUND: Neuroinflammation following acute brain trauma is considered to play a prominent role in both the pathological and reconstructive response of the brain to injury. Here we characterize and contrast both an acute and delayed phase of inflammation following experimental penetrating ballistic brain injury (PBBI) in rats out to 7 days post-injury., METHODS: Quantitative real time PCR (QRT-PCR) was used to evaluate changes in inflammatory gene expression from the brain tissue of rats exposed to a unilateral frontal PBBI. Brain histopathology was assessed using hematoxylin and eosin (H&E), silver staining, and immunoreactivity for astrocytes (GFAP), microglia (OX-18) and the inflammatory proteins IL-1beta and ICAM-1., RESULTS: Time course analysis of gene expression levels using QRT-PCR indicated a peak increase during the acute phase of the injury between 3-6 h for the cytokines TNF-alpha (8-11 fold), IL-1beta (11-13 fold), and IL-6 (40-74 fold) as well as the cellular adhesion molecules VCAM (2-3 fold), ICAM-1 (7-15 fold), and E-selectin (11-13 fold). Consistent with the upregulation of pro-inflammatory genes, peripheral blood cell infiltration was a prominent post-injury event with peak levels of infiltrating neutrophils (24 h) and macrophages (72 h) observed throughout the core lesion. In regions of the forebrain immediately surrounding the lesion, strong immunoreactivity for activated astrocytes (GFAP) was observed as early as 6 h post-injury followed by prominent microglial reactivity (OX-18) at 72 h and resolution of both cell types in cortical brain regions by day 7. Delayed thalamic inflammation (remote from the primary lesion) was also observed as indicated by both microglial and astrocyte reactivity (72 h to 7 days)

concomitant with the presence of fiber degeneration (silver staining)., CONCLUSION: In summary, PBBI induces both an acute and delayed neuroinflammatory response occurring in distinct brain regions, which may provide useful diagnostic information for the treatment of this type of brain injury.

5805. Williams, C. N., et al. (1988). "Immediate and long-term management of gunshot wounds to the lower face." Plastic and reconstructive surgery **82**(3): 433-439.

The steadily increasing level of urban violence and attempted suicides in the recent past has resulted in large numbers of gunshot injuries to the face from small-caliber weapons. Our experience with 35 consecutive cases of civilian gunshot wounds involving primarily the lower face is presented. Initial management included securing of the airway, control of bleeding, and treatment of coexisting injuries. After clinical and radiologic evaluation and conservative debridement of all devitalized tissues, the mandibular fractures were reduced and stabilized appropriately. Large bony defects were treated by stabilization of the mandibular segments followed by secondary bone grafting. Intraoral soft tissues were then repaired with local mucosal flaps or tongue flaps when necessary. Finally, the soft tissues were repaired by primary closure or local flaps. Distant flaps were used only as a secondary procedure. Our results are presented, the differences between civilian and military injuries are discussed, and the principles of gunshot ballistics are described. We conclude that most of these wounds can be treated in a relatively conservative manner immediately after the injury with good functional and cosmetic results.

5806. Williams, J. R., et al. (2014). "Penetrating brain injury after suicide attempt with speargun: case study and review of literature." Frontiers in neurology **5**: 113.

Penetrating cranial injury by mechanisms other than gunshots are exceedingly rare, and so strategies and guidelines for the management of PBI are largely informed by data from higher-velocity penetrating injuries. Here, we present a case of penetrating brain injury by the low-velocity mechanism of a harpoon from an underwater fishing speargun in an attempted suicide by a 56-year-old Caucasian male. The case raised a number of interesting points in management of low-velocity penetrating brain injury (LVPBI), including benefit in delaying foreign body removal to allow for tamponade; the importance of history-taking in establishing the social/legal significance of the events surrounding the injury; the use of cerebral angiogram in all cases of PBI; advantages of using dual-energy CT to reduce artifact when available; and antibiotic prophylaxis in the context of idiosyncratic histories of usage of penetrating objects before coming in contact with the intracranial environment. We present here the management of the case in full along with an extended discussion and review of existing literature regarding key points in management of LVPBI vs. higher-velocity forms of intracranial injury.

5807. Williams, J. R., et al. (2014). "Penetrating brain injury after suicide attempt with speargun: Case study and review of literature." Frontiers in neurology **5 JUL**.

5808. Williams, R. W., et al. (1974). "Mass casualties in a maximum security institution." Annals of surgery **179**(5): 592-597.

5809. Williamson, T., et al. (2020). "Demographic and Clinical Differences Between Patients Undergoing Craniectomy or Craniotomy for Severe Traumatic Brain Injury." Clinical neurosurgery **67**(SUPPL 1): 170-171.

INTRODUCTION: Approximately 5.5 million people suffer severe traumatic brain injuries (sTBI) annually in the US. Patients with sTBI may undergo craniotomy or craniectomy after the incident, but the reason for selecting one procedure over the other is unclear. METHODS: The Trauma Quality Improvement Program database was retrospectively analyzed to identify adult patients with sTBI who underwent either craniectomy or craniotomy between 2013 and 2015. sTBI was defined as patients who had skull fracture or intracranial injury with a Head Abbreviated Injury Scale 2-5 and Glasgow Coma Scale 3-8. Patients were divided into craniectomy and craniotomy groups, and demographic and clinical characteristics were summarized. RESULTS: Among 47,544 patients with sTBI, 5,952 had either craniectomy (n = 2,092, 35.1%) or craniotomy (n = 3,860, 64.9%). Craniotomy patients were older (median: 45 years vs. 38 years), with a greater proportion of patients >60 years old (27.0% vs. 15.9%). A higher proportion of craniectomy patients were treated in university hospitals (61.3% vs. 54.8%), and a higher proportion of craniotomy patients had inter-hospital transfer (34.9% vs. 23.9%). The craniectomy group had a higher percentage of patients with an Injury Severity Score >24 (61.0% vs. 46.0%). The craniotomy group had a higher proportion of falls (44.2% vs. 31.7%) and lower percentage of transportationrelated injuries (40.3% vs 49.2%). The craniectomy group had a higher percentage of penetrating injury (12.7% vs. 9.0%) and lower percentage of hematoma (72.6% vs. 80.7%). Patients who underwent craniectomy spent more time in the hospital (16 days vs. 13 days), in the ICU (11 days vs. 9 days), and on a ventilator (9 days vs. 6 days). In-hospital mortality was higher among craniectomy patients (37.9% vs. 28.0%), whereas a higher percentage of craniotomy patients were discharged to home (18.8% vs. 8.1%). CONCLUSION: Patients undergoing craniectomy were younger, but suffered a higher proportion of transportation-related injuries, were more severely injured, had a more protracted hospital course, and had higher in-hospital mortality than craniotomy patients. This suggests that sTBI patients with more severe injuries aremore likely to undergo craniectomy than craniotomy.

5810. Willy, C., et al. (2008). "[Patterns of injury in a combat environment. 2007 update]." Kriegschirurgische Verletzungsmuster. UPDATE 2007. **79**(1): 66-76.

BACKGROUND: Epidemiological analysis of injury patterns and mechanisms help in identifying the expertise that military surgeons need in a combat setting and also in adjusting training requirements accordingly. This paper attempts to assess the surgical specialties and skills of particular importance in the management of casualties in crisis areas., METHODS: MEDLINE (1949-2007) and Google search were used. Causes of death among casualties in Afghanistan and the Iraq war were analyzed., RESULTS: The leading causes of injury were explosive devices, gunshot wounds, aircraft crashes, and terrorist attacks. Of the casualties, 55% died in hostile action and 45% in nonhostile incidents. Chest or abdominal injuries (40%) and brain injuries (35%) were the main causes of death for soldiers killed in action. The case fatality rate in Iraq was approximately half as high as in the Vietnam War. In contrast, the amputation rate was twice as high. Approximately 8-15% of the deaths appeared to be preventable., CONCLUSIONS: Military surgeons must have excellent skills in the fields of thoracic, visceral, and vascular surgery as well as practical skills in neurosurgery and oral and maxillofacial surgery. It also is of vital importance to ensure the availability of sufficient medical evacuation capabilities. Furthermore, there is a need for a standardized registration system for all injuries similar to the German Trauma Registry.

5811. Willyerd, F. A. and R. G. Hart (2014). "Traumatic brain injury shifts brain drug transporter levels: Implications for drug therapies." Neurocritical care **21**(1): S152.

Introduction ATP-binding cassette (ABC) transporters function to selectively regulate the brain milieu through active efflux of substrates. Little is known about how traumatic brain injury (TBI) shifts the levels of these transporters and alters microenvironments. Similarly, changes in the expression of ABC transporters after TBI could influence therapeutic drug penetration and outcomes. We hypothesize that quantifiable changes occur in ABC transporter expression after TBI. Methods Adult male Sprague-Dawley rats (n=3/group) underwent moderate TBI midline fluid percussion injury (FPI) then were killed at eight time points post-injury. Tissue from parietal cortex, hippocampus, and thalamus was analyzed via Western blot and compared to sham injured animals (n=4) using student t-test. Results Bcrp decreased ($P< 0.05$) compared to sham at days 5, 7, 14, and 56 post-injury in parietal cortex. Bcrp hippocampal and thalamic expression decreased ($P< 0.05$) at all points except day 3 post-injury. Mrp1 increased ($P< 0.05$) compared to sham at days 1, 2, 7, and 14 post-injury in parietal cortex and thalamus. Mrp1 hippocampal expression increased ($P< 0.05$) at days 7 and 14 post-injury. P-gp increased ($P< 0.05$) compared to sham at days 1,2,3, and 5 post-injury in parietal

cortex but increased (P< 0.05) on days 1 and 2 post-injury in hippocampus. Pgp in thalamic tissue increased (P< 0.05) on day 1 post-injury. Conclusions We found Bcrp decreased significantly at both early and late time point's post-TBI. This could cause decreased efflux of substrates like glutathione and estradiol. We found an increase in Mrp1 and P-gp expression acutely. Increased ABC transporters could cause elevated efflux of substrates like opioids, anti-seizure medication, and prostaglandins. These data could influence clinical care because TBI therapeutic drugs may not reach therapeutic brain levels if administered during a period of overexpression. ABC transporter expression may serve as a biomarker for personalized medicine in tailoring therapeutic delivery to individual patients.

5812. Wilson, B. C., et al. (1988). "Comparison of complications following frontal sinus fractures managed with exploration with or without obliteration over 10 years." The Laryngoscope **98**(5): 516-520.

Two hundred twelve patients were treated for facial or skull trauma at the West Virginia University Hospital between the years 1977 and 1987. Sixty-six of these patients had frontal sinus or nasofrontal duct trauma. Follow-up information was obtained on 64 of these patients through clinic visits, chart review, questionnaires to patients and physicians, and telephone calls to the patients. Follow-up greater than 1 year was obtained on 52 patients. Sixty-four patients were managed either with a frontal sinus obliteration or with an open exploratory procedure. The incidence of complications occurring in the past 10 years after each of these procedures is compared. Because the indications for each procedure vary somewhat, data is presented on fracture etiology, associated injuries, specific fracture location, fracture displacement, severity of injury, and associated cerebrospinal fluid leaks.

5813. Wilson, C., et al. (2021). "Institutional review of the management of type II odontoid fractures: associations and outcomes with fibrous union." Journal of neurosurgery. Spine **34**(4): 623-631.

OBJECTIVE: Type II odontoid fractures may be managed operatively or nonoperatively. If managed with bracing, bony union may never occur despite stability. This phenomenon is termed fibrous union. The authors aimed to determine associations with stable fibrous union and compare the morbidity of patients managed operatively and nonoperatively., METHODS: The authors performed a retrospective review of their spine trauma database for adults with type II odontoid fractures between 2015 and 2019. Two-sample t-tests and Fisher's exact tests identified associations with follow-up stability and were used to compare operative and nonoperative outcomes. Sensitivity, specificity, and predictive values were calculated to validate initial stable upright cervical radiographs related to follow-up stability., RESULTS: Among 88 patients, 10% received upfront surgical fixation, and 90% were managed nonoperatively, of whom 22% had fracture instability on follow-up. Associations with instability after nonoperative management include myelopathy (OR 0.04, 95% CI 0.0-0.92), cerebrovascular disease (OR 0.23, 95% CI 0.06-1.0), and dens displacement >= 2 mm (OR 0.29, 95% CI 0.07-1.0). Advanced age was not associated with follow-up instability. Initial stability on upright radiographs was associated with stability on follow-up (OR 4.29, 95% CI 1.0-18) with excellent sensitivity and positive predictive value (sensitivity 89%, specificity 35%, positive predictive value 83%, and negative predictive value 46%). The overall complication rate and respiratory failure requiring ventilation on individual complication analysis were more common in operatively managed patients (33% vs 3%, respectively; p = 0.007), even though they were generally younger and healthier than those managed nonoperatively. Operative or nonoperative management conferred no difference in length of hospital or ICU stay, discharge disposition, or mortality., CONCLUSIONS: The authors delineate the validity of upright cervical radiographs on presentation in association with follow-up stability in type II odontoid fractures. In their experience, factors associated with instability included cervical myelopathy, cerebrovascular disease, and fracture displacement but not increased age. Operatively managed patients had higher complication rates than those managed without surgery. Fibrous union, which can occur with nonoperative management, provided adequate stability.

Penetrating head injury from nailguns has become increasingly recognised due to their frequent use in the construction industry and home. We report a New Zealand case series of 12 penetrating nailgun head injuries, the largest of its type, detailing presentation, management, risk factors and outcomes. Recommendations based on these factors are provided, suggesting a minimal surgical approach and an individually case-assessed need for antibiotic prophylaxis and anti-epileptic drugs. Prognostic factors on initial imaging are discussed. The majority of injuries, despite being visually impressive, are associated with minimal neurological impairment.

5818. Winer, J. W., et al. (1991). "Electroencephalographic activity and serum and cerebrospinal fluid pentobarbital levels in determining the therapeutic end point during barbiturate coma." Neurosurgery **29**(5): 739-732.

Controversy exists regarding the optimal means for monitoring the patient receiving pentobarbital therapy during medical coma. Serum pentobarbital levels have been used traditionally to gauge cerebral penetration and efficacy of the drug. These peripheral levels have been assumed to reflect pentobarbital concentrations in the cerebrospinal fluid (CSF) and, therefore, the physiological effect on the central nervous system. To determine the relative accuracy of serum versus CSF pentobarbital levels, continuous electroencephalographic (EEG) monitoring in 10 consecutive patients was studied prospectively. Each patient received pentobarbital therapy for cerebral protection in the face of a traumatic injury. Simultaneous serum and CSF pentobarbital levels were obtained 1) before and after the initial barbiturate bolus, 2) every 12 hours during constant infusion therapy, and 3) before and after subsequent boluses necessary because of elevated intracranial pressure (ICP) (ICP greater than 15 mm Hg) or loss of burst suppression by continuous EEG monitoring (defined as greater than five bursts per minute). ICP and relevant clinical events were recorded hourly. Serum and CSF levels ranged from 33 to 74 mg/L and 4 to 54 mg/L, respectively. There was poor correlation between serum and CSF pentobarbital levels at any given time, although patients remained in burst suppression 73% of the time during their therapy. The EEG monitoring not only provided dynamic physiological monitoring, but it also permitted the lowest pentobarbital dose to maintain burst suppression for a specific patient's metabolism, reducing the likelihood of toxicity. In conclusion, CSF pentobarbital levels are of no greater accuracy than serum pentobarbital levels in predicting physiological effect.(ABSTRACT TRUNCATED AT 250 WORDS)

5819. Wing, I. D., et al. (2013). "Development of a miniaturized position sensing system for measuring brain motion during impact." Biomedical sciences instrumentation **49**: 281-288.

Since 2000, the Department of Defense has documented more than 253,000 cases of Traumatic Brain Injury (TBI). A significant portion of these injuries were attributed to explosive events, yet ninety-eight percent were non-penetrating. Understanding the response of the brain to blast events is critical, yet the mechanisms of brain injury from explosive trauma are poorly understood. This knowledge gap has led to an increased research focus on devices capable of investigating human brain response to non-penetrating, blast-induced loading. Furthermore, traumatic brain injury is a major issue for the civilian population as well with over 1.7 million cases of TBI per year in the US, primarily from falls and motor vehicle accidents. Current head surrogates and instrumentation are incapable of directly measuring critical parameters associated with TBI, such as brain motion, during dynamic loading. To this end, a novel sensor system for measuring brain motion inside of a human head surrogate was conceptualized and developed. The positioning system is comprised of a set of three fixed "generator" coils and a plurality of mobile, miniaturized "receiver" coil triads. Each generator coil transmits a sinusoidal electromagnetic signal at a unique frequency, and groups of three orthogonally arranged "receiver" coils detect these signals. Because of the oscillatory nature of these signals, the magnetic flux through the coil is always changing, allowing the application of Faraday's Law of Induction and the point dipole model of an electric field to model the strength and direction of the field vector at any given point. Thus, the strength of the signal measured by a particular receiver coil depends on its position and orientation relative to the fixed position of the generators. These predictable changes are used to determine the six degrees of freedom (6-DOF) motion of the receiver. To calibrate and validate the system, a receiver coil was moved about in a controlled manner, and its actual position

recorded by optical methods. Comparing the known position to the computed position at each time instance, a set of calibration constants were developed for each receiver triad. These constants were then utilized to convert receiver signal data into actual receiver position and orientation. Comparing this test case and several others like it, mean error was determined to be almost always less than 1.0 mm, and less than 0.5 mm >85% of the time. Additionally, high rate validation was conducted to confirm operation of the system in the impact domain. A coil was accelerated to approximately 15 m/sec along a fixed axis by ballistic impact and tracked by high speed video. The computed position was within 1 mm of the actual position 93% of the time and within 0.5 mm 83% of the time. The successful development and calibration of this sensing system now enables the direct measurements of brain displacement due to mechanical insults applied to a human head surrogate. © 2013.

Since 2000, the Department of Defense has documented more than 253,000 cases of Traumatic Brain Injury (TBI). A significant portion of these injuries were attributed to explosive events, yet ninety-eight percent were non-penetrating. Understanding the response of the brain to blast events is critical, yet the mechanisms of brain injury from explosive trauma are poorly understood. This knowledge gap has led to an increased research focus on devices capable of investigating human brain response to non-penetrating, blast-induced loading. Furthermore, traumatic brain injury is a major issue for the civilian population as well with over 1.7 million cases of TBI per year in the US, primarily from falls and motor vehicle accidents. Current head surrogates and instrumentation are incapable of directly measuring critical parameters associated with TBI, such as brain motion, during dynamic loading. To this end, a novel sensor system for measuring brain motion inside of a human head surrogate was conceptualized and developed. The positioning system is comprised of a set of three fixed generator'' coils and a plurality of mobile, miniaturized receiver'' coil triads. Each generator coil transmits a sinusoidal electromagnetic signal at a unique frequency, and groups of three orthogonally arranged receiver'' coils detect these signals. Because of the oscillatory nature of these signals, the magnetic flux through the coil is always changing, allowing the application of Faraday's Law of Induction and the point dipole model of an electric field to model the strength and direction of the field vector at any given point. Thus, the strength of the signal measured by a particular receiver coil depends on its position and orientation relative to the fixed position of the generators. These predictable changes are used to determine the six degrees of freedom (6-DOF) motion of the receiver. To calibrate and validate the system, a receiver coil was moved about in a controlled manner, and its actual position recorded by optical methods. Comparing the known position to the computed position at each time instance, a set of calibration constants were developed for each receiver triad. These constants were then utilized to convert receiver signal data into actual receiver position and orientation. Comparing this test case and several others like it, mean error was determined to be almost always less than 1.0 mm, and less than 0.5 mm >85% of the time. Additionally, high rate validation was conducted to confirm operation of the system in the impact domain. A coil was accelerated to approximately 15 m/sec along a fixed axis by ballistic impact and tracked by high speed video. The computed position was within 1 mm of the actual position 93% of the time and within 0.5 mm 83% of the time. The successful development and calibration of this sensing system now enables the direct measurements of brain displacement due to mechanical insults applied to a human head surrogate.

5821. Winkler, A. M., et al. (2009). "Early trauma induced coagulopathy: A pilot study." Transfusion **49**: 157A.

Background: Approximately 5 million people die worldwide each year from trauma, most commonly as a result of brain injury and hemorrhage. Both traumatic head injuries and massive hemorrhage have been linked to the development of coagulopathy, a major contributor to trauma related mortality. This secondary coagulopathy resulting from dilution and consumption of coagulation factors, acidosis, and hypothermia has been termed “the bloody vicious cycle.” On the other hand, coagulopathy as a primary or early event has become increasingly recognized as an independent predictor of mortality. However, the pathophysiology of this early trauma induced coagulopathy (ETIC) is not entirely understood. Methods: A prospective observational cohort study of consecutive trauma patients who presented to a level I trauma center was conducted from 7/15/08-12/31/08. Patients were included if they met trauma team activation criteria published by the American College of Surgeons Committee on Trauma and modified by our institution. Patients were additionally excluded if known to be taking anticoagulant or anti-platelet medications, or had a personal history of a coagulation or platelet defect. Demographics, injury event and time, fluid and blood administration, vital signs, injury severity score, and presence of head injury were collected from EMS and by observation in the ED from

arrival to time of first blood sample collection. Standard coagulation parameters including prothrombin time (PT), partial thromboplastin time (PTT) were performed. The primary outcome was 28 day mortality. Results: 270 patients met enrollment criteria and had adequate data collection. The cohort was 75.6% male with a mean age of 39 years of which 26% suffered penetrating trauma. The overall mortality was 7.8% and ETIC, defined as a prolonged PT or PTT upon admission, had a prevalence of 19.3%. In univariate analysis, a prolonged PT and PTT were associated with increased mortality ($p = .03$ and $p = .01$, respectively). The association between PT ($p = .02$) and injury severity score ($p < .01$) with mortality was confirmed in multivariate analysis; however the association with PTT ($p = .06$), age ($p = .13$) and positive head CT ($p = .07$) were not associated with mortality. Conclusion: In this pilot prospective cohort study, ETIC was associated with increased mortality. With increased patient data and mechanistic studies, it is envisioned that ETIC can be understood both clinically and physiologically, which will optimally lead to improvement in the survival of trauma patients.

5822. Winkler, B. and J. K. Margerison (2012). "Mechanical properties of the bovine claw horn during lactation." Journal of dairy science **95**(4): 1714-1728.

Claw horn disorders are one of the main causes of lameness in dairy cows globally. This study aimed to develop material testing techniques to assess changes in the mechanical properties of bovine claw horn (BCH) and to compare these mechanical properties with existing methods of assessing claw horn disorders during lactation. Lameness was also measured through locomotion scoring to assess the clinical significance of changes observed in the scoring for lesions. Experiment 1 used 8 claws collected from four 12 to 18 mo old beef heifers, to develop BCH sample storage methods and techniques to test the mechanical properties of BCH (puncture resistance and elastic modulus). The increase in the moisture content of BCH had a significant negative exponential effect on the elastic modulus of the sole and white line claw horn and a linear reduction in the puncture resistance of BCH. Placing BCH samples in sealed plastic bags and storing them either at 2degreeC or by freezing samples at -22degreeC did not alter the dry matter content and, consequently, the mechanical properties of the claw horn tissue. In experiment 2, BCH was collected from 36 lactating dairy cows and mechanical properties were tested using puncture resistance. Puncture resistance of the sole area of the claw horn decreased significantly when hemorrhages in the tested area increased. The puncture resistance of the sole and white line areas decreased at d 160 postpartum when the cows exhibited higher lesion scores and was lower in hind claws that had higher lesion scores when compared with the fore claws. The highest puncture resistance was found at 270 d postpartum, when the animals were at pasture. Puncture resistance was found to be an effective technique for assessing the effect of period of lactation and increasing hemorrhage levels on the mechanical properties and structural strength of bovine claw horn. It was found to be a good method of comparing changes and differences in mechanical properties and structural strength of BCH from the sole and white line areas within each claw and differences between claws. White line BCH consistently had significantly lower puncture resistance compared with the sole. Bovine claw horn with greater levels of hemorrhage or lower puncture resistance, or both, may provide less protection and increase the risk of foreign body penetration, trauma, and secondary infection of the corium of the claw.

5823. Winkler, G., et al. (2005). "[Extraordinary cause of a self-induced focal epilepsy]." Ungewohnliche Ursache einer selbstinduzierten fokalen Epilepsie. **76**(12): 1520-1523.

Epilepsies and psychiatric disorders such as psychoses are known to have reciprocal influence. There are problems in patient compliance and pharmacological interactions between the drugs used for treatment. We report an unusual, self-induced, focal, symptomatic epilepsy in a hitherto unrevealed schizophrenic psychosis. The interdisciplinary treatment of three different departments was necessary. The initial symptom of a diffuse frontal headache and the patient's penetration of his own skull in an attempt at self-treatment led to the development of a frontal abscess around a foreign body and the described focal epilepsy.

5824. Winkler, S. S. and J. F. Sackett (1980). "Explanation of metrizamide brain penetration: a review." Journal of computer assisted tomography **4**(2): 191-193.

The penetration of intrathecally injected metrizamide into brain and spinal cord substance is a phenomenon that has surprised and puzzled radiologists. No suitable explanation has been offered in the radiologic literature. This article reviews the recent literature on the relationship between the cerebrospinal fluid (CSF) space and the extracellular

fluid (ECF) space of the brain. Recent evidence has shown that these spaces are in fact one compartment with no diffusion barrier between them. Thus, penetration of metrizamide into the brain is an expected rather than surprising phenomenon. An explanation is offered as to why metrizamide does not penetrate edematous or infarcted portions of brain on the basis of a pressure gradient between damaged brain ECF and CSF spaces.

5826. Winston, K. R., et al. (2015). "Packing to tamponade severe intracranial hemorrhage in pediatric patients." Pediatric neurosurgery **50**(2): 63-67.

The medical records of all children in whom packing was used to control severe intracranial hemorrhage were reviewed. Eight children, with ages ranging from newborn to 4 years, met the inclusion criteria and all survived. Five were victims of severe closed head trauma, 2 had received penetrating cranial injuries, and 1 developed severe bleeding while undergoing surgery for a malignant tumor in the posterior fossa. Blood loss at the time of removal of the packing was minimal in 7 patients and was surgically controllable in the other. Packing is a simple, efficient, and safe maneuver which can very often halt intracranial bleeding that is considered to be otherwise uncontrollable, and can thereby limit the consequences of prolonged or repeated periods of hypotension and possible exsanguination.

5827. Winter, B., et al. (2017). "Spinal cord injury." Anaesthesia and Intensive Care Medicine **18**(8): 404-409.

With an annual incidence of 13 per million, around 40,000 people in the UK live with spinal cord injury (SCI). The extent of morbidity and mortality and thus quality of life, is highly dependent on meticulous management from the first point of contact with medical services. Treatment is focused on reducing the risk of further cord injury and prevention of secondary (penumbral) damage through avoidable complications. As key members of trauma, theatre, intensive care and pain teams, anaesthetists and intensivists play a crucial role in influencing patient outcome in both the acute setting and in managing patients with chronic SCI presenting for emergency or elective surgical intervention.

5828. Wirth, I., et al. (2008). "[Homicide-suicide by a single gunshot to the head]." Suizid und vorsatzliche Totung durch einmalige Schussabgabe in den Kopf. **221**(1-2): 17-27.

Apart from typical suicides, there are sometimes unusual deaths from gunshots to the head. The presented case is a double death from the autopsy material of the Institute of Legal Medicine in Berlin. The report deals with a murder-suicide of a man, who killed himself and his 2-year-old daughter by a single gunshot. After having administered a tranquilizer to the child, he held her head to his own and fired a contact shot to his right temple so that the bullet passed through both heads.

5829. Wirth, I., et al. (1984). "[Craniocerebral injuries caused by animal anesthesia equipment]." Schadel-Hirn-Verletzungen durch Viehbetaubungsgerate. **45**(3): 169-178.

A consequence of the rareness of bullet injuries in the GDR are the uncertainties in the recognition and assessment of injuries caused by cattle anaesthetising devices which have become evident in connection with the relevant expertises of the respective cases. In view of this situation, the design and the mode of functioning of these devices as well as selected clinical aspects of such injuries are described. Besides the local findings, the computer tomography is of paramount importance in the diagnosis for both the recognition of the typical calvarial bursting and the representation of the shot channel with a demonstration of the imprimatum. Whenever possible, the therapy should consist in an early surgical procedure according to the principles to be applied to open craniocerebral injuries.

5830. Witjes, M., et al. (2019). "The Implementation of a Multidisciplinary Approach for Potential Organ Donors in the Emergency Department." Transplantation **103**(11): 2359-2365.

BACKGROUND: The aim of this study was to evaluate the implementation process of a multidisciplinary approach for potential organ donors in the emergency department (ED) in order to incorporate organ donation into their end-of-life care plans., METHODS: A new multidisciplinary approach was implemented in 6 hospitals in The Netherlands between January 2016 and January 2018. The approach was introduced during staff meetings in the ED, intensive care unit (ICU), and neurology department. When patients with a devastating brain injury had a futile prognosis in the ED, without contraindications for organ donation, an ICU admission was considered. Every ICU admission to incorporate organ donation into end-of-life care was systematically evaluated with the involved physicians using a standardized questionnaire., RESULTS: In total, 55 potential organ donors were admitted to the ICU to incorporate organ donation into end-of-life care. Twenty-seven families consented to donation and 20 successful organ donations were performed. Twenty-nine percent of the total pool of organ donors in these hospitals were admitted to the ICU for organ donation., CONCLUSIONS: Patients with a devastating brain injury and futile medical prognosis in the ED are an important proportion of the total number of donors. The implementation of a multidisciplinary approach is feasible and could lead to better identification of potential donors in the ED.

5831. Wittschieber, D., et al. (2016). "The role of 3DCT for the evaluation of chop injuries in clinical forensic medicine." Forensic science international **266**: e59-e63.

As hatchet blows to the human head frequently cause fatal injuries, the forensic examination of survivors with cranial chop injuries is a rare phenomenon in forensic casework. Besides evaluation of clinical records, photographs, and medico-legal physical examination, the analysis and 3-dimensional reconstruction of pre-treatment computed tomography data (3DCT) must be considered an important and indispensable tool for the assessment of those cases because the characteristics of chopping trauma often appear masked or changed by clinical treatment. In the present article, the role of 3DCT for the evaluation of chop wounds in clinical forensic medicine is demonstrated by an illustrative case report of a young man who was attacked with a hatchet. 3DCT provides additional possibilities for supplementing missing information, such as number and direction of blows as well as weapon identification. Furthermore, 3DCT facilitates demonstration in court and understanding of medical lay people. We conclude that 3DCT is of particular value for the evaluation of survivors of life-threatening head and face injury. An increasing significance of this technique may be expected.

5832. Witzmann, A., et al. (1981). "[Glioblastoma multiforme developing after a gunshot injury of the brain (author's transl)]." Glioblastoma multiforme nach Kopfschuss. **24**(6): 202-206.

We report the case of a 28-year-old male who suffered a frontal penetrating gunshot injury with subsequent bifrontal brain abscess and subdural empyema, and five years later developed a large bifrontal tumour at the precise site of the meningo-cerebral scar and posttraumatic defect. Histological examination showed a glioblastoma multiforme adjacent to the dural scar and, in addition, old suture material was found within the glioma tissue. In spite of combined radiation and polychemotherapy the patient died eleven months after partial tumour resection. The temporal and local association of missile injury with subsequent recurred abscess and scar formation and the malignant glioma is highly suggestive of a causal relationship between trauma and the development of a brain tumour.

5833. Wojcik, K., et al. (2006). "[Brain abscess: analysis of prevalence and clinical course]." Bakteryjne ropnie mozgu jako problem oddzialu zakaznego. **60**(2): 265-271.

The aim of the study was the analysis of the patients with bacterial meningitis and brain abscess who were treated in the Department of Infection Disease and Hepatology of Medical University in Lodz in years 1996-2005. We reviewed their clinical presentation, bacteriology treatment and outcome retrospectively. Among 135 patients who were confirmed cases of bacterial meningitis 16 identified as having brain abscesses. The prevalence rate of brain abscesses significantly increased in years: 2004-2005. The common predisposing factors were otic and teeth infections, sinusitis, penetrating head trauma, and bacterial endocarditis. Solitary abscess was found in 56% of the cases while in 44% of the cases multiple abscess were found. The most common presentation: headache, fever and neurological deficit were present in 37% of the cases. 75% of patients were disqualified from early neurosurgical intervention and antibiotic therapy were recommended. The antibiotic therapy was effective only in 1 patient. The mortality rate was 38% and 56% of the survivors had late neurological defects. The prevalence rate of brain abscesses significantly increased in years 2004-2005. Over all mortality was very high and antibiotic therapy hasn't been effective treatment in brain abscess at

the late stage of its evolution. The early neurosurgical intervention is recommended. Late neurosurgical intervention strongly influences poor outcome in patients with brain abscess.

5834. Wolf, J., et al. (2015). "The phase II ASCEND-7 (CLDK378A2205) trial: Ceritinib in patients (pts) with ALK-rearranged (ALK+) Non-Small Cell Lung Cancer (NSCLC) metastatic to the brain and/or leptomeninges." Oncology Research and Treatment **38**: 138.

Introduction: In pts with ALK+ NSCLC receiving the ALK inhibitor (ALKi) crizotinib (CRZ), disease progression often occurs within 1 year with the brain/central nervous system (CNS) as a common site of progression and relapse. The oral ALKi ceritinib showed a 20-fold greater potency than CRZ in enzymatic assays and crosses the blood-brain barrier with good CNS penetration in preclinical studies. In the pivotal phase I study (NCT01283516) ceritinib was highly active in ALK+ NSCLC pts regardless of prior CRZ exposure and achieved intracranial responses in 7 of 14 pts with measurable baseline brain lesions. Adverse events profile in these pts was similar to that of the full study population. Methods: This prospective phase II study is designed to evaluate the antitumor activity of ceritinib in pts with ALK+ NSCLC metastatic to the brain or leptomeninges. Eligible pts must have investigator assessed ALK+ NSCLC metastatic to the brain and ≥1 extracranial measurable lesion (RECIST v1.1). Pts must be neurologically stable ≥1 week prior to ceritinib and will be allocated to 1 of 5 cohorts: Ceritinib will be dosed 750 mg/day on a continuous schedule; study assessments are consistent across cohorts. Primary and key secondary objectives are whole body overall response rate and disease control rate, respectively. Other secondary objectives include intracranial and extracranial responses for all pts and for each cohort 1-4; overall survival and safety for all pts and for each cohort 1-5; and ceritinib pharmacokinetics in all pts. (Table Presented).

5835. Wolf, S., et al. (2017). "Nostra III-an ongoing phase 3 registration study in moderate and severe traumatic brain injury (TBI)." Neurocritical care **27**(2): S86.

Introduction TBI remains the leading cause of death and disability in young adults in the US and Europe. Thus far, pharmacological and non-pharmacological intervention studies did not confirm benefits on functional outcomes. Methods The inducible enzyme Nitric Oxide Synthase (iNOS) is upregulated in response to brain injury, causing excessive production of NO, a key driver of secondary injury after TBI. The antipterin VAS203 is a structural analogue of the endogenous NOS cofactor and a potent in-vivo selective inhibitor of iNOS. A randomized, placebo-controlled Phase 2 study examined 3 dose levels of VAS203 in 32 patients with acute moderate or severe TBI. Cerebral microdialysis showed pharmacologically relevant drug concentrations close to the injury and a tendency for VAS203 to increase the arginine/citrulline ratio, an indirect marker of NOS inhibition (Stover et al., J Neurotrauma 2014). VAS203 conferred a significant benefit on the extended Glasgow Outcome Scale Interview (eGOS-I) at 6 and 12 months after injury. No changes in systemic blood pressure or partial brain oxygen pressure were noted. A recent pharmacokinetics and pharmacodynamics study further corroborated the selective iNOS inhibition by VAS203. Results The confirmatory NOSTRA Phase 3 trial (EudraCT no. 2013-003368-29; ClinicalTrials.gov identifier NCT02794168) was initiated in 2016. Adult patients with a non-penetrating head trauma, GCS > 3 and requiring intracranial pressure monitoring, are randomized 1:1 to VAS203 or placebo, administered in addition to standard of care, as intravenous continuous infusion for 48 hours, starting between 6 and 18 hours post TBI. The primary efficacy endpoint is eGOS-I at 6 months post injury. Additional endpoints include the daily therapy intensity level and TBI-specific quality of life measures. Continuous safety monitoring is performed by an independent committee. Conclusions NOSTRA III, the only ongoing registration study in acute moderate and severe TBI, is sponsored by vasopharm GmbH, and plans to recruit 232 patients by Q3 2018.

5836. Wolford, L. M. and D. B. Rodrigues (2011). "Autogenous grafts/allografts/conduits for bridging peripheral trigeminal nerve gaps." Atlas of the oral and maxillofacial surgery clinics of North America **19**(1): 91-107.

Nerve repairs and grafting techniques have been around for many years. Autogenous nerve grafts have worked reasonably well in the right circumstances but are associated with difficulties in achieving a proper donor-host match and with postsurgical sequelae at the donor site. Vein grafts seem to work almost as well as autogenous nerve grafts in digital nerve repairs that require a graft less than 3 cm in length. Currently, the most promising nerve graft materials are the polyglycolic acid tubes and processed decellularized allografts, which have shown good results without the morbidity of autogenous nerve grafts. However, more research studies using these materials for TN repairs are essential to validate the superiority of these procedures.

5838. Wolstenholme, C. R., et al. (2006). "The endoscopic management of a penetrating injury of the anterior skull base." Otorhinolaryngologist **1**(1): 43-45.

Intranasal foreign bodies are common and can penetrate the skull base. Transnasal endoscopic management of cerebrospinal fluid (CSF) leaks has become the treatment of choice for most anterior cranial CSF leaks. We present the endoscopic management of a transnasal penetrating injury of the anterior skull base. This has not previously been described in the literature.

5839. Wong, H., et al. "Strategies for use of blood products for major bleeding in trauma." (4).

This is a protocol for a Cochrane Review (Intervention). The objectives are as follows:, The objective of this review is to assess the effects and safety of blood product transfusion strategies started in the first 24 hours after injury for trauma patients of all ages with major bleeding.

5840. Wong, K. and J. Petchell (2005). "Severe trauma caused by stabbing and firearms in metropolitan Sydney, New South Wales, Australia." ANZ journal of surgery **75**(4): 225-230.

BACKGROUND: Stabbing and firearm trauma causing severe injuries (injury severity score (ISS) >15) and death is uncommon in Australia. The present study describes the experience with stabbings and firearm trauma causing severe injuries at a major Australian urban trauma centre., METHODS: Data from a prospectively generated trauma registry regarding all patients presenting to Royal Prince Alfred Hospital (RPAH), Sydney, Australia with penetrating trauma causing severe injuries from July 1991 to June 2001 was retrospectively analysed., RESULTS: Of all patients presenting to RPAH with stabbing and firearms wounds over the 11 year study period, 28% received an ISS >15. One hundred and forty patients were identified. 94% were male. The mean age was 34 years (15-82 years). The number of cases/year has not shown an increasing trend. Thirty per cent of patients sustained firearm related injuries, with the remainder mainly caused by knives or machetes. Fifteen per cent of injuries were self inflicted. The most common location of injury was on a public street. Fifty-two per cent of patients were injured in more than one anatomical region, with the abdomen being the most common site of injury (53%). On hundred and seventy-four operations were performed - laparotomies (43%), thoracotomies (26%), craniotomies (5%) and orthopaedic, vascular, wound explorations and other procedures (26%). Twenty-eight per cent of patients suffered at least one complication during their admission, with coagulopathy being the most common complication (20%). Mean length of stay was 10.4 days (1-107 days). The total mortality rate for the severely injured patients was 21%, with gun-related injuries having a higher mortality rate than stabbing injury (36%vs 15%). Sixty per cent of deaths were related to exsanguination., CONCLUSIONS: Stabbings and firearm trauma are associated with significant morbidity, mortality and utilization of hospital resources in metropolitan Sydney. Overall mortality rates are similar to institutions with higher volumes of penetrating trauma.

5842. Wong, V., et al. "Acupuncture for acute management and rehabilitation of traumatic brain injury." (3).

Background, Traumatic brain injury (TBI) can be life threatening depending on the severity of the insult to the brain. It can also cause a range of debilitating sequelae which require cognitive, motor, communication, emotional, or behavioral rehabilitation of varying intensity and duration. A number of studies conducted and published in China have suggested that acupuncture may be beneficial in the acute treatment and rehabilitation of TBI., Objectives, To determine the efficacy and safety of acupuncture in the acute management or rehabilitation (or both) of patients with a TBI, including cognitive, neurological, motor, communication, emotional, or behavioral complications, or a combination of such complications., Search methods, We searched the Cochrane Injuries Group Specialised Register, Cochrane

Central Register of Controlled Trials (The Cochrane Library), MEDLINE, EMBASE, CINAHL, AMED, PsycINFO and others. We also searched the Chinese Acupuncture Studies Register, the Studies Register of the Cochrane Complementary Medicine Field, NCCAM, and NIH Clinical Studies Database. Three major Mainland Chinese academic literature databases (CNKI, VIP and Wang Fang Data) were also searched using keywords in simplified Chinese. We searched all databases through December 2009, and some searches have been updated to October 2012., Selection criteria, Randomized controlled studies evaluating different variants of acupuncture and involving participants of any age who had suffered a TBI. Included trials compared acupuncture with placebo or sham treatment, or acupuncture plus other treatments compared with the same other treatments. We excluded trials that only compared different variants of acupuncture or compared acupuncture alone against other treatments alone, as they did not yield the net effect of acupuncture., Data collection and analysis, Two review authors identified potential articles from the literature search and extracted data independently using a data extraction form. We performed methodological assessment of included studies using the Cochrane Collaboration's tool for assessing risk of bias. We were unable to perform quantitative data analysis due to insufficient included studies and available data., Main results, Four RCTs, including 294 participants, reported outcomes specified by this review. Three investigated electro-acupuncture for TBI while one investigated acupuncture for acute TBI. The results seem to suggest that acupuncture is efficacious for these indications, however the low methodological quality of these studies renders the results questionable. No adverse effects of acupuncture were reported in any of the studies., Authors' conclusions, The low methodological quality of the included studies does not allow us to make conclusive judgments on the efficacy and safety of acupuncture in either the acute treatment and/or rehabilitation of TBI. Its beneficial role for these indications remains uncertain. Further research with high quality trials is required.

5843. Woo, X., et al. (2022). "Accidental Low-Velocity Penetrating Brain Injury by Glass Marble." Asian journal of neurosurgery **17**(1): 116-119.

Penetrating brain injury from marble is rare. Marbles, commonly known as "guli" among locals, is a popular children's traditional game in Malaysia. This study discusses two cases of intracranial marble injury, both accidentally shot by children with home-made air guns during the period of Movement Control Order with one elderly patient who passed away. While the diagnosis was uneventful, the management was not straightforward. Strategies of prehospital, operative, postoperative management, and rehabilitation are discussed, including prognostic factors. Because of its rarity, the management of such injuries is complex and nonstandardized. Copyright Asian Congress of Neurological Surgeons. 5844. Woodbury, S. C., et al. (1998). "Options for immediate reconstruction of the traumatized temporomandibular joint." The Journal of cranio-maxillofacial trauma **4**(2): 22-21.

The management of condylar fractures is one of the most controversial topics in the repair of the maxillofacial skeleton. An extensive volume of literature exists describing the various indications for a specific treatment of this injury. This article outlines the absolute and relative indications for an open procedure and describes three different modalities for the immediate reconstruction of the temporomandibular joint system. Three different case reports are used to illustrate the respective procedures--replacement of the temporomandibular joint with autologous rib graft, replacement of the temporomandibular joint with an alloplast, and vertical ramus osteotomy for repositioning of the condylar stump. The discussion section reviews the findings and preferences of various treatment modalities described in the literature, along with the advantages and disadvantages.

5845. Woodruff, G., et al. (2022). "Nine years of pediatric gunshot wounds: A descriptive analysis." Preventive Medicine Reports **28**.

Pediatric firearm violence carries significant morbidity and mortality. Studies targeting children ≤14 years are limited. Our goal was to study the distribution and determinants of GSWs in the pediatric population. We performed a retrospective review of children ≤14 years presenting with GSWs at this level 1 trauma center. This cohort was split into younger children, 0–12 years, and older children, 13–14 years. Summary and bivariate statistics were calculated using Stata v10. 142 patients (68.3% black, 76.7% male) were identified. Injuries more often occurred at home (39.6%) by

family or friends (60.7%). Older children often suffered handgun injuries (85.5%) and more often were sent immediately to the OR on presentation (29.2%). Younger children more often suffered from air-gun (50%) and pistols (40%). Younger children more commonly had blood transfusions (9.4%) compared to exploratory laparotomy in older children (13.5%). The most common disposition from the ED was home (36.2%). Descriptive data entailing incident specifics such as time of injury and CPS involvement were frequently missing in the healthcare record. Older children were more likely to be injured by strangers, have longer lengths of stay especially associated with surgical operations, and have a disposition of immediate arrest compared to their younger cohort. Consequently, this group may benefit from interventions typically aimed at older patients such as violence intervention programs. When available, differences in demographics and outcomes were identified which could shape novel prevention strategies for firearm injury.

5846. Woodworth, B. A., et al. (2006). "Sphenoid sinus cerebrospinal fluid leaks." Operative Techniques in Otolaryngology - Head and Neck Surgery **17**(1): 37-42.

There are a number of special considerations regarding endoscopic repair of cerebrospinal fluid (CSF) leaks and encephaloceles occurring in the sphenoid sinus. The sphenoid sinus is formed by the anterior and middle cranial fossae, is in close proximity to the internal carotid artery and optic nerve, and may have extreme lateral pneumatization that limits accessibility via normal endoscopic routes. Although CSF leaks and encephaloceles can occur anywhere within the sphenoid sinus, they are generally divided into a medial, perisellar type and a lateral, sphenoid recess type. The diverse etiologies of sphenoid sinus CSF leaks make it essential to have a thorough understanding of the underlying pathophysiology, and treatment principles and treatment options to achieve excellent outcomes. The specific surgical approach for a sphenoid sinus skull base defect is dependent on the exact site of the defect within the sphenoid sinus. Once an appropriate endoscopic approach with wide local exposure is obtained, reconstruction of the skull base is dependent on the etiology of the leak and other factors, including the underlying intracranial pressure. This article will highlight the surgical techniques and perioperative care relevant to sphenoid CSF leaks and encephaloceles.

We present a case of recurrent carotid-cavernous fistula after prior ipsilateral carotid artery ligation. Due to lack of endovascular access, embolization was performed by direct puncture of the cavernous sinus via a transorbital approach. Operative technique and an anatomical basis for treatment are described.

5848. Worley, G., et al. (1995). "18-Fluorodeoxyglucose positron emission tomography in children and adolescents with traumatic brain injury." Developmental medicine and child neurology **37**(3): 213-220.

Twenty-two previously normal children and adolescents who suffered a severe, non-penetrating traumatic brain injury had PET during rehabilitation at a median of 1.5 months after the injury. Outcome was assessed at a median of 25 months after brain injury. 16 subjects had CT or MRI within 24 days of PET and 11 subjects had a second PET at the point of outcome (median 28 months after first PET). The PET score (obtained by adding the score of 15 brain regions: normal metabolism = 1; reduced = 0) was significantly associated with the clinical outcome measure. PET earlier than 12 weeks after head trauma correlated with outcome, but later PET did not. PET scores improved significantly between rehabilitation and outcome for the 11 subjects who had two PETs, but improvement was not associated with improvement in clinical condition. PET score did not add to the amount of variance explained in the last regression model for prediction of outcome when the results of contemporaneous CT/MRI and clinical condition were taken into account. The data suggest that routine PET during rehabilitation is no more useful than contemporaneous CT or MRI for prediction of outcome.

5849. Wozniak, K., et al. (2009). "[Postmortem CT examination with 3D reconstruction in gunshot and post explosion injuries]." Posmiertne badania obrazowe TK z rekonstrukcja 3D u ofiar postrzalow z broni palnej i eksplozji ladunkow wybuchowych. **59**(2): 85-92.

The authors presented the results of postmortem examinations of four cases related to gunfire and post explosion injuries. Prior to "classic" forensic autopsies, the corpses were examined using CT imaging. The findings

(injuries and foreign bodies) are presented in the table and in images: 3D reconstructions contrasted with actual autopsy specimens. The enclosed CD includes 3D animations.

5850. Wozniak, K. and J. Pohl (2003). "[Suicidal single intraoral shooting by a shotgun--risk of misinterpretation at the crime scene]." Samobojcze postrzaly z broni srutowej po wprowadzeniu lufy do ust a ryzyko blednej oceny na miejscu ujawnienia zwlok. **53**(4): 347-355.

The authors presented two cases of suicidal single intraoral shooting by a shotgun. The first case relates to a victim found near the peak of Swinica in the Tatra mountains. When the circumstances could have suggested fatal fall from a height and minute, insignificant external injuries were found, the pistol found at the scene has been the most important indicator leading to the actual cause of death. The second case relates to a 38-year-old male found in this family house in a village. Severe internal cranial injury (bone fragmentation) was diagnosed at the scene. A self-made weapon was previously removed and hidden from the scene by a relative of the victim. Before regular forensic autopsy X-ray examination was conducted which revealed multiple intracranial foreign bodies of a shape of a shot. After the results of the autopsy the relative of the deceased indicated the location of the weapon.

5851. Wozniak, K. and E. Rzepecka-Wozniak (2003). "[Routine examination of cervical spinal cord and spinal column during forensic autopsies]." Rutynowe badanie odcinka szyjnego rdzenia kregowego i kregoslupa podczas sekcji sadowo-lekarskich. **53**(2): 91-107.

Examination of the cervical spinal cord is a rare additional autopsy technique applied in forensic autopsies. Injuries of the neck region are fatal in a considerable number of cases. However, such technique is neglected especially while a different cause of death is found. Research on 316 autopsy cases (about 10% of all cases during that time) was undertaken. Groups of "possible trauma" (gross anatomy and microscopic examination of the cervical spinal cord) and "possible non-trauma" (gross anatomy examination) cases were investigated. There were 68 gross anatomy and 61 microscopic (blood suffusions) "positive" findings. There were about 40% gross anatomy and about 46% microscopic (blood suffusions) changes giving evidence of trauma of that region in groups of victims of traffic accidents. Techniques of examination of the cervical spinal cord and spinal column with the addition of microscopy in selected cases can prove the cause and mechanism of death. While neglected, especially in obscure autopsy cases, could give the reason that possible medical malpractice occurred.

5852. Wright, J. W., Jr. and C. E. Taylor (1972). "Facial nerve abnormalities revealed by polytomography." Archives of otolaryngology (Chicago, Ill. : 1960) **95**(5): 426-430.

5853. Wright, M. S. (1995). "Update on pediatric trauma care." Current opinion in pediatrics **7**(3): 292-296.

Injuries are responsible for more deaths in the pediatric age group than all other causes combined. Care of the injured child, with attention to the way in which patterns of injury and therapeutic responses differ from adults, is a fundamental tenet of pediatric trauma care. As appropriate resource utilization is increasingly mandated, those involved in the care of traumatized children are investigating the efficient application of laboratory and radiologic resources for the evaluation of the pediatric trauma patient and the differential use of hospital resources by various treatment strategies. Familiar diagnostic modalities are put to new uses in the care of the trauma patient. Finally, the alarming increase in violent injury of children and adolescents is bringing a change in the epidemiology of injuries observed in pediatric trauma centers.

5854. Wright, P. J. and R. J. Murray (1989). "Penetrating craniocerebral airgun injury. Anaesthetic management with propofol infusion and review of recent reports." Anaesthesia **44**(3): 219-221.

Low velocity cerebral missile injuries inflicted by air guns frequently cause little primary neurological damage, but the patient often suffers severe later deterioration which has been classified as a type of 'talk and die' head injury. The anaesthetic management of a penetrating air rifle missile injury using an infusion of propofol is described.

5855. Wu, A., et al. (2021). "Pediatric evidence-based imaging guidelines for adult trauma providers significantly reduces radiation exposure to children." Trauma (United Kingdom).

Introduction: Evidence suggests that stand-alone pediatric trauma centers outperform adult and combined adult/pediatric trauma centers in limiting radiation exposure to injured children. We sought to determine the impact of implementing evidence-based guidelines for pediatric imaging at a combined adult (level 1) and pediatric (level 2) center. The initiative focused on trauma/critical care surgeons as the pediatric surgeons did not participate in the resuscitation and initial evaluation of injured children. Methods: Imaging guidelines were developed from existing clinical studies. After 3 months of education, guidelines were implemented, and regular feedback was given to providers regarding compliance. Data were collected from the trauma registry for all pediatric patients (aged less than 15 years), in calendar years 2017 (pre-guideline) and 2019 (post-guideline). All admissions were analyzed, with subgroup analysis of children with multisystem trauma admitted to the trauma surgery service. Results: Following guideline implementation, mean computed tomography (CT) scans per injured child fell by over 50% (.93 vs.45). For patients admitted to the trauma service, the mean fell by 58% (1.82 vs 0.76). The number of patients receiving more than 1 CT significantly decreased for all children (26% vs 10%), and particularly those admitted to the trauma service (52% vs 17%). During this time, there was only one injury missed at the initial admission, which was clinically insignificant (non-displaced skull fracture). Conclusions: Implementation of evidence-based guidelines for imaging eliminates disparity in practices between a combined adult/pediatric trauma center and stand-alone pediatric trauma centers.

5856. Wu, Q., et al. (2012). "Low-level laser therapy for closed-head traumatic brain injury in mice: effect of different wavelengths." Lasers in surgery and medicine **44**(3): 218-226.

BACKGROUND AND OBJECTIVES: Traumatic brain injury (TBI) affects millions worldwide and is without effective treatment. One area that is attracting growing interest is the use of transcranial low-level laser therapy (LLLT) to treat TBI. The fact that near-infrared light can penetrate into the brain would allow non-invasive treatment to be carried out with a low likelihood of treatment-related adverse events. LLLT may treat TBI by increasing respiration in the mitochondria, causing activation of transcription factors, reducing inflammatory mediators and oxidative stress, and inhibiting apoptosis., STUDY DESIGN/MATERIALS AND METHODS: We tested LLLT in a mouse model of closed-head TBI produced by a controlled weight drop onto the skull. Mice received a single treatment with continuous-wave 665, 730, 810, or 980 nm lasers (36 J/cm(2) delivered at 150 mW/cm(2)) 4-hour post-TBI and were followed up by neurological performance testing for 4 weeks., RESULTS: Mice with moderate-to-severe TBI treated with 665 and 810 nm laser (but not with 730 or 980 nm) had a significant improvement in Neurological Severity Score that increased over the course of the follow-up compared to sham-treated controls. Morphometry of brain sections showed a reduction in small deficits in 665 and 810 nm laser treated mouse brains at 28 days., CONCLUSIONS: The effectiveness of 810 nm agrees with previous publications, and together with the effectiveness of 660 nm and non-effectiveness of 730 and 980 nm can be explained by the absorption spectrum of cytochrome oxidase, the candidate mitochondrial chromophore in transcranial LLLT.

5857. Wu, R., et al. (2018). "Management of Penetrating Brain Injury Caused by a Nail Gun: Three Case Reports and Literature Review." World neurosurgery **112**: 143-147.

BACKGROUND: Penetrating brain injury (PBI) caused by a nail gun is an extremely rare neurosurgical emergency that poses a challenge for neurosurgeons because of its rarity and complexity., CASE DESCRIPTION: Here we present 3 cases of PBI caused by a nail gun. In the first case, the nail entered through the right parietal bone and lodged in the right parietal lobe and basal ganglia. In the second case, the nail entered through the right occipital bone and lodged in the right occipital lobe. In the third case, the nail entered through the right parietal bone and lodged in the right frontal and parietal lobes. All patients underwent surgical removal of the nail. The first patient presented with reduced left-side strength, whereas the second and third patients were neurologically intact on presentation., CONCLUSIONS: PBI caused by a nail gun can present with differing clinical manifestations, and most cases require immediate surgery. A rational management strategy should provide a good postoperative prognosis with minimal neurologic deficits in these patients.

5858. Wu, W., et al. (2011). "Endoscopic transorbital approach for repair of cerebrospinal fluid leakage following removal of an orbito-cranial foreign body." Clinical & experimental ophthalmology **39**(4): 375-377.

5859. Wu, X., et al. (2014). "Removal of orbital-maxillary sinus-pterygopalatine fossa foreign body with external and endoscopic combined approach." The Journal of craniofacial surgery **25**(4): 1547-1549.

Craniofacial trauma involving the pterygopalatine fossa region is reported to be rare. We present a case of a foreign body involving the orbit, maxillary sinus, and pterygopalatine fossa in a 4-year-old boy. The object was a reed shaft. Three-dimensional computed tomographic scans and magnetic resonance imaging were done to make a correct diagnosis and to apply the best surgical treatment. The Caldwell-Luc approach combined with endoscopic approach was applied to remove all the fragments of the foreign body, which had been decayed in the human body. One month later, the patient showed satisfactory aesthetic and functional results.

5860. Wu, X., et al. (2019). "Synthesis and evaluation of novel PD-L1-targeted small molecules for 18F-labeling and PET imaging." Journal of Nuclear Medicine **60**.

Objectives: The immune checkpoint pathways play important roles for vertebrates to control the immune response. However, cancer cells also exploit these checkpoint pathways to evade antitumor immune responses, and hence immune checkpoint pathways are viable target for anti-cancer therapies and attracted much attention in recent years. At present, several immune checkpoint blocking antibodies have been approved by the U.S. Food and Drug Administration and used as effective treatment against metastatic melanoma, non-small-cell lung cancer (NSCLC) and renal cell carcinoma in the clinic. It is also important to measure the expression of immune checkpoint associated proteins before the applications of immune checkpoint blocking antibodies to optimize and predict the anti-cancer therapeutic effects. Though radiolabeled proteins/antibodies have been reported as promising PD-L1 imaging agents, the disadvantages of protein-based and antibody-based imaging agents, i.e., slow clearance rate, low brain penetration (for primary/metastatic lesions in brain), call for small molecule-based PD-L1 imaging agents. Based on the structures revealed by Bristol-Myers-Squibb (BMS), we synthesized a small library of fluorine-containing PD-L1 ligands, to identify suitable PET tracers with high affinities to human PD-L1, and reasonable logP values for brain penetration. Methods: A total of 20 compounds were prepared from commercially available starting materials, using methods adapted from literatures with slight modifications. All the target compounds in this investigation were readily prepared using Mistunobu reaction or Buchwald-Hartwig cross coupling reactions as key steps to get the biphenyl intermediates, followed with sodium cyanoborohydride-mediated reductive amination or cesium carbonate-promoted O-alkylation before the reductive amination. Homogeneous Time-resolved Fluorescence (HTRF) human PD1/PD-L1 Binding Assay was performed to evaluate the IC50s of the newly synthesized PD-L1 ligands. Compound 9 showed most potent inhibitory and its organotin precursor was synthesized from the corresponding brominated analog using palladium catalyst. Results and Discussion: All compounds were successfully synthesized in 4-5 steps with overall yields ranging from 24%-35%, and the organotin precursor was also synthesized via bromo intermediate. Compound 9 showed the most potent activity with IC50 being 4 nM, which is followed by compound 10 (9 nM), compound 7 (10 nM) and compound 11 (10 nM). Structure activity relationship analysis showed the influences of various substituents at the 1, 3, 4 and 6 position of the 'core ring' of the lead compound from the BMS patent (see Figure). Studies indicate that the modification of R1 will slightly increase the activity, and the introduction of pyridine at the 3position (R3) of the benzene ring will also slightly increase the activity. Introduction of bromide at 6 position (R4) did not improve the biochemical potencies, but the chiral six membered substituent at 4 position (R2) showed good bioactivities. Importantly, the substitution with fluorine at the 6 position of the core ring did not significantly influence the binding affinity. And this allows for the radiofluorination to generate radiotracers for PET imaging. Conclusions: To develop small molecule-based PD-L1 PET imaging probes, we designed and synthesized a library of fluorinated PD-L1 ligands based on the biphenyl pharmacophore. In vitro binding assay showed that several of the compounds possess nano-molar affinities to human PD-L1, and are potential PD-L1 PET imaging probe candidates. The radiolabeling and in vitro and in vivo pharmacology and pharmacokinetics studies of these PET tracers are under the way. Figure 1. The structure of the lead compound and the regions for SAR.

5861. Wu, Y., et al. (2020). "Orbitocranial Penetrating Injury With Multiple Vessel Invasion in an Infant: A Case Report and Literature Review." Frontiers in neurology **11**.

Orbitocranial penetrating injury (OPI) with multiple vascular invasions is a rare occurrence. To our knowledge, experience with its clinical treatment is rather limited, especially for infants. This case report describes an infant who fell

from a 0.5 m high bed and landed on a toy with a keen-edged plastic rod. The fractured end of the rod was noted at the medial aspect of the left eyelid, and she was experiencing impaired consciousness. Computed tomography showed that the foreign body penetrated the cavernous sinus with internal carotid artery involvement, and compressed the transverse sinus through the cerebellum. Emergency surgery was performed with temporal occlusion of the left common carotid artery. The rod was removed from the orbital side, and bleeding from cavernous sinus region was effectively controlled under direct inspection via a sub-temporal approach. The patient was successfully treated and recovered consciousness after 17 days. This is the first report of successful management of OPI combined with multiple vascular injury in an infant. Herein, we highlight the anatomical imaging features of the injuries and also the individualized strategy concerning vascular invasion.

5862. Wu, Y., et al. (2021). "Trans-base and trans-vault low-velocity penetrating brain injury: A retrospective comparative study of characteristics, treatment, and outcomes." Chinese journal of traumatology = Zhonghua chuang shang za zhi **24**(5): 273-279.

PURPOSE: Low-velocity penetrating brain injury (LVPBI) caused by foreign bodies can pose life-threatening emergencies. Their complexity and lack of validated classification data have prevented standardization of clinical management. We aimed to compare the trans-base and trans-vault phenotypes of LVPBI to help provide guidance for clinical decision-making of such injury type., METHODS: A retrospective study on LVPBI patients managed at our institution from November 2013 to March 2020 was conducted. We included LVPBI patients admitted for the first time for surgery, and excluded those with multiple injuries, gunshot wounds, pregnancy, severe blunt head trauma, etc. Patients were categorized into trans-base and trans-vault LVPBI groups based on the penetration pathway. Discharged patients were followed up by outpatient visit or telephone. The data were entered into the Electronic Medical Record system by clinicians, and subsequently derived by researchers. The demography and injury characteristics, treatment protocols, complications, and outcomes were analyzed and compared between the two groups. A t-test was used for analysis of normally distributed data, and a Mann-Whitney U test for non-parametric data. A generalized linear model was further established to determine whether the factors length of stay and performance scale score were influenced by each factor., RESULTS: A total of 27 LVPBI patients were included in this analysis, comprised of 13 (48.1%) trans-base cases and 14 (51.9%) trans-vault cases. Statistical analyses suggested that trans-base LVPBI was correlated with deeper wounds; while the trans-vault phenotype was correlated with injury by metal foreign bodies. There was no difference in Glasgow Coma Scale score and the risk of intracranial hemorrhage between the two groups. Surgical approaches in the trans-base LVPBI group included subfrontal (n = 5, 38.5%), subtemporal (n = 5, 38.5%), lateral fissure (n = 2, 15.4%), and distal lateral (n = 1, 7.7%). All patients in the trans-vault group underwent a brain convex approach using the foreign body as reference (n = 14, 100%). Moreover, the two groups differed in application prerequisites for intracranial pressure monitoring and vessel-related treatment. Trans-base LVPBI was associated with higher rates of cranial nerve and major vessel injuries; in contrast, trans-vault LVPBI was associated with lower functional outcome scores., CONCLUSION: Our findings suggest that trans-base and trans-vault LVPBIs differ in terms of characteristics, treatment, and outcomes. Further understanding of these differences may help guide clinical decisions and contribute to a better management of LVPBIs.

5863. Wulffeld, S., et al. (2017). "The effect of CT scanners in the trauma room - an observational study." Acta anaesthesiologica Scandinavica **61**(7): 832-840.

BACKGROUND: A CT scanner incorporated in the trauma resuscitation bay may benefit trauma patients by fastening work-up times; however, evidence in the area is still sparse. We assessed if time from admission to first CT scan was lower after incorporation of a CT scanner in the resuscitation bay., METHODS: We included trauma patients admitted in two 1-year periods, before and after a major rebuilding of the trauma room. Beforehand, one CT scanner was located in an adjacent room. After the rebuilding, two mobile CT scanners were placed in the resuscitation bays, where a moving gantry was combined with a trauma resuscitation table. Subgroup analyses were performed on severely injured and patients with traumatic brain injury., RESULTS: We included 784 patients before and 742 patients after the reconstruction. Case-mix differed between study periods as there was a higher proportion of severe injuries, traumatic brain injury and penetrating trauma in the after period. We found a minor increase in time to CT in the after period (20 vs. 21 min, P = 0.008). In a multivariate regression analysis adjusted for differences in case-mix and with time to CT as outcome, period was an insignificant explanatory variable [beta (before vs. after): 0.96 min 95% CI: 0.9-1.02, P = 0.3]. In

both subgroups, we found no significant difference in time to CT., CONCLUSION: We found no reduction in time to CT scan, when comparing a period with mobile CT scanners incorporated in the resuscitation bay to an earlier period with a CT scanner next to the trauma room. 5864. Wullenweber, R., et al. (1977). "[A computer-tomographical examination of cranial bullet wounds (author's transl)]." Computertomographische Untersuchungen bei Schadel-Schuss-Verletzungen. **80**(3): 227-246.

The report covers the computer-tomographical examination of six patients with acute cranial bullet injuries and fifteen patients suffering from the sequels of such injuries. The diagnostic and prognostic significance of this method of examination in the case of acute injuries is described. The extent of cerebral defects in the case of sequels can be documented during this process by means of x-ray. The computer-tomography therefore offers an objective basis for the assessment of this type of sequela.

5865. Wyatt, E. A. and M. E. Davis (2017). "Breast cancer brain metastasis (BCBM) model for determination of therapeutic brain penetration." Cancer Research **77**(13).

Purpose Brain metastases are presenting an increasing problem in the clinic, and especially in treatment of patients with human epidermal growth factor receptor-2 (HER2)-amplified breast cancer. Although extracranial metastases respond well to HER2 inhibitors, human clinical data shows brain metastases hide behind an intact blood-brain barrier (BBB) and are largely untreatable. Many current preclinical models lack this barrier integrity, limiting their utility in understanding delivery of drugs to the brain. We present here the development of a new model suitable for evaluating therapeutic brain penetration in addition to efficacy. Experimental procedures Human HER2-amplified BT-474 breast cancer cells were inoculated intravenously (tail vein) in female Rag2-/-;Il2rg-/- mice (2 million cells/mouse) to induce multiorgan metastasis. Formation of metastatic brain lesions was monitored by magnetic resonance imaging (MRI). For comparison, BT-474 cells were inoculated intracranially for direct brain tumor implantation (50,000 cells/mouse). Response to a suite of HER2-targeted therapies known not to appreciably cross an intact BBB (trastuzumab, lapatinib, etc.) was monitored by MRI for both metastatic and implanted brain tumors. Mice were sacrificed following signs of prolonged distress or loss of >20% body weight. Organs were collected for standard histological and immunohistochemical analysis, as well as for CLARITY tissue clearing and large-scale 3D macromolecule mapping. Results Intravenous inoculation of BT-474 cells into Rag2-/-;Il2rg-/- mice consistently reproduced the full metastatic profile seen in humans, with metastases in the lung, bone, liver, ovary, lymph, and brain tissues. Brain metastases were detected in >90% of mice inoculated intravenously. Histological analysis of metastatic brain tumors showed different morphologies and invasive characteristics compared to those intracranially implanted. Additional differences in vasculature between metastatic and implanted brain tumors were identified by CLARITY. Importantly, HER2-targeted therapy markedly delayed progression of implanted brain tumors, but failed to control metastatic brain tumor growth, recapitulating the clinical situation. Conclusions These data, together with ongoing efforts to further characterize therapeutic transport to these brain tumors, suggest that intracranial inoculation disrupts the BBB and creates artificial routes for therapeutics to reach implanted brain lesions, resulting in anomalous tumor response. In contrast, this new metastatic model reproduces the discordant effects of HER2-targeted therapy in patients, and offers a platform for studying the efficiency of therapeutic delivery across an intact BBB as well as antitumor activity, both of which are critical to effective clinical translation.

Emerging evidence suggests a neuroprotective role for oestrogens following damage to the vertebrate brain. Aromatase (oestrogen synthase) is rapidly transcribed and translated in glial cells around areas of neural damage in several vertebrates. However, the potential neuroprotection afforded by locally up-regulated glial aromatase immediately surrounding the injury remains to be tested. Towards this end, individual birds sustained penetrating

mechanical injuries via a needle that contained either vehicle or the aromatase inhibitor fadrozole into contralateral hemispheres. Seventy-two hours later, the size of neural injury (as assessed by the extent of necrotic tissue) and the number of apoptotic cells around the injuries were evaluated. The size of injury in the hemisphere injected with fadrozole was significantly larger than the injury caused by vehicle injection. Furthermore, a greater number of apoptotic nuclei were found around the fadrozole-associated lesion relative to vehicle. Finally, constitutively expressed, neuronal aromatase close to the injury site did not differ between hemispheres. We conclude that local inhibition of glial aromatase immediately around the site of injury plays a neuroprotective role in the songbird brain and this protection involves apoptotic pathways. Local up-regulation of glial aromatase may play a pivotal role in the limitation of secondary damage and/or the acceleration of restorative processes following injury to the vertebrate brain.

5868. Xia, X., et al. (2012). "Stab wound with lodged knife tip causing spinal cord and vertebral artery injuries: case report and literature review." Spine **37**(15): E931-934.

STUDY DESIGN: Case report and literature review., OBJECTIVE: To report the case of a young patient who sustained a penetrating wound with a knife tip retained in his cervical vertebrae and to review the literature., SUMMARY OF BACKGROUND DATA: Stab wound with foreign body retained, associated with spinal cord injury and vertebral artery injury, is not commonly reported. The timing and approach of surgical intervention are still controversial., METHODS: A 17-year-old boy with a wound in the neck presented with diminishing feeling and dysfunction of the left leg and arm. Radiographs demonstrated a foreign body at the C4 level, and possible spinal cord and vertebral artery injuries were detected by computed tomography. Digital subtracted angiography showed a small lateral opening of the injured artery, which was successfully embolized. The knife tip was removed from the original wound without severe cerebrospinal fluid leakage or bleeding,, RESULTS: The patient achieved immediate improvement after the operation., CONCLUSION: Cases of simultaneous spinal cord injury and vertebral artery injury in which the foreign body is retained are uncommonly reported. Digital subtracted angiography is necessary for cervical penetrating wounds and surgical approach should be individualized.

5871. Xie, D., et al. (1995). "The oligodendroglial reaction to brain stab wounds: an immunohistochemical study." Journal of neurocytology **24**(6): 435-448.

Myelin/oligodendrocyte specific protein was compared to glial fibrillary acidic protein and 2'3'-cyclic nucleotide 3'-phosphodiesterase expression in normal rat brains and following stab wounds to the cerebral cortex, corpus callosum and hippocampus. Animals with stab wounds were allowed to recover for 5, 15, 28, 45 and 70 days post-operation before fixation by perfusion. Sections were reacted with antibodies against myelin/oligodendrocyte specific protein, glial fibrillary acidic protein and 2'3'-cyclic nucleotide 3'-phosphodiesterase, and observed by light and electron microscopy. Normal cerebral cortex had very few myelin/oligodendrocyte specific protein-positive and 2'3'-cyclic nucleotide 3'-phosphodiesterase-positive cells, but some glial fibrillary acidic protein-positive cells. The myelinated fibres of the corpus callosum were heavily stained for myelin/oligodendrocyte specific protein but unstained by glial fibrillary acidic protein or 2'3'-cyclic nucleotide 3'-phosphodiesterase antibodies. Some immunopositive cells were present in the corpus callosum and hippocampus with all three antibodies. After stab wound myelin/oligodendrocyte specific protein-positive reactive cells had more and longer processes and stained more intensely than equivalent cells in normal brain. These cells were distributed along the wound track, including within the cerebral cortex. The numbers of these cells increased

until 28 days post-operation and then decreased so that very few were found at 70 days post-operation except in the corpus callosum. Where demyelination occurred myelin/oligodendrocyte specific protein-staining was lost. Staining for 2'3-cyclic nucleotide 3'-phosphodiesterase revealed a similar pattern. Glial fibrillary acidic protein-positive reactive cells, which were also more robust than the normal cells, were more widely distributed. They increased in number throughout the time periods studied and gliosis was evident on the contralateral side. The glial fibrillary acidic protein-positive astrocytes were also different from the myelin/oligodendrocyte specific protein-positive and 2'3'-cyclic nucleotide 3'-phosphodiesterase-positive oligodendrocytes in terms of cell shape. With electron microscopy myelin/oligodendrocyte specific protein-positive cells showed features typical of immature oligodendrocytes. We conclude that the injury caused a numerical increase in oligodendrocytes and that myelin/oligodendrocyte specific protein is a good marker for the oligodendroglial response and demyelination in pathological conditions.

5872. Xie, H. and S. Chen (2013). "Ocular siderosis." Eye science **28**(2): 108-112.

Ocular siderosis refers to intraocular iron deposition in ocular tissues caused by the long-time retention of penetrating iron-containing foreign bodies, commonly leading to a series of characteristic alterations and severe disorder of visual function. Ocular siderosis, rarely seen in the clinic, can cause irreversible retinal injuries and visual function damage and can even affect the appearance of the eyeballs. These effects significantly decrease the quality of life of patients and lead to poor prognosis. This study summarizes ocular siderosis with respect to pathogenesis, clinical manifestations, diagnosis, treatment, and sequelae, with the aim of assisting clinicians in the diagnosis and treatment of ocular siderosis.

Combined photothermal/photodynamic therapy is a promising strategy to achieve an enhanced anticancer effect. However, hypoxia is one of the representative characteristics of the microenvironment of solid tumors, which not only attenuates the therapeutic effects but also promotes tumor invasion and metastasis. Herein, a PtBi-beta-CD-Ce6 nanoplatform for the generation of sustained O2 was constructed for more effective tumor therapy. In detail, the catalase (CAT)-like nanozyme, PtBi, which could decompose H2O2 to produce O2, was modified with beta-cyclodextrin (beta-CD). O2 would be converted into 1O2 by PtBi-beta-CD-Ce6 for enhanced photodynamic therapy (PDT) under 650 nm laser irradiation. In addition, by reason of excellent absorption in the near-infrared-II (NIR-II) region, PtBi-beta-CD-Ce6 was used for photoacoustic imaging (PA) and photothermal imaging (PT)-guided photothermal therapy (PTT) in the NIR-II biowindow. Furthermore, PtBi-beta-CD-Ce6 could be elected to serve as a contrast agent for X-ray computed tomography (CT) imaging due to the apparent X-ray attenuation capability of the Pt and Bi elements themselves. Therefore, by integrating the advantages of overcoming the hypoxia function and photothermal effect into a single nanoplatform, PtBi-beta-CD-Ce6 showed an immense possibility in multimodal imaging-guided combined PDT/PTT.

5874. Xiong, C. K., et al. (2011). "A 10-year profile (2001 to 2010) of trauma admissions caused by interpersonal violence: A major trauma centre's experience." Annals of the Academy of Medicine Singapore **40**(7): S16-S17.

Introduction: This study aims to characterise trauma admissions caused by interpersonal violence. Methods: This is a retrospective study of patients who were presented to the Tan Tock Seng Hospital Emergency Department during the 10-year period from 1 January 2001 to 31 December 2010 for injuries caused by interpersonal violence. Data were obtained from the Trauma Registry, case notes and electronic records for descriptive analysis. Results: Four hundred and forty-four patients were admitted in total (99.1% males, 9.9% females). Average age was 36.6 years (range, 14 to 83). Though Chinese (53.4%) was the most common ethnic group, Indians (20.7%), Malays (17.1%) and Others (8.78%) experienced a disproportionately higher burden of interpersonal violence. Of the patients, 77.3% were Singaporeans. There was an increase from 10 to 96 cases annually in the first 8 years, followed by a decrease in the last 2 years (55 in 2010). Time of injury was predominantly from 0000 to 0559 (72.3%). Injury type was mainly blunt (58.3%). Mechanism was mostly sharp/blunt instruments (78.6%). Females more commonly experienced interpersonal violence at home, and males at public places. Interpersonal violence most commonly occurred in public sites (88.7%). Average GCS was 13.5 (range, 3 to 15) and 73 (16.4%) had moderate/ severe brain injury. Average ISS was 13.5 (range, 1 to 75) and 155 (34.9%) were major trauma cases. There were 6 deaths (ISS of ≥26) which were mostly associated with penetrating trauma (83.3%) and public sites (83.3%). Conclusion: A better understanding of the epidemiology, injury characteristics and

outcomes of interpersonal violence was achieved. It is hoped that these data will prompt further research, leading to formulation of preventive strategies.

5875. Xu, F., et al. (2013). "The surgical management of a penetrating orbitocranial injury with a bakelite foreign body reaching the brain stem." Brain injury **27**(7-8): 951-956.

BACKGROUND: Penetrating orbital injuries constitute a significant threat to ocular and cerebral structures. The incidence of central nervous system damage from orbital injury is related to the orbital anatomy and the characteristics of the penetrating object. Penetrating orbital injuries involving the brain stem are extremely rare., OBJECTIVES: To present an uncommon case of penetrating orbital injury and to discuss surgical management., CASE STUDY: A patient suffered from a penetrating injury by a Bakelite comb which extended from his left orbit through the cavernous sinus to the pons. Complete occlusion of the left cavernous segment of the internal carotid artery was detected and a frontotemporal craniotomy with lateral superior orbitotomy was performed to remove the object. A delayed asymptomatic carotid-cavernous fistula was identified 1 year later., CONCLUSION: Surgical treatment remains the mainstay of intervention for penetrating orbitocranial injuries. The rationale of surgical removal of a foreign body should focus on safe exposure and removal of the object at the earliest without inflicting further injuries. Close follow-up for a delayed carotid-cavernous fistula is necessary.

5876. Xu, G., et al. (2018). "Prediction of potential for organ donation after circulatory death in neurocritical patients." The Journal of heart and lung transplantation : the official publication of the International Society for Heart Transplantation **37**(3): 358-364.

BACKGROUND: The success or failure of donation after circulatory death depends largely on the functional warm ischemia time, which is closely related to the duration between withdrawal of life-sustaining treatment and circulatory arrest. However, a reliable predictive model for the duration is absent. We aimed to compare the performance of the Chinese Donation after Circulatory Death Nomogram (C-DCD-Nomogram) and 3 other tools in a cohort of potential donors., METHODS: In this prospective, multicenter, observational study, data were obtained from 219 consecutive neurocritical patients in China. The patients were followed until circulatory death after withdrawal of life-sustaining treatment., RESULTS: The C-DCD-Nomogram performed well in predicting patient death within 30, 60, 120 and 240 minutes after withdrawal of life-sustaining treatment with c-statistics of 0.87, 0.88, 0.86 and 0.95, respectively. The DCD-N score was a poor predictor of death within 30, 60 and 240 minutes, with c-statistics of 0.63, 0.69 and 0.59, respectively, although it was able to predict patient death within 120 minutes, with a c-statistic of 0.73. Neither the University of Wisconsin DCD evaluation tool (UWDCD) nor the United Network for Organ Sharing (UNOS) criteria was able to predict patient death within 30, 60, 120 and 240 minutes after withdrawal of life-sustaining treatment (UWDCD tool: 0.48, 0.45, 0.49 and 0.57; UNOS criteria: 0.50, 0.53, 0.51 and 0.63)., CONCLUSION: The C-DCD-Nomogram is superior to the other 3 tools for predicting death within a limited duration after withdrawal of life-sustaining treatment in Chinese neurocritical patients. Thus, it appears to be a reliable tool identifying potential donors after circulatory death.

5877. Xu, J., et al. (1993). "Variation with age in the labelling of amoeboid microglial cells in rats following intraperitoneal or intravenous injection of a fluorescent dye." Journal of anatomy **182 (Pt 1)**: 55-63.

Amoeboid microglial cells (AMC) in the corpus callosum were selectively labelled following a single intraperitoneal (i.p.) injection of the fluorescent dye, rhodamine isothiocyanate (RhIc) into postnatal rats. The frequency of RhIc-labelled cells varied with age, with the largest number occurring in 7-d-old animals. Thereafter, the labelled cells declined drastically in number and fluorescence and were barely detectable in 12-d-old injected rats. Labelled cells were absent in 13-d or older rats given an RhIc injection. When the injected RhIc was followed over a time course sequence, it was first detected in the cerebral blood vessels and their lining endothelia within 5 min after the injection. A variable number of AMC emitting a weaker fluorescence were closely adherent to the outer walls of the blood vessels. With time, the fluorescence in the AMC was progressively enhanced, but that in the blood vessels showed a concomitant reduction. In the rats that received an intravenous (i.v.) injection of RhIc, the labelling pattern of AMC, both in terms of its variation with age and in temporal sequence, paralleled that in rats given i.p. injections. In 12-d-old rats subjected to a stab wound coupled with an i.p. injection of RhIc, a considerable number of AMC not normally labelled at this age were activated. The cells exhibited an intense fluorescence and expressed MHC surface antigen immunoreactivity. It is

concluded from this study that when injected i.p. or i.v., RhIc is readily circulated to the cerebral vessels, where it enters brain tissue by transendothelial transport.(ABSTRACT TRUNCATED AT 250 WORDS)

5878. Xu, J., et al. (2013). "Foreign body retained in liver long after gauze packing." World journal of gastroenterology **19**(21): 3364-3368.

This case report describes a foreign body retained in the liver long after perihepatic gauze packing. A 64-year-old female patient had suffered a rib fracture and liver rupture during a traffic accident in 1973. She discovered a mass in her right hypochondrium. Her hepatic ultrasonography showed a round mass (20.3 cm x 17.3 cm x 16.0 cm in size) with fluid echogenicity in the right lobe of her liver, and a hepatic cystic-solid mass (19.7 cm x 18.5 cm x 15.6 cm in size) was identified in an abdominal computerized tomography scan. Several pieces of gauze were extracted, and brown pus from the hepatic mass was suctioned during her exploratory laparotomy. Histology documented gauze remnants with necrotic material inclusions and fibrotic capsules. To our knowledge, this patient's case represents the longest time for which a foreign body has been retained in the liver. In addition, we conducted a comprehensive literature review of foreign bodies retained in the liver. Foreign bodies may be introduced into the liver via penetrating trauma, surgical procedures or the ingestion of foreign bodies (which then migrate from the gut). Thus, they can be classified into the following three categories: penetrating, medical and migrated foreign bodies. The details of the case are thoroughly described.

5879. Xu, L., et al. (2020). "The Surgical Strategies and Techniques of Transorbital Nonmissile Brain Injury." World neurosurgery **144**: e856-e865.

OBJECTIVE: This study aimed to summarize the experience with the management of transorbital brain injury (TOBI) at our institution that may help inform surgical decision-making., METHODS: Four adults with TOBIs were admitted to our hospital and received surgical treatment. The patients' clinical manifestations, physical findings, imaging data, surgical treatment, and postoperative outcome were prospectively collected and subject to retrospective analysis., RESULTS: All patients were male. In 2 patients, the entry point of the cranium was the superior orbital fissure, whereas in the other 2, the entry point was the orbital roof. Thorough physical examination and comprehensive diagnostic imaging were performed preoperatively in all patients for careful assessment of the foreign body and its surrounding important structures. In collaboration with our multidisciplinary trauma team, individualized surgeries were successfully designed and performed in the 4 patients to remove the foreign bodies along the path of their trajectories. Three patients had uneventful postoperative courses, whereas 1 patient died because of severe cerebral ischemia and refractory brain swelling after decompressive craniectomy., CONCLUSIONS: A comprehensive understanding of the regional anatomy of the trajectory is the cornerstone for surgical management of TOBIs. Adequate preoperative imaging examinations are essential for the evaluation of surgical risks and for making a tailored management strategy. Early surgical exploration through multidisciplinary collaboration is highly recommended for achieving a favorable outcome.

5882. Xue, H., et al. (2020). "Transorbital nonmissile penetrating brain injury: Report of two cases." World journal of clinical cases **8**(2): 471-478.

BACKGROUND Penetrating brain injury (PBI) is an uncommon emergency in neurosurgery, and transorbital PBI is a rare type of PBI. Reasonable surgical planning and careful postoperative management can improve the prognosis of patients CASE SUMMARY The first case is a 68-year-old male patient who was admitted to the hospital because a branch punctured his brain through the orbit for approximately 9 h after he unexpectedly fell while walking. After admission, the patient underwent emergency surgical treatment and postoperative anti-infection treatment. The patient was able

to follow instructions at a 4-mo follow-up review. The other case is a 46-year-old male patient who was admitted to the hospital due to an intraorbital foreign body caused by a car accident, after which the patient was unconscious for approximately 6 h. After admission, the patient underwent emergency surgical treatment and postoperative anti-infection treatment. The patient could correctly answer questions at a 3-mo follow-up review. CONCLUSION Transorbital PBI is a rare and acute disease. Early diagnosis, surgical intervention, and application of intravenous antibiotics can improve the prognosis and quality of life of patients.

5883. Xue, H., et al. (2020). "Transorbital nonmissile penetrating brain injury: Report of two cases." World journal of clinical cases **8**(2): 471-478.

5885. Yadav, Y. R., et al. (2013). "Modified twist drill technique in the management of chronic subdural hematoma." Turkish neurosurgery **23**(1): 50-54.

AIM: Burr-hole craniostomy is the most efficient and safe choice for surgical drainage of chronic subdural hematoma (CSDH). Although the twist-drill drainage is also relatively safe and time-saving, it carries the risk of inadequate drainage, brain penetration and hematoma formation. Our modified technique helps in avoiding bleeding and brain penetration., MATERIAL AND METHODS: The preferred sites for twist drill were the most curved parts on the cranium. Normal drilling at about 90 degree angle was done on the most curved surfaces while it was at about 60 degree angles on flat surface. This angled drilling and the curved guide wire (hooked in the distal blind end of infant feeding tube), helped to guide infant feeding tube in the hematoma cavity. Dura matter was coagulated using insulated wire., RESULTS: There was no procedure related hematoma, brain penetration and mortality in any of the 50 patients managed by the modified technique. Infant feeding tube was properly positioned in all the cases. Burr hole evacuation was done in 7 cases (14%) due to inadequate evacuation of the hematoma after TDC., CONCLUSION: Our modified technique of twist drill drainage is inexpensive, simple, safe and effective alternative technique in the treatment of CSDH.

5886. Yadollahi, M., et al. (2015). "Epidemiologic study of trauma patients admitted to a level 1 trauma center in Shiraz: One year survey." Razavi International Journal of Medicine **3**(4).

Background: Traumatic injuries exert significant burden on human populations around the world. Iran as a developing country is at top 5 deadliest countries regarding injuries; however, few studies have examined the descriptive epidemiology of trauma in Iran. Objectives: To describe injuries regarding age, gender and injury mechanism and also time trend in emergency departments of Shahid Rajaee Trauma Center affiliated to Shiraz University of Medical Sciences. Patients and Methods: This descriptive cross-sectional study was carried out on all trauma patients (n = 21542) admitted to Shahid Rajaee Trauma Hospital (level I trauma referral center in Shiraz) between March 2011 and March 2012. Data were analyzed separately by age, gender, month of admission, and injury mechanisms (motorcycle collision, car-pedestrian accidents, car-car accidents, fall from height, stab wounds and gunshot injuries). Results: With a mean

age of 36.0 ± 17.2 years, a total number of 21542 patients were visited, 16524 (76.7%) of whom were male. The male to female ratio was 3.3:1 with injured men being significantly younger than women (mean age 33.7 + 16.6 and 43.6 ± 19.2 years, respectively). There were 1492 trauma victims older than 60 years accounting for the smallest proportion of the population (6.92%). On admission, 1699 patients (7.9%) required cardiopulmonary cerebral resuscitation (CPCR) with a sex ratio of 2:1. Among those requiring CPCR, falling down was the major cause (45.24%) of injury in elderly (patients over 60 year) and car accident in those under 60 year (43.94%). Conclusions: Injuries affect all age groups; however, the disproportionately at risk population is the productive youth. Preventive strategies should focus on reducing trauma incidence among young men at population level. Considering the higher number of incidents occurring in mid spring and late summer, authorities should devise preventive plans mainly through alteration of traffic rules in this period.

5887. Yagmur, Y., et al. (1999). "Looking at trauma and deaths: Diyarbakir city in Turkey." Injury **30**(2): 111-114.

There were 329 trauma related deaths in Diyarbakir in 1997. Of these 226 were male (69%) and 103 were female (31%). The median age was 20 years old (range 1-82 years). Of the deaths, 30.5% were under 10, 51% were under 20 and 67% were under 30 years old. Two hundred and eleven deaths occurred in the hospital while 118 deaths occurred prehospital. Seventy-seven percent of hospital deaths (191) occurred in the first day. The most common cause of death was multiple injuries (151, 46%). Head injuries were the main reason for 128 deaths (46%). The most common mechanism of death was motor vehicle accident (131, 40%). The second was falls from a residential building (117, 33.7%).

5889. Yajima, Y., et al. (2005). "Concentrations of toluene in the body killed by an injury to the head shortly after ingesting thinner." Forensic science international **147**(1): 9-12.

An autopsy was conducted on a male showing leather-like skin damage, revealing the cause of death to be an injury to the head. Thinner was found scattered around the scene of death, and stomach and intestine contents smelled strongly of solvent. Toxicological analysis was conducted to determine whether or not the solvent was of a lethal level. Using gas chromatography, peaks of toluene, xylene, and ethylbenzene were detected in the blood and gastric contents. No toluene was detected in the urine, and therefore it was concluded that the decedent died of a severe head injury shortly after solvent ingestion. In the literature, toluene concentrations in blood and lung samples were determined as both fatal and non-fatal but clear differences in the fatality of toluene in solid organ samples, namely, the brain, liver and kidneys were shown. The brain is especially useful in postmortem analysis. In this case, the concentration of toluene in the brain was 20.0 microl/g, which was considered as a non-lethal level.

5890. Yakirevich, I. and A. Popov (2012). "Aircraft medevac by medical modules of emercom of Russia." Journal of Emergency Medicine **43**(5): 919.

Objective: During elimination of medical consequences of emergencies, the issues concerning victims' mass evacuation to a specialized hospital are constantly brought up. At the disposal of the Central Airmobile Rescue Service of EMERCOM of Russia there are two types of medical modules. Medical Airplane Module (MMS) is used for medical evacuation of 4 victims aboard an Ilyushin 76 aircraft. Medical Helicopter Module (MMV) is used for medical evacuation of 2 victims aboard an MI-8 helicopter. MMS and MMV ensure mobility and versatility. Methods: From December 2008 until now, 37 medical evacuations were carried out using MMS aboard an Iluyshin 76 aircraft: traffic accident victims, terrorism act victims, and victims of man-made catastrophes. In total, 272 patients were evacuated (including 16 children); 68 victims with artificial lungs ventilation (ALV). Medical evacuation of severely injured victims from regional hospitals to Moscow specialized hospitals to provide efficient and modern medical aid was carried out using MMV. In total, 27 patients were evacuated, 5 with ALV. The majority of victims were in severe and extremely severe condition with associated multi-system trauma. Closed craniocerebral injury was observed in 75% of victims, with mass affection of locomotor apparatus, mine and explosion trauma, gunshot wounds, burn shock, and burn disease. Constant monitoring, oxygen therapy, ALV, analgesia and sedation, intensive and anti-shock care were carried out in flight.

Condition was evaluated according to Glasgow, APACHE II and SOFA scales. Results: MMS and MMV application in case of mass evacuation in flight ensures spared victims' transportation, total monitoring, and treatment continuity. It enables caregivers to carry out anesthetic and resuscitation treatment, intensive care, monitoring and treatment of all the victims. Conclusions: The quality of mass medical evacuation of extremely injured victims has considerably improved, and the time of transportation from emergency area to specialized hospitals to render them efficient medical aid has decreased.

5891. Yakirevich, I. and A. Popov (2012). "Mass evacuation of victims from emergency areas by medical modules aboard the aircraft of EMERCOM of Russia." Critical Care **16**: S171-S172.

Introduction During elimination of medical consequences of various emergencies the issues concerning victims' mass evacuation to a specialized hospital base are constantly brought up. The physicians of the Central Airmobile Rescue Service of EMERCOM of Russia and the specialists of Kazan Helicopter Plant 'Zarechye' developed two types of modules. The Medical Airplane Module (MMS) is used for medical evacuation of four victims aboard Ilyushin 76 aircraft. The Medical Helicopter Module (MMV) is used for medical evacuation of two victims aboard an MI 8 helicopter. MMS and MMV advantages are: mobility - the possibility of installation in various aircraft cabins types; and versatility - the possibility of any required equipment installation for the treatment of victims with various trauma severity, safe fixation of medical equipment straight on the module, equipment operation off- line as well as using the aircraft power supply network. Methods From December 2008 until now 28 medical evacuations were carried out using MMS aboard Iluyshin 76 aircraft: traffic accident victims, terrorism act victims and manmade catastrophes. In total, 198 patients were evacuated (including 12 children), 55 victims with artificial lung ventilation (ALV). Medical evacuation of severely injured children and adults from regional hospitals to Moscow specialized hospitals in order to provide efficient and modern medical aid was carried out using MMV. In total, 27 patients were evacuated (including five children), five patients with ALV. The majority of victims were in severe and extremely severe conditions with associated multisystem trauma. Closed craniocerebral injury was observed in 75% of victims with mass affection of locomotor apparatus, mine and explosion trauma, gunshot wounds, burn shock and burn disease. Constant monitoring, oxygen therapy, ALV, analgesia and sedation, intensive and anti-shock care as well as wound dressing were carried out in flight. The victims' general condition was evaluated according to the Glasgow Coma Scale, APACHE II and SOFA scales. Results MMS and MMV application in case of mass evacuation in flight ensures spare victims' transportation, total monitoring and treatment continuity. It enables one to carry out anesthetic and resuscitation treatment, intensive care, monitoring and treatment of all the victims. Conclusion The quality of mass medical evacuation of extremely injured victims has considerably improved and the time of transportation from emergency area to specialized hospitals to render them efficient medical aid has reduced.

5893. Yalnda-Öztürk, N. and E. Aksu (2014). "Is it the scythe or the medicine? A case calling caution for contrast imaging and empiric nephrotoxic antibiotherapy." Pediatric Critical Care Medicine **15**(4): 165.

Background and aims: Contrast imaging became an integral part of medicine to assist with a diagnosis, and antibiotics are essential for treatment of complicated infections. Both can be harmful if not chosen wisely. Results: Six year old boy presented with multi system organ failure due to septic shock. He had a history of penetrating trauma via a scythe to his right eye with resultant orbital cellulitis and endophthalmitis. His perforated cornea was sutured, and he received empiric broad spectrum antimicrobial therapy (meropenem, vancomycin and gentamycin, amphotericin B). His orbit was imaged with 2 contrast computed tomographies and a magnetic resonance imaging before his admission to the PICU. There was questionable orbital abscess in the images, but no surgical intervention was performed. He had generalized edema, especially on his face and neck. He was intubated due to respiratory failure and started on continuous venovenous hemodiafiltration (CVVHDF) secondary to acute anuric kidney injury and received inotropic support. Laboratory investigations revealed anemia, thrombocytopenia and leukocytosis, and elevated inflammation markers. He was on CVVHDF for a week, extubated one day later and discharged two weeks after enucleation of his right eye. With the help of supportive therapy, timely initiation of CRRT, careful antibiotic usage with daily adjustments per calculated glomerular filtration rate and proper surgical intervention the patient survived with normal renal functions.

Conclusions: The decision for imaging with contrast media and the choice of empiric antibiotics deserves special consideration in sick children. Physicians need to be very careful, since both may deteriorate renal functions as in our patient.

The case of a 53-year-old man who attempted suicide by introducing a wooden chopstick through his nostril into his brain is reported. The importance of computed tomography is stressed in the diagnosis of intracranial wooden foreign bodies.

5896. Yamamoto, Y., et al. (2017). "Prediction of cerebral morphine concentration in paediatric traumatic brain injury (TBI) with the rat physiologically based pharmacokinetic (PBPK) model." Child's Nervous System **33**(10): 1832-1833.

OBJECTIVE:Several acute neurosurgical conditions use various therapeutic drugs but our understanding of how these enter the brain is limited. In paediatric traumatic brain injury (pTBI) analgesia and sedation are essential but evidence-based regimens are lacking and a better understanding of drug distribution in the brain is needed. A pharmacokinetic (PBPK) model using rat physiological data for describing pharmacokinetics (PK) at cerebral locations (brain extracellular fluid [ECF] and cerebrospinal fluid [CSF]) was developed. We aimed to determine the feasibility of using a humanised version of this model to predict cerebral morphine drug concentrations. MATERIAL-METHODS:Participants included children with severe TBI (GCS≤8) who underwent cerebral microdialysis monitoring. ECF from themicrodialysis catheter was collected hourly for chemistry analysis and remnant fluid was stored.Morphine concentrations in the ECF and blood were measured using liquid chromatography mass spectrometry, and compared to the rat PBPK model that was translated by replacing system-and drug-specific parameters. RESULTS:Eight patients (median age 8 [2.8-13] years, median weight 24 [14.5-55] kg) received morphine infusions [10-40 mcg/kg/hour] and underwent microdialysis monitoring. The rat PBPK model was translated by scaling up the drug transport clearance at the blood brain barrier (brain weight) and the brain drug diffusion rate (brain and CSF volume). The humanised model predicted morphine concentrations within the 90% prediction interval in 97% of plasma samples, and in ECF samples from normal-appearing brain tissue. CONCLUSIONS:Cerebral morphine drug recovery with microdialysis is feasible in pTBI. The rat PBPK model can be translated to adequately predict paediatric brain morphine PK in normal appearing tissue. These pilot data suggest that combining pharmacokinetic modelling with data from microdialysis may contribute to developing evidence-based pharmacotherapy in pTBI. Further validation is ongoing but this may be an important foundation for future studies of cerebral drug penetration generalisable to other conditions.

5897. Yaman, F., et al. (2012). "Evaluation of mandibular fractures in children during five years' in a dental school." HealthMED **6**(2): 654-658.

Mandibular fractures are rarely encountered among the pediatric population, and when they do present, their clinical features differ from those in adults. This retrospective study looked at the age, sex, type and cause of fracture, treatment method and associated injuries and complications in 260 cases of mandibular fracture in children under age 16. Among the most significant findings: Fracture incidence had a 3:5 male:female ratio; 52% of all mandibular fractures involved condyle/subcondyle fractures and 50.7% involved symphysis/ parasymphysis fractures; the most common treatment method was intermaxillary fixation; in no cases were severe complications observed during the healing period.

5898. Yamasaki, F., et al. (2013). "[Transorbital penetrating intracranial injury by a chopstick: a case report and review of the literature]." No shinkei geka. Neurological surgery **41**(11): 1001-1009.

This 4-year-old girl fell while holding plastic chopsticks and a chopstick penetrated her left eye. The chopstick was removed immediately by herself. Conventional CT and MR images showed a penetration track from the orbital roof

to the basal ganglia. On susceptibility-and diffusion-weighted images the track and surrounding cytotoxic edema were visualized more clearly. Although antibiotics were started at the time of admission to prevent intracranial infection, she developed meningitis. Subsequent treatment with carbapenem antibiotic-and vancomycin therapy was curative and she was discharged home 4 weeks after the injury. In our review of the literature on intracranial penetrating injuries via the orbita we compared the injury patterns inflicted by and the clinical observations reported on damage induced by wooden-, plastic-, and metal chopsticks. We also evaluated diagnostic CT and MR images in patients with intracranial penetrating injuries caused by chopsticks and documented the advantage of susceptibility-and diffusion-weighted imaging over conventional CT-and MR imaging.

Case report of a 39 years old male patient who attempted suicide by introducing two nails in the midline of the head. He was successfully submitted to an extensive paramedian bifrontotemporal craniotomy, and survived without motor deficits.

5900. Yamashita, T., et al. (2007). "Transorbital intracranial penetrating injury from impaling on an earpick." Journal of neuro-ophthalmology : the official journal of the North American Neuro-Ophthalmology Society **27**(1): 48-49.

An inebriated 86-year-old man impaled himself on a wooden earpick that penetrated through the superior orbital fissure into the prepontine cistern. The patient underwent surgery immediately by a lateral suboccipital approach, and the earpick was pulled out through the wound with control of hemorrhage from the cavernous sinus. He survived this event with no neurologic deficits apart from complete ipsilateral ophthalmoplegia and ptosis. Prompt imaging and surgical intervention allowing direct visualization of the foreign body and prevention of intracranial complications are part of proper management of this problem.

5901. Yan, H.-J. (2007). "Epidural hematoma following use of a three-point skull clamp." Journal of clinical neuroscience : official journal of the Neurosurgical Society of Australasia **14**(7): 691-693.

We report an unusual case of epidural hematoma secondary to the use of a three-point skull-fixation device. Initially, a posterior-fossa brain tumor with hydrocephalus was diagnosed in a 15-year-old boy. Midline suboccipital craniectomy was performed with the patient placed in the prone position. A Mayfield (Ohio Medical Instrument Co., Cincinnati, OH, USA) skull clamp was used for fixation of the head during the surgical procedure, following which, a huge epidural hematoma developed within 6 hours of surgery, due to skull penetration and fracture at one of the clamp's pin sites located proximate to the coronal suture.

5902. Yan, S. C., et al. (2015). "The Assassination of Abraham Lincoln and the Evolution of Neuro-Trauma Care: Would the 16th President Have Survived in the Modern Era?" World neurosurgery **84**(5): 1453-1457.

Abraham Lincoln was the 16(th) President of the United States of America. On April 14, 1865, shortly after his re-election and the conclusion of the Civil War, Lincoln was shot and killed by John Wilkes Booth. Although numerous physicians tended to the President shortly after his injury, he passed away the next morning. Today, we recognize Lincoln as one of the greatest Presidents in American history. His assassination profoundly influenced the future of the United States, especially as the country was coming back together again following the Civil War. Testaments to his lasting legacy can be seen in many places, from the stone carving of him on Mount Rushmore to his image gracing the $5 bill. What if the President had survived his injury? Would he have had a different outcome utilizing current critical care treatment? Neurotrauma care in 1865 was not yet developed, and head wounds such as the one Lincoln sustained were almost always fatal. The medical attention he received is considered by historians and physicians today to be excellent for that time. We look at the evolution of neurotrauma care during the last 150 years in the US. Particular focus is paid to the advancement of care for penetrating brain injuries in modern trauma centers.

5903. Yang, G. L., et al. (2022). "The Effects of the COVID-19 Pandemic on Penetrating Neurotrauma at a Level 1 Trauma Center." Clinical neurosurgery **68**(SUPPL 1): 72.

INTRODUCTION: The COVID-19 pandemic forced the implementation of social distancing guidelines to minimize spread of the coronavirus. However, it is not yet understood what effects these precautions had on the rates of penetrating neurotrauma. METHODS: We retrospectively analyzed neurotrauma data from our institutional trauma registry from distinct periods defined as pre-COVID-19 (March 2019-September 2019) and COVID-19 (March 2020-September 2020). Demographics, injury characteristics, mechanisms of trauma, and past medical history (including psychiatric diagnosis) were collected. Data were analyzed for between-group differences and presented as odds ratios. RESULTS: We observed a significant rise in the number of neurotrauma cases in 2020 (558 vs. 630, OR 1.129 [1.0071, 1.2657]). There was a decrease in the proportion of male victims (71.3% vs. 68.6%, p = 0.03). There were significant differences noted in the mechanism of injury between groups. Patients in 2020 were less likely to present with falls (42.3% vs. 34.3%, OR 0.7119 [0.5627, 0.9005]) and more likely to present with GSW (4.48% vs. 7.78%, OR 1.7981 [1.0951, 2.9523]). Of the patients with penetrating cranial injuries, the most common motive was assault (56.7% vs. 60.0%), followed by self-inflicted (13.3% vs. 20.0%) and accidental (20.0% vs. 18.3%) with a significant difference between years (p = 0.0043). The presence of comorbid psychiatric illness or substance abuse did not confer an increased odds of presenting with penetrating injuries. No significant differences were noted in mean arrival or discharge GCS or injury severity as measured by ISS. However we did observe significant increases in patients presenting with bilaterally reactive pupils (48.3% vs 59.3%, p = 0.0025), patients discharged home (27.6% vs 37.3%, p = 0.0002), and survival at 6 months (41.4% vs. 54.2%, p = 0.0188). CONCLUSION: We observed a higher rate of penetrating neurotrauma while social distancing measures were in place. It is unclear if the psychosocial effects of quarantine and social distancing had a causative relationship with the increased rates of assault and self-inflicted penetrating injuries.

5904. Yang, G. L., et al. (2022). "The Effects of the COVID-19 Pandemic on Penetrating Neurotrauma at a Level 1 Trauma Center." World neurosurgery **164**: e530-e539.

BACKGROUND/OBJECTIVE: The COVID-19 pandemic has had a profound impact on the global delivery of health care. Recent data suggest a possible impact of the pandemic on patterns of neurotrauma. The aim was to assess the impact of the pandemic on the incidence of neurotrauma, with a focus on cranial gunshot wounds (cGSWs) at a large Midwestern level 1 trauma center., METHODS: We conducted a retrospective review of our trauma registry from March through September 2020 and compared it to the same months in 2019. Odds ratios were utilized to assess for differences in patient demographics, injury characteristics, rates of neurotrauma, and rates of cGSWs., RESULTS: A total of 1188 patients presented with neurotrauma, 558 in 2019 and 630 in 2020. The majority of patients were male (71.33% in 2019; 68.57% in 2020) and Caucasian (78.67% in 2019; 75.4% in 2020). Patients presented with cGSWs more frequently in 2020 (n = 49, 7.78%) than in 2019 (n = 25, 4.48%). The odds of suffering a cGSW in 2020 was 73.6% higher than those in 2019 (95% confidence interval = [1.0871, 2.7722]; P = 0.0209). The etiology of such injury was most commonly assault (n = 16, 21.62% in 2019; n = 34, 45.95% in 2020), followed by self-inflicted injury (n = 4, 5.41% in 2019; 12, 16.22% in 2020)., CONCLUSIONS: Despite the government-mandated shutdown, we observed an increase in the number of neurotrauma cases in 2020. There was a significant increase in the incidence cGSWs in 2020, with an increase in assaults and self-inflicted injuries. Further investigation into socioeconomic factors for the observed increase in cGSWs is warranted.

5905. Yang, H.-S. and D.-E. Oh (2011). "A case of delayed oculocardiac reflex induced by an intraorbital foreign body." Ophthalmic plastic and reconstructive surgery **27**(1): e2-4.

A 56-year-old male presented with a history of left periorbital pain, nausea, vomiting, dyspnea, sweating, and pallor. His left eye was injured by a bomb explosion approximately 40 years ago. Evisceration was performed. There were no cardiopulmonary and gastroenterological findings except mild bradycardia (54/min). CT evaluation revealed a 4-cm-sized, sharp, metallic, intraorbital foreign body in the left orbit. After the removal of the foreign body, the symptoms completely resolved with a normal heart rate (69/min). The authors present a case of delayed oculocardiac reflex induced by an old intraorbital foreign body.

5906. Yang, H. Y., et al. (1997). "A subpopulation of reactive astrocytes at the immediate site of cerebral cortical injury." Experimental neurology **146**(1): 199-205.

We have identified an early-appearing intermediate filament-associated protein (IFAP-70/280 kDa) in radial glia and their immediate derivatives. This IFAP is absent in the adult CNS. In this study, we examined the reexpression of this early glial differentiation trait in rat reactive astrocytes induced by stab injury of the cerebrum. Double-label immunofluorescence microscopy demonstrated that by 36 h postlesion, IFAP-70/280 kDa was present in a few GFAP-positive astrocytes in the area adjacent to the wound. As the gliotic reaction progressed, the number of IFAP-positive reactive astrocytes increased and by 5-6 days postlesion, IFAP-70/280 kDa was present in most of the hypertrophied astrocytes in tissue immediately adjacent to the wound. By 8 days postlesion, while the number of IFAP-negative reactive astrocytes away from the wound diminished, the IFAP-containing reactive astrocytes close to the wound persisted. Concurrently, they began to change from a stellate form to an elongated shape, with their longitudinal axes radiating from the wound. The immunoreactivity of this IFAP started to diminish at 20 days postlesion, and by 30 days postlesion, it was not observed in the remaining gliotic cells. These results demonstrate that reactive astrocytes induced by stab-wound injury can be divided into two subtypes: persistent IFAP-70/280 kDa-containing cells which are close to the wound in the area of the glial scar and transient IFAP-70/280 kDa-negative cells which are farther from the wound. The reappearance of IFAP-70/280 kDa also suggests that some reactive astrocytes have the capacity to recapitulate early developmental stages.

5907. Yang, L. and L. S. Benardo (2000). "Valproate prevents epileptiform activity after trauma in an in vitro model in neocortical slices." Epilepsia **41**(12): 1507-1513.

PURPOSE: Epileptogenesis is a hallmark of severe cortical trauma, with up to approximately 80% of patients experiencing seizures in the first 24 hours after penetrating head injury. An in vitro model of traumatic brain injury was developed to investigate hyperexcitability and epileptogenesis and their prevention. We determined whether sodium valproate would prevent epileptiform activity in this experimental model., METHODS: Rat cortical slices were prepared and maintained in vitro using standard methods. Trauma was effected by removing the superficial 450-500 microm of slices. Traumatized slices were exposed to valproate at various time points. Intracellular and extracellular recordings were used to assess evoked activities., RESULTS: In untreated traumatized deep segments, hyperexcitability was manifested by depressed inhibition and often (54%) by epileptiform activity. Preparations exposed to valproate at 30 minutes or later after trauma showed abnormal activity similar to control traumatized slices. Epileptogenicity in deep segments was significantly reduced when slices were exposed to valproate (a) continuously immediately after trauma, (b) after a 20-minute delay, or (c) immediately after trauma for 1 hour and then returned to physiological solution. Finally, slices that were exposed to valproate or pentobarbital beginning 20 minutes after trauma for only 1 hour and then returned to physiological medium showed a significant reduction in abnormal activity. Valproate was found to enhance fast gamma-aminobutyric acid(A)-ergic inhibitory strength., CONCLUSIONS: Valproate significantly reduces epileptiform activity after trauma to the neocortex, likely by restoring the excitation-inhibition balance, perhaps through augmentation of gamma-aminobutyric acid transmission. The timing of this action may have implications for mechanisms of seizure genesis and may suggest a role for rapid treatment.

5908. Yang, Q.-T., et al. (2012). "The therapeutic efficacy of endoscopic optic nerve decompression and its effects on the prognoses of 96 cases of traumatic optic neuropathy." The journal of trauma and acute care surgery **72**(5): 1350-1355.

BACKGROUND: Traumatic optic neuropathy (TON) is an important cause of severe loss of vision due to blunt or penetrating head trauma. The pathogenesis of TON remains unclear, and there are several potential causes for the observed loss in vision. Endoscopic optic nerve decompression (EOND) has been reported to improve the visual prognosis in TON cases, but its efficacy remains controversial. It is important to investigate the therapeutic efficacy of EOND in the treatment of TON and to evaluate the relevant prognostic factors., METHODS: A retrospective study was conducted to analyze the clinical characteristics and prognoses of 96 TON cases. The chi(2) test and multiple logistic regression analyses were used to evaluate potential prognostic factors., RESULTS: : The overall rate of EOND effectiveness was 40.6% (39 of 96). A significantly higher effective rate (83.3%) was observed for patients with light perception compared with those without light perception (26.4%, $p < 0.05$). Univariate and multiple logistic regression analyses identified three variables (no light perception, undergoing EOND 3 days after trauma, and hemorrhage within the ethmoid and/or sphenoid sinus) that were significantly associated with unrecovered visual acuity. Age, loss of consciousness, optic canal fracture, preoperative steroid megadose treatment, and optic nerve sheath incision were all factors that showed no significant correlation with therapeutic efficacy. However, patients with fractures in a single medial wall of the optic canal appeared to have better prognoses than patients with multiple fractures or those with a

single fracture in a lateral wall., CONCLUSIONS: The overall therapeutic efficacy of EOND for the treatment of TON is far from satisfactory, especially for patients without light perception. The factors that impact TON prognoses are complex and may be interrelated. The indication for EOND must be individualized., LEVEL OF EVIDENCE: III, epidemiological study.

5909. Yang, R., et al. (2011). "Free flaps for pediatric facial reconstruction: The Maryland experience." International journal of oral and maxillofacial surgery **40**(10): 1044.

Introduction: The advances of microsurgical techniques have made the use of free tissue transfer in the pediatric population a viable reconstructive option. Objective: The purpose of this abstract is to review the use of free tissue microvascular transfer in the pediatric population with head and neck defects at the University of Maryland, Department of OMS. Patients and methods: A retrospective chart audit of the past 10 years was performed. All patients 18 years and younger who received a microvascular reconstruction for a head and neck defect were included in this review. Results: There were 12 patients requiring 13 flaps. One patient with a gunshot injury required 2 flaps. The average age at surgery was 15 years (range 12-18). The reasons for reconstruction were as follows: benign tumor (9), malignant tumor (2), and trauma (2). The defects were mostly osseous mandible (10) with only 3 soft tissue reconstructions. Flap selection included 10 fibulas (w or w/o skin), 2 radial forearms, and 1 anterolateral thigh. There were no immediate flap complications and one minor wound complication. Average length of hospital stay was 7 days (5-10). Conclusion: In many ways children constitute an ideal patient population for microsurgical reconstruction despite rare indications. In general the pediatric patient has pristine anatomy, no complications of chronic disease, as well as an excellent healing capacity. Consideration should be given however to future growth at both the recipient and donor site as well as tissue available in the skeletally immature patient.

5910. Yang, S., et al. (2018). "Management of gunshot wound injuries to the lateral skull base." Journal of Neurological Surgery, Part B: Skull Base **79**.

Background: Gunshot wounds (GSWs) to the lateral skull base can involve several critical neurovascular structures and present dilemmas in management. Chicago and its neighboring suburbs are experiencing a wave of gunshot victims. We review our experience at a Level 1 Trauma Center in the western suburbs of Chicago over the past 10 years of GSW to the temporal bone and lateral skull base and discuss their presentation, management, and patient outcomes. Objective: To review the incidence and presentation of patients with GSW to the temporal bone and lateral skull base. To discuss nonsurgical and surgical management as well as patient outcomes. Methods: Retrospective review of all patients who presented with GSW to the temporal bone and lateral skull base from August 2007 to present at the Loyola University Medical Center. Patients were identified using the ICD-9 diagnosis codes for GSW to the auricle, ear, and head and chart review was performed to identify those patients with involvement of the temporal bone. IRB approval was obtained prior to the start of the study. Results: Data are currently being collected. A total of seven patients were identified, all of whom were male. The average age at presentation was 27 years. Six out of the seven patients denied any prior medical history. One patient reported a history of depression and anxiety disorder. One of the seven injuries was self-inflicted. All GSW involved the temporal bone; the squamous segment was involved in 43% of cases, tympanic segment in 57%, mastoid segment in 71%, and petrous segment in 29%. The otic capsule was involved in four of seven patients and four of seven patients had complete facial paralysis (House-Brackmann's scale of 6) at presentation. Additional presenting injuries included cerebrospinal fluid (CSF) leak (four of seven), intracranial injury (five of seven), facial fractures (three of seven), and optic nerve injury (two of seven). Fifty-seven percent of patients underwent surgical intervention, which include facial nerve decompression, lateral temporal bone resection, labyrinthectomy, and facial nerve neurorrhaphy for management of GSW to temporal bone. Average time from presentation to surgery was 20 days. Of the patients with complete facial paralysis at presentation who underwent surgical intervention, one patient had HB 6 at 1-month follow-up and the other had HB 3 at 5-month follow-up. None of the patients had audiograms performed at initial presentation. All patients with involvement of the otic capsule had profound sensorineural hearing loss on follow-up. Postoperative complications occurred in two out of seven patients; one patient had a CSF leak and infected carotid pseudoaneurysm and the other had an intracranial abscess and osteomyelitis. One of the seven patients died due to GSW injury. Conclusion: GSW to the temporal bone can have varying presentations depending on the site involved. Injury to facial nerve and otic capsule are common and can have lasting sequelae. Surgical management depends on site of injury and presenting symptoms.

5911. Yang, Z., et al. (2019). "Serum-Based Phospho-Neurofilament-Heavy Protein as Theranostic Biomarker in Three Models of Traumatic Brain Injury: An Operation Brain Trauma Therapy Study." Journal of neurotrauma **36**(2): 348-359.

Glial fibrillary acidic protein (GFAP) and ubiquitin C-terminal hydrolase (UCH-L1), markers of glial and neuronal cell body injury, respectively, have been previously selected by the Operation Brain Trauma Therapy (OBTT) pre-clinical therapy and biomarker screening consortium as drug development tools. However, traumatic axonal injury (TAI) also represents a major consequence and determinant of adverse outcomes after traumatic brain injury (TBI). Thus, biomarkers capable of assessing TAI are much needed. Neurofilaments (NFs) are found exclusively in axons. Here, we evaluated phospho-neurofilament-H (pNF-H) protein as a possible new TAI marker in serum and cerebrospinal fluid (CSF) across three rat TBI models in studies carried out by the OBTT consortium, namely, controlled cortical impact (CCI), parasagittal fluid percussion (FPI), and penetrating ballistics-like brain injury (PBBI). We indeed found that CSF and serum pNF-H levels are robustly elevated by 24 h post-injury in all three models. Further, in previous studies by OBTT, levetiracetam showed the most promising benefits, whereas nicotinamide showed limited benefit only at high dose (500 mg/kg). Thus, serum samples from the same repository collected by OBTT were evaluated. Treatment with 54 mg/kg intravenously of levetiracetam in the CCI model and 170 mg/kg in the PBBI model significantly attenuated pNF-H levels at 24 h post-injury as compared to respective vehicle groups. In contrast, nicotinamide (50 or 500 mg/kg) showed no reduction of pNF-H levels in CCI or PBBI models. Our current study suggests that pNF-H is a useful theranostic blood-based biomarker for TAI across different rodent TBI models. In addition, our data support levetiracetam as the most promising TBI drug candidate screened by OBTT to date.

5912. Yang, Z., et al. (2018). "PNF-H as theranostic biomarker in three models of traumatic brain injury: An operation brain trauma therapy study." Journal of neurotrauma **35**(16): A192.

Glial fibrillary acidic protein (GFAP) and ubiquitin C-terminal hydrolase (UCH-L1), markers of glial and neuronal cell body injury respectively, have been previously selected by the Operation Brain Trauma Therapy (OBTT) pre-clinical therapy and biomarker screening consortium as drug development tools. However, traumatic axonal injury (TAI) also represents a major consequence and determinant of adverse outcomes following traumatic brain injury (TBI). Thus, biomarkers capable of assessing TAI are much needed. Neurofilaments (NFs) are found exclusively in axons. Here, we evaluated phospho-neurofilament-H (pNF-H) protein as a possible new TAI marker in serum and CSF across three rat TBI models in studies carried out by the OBTT consortium, namely, controlled cortical impact (CCI), parasagittal fluid percussion (FPI) and penetrating ballistics-like brain injury (PBBI). We indeed found that CSF and serum pNF-H levels are robustly elevated by 24 h post injury in all three models. Further, in prior studies by OBTT, levetiracetam showed the most promising benefits, while nicotinamide showed minimal benefit only at high dose (500mg/kg). Thus, serum samples from the same repository collected by OBTT were evaluated. Treatment with 54mg/kg IV of levetiracetam in the CCI model and 170mg/kg in the PBBI model significantly attenuated pNF-H levels at 24 h post-injury as compared to respective vehicle groups. In contrast, nicotinamide (50 mg/kg or 500 mg/kg) showed no reduction of pNF-H-levels in CCI or PBBI models. Our current study suggests that pNF-H is a useful theranostic blood-based biomarker for TAI across different rodent TBI models. In addition, our data support levetiracetam as the most promising TBI drug candidate screened by OBTT to date.

5913. Yang, Z. R., et al. (2006). "Hemostatic effects of a self-designed rapid-hemostatic-dressing on bleeding of partially ruptured superior sagittal sinus in dogs." Academic Journal of Second Military Medical University **27**(10): 1131-1133.

Objective: To evaluate hemostatic effects of a self-designed rapid-hemostatic-dressing (RHD) on bleeding of the partially ruptured superior sagittal sinus in dogs. Methods: Bleeding models of the partially ruptured superior sagittal sinus were established in 15 dogs by gunshot and surgery. The 15 model dogs were divided into 2 groups: RHD group (n=10) and control group (treated with surgicel, n=5). The survival time, blood loss, and other hematological parameters were measured over a 1-hour period. Results: The bleeding models of the partially ruptured superior sagittal sinus were successfully established in dogs. There were no significant differences in the baseline parameters of dogs compared with those 60 minutes after RHD treatment. The survival time in RHD group was significantly longer than that in control group and the blood loss was significantly lower than that of the control group (both $P<0.05$). Conclusion: RHD has satisfactory hemostatic effects on partially ruptured superior sagittal sinus in dogs, indicating it is an excellent hemostatic dressing.

5914. Yano, H., et al. (1995). "An intracranial wooden foreign body without neurological findings: case report." The Journal of trauma **38**(5): 830-832.

We encountered an unusual case of an intracranial wooden stick penetrating through the frontal bone, without remarkable neurological findings. That foreign body was shown to be a low-density area similar to an intracranial air pocket by a standard computed tomogram. Here we discuss the potential hazards of intracranial wooden foreign bodies and emphasize the necessity for special attention to them during radiologic examination.

5915. Yao, C., et al. (2009). "The effect of selective brain cooling on hemeoxygenase-1 (HO-1, HSP 32) expression following penetrating ballistic-like brain injury in rats." Journal of neurotrauma **26**(8): A71.

Hypothermia has been acknowledged as a powerful neuroprotective method in treating acute brain injuries. The mechanisms through which hypothermia protects the injured brain can be multifactorial, but one of its major benefits is to reduce injury-induced brain edema and consequently decrease elevated intracranial pressure (ICP). Recently we demonstrated that selective brain cooling (SBC) therapy by means of extraluminal cooling of bilateral carotid arteries could ameliorate intracerebral hemorrhage (ICH), brain edema, and elevated ICP in an experiment model of penetrating ballistic-like brain injury (PBBI) in rats. Other studies have shown that hemoxygenase-1 (HO-1) protein is implicated in hemorrhage induced brain edema. In order to understand the possible role of HO-1 in PBBI-induced ICH, we investigated the time course of HO-1 changes following PBBI in rats and evaluated the effect of SBC on PBBI-induced HO-1 changes. Rats received unilateral 10% frontal PBBI or sham surgeries immediately followed by 2h SBC which reduced the brain temperature by 3°C. Control rats received PBBI or sham surgeries without SBC. Brain tissues and blood were collected at 6, 24,48, 72h, and 7 days post injury and HO-1 was measured by Western blot. Our results show that following PBBI, HO-1 protein increased in brain and plasma at all time points studied, reaching the peak level at 48 h. SBC attenuated PBBI induced up-regulation of HO-1, but did not affect HO-1 expression in the sham controls. These results suggest that altered expression of HO-1 may play an important role in the formation of brain edema following PBBI and neuroprotective effects of SBC may be related to reduction in brain edema. Furthermore, these changes in HO-1 could also be used as a hemorrhagic brain injury biomarker for therapeutic intervention.

5916. Yao, C., et al. (2009). "P43/pro-EMAPII: a potential biomarker for discriminating traumatic versus ischemic brain injury." Journal of neurotrauma **26**(8): 1295-1305.

To gain additional insights into the pathogenic cellular and molecular mechanisms underlying different types of brain injury (e.g., trauma versus ischemia), recently attention has focused on the discovery and study of protein biomarkers. In previous studies, using a high-throughput immunoblotting (HTPI) technique, we reported changes in 29 out of 998 proteins following acute injuries to the rat brain (penetrating traumatic versus focal ischemic). Importantly, we discovered that one protein, endothelial monocyte-activating polypeptide II precursor (p43/pro-EMAPII), was differentially expressed between these two types of brain injury. Among other functions, p43/pro-EMAPII is a known pro-inflammatory cytokine involved in the progression of apoptotic cell death. Our current objective was to verify the changes in p43/pro-EMAPII expression, and to evaluate the potentially important implications that the differential regulation of this protein has on injury development. At multiple time points following either a penetrating ballistic-like brain injury (PBBI), or a transient middle cerebral artery occlusion (MCAo) brain injury, tissue samples (6-72 h), CSF samples (24 h), and blood samples (24 h) were collected from rats for analysis. Changes in protein expression were assessed by Western blot analysis and immunohistochemistry. Our results indicated that p43/pro-EMAPII was significantly increased in brain tissues, CSF, and plasma following PBBI, but decreased after MCAo injury compared to their respective sham control samples. This differential expression of p43/pro-EMAPII may be a useful injury-specific biomarker associated with the underlying pathologies of traumatic versus ischemic brain injury, and provide valuable information for directing injury-specific therapeutics.

5917. Yao, C., et al. (2008). "Detection of protein biomarkers using high-throughput immunoblotting following focal ischemic or penetrating ballistic-like brain injuries in rats." Brain injury **22**(10): 723-732.

PRIMARY OBJECTIVE: Recent efforts have been aimed at developing a panel of protein biomarkers for the diagnosis/prognosis of the neurological damage associated with acute brain injury., METHODS AND PROCEDURES: This study utilized high-throughput immunoblotting (HTPI) technology to compare changes between two animal models of acute brain injury: penetrating ballistic-like brain injury (PBBI) which mimics the injury created by a gunshot wound and

transient middle cerebral artery occlusion (MCAo) which is a model of stroke. Brain and blood were collected at 24-hours post-injury., MAIN OUTCOMES AND RESULTS: This study identified the changes in 18 proteins following PBBI and 17 proteins following MCAo out of a total of 998 screened proteins. Distinct differences were observed between the two models: five proteins were up- or down-regulated in both models, 23 proteins changed in only one model and one protein was differentially expressed. Western blots were used to verify HTPI results for selected proteins with measurable changes observed in both blood and brain for the proteins STAT3, Tau, PKA RII beta, 14-3-3 epsilon and p43/EMAPII., CONCLUSIONS: These results suggest distinct post-injury protein profiles between brain injury types (traumatic vs. ischemic) that will facilitate strategies aimed at the differential diagnosis and prognosis of acute brain injury.

5918. Yao, H., et al. (2020). "Association between initial ICU admission diagnosis and outcomes in chronic critically ill patients: A retrospective cohort study." Canadian Journal of Respiratory, Critical Care, and Sleep Medicine **4**(3): 187-193.

INTRODUCTION: Advancements in the care of acutely ill patients has reduced intensive care unit (ICU) mortality but has also led to the emergence of a group of patients who have a prolonged dependency on life support measures. Despite this rapidly growing demographic, a relatively minimal amount is known in the way of identifiable risk factors for outcomes in chronic critically ill patients. We sought to explore the association between admission diagnostic category and acute hospital mortality in chronic critically ill patients. METHODS: The study is a retrospective cohort study of adult patients aged 18 and over, admitted to two Canadian, university associated ICUs between July 2012 and June 2013. We included in our study all patients who had a tracheostomy placed for prolonged mechanical ventilation in the ICU. The primary outcome was ultimate acute hospital mortality. A univariate and multivariate analysis was performed to assess the association of admission diagnostic category and ultimate acute hospital mortality. RESULTS: One hundred and forty-four patients received a tracheostomy in the ICU during the study period with 134 patients eligible for analysis. We demonstrated both baseline characteristics and outcomes differences between medical patients, non-trauma surgical patients and trauma patients. The trauma group had a lower ICU and hospital mortality even after adjusting for potential confounders such as severity of illness and co-morbidities (OR: 0.1 95% CI 0.0-0.3, p ' 0.001). They were also more likely to be discharged home or to a rehabilitation center. CONCLUSION: In conclusion, we demonstrated that ICU admission diagnostic category is associated with acute hospital mortality. Chronic critically ill trauma patients were found to have lower acute hospital mortality rates than medical or non-trauma surgical patients even after adjustment for confounders using severity of illness scores that contain variables for admission type. Admission diagnostic category should inform patients, surrogate decision makers and the health care team regarding decisions related to tracheostomy placement and prolonged supportive care.

5920. Yarandi, K. K., et al. (2018). "Stab Wounds to the Head; Case Series, Review of Literature, and Proposed Management Algorithm." Asian journal of neurosurgery **13**(3): 754-759.

BACKGROUND AND OBJECTIVES: Stabbing the head is a rare event. It may occur following an assault or self-inflicted injury. We intend to report our experience with four such cases and review narratively the relevant literature. A treatment algorithm will be delivered., MATERIALS AND METHODS: We have reviewed four of our cases; three were stabbed to the orbit and one to the head., RESULTS: Enucleation was performed in one case. Vision could be preserved in the other two and brain abscess developed in the other cases due to a retained piece of knife. We made a comparison between our cases and those limited reports in the literature to reach an algorithm., CONCLUSION: The temporal region and the orbit are the targets mostly attacked in the craniofacial stabs. Since knives have a sharp and thin edge, they may break when penetrating the skull. The damage to the brain tissue and the retained piece of knife may be missed easily by overlooking the small injury to the scalp. The suggested algorithm would be a contrast-enhanced computed tomography scan of the skull and brain and a kind of brain vascular study are necessary, considering the location of the knife in the skull and brain passing the area with crowded vasculature. The best treatment protocol is surgery accompanied by antibiotic therapy.

5921. Yardley, A.-M. E., et al. (2015). "Running with scissors." The Journal of pediatrics **166**(1): 205.

5922. Yarlagadda, B., et al. (2012). "Retrieval of projectile foreign bodies from the paranasal sinuses and skull base." American journal of rhinology & allergy **26**(3): 233-236.

BACKGROUND: Penetrating trauma to the paranasal sinuses and skull base with retained foreign bodies represents a unique challenge for head and neck surgeons. Management of these injuries is complicated by associated injuries and the proximity to vital neurovascular structures. This study was designed to review the clinical experience with retained sinonasal and skull base projectile foreign bodies at a single academic tertiary care institution., METHODS: A retrospective review of patients who suffered penetrating trauma to the head with retained metallic foreign bodies in the paranasal sinuses and/or skull base between January 2002 and August 2011 was performed at a single academic medical center., RESULTS: There were 599 patients who suffered penetrating trauma to the head and neck, with 13 patients having retained metallic foreign bodies in the sinuses and/or skull base, mostly bullets or nails. Ten patients underwent urgent (n = 5) or delayed (n = 5) removal of foreign bodies accessible without compromise of adjacent structures either through an endoscopic or open approach. Three patients had multiple foreign bodies that were not removed. Three patients experienced traumatic cerebrospinal fluid fistula managed with either conservative measures (n = 2) or intraoperative repair at the time of foreign body retrieval (n = 1). All patients received prophylactic antibiotic coverage. No patients suffered infectious complications such as sinusitis from retained foreign bodies., CONCLUSION: Although not all retained foreign bodies after penetrating trauma to the head require removal, those that are safely accessible and at risk for infectious complications should be recovered. The timing and approach of retrieval are dictated by the clinical scenario.

5925. Yattoo, G. H. and S. A. Tabish (2013). "The profile of head injuries and traumatic brain injury deaths in Kashmir." Journal of Head Trauma Rehabilitation **28**(5): E65.

Introduction/Rationale: Head injury is considered to be a major health problem that is a frequent cause of death and disability and that makes considerable demands on health services. In developing countries, accident rates, in general, and traumatic brain injury (TBI) in particular, are increasing as traffic increases and as industrialization, falls and ballistic trauma occurs. Head injuries account for one quarter to one third of all accidental deaths, and for two thirds of trauma deaths in hospitals. Method/Approach This study was conducted on head injury patients admitted to the Accident and Emergency Department of Sher-i-Kashmir Institute of Medical Sciences. The purpose was to track and evaluate the number of head injury patients, nature of head injuries, condition at presentation, treatment given in the hospital and the outcome of intervention. Traumatic brain injury (TBI) deaths were also studied retrospectively for a period of eight years (1996 to 2003). Results/Effects The number of TBI deaths showed a steady increase from year 1996 to 2003 except for 1999 where there was a decline. The highest number of TBI deaths was in the age group of 21-30 years (18.8%), followed by 11-20 years where it was a (17.8%) and 31-40 years was (14.3%). TBI death was more common in males than in females. The maximum number of TBI deaths was from rural areas as compared to urban areas. Conclusions/Limitations To minimize the morbidity and mortality resulting from head injury and TBI, there is a need for improved roadmaintenance, visibility and lighting, proper mechanical maintenance of automobiles and other vehicles, rigid enforcement of traffic rules, compulsory wearing of crash helmets by motor cyclist and scooterists, shoulder belts in cars, and compulsory road safety education for school age children.

5926. Yaw, T. J., et al. (2020). "Postmortem Evaluation of Reintroduced Migratory Whooping Cranes (Grus americana) in Eastern North America." Journal of wildlife diseases **56**(3): 673-678.

We reviewed necropsy records of 124 Whooping Cranes (Grus americana) recovered following reintroduction of 268 individuals from 2001 to 2016 in the eastern US. Causes of death were determined in 62% (77/124) of cases

facilitated by active monitoring that limited decomposition and scavenging artifact. The greatest proportions of mortality were caused by predation (0.468; 95% confidence interval 0.356-0.580; 36/77), collision with power lines or vehicles (0.260; 0.162-0.358; 20/77), and gunshot (0.169; 0.085-0.253; 13/77). Six deaths were attributed to infection (0.078; 0.018-0.138; 6/77), including bacterial and fungal etiologies. Lead analysis of 50 liver samples yielded two results with elevated concentrations (3.65 and 10.97 ppm wet weight), and 10 bone samples from partial carcasses lacking suitable liver tissue resulted in one elevated result (48.82 ppm dry weight). These data indicate that underlying subclinical or clinical lead toxicosis may be a factor in up to 5% of deaths attributed to predation or impact trauma. Brain cholinesterase activity testing indicated no exposure to organophosphate or carbamate pesticides (mean+/-SD=17.32+/-2.90 micromol/min/g, 31/71). The causes of death and potential underlying factors summarized in this study constitute the first definitive mortality survey of migratory Whooping Cranes based on a high carcass recovery rate. Causes of death by infectious etiologies remained comparatively rare in this study, and occurred as single cases with no evidence of sustained transmission among reintroduced Whooping Cranes.

5927. Yawn, R. J., et al. (2016). "Facial nerve repair after operative injury: Impact of timing on hypoglossal-facial nerve graft outcomes." American journal of otolaryngology **37**(6): 493-496.

PURPOSE: Reanimation of facial paralysis is a complex problem with multiple treatment options. One option is hypoglossal-facial nerve grafting, which can be performed in the immediate postoperative period after nerve transection, or in a delayed setting after skull base surgery when the nerve is anatomically intact but function is poor. The purpose of this study is to investigate the effect of timing of hypoglossal-facial grafting on functional outcome., MATERIALS AND METHODS: A retrospective case series from a single tertiary otologic referral center was performed identifying 60 patients with facial nerve injury following cerebellopontine angle tumor extirpation. Patients underwent hypoglossal-facial nerve anastomosis following facial nerve injury. Facial nerve function was measured using the House-Brackmann facial nerve grading system at a median follow-up interval of 18months. Multivariate logistic regression analysis was used determine how time to hypoglossal-facial nerve grafting affected odds of achieving House-Brackmann grade of <=3., RESULTS: Patients who underwent acute hypoglossal-facial anastomotic repair (0-14days from injury) were more likely to achieve House-Brackmann grade <=3 compared to those that had delayed repair (OR 4.97, 95% CI 1.5-16.9, p=0.01)., CONCLUSIONS: Early hypoglossal-facial anastomotic repair after acute facial nerve injury is associated with better long-term facial function outcomes and should be considered in the management algorithm.

5928. Yazar, U. (2021). "Penetrating craniocerebral nail gun injury in a child: a case report." Child's nervous system : ChNS : official journal of the International Society for Pediatric Neurosurgery **37**(4): 1345-1349.

Penetrating craniocerebral injuries with a nail gun are extremely rare and even rarer in children. In this case, a 2-year-old boy, who was the youngest patient in the literature with an intracranial nail gun injury involving penetration of the right temporal lobe, was reported. The patient was evaluated by plain radiography and computed tomography. The nail was loosened and pulled gently out by creating a small craniotomy around the nail entrance. Although clinical characteristics and treatment methods of penetrating craniocerebral injuries were similar for reported in literature, the injury mechanism of presented case was different. Penetrating craniocerebral injuries with a nail gun are very dramatic situation, but mortality and morbidity are low. Without major vascular injury, a nail can be removed through a small incision. Penetrating injuries often occur accidentally in the pediatric age group, but the risk of child abuse should always be considered.

5929. Yazgan, S., et al. (2017). "An excellent anatomical and visual recovery after surgical repair of an open eye injury with poor baseline prognostic factors." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES **23**(2): 167-169.

Presently described is case of a 42-year-old woman with eye injury that was result of gunshot fired by a man at a wedding celebration. Bullet penetrated inferior quadrant of nasal sclera of left eye 7-12 mm behind limbus. Choroid and vitreous were prolapsed around bullet. Hemorrhage, vitreous prolapse and lens subluxation were present in anterior chamber. Presenting visual acuity (VA) was hand motion. Bullet 14x5 mm in size was carefully extracted from the eye. Fifteen days later, argon laser photocoagulation was performed on retina in area of bullet entry point. VA was 20/25

(Snellen) at final visit. In this case, although foreign body was large, area of penetration was Zone III, and initial VA was poor, early and appropriate surgical repair achieved integrity of the globe and good vision prognosis.

5930. Yazici, B., et al. (2007). "Intraorbital arteriovenous fistula secondary to penetrating injury." Ophthalmic plastic and reconstructive surgery **23**(4): 275-278.

PURPOSE: : To describe the clinical and radiologic features and management of an intraorbital arteriovenous fistula secondary to penetrating injury., METHOD: : Interventional case report and literature review., RESULTS: : We describe a 13-year-old girl with a history of penetrating orbital injury who presented with proptosis, eyelid hyperemia, and orbital venous congestion. Computed tomography showed a large foreign body in the superiormedial orbit and an enlarged superior ophthalmic vein (SOV). Doppler ultrasonography revealed arterialized flow in the SOV. Removal of the foreign body did not alter the orbital symptoms. Carotid angiography disclosed a fistula between the ophthalmic artery and the SOV. The patient underwent an attempted coil embolization of the fistula through the femoral vein, which was unsuccessful, but she developed profound thrombosis of the SOV, which propagated through the orbital venous system. Although orbital venous congestive symptoms were acutely exacerbated, they regressed spontaneously within 1 month. The patient was followed for 23 months without recurrence., CONCLUSIONS: : Penetrating injury of the orbital apex may lead to the formation of an arteriovenous fistula, transvenous embolization of which may be complicated by thrombosis of the SOV. In our case, this unintentional result facilitated the resolution of the fistula.

5931. Yazici, P., et al. (2010). "Comparison of isolated and concomitant liver injuries: is hepatic trauma entirely responsible for the outcome?" Acta chirurgica Belgica **110**(6): 598-602.

OBJECTIVE: This study was undertaken to examine both isolated and concomitant liver injuries to clarify the role of liver trauma on outcome., PATIENTS AND METHODS: This retrospective study was a review of all abdominal trauma patients who presented with liver injuries, with or without concomitant injury at Ege University School of Medicine over a 3-year period. Presentation, injury grade, management, and outcomes were analyzed. Patients with isolated hepatic injury (Group A) were compared with patients who had concomitant hepatic injury (liver and spleen/small bowel) (Group B). Significance was set at 95% confidence intervals., RESULTS: Of 368 patients, 80 (21%) presented with liver injury. Of these, the aetiology was as follows: 53 (66.2%) blunt injury, 19 (23%) penetrating injury, and 8 (10%) gun shot trauma. There were 38 patients in Group A and 42 in Group B. Of these 42 patients, 19 were diagnosed with serious types of injury ; eight thoracic, three open long bone fracture, one intra-cardiac, one intracranial. Six additional patients were observed with injuries to large abdominal vessels. Eleven patients (28.9%) with isolated hepatic injury were managed non-operatively. Mortality, intensive care unit and hospital length of stay, and transfusion requirements were significantly higher in Group B. Only the number of transfused blood units and the grade of liver injury were found to be effective on outcome whereas stepwise regression analysis revealed that injury type (penetrating) and blood transfusion were predictive for mortality., CONCLUSION: This study highlighted that although isolated liver injury results in good outcome with non-operative management, concomitant injuries to the liver lead to a higher failure and mortality rate. However, liver injury itself is rarely responsible for death.

5932. Ye, C. N., et al. (2020). "Double penetration wound: A nail gun injury involving the head and heart." Radiology Case Reports **15**(4): 334-338.

Nail gun injuries usually occur at the extremities due to working accidents. Intracranial or intrathoracic injuries are relatively rare, and cases combined with both injuries are even rarer. Such situations pose challenges for surgeons due to their uniqueness during operation. Radiologic imaging findings in our case were significant in indicating surgical findings. Herein, we report a patient who shot himself using a nail gun, damaging his brain and heart.

5933. Yeakley, J. W. (1999). "Temporal bone fractures." Current problems in diagnostic radiology **28**(3): 65-98.

High-resolution technique is essential to the evolution of temporal bone fractures. Axial and coronal scan planes are optimal but may not be possible in acutely traumatized patients. A knowledge of normal temporal bone anatomy is important and can be obtained from standard texts, so it will not be considered in detail in this article. Classically, petrous temporal bone fractures have been classified as longitudinal, transverse, or mixed. Recent publications have emphasized the importance of describing fractures in terms of planes rather than lines. According to this concept, most

temporal bone fractures are actually oblique, and true longitudinal fractures are rare. Petrous temporal bone fractures may be associated with cranial nerve or vascular injuries when the fracture extends to the skull base. This is particularly true of the oblique fracture, which characteristically extends anteromedially to the skull base through weak places in that area, thus avoiding the compact bone of the otic capsule surrounding the labyrinth. The most common associated injury is to the facial nerve in its geniculate or proximal tympanic segment. Transverse fractures frequently involve the labyrinth. A careful search for various types of ossicular dislocation should be performed in association with temporal bone fractures, because this may result in conductive hearing loss. The site of cerebrospinal fluid otorhinorrhea resulting from temporal bone fractures can usually be defined on plain high-resolution temporal bone images, but intrathecal contrast may be helpful. Temporal bone fractures caused by gunshot wounds are frequently complex and may be limited by metallic streak artifacts. Pediatric patients have different proportions of facial nerve injury and types of hearing loss as compared with adults.

5934. Yeates, K. O. and B. G. Enrile (2005). "Implicit and explicit memory in children with congenital and acquired brain disorder." Neuropsychology **19**(5): 618-628.

Implicit and explicit memory were examined in 8- to 15-year-old children with myelomeningocele and shunted hydrocephalus, severe traumatic brain injuries, or orthopedic injuries. Each group included between 22 and 29 children. Children completed a fragmented picture identification task to assess perceptual priming and a semantic decision-making task to assess conceptual priming. Each task also assessed procedural learning as well as explicit recall and recognition. All 3 groups showed significant perceptual and semantic priming of similar magnitude. In contrast, both brain-disordered groups displayed poorer explicit memory than did the comparison group. No group showed significant procedural learning on either task. Age and IQ were stronger predictors of explicit recall than of implicit memory. The findings indicate that implicit memory is relatively intact in many children with congenital and acquired brain disorders, despite deficits in explicit memory, and support the existence of separate memory systems in children.

5935. Yeatts, R. P., et al. (1994). "Ocular injury secondary to periorbital use of stainless-steel wire and suture." Archives of ophthalmology (Chicago, Ill. : 1960) **112**(2): 213-216.

OBJECTIVE: To describe previously unreported ocular injuries from stainless-steel wire or suture used for facial skeletal or soft-tissue repair., PARTICIPANTS: Three patients who underwent orbital reconstruction (n = 2) or ptosis repair with excision of the orbiculus oculi (n = 1) were referred with signs and symptoms of ocular injury., INTERVENTIONS: Removal of the wires and sutures., RESULTS: Treatment resolved discomfort and irritation and diminished ocular motility, iritis, and bullous keratopathy but did not improve diminished vision in one of the patients., CONCLUSIONS: Occult ocular injury from misdirected or migrating stainless-steel wire should be considered in any case of ocular injury following orbital fracture or reconstructive repair when other disease processes are readily excluded. In these three cases, stainless-steel wire or suture impinged against or impaled the globe. The use of rigid plate fixation for orbital reconstruction or otherwise placing all stainless-steel wires and sutures outside the confines of the orbit would avoid such ocular injury.

5936. Yeh, A., et al. (2020). "End of Life in the Neurological Intensive Care Unit: Is Extubating to Comfort Care Comfortable? (S707)." Journal of Pain and Symptom Management **59**(2): 532.

Objectives: • Discuss potential correlation of signs of distress in neurologically devastated patients with the underlying neurological pathology. • Debate standardization of sedation prior to and during extubation of neurologically devastated patients to comfort care. Original Research Background: Patients extubated to comfort care in the neurological intensive care unit (Neuro-ICU) comprise a unique population because their end of life signs of distress can be related to both neurological pathology and multisystem dysfunction. Little is known about distress development and control in these patients. Research Objectives: To determine if patients in the Neuro-ICU have persistent signs of distress after removal of life-sustaining therapies and, if signs of distress do develop, determine the time to distress control. Methods: Retrospective medical record review of patients who died in a Neuro-ICU at a single tertiary center over a 12-month period. Inclusion criteria were mechanical ventilation with extubation to comfort care and deaths from neurologic pathology. Patients were excluded if under the age of 18, pregnant, had penetrating brain injury, declared brain dead, received cardiopulmonary resuscitation < 24 hours prior to cardiac death, or had incomplete medical record

documentation. Results: Of the 38 patients, 28 (73.7%) developed signs of distress, with 23 (60.5%) patients developing signs of distress immediately after extubation. Twenty (52.6%) patients developed signs of distress that took >50% of their remaining time after extubation to attempt to achieve distress control. The median time in attempting to achieve distress control was 2.4 hours (S.D.: 4.7 hours). The median time to cardiac death was 2.7 hours (S.D.: 5.8 hours). Conclusion: Almost 75% of patients extubated to comfort in the Neurological ICU are likely to develop signs of distress requiring pharmacologic intervention; and of these patients who develop signs of distress, over 70% will develop persistent signs of distress that will be difficult to control. Implications for Research, Policy, or Practice: Results could hopefully change how providers approach patients who are planned for extubation to comfort care in terms of pre-medication or post-extubation liberalization of medications as well as lead to prospective studies for standardization of end of life care management.

5937. Yen, K., et al. (2003). "Blood-spatter patterns: hands hold clues for the forensic reconstruction of the sequence of events." The American journal of forensic medicine and pathology **24**(2): 132-140.

Biologic and nonbiologic traces on the hands are of particular importance for the forensic reconstruction of shooting incidents; gunpowder residue analysis in particular helps determine whether the gunshot is close range or distant. In crime scene investigation, knowledge about the morphology of bloodstain patterns-including gunshot-related back spatter-has increased since various experimental examinations have been performed in the last years; nowadays, these traces are frequently used for forensic crime scene reconstruction. The goal of this study was to deduce the position and orientation of the hands, and therefore the firearm, according to the bloodstain patterns on the hands of the deceased. For this purpose blood-spatter stains on the hands were examined on site in 5 suicides caused by gunshot. In all cases, forensically relevant conclusions regarding forensic reconstruction were enabled through close examination of the spatter marks. Therefore, in shooting incidents, analysis and documentation of blood-spatter findings on the hands is recommended before hands are tested for gunpowder residue or wrapped for the transport of the body.

5938. Yen, K. G. and M. T. Yen (2009). "Orbital approach for retrieval of transected extraocular muscles." Strabismus **17**(2): 53-56.

Transection of an extraocular muscle can occur from orbital and facial trauma, or as a complication of surgery. The injury can occur either near the muscle insertion or in the muscle belly. Identification of the proximal end of the muscle in the orbit may be difficult, especially if the transection occurs a farther distance from the insertion, and, in these cases, the muscle is often considered lost. We present two patients who suffered from traumatic transections of an extraocular muscle more than 10 mm from the insertion. Both patients underwent transconjunctival orbitotomy to retrieve and secure the severed extraocular muscle. Both patients achieved good primary gaze alignment postoperatively. Preoperative imaging should be considered in cases of traumatic extraocular muscle transection.

5939. Yengo-Kahn, A. M., et al. (2021). "The value of simplicity: externally validating the Baylor cranial gunshot wound prognosis score." Journal of neurosurgery: 1-9.

OBJECTIVE: Gunshot wounds to the head (GSWH) are devastating injuries with a grim prognosis. Several prognostic scores have been created to estimate mortality and functional outcome, including the so-called Baylor score, an uncomplicated scoring method based on bullet trajectory, patient age, and neurological status on admission. This study aimed to validate the Baylor score within a temporally, institutionally, and geographically distinct patient population., METHODS: Data were obtained from the trauma registry at a level I trauma center in the southeastern US. Patients with a GSWH in which dural penetration occurred were identified from data collected between January 1, 2009, and June 30, 2019. Patient demographics, medical history, bullet trajectory, intent of GSWH (e.g., suicide), admission vital signs, Glasgow Coma Scale score, pupillary response, laboratory studies, and imaging reports were collected. The Baylor score was calculated directly by using its clinical components. The ability of the Baylor score to predict mortality and good functional outcome (Glasgow Outcome Scale score 4 or 5) was assessed using the receiver operating characteristic curve and the area under the curve (AUC) as a measure of performance., RESULTS: A total of 297 patients met inclusion criteria (mean age 38.0 [SD 15.7] years, 73.4% White, 85.2% male). A total of 205 (69.0%) patients died, whereas 69 (23.2%) patients had good functional outcome. Overall, the Baylor score showed excellent discrimination of mortality (AUC = 0.88) and good functional outcome (AUC = 0.90). Baylor scores of 3-5 underestimated mortality. Baylor scores of 0, 1, and 2 underestimated good functional outcome., CONCLUSIONS: The Baylor score is an accurate and easy-

to-use prognostic scoring tool that demonstrated relatively stable performance in a distinct cohort between 2009 and 2019. In the current era of trauma management, providers may continue to use the score at the point of admission to guide family counseling and to direct investment of healthcare resources.

5940. Yeni-Komshian, G. H., et al. (1986). "Lesion locations associated with speech perception deficits following penetrating head injury." Neuropsychologia **24**(5): 631-647.

Speech discrimination and identification tasks assessing voicing and place distinctions were given to 16 unilaterally brain injured subjects free of aphasic or dysarthric symptoms 12-15 yr post head injury. Seven subjects did not demonstrate any difficulty with these speech tasks, while five left- and four right-brain-injured subjects showed moderate difficulties. These difficulties were more pronounced on the discrimination than on the identification tasks. Analysis of CT scans demonstrated that the lesion locations most clearly associated with the speech discrimination deficits were upper levels of the white matter subjacent to cortical regions in either hemisphere.

5941. Yergey, J. A. and M. P. Heyes (1990). "Brain eicosanoid formation following acute penetration injury as studied by in vivo microdialysis." Journal of cerebral blood flow and metabolism : official journal of the International Society of Cerebral Blood Flow and Metabolism **10**(1): 143-146.

Formation of eicosanoids has been implicated in the pathological changes that follow brain injuries. In the present study, we used a microdialysis probe to both induce acute penetration injury and also sample extracellular fluid concentrations of eicosanoids. Formation of prostaglandin (PG) D2, PGF2 alpha, and thromboxane B2 was highest in the first hour following introduction of the probe into rat striatum. In contrast, the level of PGE2 was highest during the sixth hour of collection, while 6-keto-PGF1 alpha remained stable throughout the sampling period. We conclude that in vivo microdialysis may be useful in the evaluation of the time course of the effects of acute penetration injury of the brain on the local production of eicosanoids.

5942. Yerram, S., et al. (2018). "Seizure prophylaxis in the neuroscience intensive care unit." Journal of Intensive Care **6**(1).

Background: Seizures are a considerable complication in critically ill patients. Their incidence is significantly high in neurosciences intensive care unit patients. Seizure prophylaxis with anti-epileptic drugs is a common practice in neurosciences intensive care unit. However, its utility in patients without clinical seizure, with an underlying neurological injury, is somewhat controversial. Body: In this article, we have reviewed the evidence for seizure prophylaxis in commonly encountered neurological conditions in neurosciences intensive care unit and discussed the possible prognostic role of continuous electroencephalography monitoring in detecting early seizures in critically ill patients. Conclusion: Based on the current evidence and guidelines, we have proposed a presumptive protocol for seizure prophylaxis in neurosciences intensive care unit. Patients with severe traumatic brain injury and possible subarachnoid hemorrhage seem to benefit with a short course of anti-epileptic drug. In patients with other neurological illnesses, the use of continuous electroencephalography would make sense rather than indiscriminately administering anti-epileptic drug.

5943. Yetiser, S., et al. (2008). "Facial nerve problems and hearing loss in patients with temporal bone fractures: demographic data." The Journal of trauma **65**(6): 1314-1320.

BACKGROUND: The incidence of temporal bone fractures have increased in recent decades together with the increasing traffic and population. The aim of this study is to evaluate the cause, treatment methods, radiologic, and intraoperative findings in patients with temporal bone fractures., METHODS: Thirty-five patients with temporal bone fracture who have been followed between 1992 and 2006 were retrospectively reviewed. Computerized tomography and audiometric tests were obtained. Electrophysiological evaluation of the facial nerve in patients with traumatic facial paralysis was carried by serial electromyogram (EMG). House-Brackmann grading system was used to evaluate the function of the facial nerve. Twenty-three patients underwent operation for facial paralysis or hearing loss. Results of medical and surgical therapy were documented., RESULTS: Traffic crash was the most common cause (54%). Eighteen (51.4%) of patients had conductive hearing loss, 6 (17.14%) of the patients had sensorineural hearing loss, and 11 (31.42%) had normal hearing. Transient or persistent facial paralysis was detected in 24 of 35 patients (68.57%).

Nineteen patients underwent partial or total facial decompression. Preoperative EMG of the majority of the operated patients revealed total axonal degeneration. The most common affected area of the facial nerve by trauma was the vertical segment (31.58%). House-Brackmann 1 and 2 grade was achieved in majority of the patients. Fourteen ossicular abnormalities were detected in 10 patients, and the abnormality was usually related to the incus. More than 10 dB air-bone gap closure was achieved in six of eight patients (75%)., CONCLUSIONS: Traffic crashes continue to be the main cause of temporal bone fractures. Facial paralysis caused by temporal bone trauma can be satisfactorily treated by decompression. EMG, clinical grading, and onset of the paralysis are important guides for the surgery. Restoration of the hearing can be achieved in majority of patients.

5944. Yetiser, S. and M. Kahramanyol (1998). "High-velocity gunshot wounds to the head and neck: a review of wound ballistics." Military medicine **163**(5): 346-351.

Patients who sustain gunshot injuries to the head and neck face heavy tissue damage and eventually life-threatening conditions. A very significant factor that determines the degree of injury is the course and extent of the missile track. The missile track is well correlated with bullet structure, size, and velocity, which have distinct features in civilian and military firearm injuries. The missile entrance or exist wound may be out of sight in some injuries, and often it is difficult to predict the severity of the injury in the chaotic circumstances of the battlefield. We studied the wound ballistics in five soldiers who suffered penetrating cranial and cervical firearm injuries.

5945. Yevich, S., et al. (2011). "Endovascular management of acute arterial injuries associated with penetrating trauma in the head and neck." Interventional Neuroradiology **17**: 165.

Purpose: The purpose of this study is to report the use of endovascular management of acute arterial injuries associated with penetrating trauma in the head and neck. Material and Methods: Between January 2009 and March 2011, 46 patients, with penetrating head and neck trauma were referred for diagnostic angiograms. Angiographic evaluation was performed either based on the clinical conditions or on computed tomographic findings to confirm and/or treat potential arterial injuries. Results: In 13/46 patients, major vessel injuries, requiring immediate surgical or endovascular intervention were documented. One patient with a carotid artery dissection by stent placement. 2 patients presenting with ruptured vertebral arteries were treated by coil occlusions (1) and a combination of coils and NBCA (1). In 6 patients with life-threatening blood loss, active extravasations from the maxillary (4), occipital (1) or superficial temporal (1) arteries were found and managed using NBCA (5) or Onyx (1) injections with immediate occlusion. In 2 patients, arteriovenous fistulas of the common carotid and the subclavian arteries were surgically corrected. All but two patients recovered partially or completely from their injuries. Conclusions: Penetrating trauma to the arteries in the head and neck are rare in civilian patients, but frequently seen in large trauma centers. Minor vessel injuries are often manageable with conservative management and low dose anticoagulation or antiplatelet therapy. Major vessel injuries may require stent placement or complete endovascular vessel blockage. In cases with critical blood loss, immediate transarterial embolization becomes life saving measure.

5946. Yildirim, A. E., et al. (2014). "Endoscopic endonasal removal of a sphenoidal sinus foreign body extending into the intracranial space." Ulusal travma ve acil cerrahi dergisi = Turkish journal of trauma & emergency surgery : TJTES **20**(2): 139-142.

Sphenoidal sinus foreign bodies are very rare entities that are often associated with a cranial and/or orbital trauma. In this paper, a case of a metallic foreign body that pierced the sphenoid sinus and penetrated into the intracranial space due to a work accident is presented. A 29-year-old male was referred to our clinic due to a right orbital penetrating trauma. Skull X-ray and computed tomography (CT) scans demonstrated a foreign body inside the sphenoidal sinus, extending to the left temporal fossa. The foreign body was removed using an endoscopic endonasal technique, and the skull base was reconstructed with a multilayer closure technique. There were no complications during or after the operation. Postoperative result was perfect after three months of follow up.

5947. Yildirim, A. E., et al. (2014). "Unusual posttraumatic delayed cerebrospinal fluid rhinorrhea due to gunshot wound." Turkish neurosurgery **24**(2): 276-280.

Delayed posttraumatic cerebrospinal fluid rhinorrhea (CSFr) without meningitis is considered to be relatively rare. However, even years after trauma, recurrence or delayed onset of CSFr and meningitis due to CSFr are possible. In this article, a case of delayed CSFr from the sphenoid sinus without meningitis three years after the transfacial gunshot wound is reported. Plain high-resolution computed tomography sections through the sphenoid sinus showed a bone defect at the roof with CSF-density fluid extending into the sphenoid sinus. Arachnoid membrane herniation into the sphenoid sinus was found and site of CSF fistula confirmed during the surgery. Skull base defect was reconstructed through an endoscopic approach without any complications and the patient was followed up for 12 months without recurrence. The cause, timing, clinical course and location of CSFr make this an apparently unique case. Patients with a skull base defect without CSFr should be closely followed up and may need further evaluation or management due to the possibility of CSFr development. The positive diagnosis of a CSFr raises the matter of choosing the adequate surgical approach for its repair. Endoscopic closure of CSFr is both safe and effective.

5948. Yilmaz, H., et al. (2020). "Guillain-Barre Syndrome After Craniocerebral Gunshot Injury: First Report." World neurosurgery **143**: 23-25.

BACKGROUND: Guillain-Barre syndrome (GBS) is a rare but serious disorder involving peripheral nerve inflammatory demyelination characterized by acute onset tetraparesis and areflexia. Generally, GBS is preceded by a bacterial or viral infection, and post-traumatic or postsurgical GBS is rarely seen., CASE DESCRIPTION: A 41-year-old man with severe craniocerebral gunshot injury and open depressed occipital bone fracture was operated urgently. Two weeks postoperatively, he suffered from sudden quadriparesis. He had flaccid paralysis of his bilateral muscle lower extremities (0/5), along with bilateral upper extremity weakness (2/5)., CONCLUSIONS: We report the first case, to our knowledge, with post-traumatic GBS after craniocerebral gunshot injury. We want to indicate the possibility of post-traumatic GBS in cases of unexplained quadriparesis or quadriplegia after trauma or surgery.

5949. Yilmaz, T., et al. (2006). "Delayed trigeminocardiac reflex induced by an intraorbital foreign body. Case report." Ophthalmologica. Journal international d'ophtalmologie. International journal of ophthalmology. Zeitschrift fur Augenheilkunde **220**(1): 65-68.

OBJECTIVE: To emphasize the importance of the mechanism and surgical approach to trigeminocardiac reflex (TCR) developing 48 h after orbital trauma due to a foreign body., CASE REPORT: After gunshot injury of a 17-year-old male patient, computerized tomography evaluation revealed a right globe perforation and an intraorbital metallic foreign body in the right orbita adjacent to the lateral wall. The ocular perforation was repaired, but the foreign body was not removed. Constant bradycardia (45/min) developed 48 h after the operation. Since there were no cardiological findings, a temporary cardiac pacemaker was inserted and on the 6th postoperative day, the foreign body was removed through orbitolateral approach. After the removal of the foreign body, bradycardia completely recovered., CONCLUSION: In the presence of an intraorbital foreign body accompanied by globe perforation, TCR may develop 48 h after the trauma and insertion of a temporary pacemaker may be required to control the cardiac rhythm. In this paper, the delayed TCR complication presented an indication for the removal of the intraorbital foreign body.

5950. Yip, C. C., et al. (1998). "High-pressure paint gun injury to the orbit and ocular adnexa." International ophthalmology **22**(6): 335-339.

High-pressure injection injury to the orbit and adnexa is a rare but potentially blinding type of trauma. Few cases of such injury have been reported in the literature. A 27-year-old Indian man accidentally injected paint material from a high-pressure nozzle gun into his left eye. Radiological investigation revealed the presence of paint material in the orbital tissues and the ethmoidal sinuses. The patient underwent two orbital surgeries to remove the paint material. He later developed signs suggestive of limbal stem cell failure and was treated with limbal stem cell autografting. He also has ophthalmoplegia with a compensatory anomalous head posture that was managed conservatively. We report the clinical course and outcome of this unfortunate patient to highlight the complexity of such an injury and the need for a multidisciplinary approach in its management.

5951. Ylioja, S., et al. (2010). "Are cognitive outcome and recovery different in civilian penetrating versus non-penetrating brain injuries?" The Clinical neuropsychologist **24**(7): 1097-1112.

The present study sought to determine whether cognitive outcome and course of recovery in civilian penetrating brain injury due to gunshot can be distinguished from that of non-penetrating brain injury due to motor vehicle accident. Matched survivors of penetrating and non-penetrating brain injury were assessed with a brief neuropsychological test battery at inpatient rehabilitation, 1 year post-injury, and 2 years post-injury. The traumatic brain injury groups were found to have patterns of performance marked by reliably distinct differences in isolated areas, with different cognitive predictors of brain injury type present in early versus later recovery. The degree of recovery over the first 2 years appeared to be quite similar for penetrating and non-penetrating injuries.

5952. Yoganathan, P., et al. (2008). "The use of intraoperative fluoroscopy as an aid for removal of radiopaque intraorbital foreign bodies." Ophthalmic surgery, lasers & imaging : the official journal of the International Society for Imaging in the Eye **39**(5): 436-437.

Two patients with orbital trauma and intraorbital foreign bodies, as seen on a computed tomography scan, were taken to the operating room to rule out occult ruptured globe with possible foreign body removal. The C-arm fluoroscopic unit was employed to obtain real-time images of the foreign body's location in relation to the surgeon's dissection tools and the foreign body was extracted with minimal dissection and operating time. When removal of a foreign body is warranted, intraoperative fluoroscopy can help reduce surgical time and orbital manipulation.

5953. Yokobori, S., et al. (2013). "Different blood coagulation profiles in different tbi rat models: An experimental study with thromboelastography (TEG)." Journal of neurotrauma **30**(15): A43-A44.

Introduction Recent prospective clinical trials (CRASH-2, 2012 and Narayan et al., 2008) failed to show efficacy of recombinant factor (rFVIIa) and tranexamic acid with the reduction of mortality in TBI patients. These failures in clinical trials may be caused by the pathophysiological diversity of TBI. Moreover, there is still little information on the different coagulopathic mechanisms (enzymatic coagulopathy, platelet dysfunction, and hyperfibrinolysis) underlying different type of TBI. The aim of this study is thus to clarify the coagulopathic mechanisms in different ''pure'' TBI rat models with thromboelastography (TEG), which can provide quick, simultaneous estimation of multiple coagulopathic mechanisms. Methods Sprague Dawley rats (300-350g) were subjected to one of three different injuries: penetrating ballistic brain injury (PBBI), lateral fluid percussion injury (FPI), and acute subdural hematoma (ASDH). In each TBI model, non-heparinized blood samples were collected from a tail artery catheter at different time points (PreTBI, 2.5h, 24h 7days after TBI). TEG parameters (R/K/a/MA/G/CI) were compared among the three TBI models, and at different time points. Results In the early phase (2.5h) after injury, K-value, which indicates impairment of fibrinogenesis, was significantly higher in ASDH than in FPI. (Median[IQR]: ASDH 1.7[1.4-9.5] vs. FPI 0.8[0.8± 1.0] min, $P < 0.05$ with Kruskal-Wallis test). Moreover, MA and G value, which indicate the strength of platelet-fibrin interaction, were significantly lower in ASDH than FPI. (MA: ASDH 50.5 [42.0-58.5] vs. FPI 64.6 [58.0-66.9]mm, G: ASDH 5099 [3694± 7085] vs. FPI 8640[6449-10062] dyn/cm2 $P < 0.05$, respectively). Moreover, the Coagulation Index (CI), which indicates overall status of coagulation was the lowest in ASDH. Blood coagulation profiles of PBBI were similar to ASDH, although less severe. On the other hand, the peak of coagulopathy in FPI existed on later phase (24h) after injury, and continued by the 7th day. In FPI, the coagulation status was switched to a hypercoagulation on the 7th day after injury. Conclusions Our study clarified 1) The presence of acute-severe coagulopathy in ASDH, 2) gradually worsening coagulopathy and late-onset hypercoagulation in FPI, 3) acute-mild coagulopathy in PBBI. The pathophysiology and severity of coagulopathy was specific to the type of injury and the duration after injury. These results warrant a future clinical study to profile the coagulation disorders after TBI, and possibly of ''TEG derived'' treatment for coagulation disorder in TBI.

5954. Yokoo, S., et al. (2003). "Replantation of an avulsed zygomatic bone as a freeze-preserved autologous graft: a case report." Journal of cranio-maxillo-facial surgery : official publication of the European Association for Cranio-Maxillo-Facial Surgery **31**(2): 115-119.

We describe a very rare case of midface fracture where the zygomatic bone had been completely avulsed. The fragment was preserved in a frozen state for 40 days, then replanted and the graft was taken. The conditions favourable for the taking of the freeze-preserved zygomatic graft were: (1) an appropriate preservation method, (2) conservation of

the periosteum on the zygomatic bone, (3) diversity of the haemodynamics of the zygomatic membranous bone, (4) immobilization of the zygoma by rigid fixation, and (5) a rich blood supply at the recipient site.

5955. Yolas, C., et al. (2007). "Intracerebral sewing needle." Pediatric neurosurgery **43**(5): 421-423.

A 9-year-old male patient complaining of seizure attack was admitted to the neurosurgery department. Radiologic investigations revealed a 5-cm-long metallic sewing needle extending from the right frontal cortex to the right lateral ventricle. Burr hole surgery was performed and the needle was grasped with biopsy forceps and removed with endoscopic guidance. The patient recovered without any complications. Copyright (c) 2007 S. Karger AG, Basel.

5956. Yoneoka, Y., et al. (2020). "Traumatic Nonmissile Penetrating Transnasal Anterior Skull Base Fracture and Brain Injury with Cerebrospinal Fluid Leak: Intraoperative Leak Detection and an Effective Reconstruction Procedure for a Localized Skull Base Defect Especially After Coronavirus Disease 2019 Outbreak." World neurosurgery **140**: 166-172.

BACKGROUND: Cerebrospinal fluid (CSF) leakage after penetrating skull base injury is relatively rare compared with close head injuries involving skull base fractures., CASE DESCRIPTION: We report the case of a 65-year-old man who had presented with epistaxis and serous rhinorrhea. When he had fallen to the ground near his bee boxes, a garden pole had poked into his right nostril. He had instantly removed the pole from his nostril himself. However, immediately after removal of the pole, he had developed nasal bleeding and serous rhinorrhea. He then drove to our emergency room. Computed tomography showed pneumocephalus with a minor cerebral contusion in the left frontal lobe and a penetrating injury in the left anterior skull base. His CSF leakage had not resolve spontaneously within 1 week after the injury with strict bed rest. We repaired the CSF leakage using a fat (adipose tissue)-on-fascia autograft plug and caulked the defect in the anterior skull base with the fat-on-fascia graft (FFG) plug through the left nostril with endoscopic guidance. The CSF rhinorrhea was successfully controlled. Intranasal local application of fluorescein aided in the detection of the direction of flow of the CSF leakage., CONCLUSIONS: Endonasal endoscopic caulking of a skull base defect using an FFG plug can be useful to treat CSF leakage due to the localized skull base defect, especially in the coronavirus disease 2019 pandemic. It is simple, inexpensive, and timesaving. It requires no special skills nor sophisticated instruments that can cause aerosolization, reducing the risk of infection during the surgery.

5957. Yoneoka, Y., et al. (2020). "Glass Fragment Injury to the Craniocervical Junction with Interatlantooccipital Penetration to the Subarachnoid Space: Not-To-Be-Missed Important Aspects of Craniocervical Trauma Even in the Middle of the COVID-19 Pandemic: Case Report and Review of Literature." World neurosurgery **141**: 402-405.

BACKGROUND: Nonmissile penetrating injuries to the craniocervical junction caused by a glass fragment are rare, and a standard management strategy has not been established., CASE DESCRIPTION: A 75-year-old Japanese man was brought into our emergency department after receiving a left retroauricular stab wound by broken glass fragments. After spinal immobilization, a computed tomography (CT) scan revealed glass fragments penetrating at the right craniocervical junction to the interatlantooccipital subarachnoid space. CT angiography showed that both vertebral arteries were not injured. Magnetic resonance imaging demonstrated that the glass fragments did not penetrate the cervical cord or medulla oblongata. These glass fragments were removed via a midline incision from the external occipital protuberance to the C7 and with laminectomy without suboccipital craniectomy. Five of the glass fragments were found and removed in total. The dural defect was patched with a free fascia autograft. His postoperative course was uneventful. Postoperative CT angiography showed that both vertebral arteries were intact and the glass fragments had been removed completely., CONCLUSIONS: CT graphical diagnosis is useful for the management of penetrating craniocervical junction trauma, and it should be considered in the evaluation of patients who have suffered craniocervical penetrating injury even in the absence of major wounds or bleeding. Spinal immobilization of patients with craniocervical penetrating injuries is crucial to avoid not only secondary neurologic damage but also secondary critical vascular damage. Incomplete or inadequate assessment of craniocervical stab wounds results in unexpected hazards that are preventable.

5958. Yoon, J., et al. (2022). "Blunt Cerebrovascular Injury-Like Injury Observed in Patients With Craniofacial Self-Inflicted Gunshot Wounds." The Journal of craniofacial surgery **33**(4): 1046-1050.

BACKGROUND: Although blunt cerebrovascular injury (BCVI) is recognized as a risk factor for trauma morbidity and mortality, little is described regarding similar cerebrovascular injury (CVI) in patients with penetrating wounds. The authors aim to characterize these injuries in the craniofacial self-inflicted gunshot wound (SIGSW) population., METHODS: An institutional review board (IRB)-approved retrospective nstudy was conducted on patients presenting to the R Adams Cowley Shock Trauma Center with SIGSWs between 2007 and 2016. All CVIs were categorized by location, type, and associated neurologic deficits. Demographic data, patient characteristics, additional studies, and long-term outcomes were collected. A multivariate analysis determining independent predictors of CVI in the SIGSW population was performed., RESULTS: Of the 73 patients with SIGSWs, 5 (6.8%) had CVIs separate from the bullet/cavitation tract (distant CVIs) and 9 had CVIs along the bullet/cavitation tract (in-tract CVIs). A total of 55.6% of in-tract and 40% of distant injuries were missed on initial radiology read. One distant CVI patient suffered a stroke during admission. The anterior to posterior gunshot wound trajectory was positively associated with distant CVIs when compared with no CVIs (P = 0.01). Vessel dissection was more prevalent in patients with distant CVIs, when compared against patients with in-tract CVIs (P = 0.02)., CONCLUSIONS: Nearly 20% of craniofacial SIGSW patients have CVIs and 6.8% have BCVI-like injuries, which is 2-to-6-fold times higher than traditional BCVIs. Craniofacial SIGSWs serve as an independent screening criterion with comparable screening yields; the authors recommend radiographic screening for these patients with particular scrutiny for CVIs as they are frequently missed on initial radiographic interpretations.

5960. Yorks, M. L. (2005). "More on Phineas Gage." The New England journal of medicine **352**(9): 944-944.

5961. Yoshida, K., et al. (1992). "Myocardial lesions induced after trauma and treatment." Forensic science international **54**(2): 181-189.

In order to clarify the effect of trauma and treatment as stresses on myocardia, we examined histological changes of myocardia in victims who received various kinds of traumata and treatments. We also undertook a histochemical study for calmodulin, which we found useful in the diagnosis of early ischemia. Those who died shortly after stab wounds, traffic accident or head injuries, showed mild cardiac lesions such as contraction bands or fragmentation and mild diffusion of calmodulin, a marker for necrosis. A case with hemorrhagic shock after a traffic accident, involving intense resuscitation for 2 h, showed severe cardiac lesions such as contraction bands, hydropic change and subendocardial hemorrhage along with severe diffusion of calmodulin. In most of the instant death cases after falls, severe contraction band necrosis and severe calmodulin diffusion were observed. Myocardia of victims, who died several days after head injuries or traffic accidents, generally demonstrated distinct diffusion of calmodulin as compared to the mild and non-specific lesions detected by hematoxylin-eosin (H&E) staining. In cases of long-term survival in a state of brain death, calmodulin staining was very low, which was not always associated with the severity of the lesions on H&E staining. In cases with intensive or extended treatment, it appeared to be difficult to determine the cause-effect relationship between trauma and cardiac lesions or to distinguish the lesions due to extrinsic factors from those of disease. In some cases, calmodulin intensely stained the areas with hydropic appearance or hypereosinophilia, which may be related to calcium overload.

5962. Yoshida, M. and H. Kamiishi (2003). "Traumatic aneurysm of the maxillary artery with mandibular bone fracture; case report." Japanese Journal of Plastic and Reconstructive Surgery **46**(2): 207-213.

Traumatic aneurysms of the internal maxillary artery are rare events, usually mentioned in the literature as possible complications of penetrating trauma or occurring as a result of maxillomandibular osteotomy or arthroscopy of the temporomandibular joint. More rarely, traumatic aneurysm results from blunt trauma and fracture of the mandibular condyle. A case of a traumatic aneurysm of the maxillary artery is reported. The aneurysm appeared nine days after facial injuries that included mandibular fractures. The lesion was successfully treated by ligation of the external carotid artery.

5963. Yoshigoe, A., et al. (2013). "A case of orbital-sinus wooden foreign body extracted using endoscopic sinus surgery." Oto-Rhino-Laryngology Tokyo **56**(3): 34-38.

An 81-year-old male sustained a penetrating injury at the left medial angle of the eye caused by a wooden foreign body. Computed tomography showed that the foreign body had penetrated the orbit, ethmoidal sinus, nasal septum, and finally reached just in front of the atlas. We tried to extract the foreign body as soon as possible for preventing infection using endoscopic sinus surgery, and could do so succeeded without complication. Endoscopic sinus surgery is an effective approach to extract orbital-sinus foreign body.

5964. Yoshihara, S., et al. (2019). "Craniofacial penetration by a wooden stick." European annals of otorhinolaryngology, head and neck diseases **136**(5): 393-395.

INTRODUCTION: Penetrating craniofacial injuries caused by stick-like foreign bodies occur as a result of accidents particularly in children, and often lead to significant morbidity., CASE SUMMARY: We describe a 5-year-old boy who sustained facial trauma after falling on a wooden stick which penetrated his left cheek. At the initial visit, his vital and neurological signs were normal. However, the stick had penetrated the frontal lobe to a depth of 3cm via the orbital cavity and the anterior skull base. The stick was successfully removed while visualizing the anterior skull base in an endoscopic transethmoidal approach. A follow-up examination one year after the accident demonstrated normal visual acuity and ocular motility, with no diplopia, tearing or pain., DISCUSSION: Penetrating facial injuries caused by stick-like objects carry a significantly higher risk of serious neurological involvement. Even if penetrating facial injuries sometimes appear trivial, the external injury site is often insufficient to determine the position of the object within the head. Although the cheek is a rare entry site for intracranial injuries, the extent of damage should be assessed fully before attempting removal.

5966. Yoshijima, S., et al. (1979). "[A case of successful removal of a deep-seated bullet in the brain by stereotaxic approach (author's transl)]." No shinkei geka. Neurological surgery **7**(10): 989-994.

5967. Yoshimoto, T. and B. K. Siesjo (1999). "Posttreatment with the immunosuppressant cyclosporin A in transient focal ischemia." Brain research **839**(2): 283-291.

Cyclosporin A (CsA) reduces ischemic brain damage when administered in such a way that its penetration across the blood-brain barrier is enhanced. Since only pretreatment has previously been used in focal ischemia, the objective of the present study was to establish whether posttreatment is efficacious and to assess the window of therapeutic opportunity for CsA. To that end, CsA was given 5 min to 6 h after the start of reperfusion following 2 h transient ischemia, and infarct volume was assessed after 48 h by triphenyltetrazolium chloride staining. Attempts were made to circumvent the BBB to CsA by an intracerebral needle lesion, by an increase in the intravenous CsA dose, or by osmotic opening with intracarotid mannitol. The results were compared to those obtained with FK506. Intravenous CsA in a dose of 10 mg/kg failed to reduce infarct volume, unless preceded by a needle lesion. That procedure, and an increase in CsA dose to 50 mg/kg, reduced infarct volume to about 50% of control, but the higher dose had toxic side effects. The coupled intracarotid infusion of mannitol and CsA (10 mg/kg) was more efficacious, without overt side effects. However, mannitol proved dispensable since CsA alone reduced infarct volume to 30% of control, with a therapeutic window of 3-6 h. When given after 5 min of reflow, CsA reduced infarct volume to 10% of control and was clearly more neuroprotective than FK506. Possibly, this is because CsA blocks the mitochondrial permeability transition pore which is opened under adverse conditions.

5968. Yoshioka, T., et al. (1986). "Prolonged hemodynamic maintenance by the combined administration of vasopressin and epinephrine in brain death: a clinical study." Neurosurgery **18**(5): 565-567.

The present study attempted long term hemodynamic maintenance in 16 adult brain-dead patients, 14 with head injury and 2 with cerebrovascular accidents. In addition to respiratory and fluid management, 10 were treated with continuous infusion of epinephrine to maintain systolic blood pressure above 90 mm Hg. The remaining 6 patients each

received a continuous infusion of synthetic arginine vasopressin (ADH) at a rate of 1 or 2 units/hour (285 +/- 45 microunits/kg/minute) simultaneously with epinephrine. The 10 patients treated with epinephrine alone all succumbed to cardiac arrest within 48 hours of brain death, with a mean survival time of 24.1 +/- 17.2 hours. In the patients who received simultaneous ADH infusion, a minimal dose of epinephrine of no more than 0.5 mg/hr in most instances sufficed to maintain blood pressure. Their mean survival time after brain death was remarkably prolonged to 23.1 +/- 19.1 days. In brain death, ADH plays a critical role in hemodynamic maintenance, and ADH administration permits long term hemodynamic stabilization of brain-death patients, offering increasing opportunities for organ transplantation.

5969. Youmans, Q. R., et al. (2019). "The Association of Donor Cause of Death with Outcomes Post-Heart Transplant." Journal of Cardiac Failure **25**(8): S169.

Objective: Approximately 3000 orthotopic heart transplants (OHT) occur annually in the United States. Donor selection is a key decision point for patients undergoing transplantation. Donor factors such as age, BMI, left ventricular function, chest trauma, history of hemodynamic compromise, donor-recipient compatibility, and ischemic time have all been associated with post-transplant survival. Few studies have examined donor cause of death (DCOD) and its association with post-transplant outcomes. In this study we examine the association of DCOD with post-transplant primary graft dysfunction (PGD), rejection and survival. Methods: This study was a retrospective analysis of 40,485 patients captured in the United Network for Organ Sharing (UNOS) registry. Included in this analysis were adult OHT recipients older than 18 years of age from 1989 to 2017. DCOD was categorized into blunt trauma (BT), cerebral vascular accidents (CVAs), and penetrating trauma (gunshot and stab wounds). Chi square analysis was used to compare baseline characteristics among the three groups. The Cox proportional hazard model was used to estimate the association of DCOD with PGD and acute rejection. The cumulative incidence competing risk method was used for survival analysis. Results: Donors had a median age of 31 (interquartile range 22, 43), were predominately Caucasian (69%), and were predominately male 78%. 992 episodes of PGD were observed and occurred more frequently in the CVA group (41% vs BT 38% and penetrating trauma 19%, p 0.03). Univariate analysis showed a higher risk of acute graft failure (HR 1.24, CI 1.19-1.29, P <0.001) in the CVA group. Conclusions: DCOD by CVA is associated with an in increased risk of PGD and acute graft failure. Further multivariate analysis is needed.

5970. Young, A. (1974). "Gunshot injury to the mandible. A case report." British dental journal **137**(4): 136-138.

5971. Young, B., et al. (1981). "Early prediction of outcome in head-injured patients." Journal of neurosurgery **54**(3): 300-303.

The relationship between Glasgow Coma Scale (GSC) scores obtained during the 1st week after head injury and outcome at 1 year was analyzed in 170 patients. Seventy-two of 76 patients with initial GCS scores of 3 or 4 lived, and only one had a favorable outcome. Favorable and unfavorable outcomes were almost equally divided when the initial GCS scores were in the intermediate range of 5, 6, or 7. No patients with an initial GCS score in this intermediate range that subsequently worsened had a favorable outcome, while over 80% of those improving to a score higher than 7 had a favorable outcome. Only 12% of those persisting with a score of 5, 6, or 7 for 1 week had favorable outcome. Outcome predictions using the multiple logistic model were made for this intermediate group of patients based on GCS scores and data on midline shift derived from computerized tomography (CT). The patients with initial scores of 5, 6, or 7 with midline shifts of less than 4.1 mm on initial CT scanning had a significantly higher favorable outcome rate compared with patients with a larger shift. However, outcome prediction made by combining shift data and initial GCS scores are not significantly more accurate than predictions based solely on initial GCS scores. Combining 48-hour GCS scores and shift data significantly improves predictive accuracy based only on coma scores. The data obtained by combining GCS scores at 72 hours and 1 week and shift data is marginally significant for improving accuracy of outcome predictions. It is concluded that GCS scores and shift data are highly accurate indicators of outcome in head-injured patients.

5972. Young, P. A. and D. H. Rice (2007). "Management of a type II nasoethmoid orbital fracture and near-penetration of the intracranial cavity with transnasal canthopexy." Ear, nose, & throat journal **86**(6): 344-360.

Nasoethmoid orbital fractures are perhaps the most complicated aspect of craniomaxillofacial trauma. Involvement of the medial canthal tendon markedly increases the complexity of the repair. We report a case of type II

nasoethmoid orbital fracture in a 32-year-old man that was managed without formal medial canthal tendon repair; instead, we used open reduction and internal fixation of the central fragment and the nasoethmoid complex. However, during the immediate postoperative period, we noted anterior and inferior displacement of the medial canthus. We took the patient back to the operating room to address the detachment. Revision surgery was successful, and at the 6-month follow-up, his medial canthi were completely symmetrical in all dimensions. We describe our intraoperative technique and measures to prevent complications that can help the surgeon intraoperatively. We also discuss an important point that has not been adequately addressed in the literature to date--that is, the fact that the use of the frontoethmoid suture line and the anterior ethmoid artery as a guide to the skull base can be inaccurate. Problems associated with this inaccuracy can be avoided by carefully reviewing preoperative computed tomography, which can help keep the surgeon from entering the intracranial cavity while fixing the medial canthal tendon during transnasal canthal repair.

5973. Young, W. F., Jr., et al. (1993). "Spontaneous migration of an intracranial bullet into the cervical canal." Southern medical journal **86**(5): 557-559.

We have reported a case of intracranial to intraspinal migration of a retained bullet fragment over a course of approximately 4 years. The patient remained asymptomatic. The bullet was removed via a posterior cervical laminectomy. Migration of bullet fragments, though rare, should be included as one of the delayed complications of gunshot wound to the head.

5974. Young, W. F., et al. (1994). "Diagnosis and management of occipital condyle fractures." Neurosurgery **34**(2): 257-251.

The authors recently treated three cases involving fractures of the occipital condyle. First described by Bell in 1817, this lesion has proven to be very rare, with only 32 cases previously reported in the literature. Plain films often do not reveal any abnormality, making diagnosis difficult. High-resolution computed tomography has been demonstrated to be very sensitive in diagnosing this lesion. This fact was borne out in the authors' series. All of the authors' patients were managed either with a Philadelphia collar or with halo fixation, with excellent outcomes.

5975. Youssef, A. S., et al. (2008). "Penetrating craniofacial injury inflicted by a knife." The Journal of trauma **64**(6): 1622-1624.

5976. Yu, A.-Y., et al. (2014). "Characteristics of a rat model of an open craniocerebral injury at simulated high altitude." Neuroreport **25**(16): 1272-1280.

To establish a rat model of an open craniocerebral injury at simulated high altitude and to examine the characteristics of this model. Rats were divided randomly into a normobaric group and a high-altitude group and their corresponding control groups. A rat model of an open craniocerebral injury was established with a nail gun shot. Simulated high-altitude conditions were established with a hypobaric chamber at 0.6 ATA to mimic pressure at an altitude of 4000 m. Mortality, brain water content (BWC), Evans blue content, pathology, regional cerebral blood flow (rCBF), partial pressure of brain tissue oxygen (PbtO2), and brainstem auditory-evoked potential were observed after injury. The mortality of the high-altitude group was significantly greater than that of the normobaric group within 72 h after injury ($P<0.05$). BWC and Evans blue content increased by 48 h after injury ($P<0.05$); pathological changes in damaged brains were more serious. In contrast, rCBF and PbtO2 had decreased markedly by 72 h ($P<0.01$); brainstem auditory-evoked potential values were significantly prolonged ($P<0.05$). Moreover, an inverse correlation between rCBF and BWC and a positive correlation between rCBF and PbtO2 were found. The rat model of an open craniocerebral injury at simulated high altitude can be established successfully using a nail gun shot and a hypobaric chamber. The injury characteristics at high altitude were more serious, rapid, and prolonged than those in the normobaric group.

5977. Yu, C., et al. (2015). "A systems biology strategy to identify molecular mechanisms of action and protein indicators of traumatic brain injury." Journal of neuroscience research **93**(2): 199-214.

The multifactorial nature of traumatic brain injury (TBI), especially the complex secondary tissue injury involving intertwined networks of molecular pathways that mediate cellular behavior, has confounded attempts to elucidate the pathology underlying the progression of TBI. Here, systems biology strategies are exploited to identify novel molecular mechanisms and protein indicators of brain injury. To this end, we performed a meta-analysis of four distinct high-throughput gene expression studies involving different animal models of TBI. By using canonical pathways and a large human protein-interaction network as a scaffold, we separately overlaid the gene expression data from each study to identify molecular signatures that were conserved across the different studies. At 24 hr after injury, the significantly activated molecular signatures were nonspecific to TBI, whereas the significantly suppressed molecular signatures were specific to the nervous system. In particular, we identified a suppressed subnetwork consisting of 58 highly interacting, coregulated proteins associated with synaptic function. We selected three proteins from this subnetwork, postsynaptic density protein 95, nitric oxide synthase 1, and disrupted in schizophrenia 1, and hypothesized that their abundance would be significantly reduced after TBI. In a penetrating ballistic-like brain injury rat model of severe TBI, Western blot analysis confirmed our hypothesis. In addition, our analysis recovered 12 previously identified protein biomarkers of TBI. The results suggest that systems biology may provide an efficient, high-yield approach to generate testable hypotheses that can be experimentally validated to identify novel mechanisms of action and molecular indicators of TBI.

5978. Yu, D.-z., et al. (2012). "[Successful treatment of a patient with craniocervical penetrating injury by a steel bar]." Zhonghua er bi yan hou tou jing wai ke za zhi = Chinese journal of otorhinolaryngology head and neck surgery **47**(5): 424.

5979. Yu, H., et al. (2021). "Anterograde venous bullet embolism from the left facial vein to the right ventricle." Trauma case reports **36**.

A young man presented to the emergency department reporting he had been recently shot in the face and chest with an unknown weapon. Initial physical examination only found bruising by the left hemimandible, but CT angiography of the thorax revealed a BB in the right ventricle. A subsequent CT angiography of the head and neck showed no major arterial injury but noted stranding and irregularity of the left facial vein directly deep to the injury site. The findings favoured anterograde venous bullet embolism from the left facial vein to the right ventricle. To our knowledge, this is the first report of a relatively small diameter and superficial vein of the face resulting in this phenomenon.

5980. Yu, J. L., et al. (2014). "Frontal sinus volume predicts incidence of brain contusion in patients with head trauma." The journal of trauma and acute care surgery **76**(2): 488-492.

BACKGROUND: The function of the paranasal sinuses is a topic of debate. One hypothesis suggested has been that sinuses act as a "crumple zone," serving to protect the contents of the head from impact. In this study, we examine the interactions of the frontal sinus and the brain in the setting of head trauma. Our formal hypothesis is that frontal sinus volume is less in head trauma patients with contusion than in head trauma patients without contusion., METHODS: Computed tomographic (CT) scans of patients who sustained blunt head trauma performed at the University of Pittsburgh Medical Center from 2007 to 2012 were reviewed retrospectively. Inclusion criteria were presence of blunt trauma and complete brain and maxillofacial CT scan. Exclusion criteria included patients with incomplete imaging, imaging unrelated to trauma, previous cranial injury, and penetrating trauma.With the use of maxillofacial CT scans, height, depth, and width were measured, and a cubical approximation of volume was determined for each frontal sinus. Presence of frontal sinus fracture was considered an indicator of high-impact trauma. Grading of brain contusion severity was performed using head CT scans. A scale of 0 to 5 was used based on the Marshall Criteria.Categorical data were analyzed using the chi(2) or Fisher's exact test. Continuous data were analyzed using Student's t test or analysis of variance. $p < 0.05$ was considered statistically significant., RESULTS: Among patients with frontal sinus fracture, the average sinus volume of those without contusion was 32.72 mL, while the average sinus volume of those with brain contusion was 21.85 mL ($p = 0.023$). Thus, the volume of the frontal sinuses was 33% less in patients with contusion than in patients without contusion., CONCLUSION: Our study supports the theory that the frontal sinuses impart a protective advantage against frontal brain contusion. The dynamics of head injury and force distribution during trauma may be the basis for more advanced protective devices., LEVEL OF EVIDENCE: Prognostic study, level III.

5981. Yu, M., et al. (2012). "The treatment strategies of penetrating orbito-cranial injuries: Two cases reports and literature review." Brain injury **26**(4-5): 466-467.

Objective: To report two cases with penetrating orbito-cranial injuries. One case was operated by early surgical debridement. Another patient experienced the third operation for cellulitis in the orbit, brain abcess and subperiosteal abscess after two operations. We discuss treatment keypoints of penetrating orbito-cranial injuries and infectious complications. Methods: The relationship of preoperative evaluation and treatment strategies with curative effect is analyzed in a case for early debridemen. At the same time, the treatment process and operation strategy of another patient with cellulitis in the orbit, brain abcess and subperiosteal abscess are introduced. The second patient experienced a debridement for orbito-cranial penetrating wounds first and the resection of right frontal brain abscess afterwards, then transferred to our hospital for the third operation. Results: The first patient experienced a early complete debridement, foreign body excise, the optic canal and supraorbital split decompression, cranium reconstruction at the same time, and his wound was healed at phase 1. Follow-up has been done for 11 months postoperation. He got good recovery of eyesight, eye movement, satisfactory appearance and no postoperative complications. The second patient experienced one operation for puncture drainage of brain abscesses, surgical debridement and drainage of intraorbit and frontal subperiosteal abscess, who was cured and recovered better without relapse after follow-up of 10 months. Conclusion: The state of penetrating orbito-cranial wounds is complicated, which can cause brain injury, also accompanied by ocular trauma, cranial nerves and big vascular injury, and may lead to orbito-cranial deformity, nerve dysfunction or lifethreatening. So the treatment is very difficult. Once infectious complications occur, it will be difficult to handle and may directly endanger life. The ideal treatment of penetrating orbit-cranial wounds includes: early thorough debridement, exact hemostatic, regular strictly skull base reconstruction, recovering satisfactorily appearance, and preventing complications. The early complete debridement is the key, which often need multidisciplinary cooperation.

5982. Yu, M. K. (2014). "The surgical strategy of penetrating orbitocranial combined injuries from high temperature liquid plastic: Case report." Journal of neurotrauma **31**(12): A17.

The objective is to report the surgical experience for one case with penetrating orbito-cranial combined injuries from high temperature plastic, we discuss the surgical key points and some announcements. By imaging examination and physical examination, we found that the plastic foreign bodies were inserted into the patient's right eye socket, which passed across orbital medial penetrating orbital plate into the supraorbital fissure and anterior skull base. Using the right frontotemporal joint approach, the intracranial wound track was fully exposed in operation. Due to the larger volume tip of foreign bodies which were fixed in the orbit and could not be removed directly by cranial or orbital department, intracranial foreign body could be only disconnected from the orbital plate first, and then a thorough debridement was done. The tissue spaces around the orbital foreign bodies were then separated out, and the residual plastic foreign bodies incarcerated in upper eyelid, intraorbital and outside the orbit were taken out. Finally, the reconstruction of the skull base was implemented by neurosurgery. After joint surgery by neurosurgeon and ophthalmology, removal of orbital cranial foreign bodies, orbital-cranial wound debridement, and the reconstruction of the skull base were finished during the same period. The patient was cured through an operation with intact eye ball at the injury side. The state of these penetrating orbito-cranial wounds is complicated, which will be difficult to handle and may directly endanger life. Methods of dealing with orbital cranial penetrating injury have their particularity. Based on the application of effective broad spectrum antibiotics, the situation of foreign bodies and the wounded, and their correlation with orbital or cranial injury should be clearly detected as early as possible. According to the traumatic condition, it is the key to take the appropriate surgical strategy for cure of this combined injury. Because of complex structure and wide range around the injury, the operation often needs multidisciplinary collaboration.

5983. Yuan, Y.-K., et al. (2020). "Rational design of secondary operation for penetrating head injury: A case report." Chinese journal of traumatology = Zhonghua chuang shang za zhi **23**(2): 84-88.

Penetrating head injury is rare, and thus management of such injuries is non-standard. Early diagnosis and intraoperative comprehensive exploration are necessary considering the complexity and severity of the trauma. However, because of the lack of microsurgical techniques in local hospitals, the possible retained foreign bodies and other postoperative complications such as cerebrospinal fluid (CSF) leak usually require a rational design for a secondary operation to deal with. We present a case of a 15-year-old boy who was stabbed with a bamboo stick in his left eye. The chopsticks passed through the orbit roof and penetrated the skull base. In subsequent days, the patient sustained CSF

leak and intracranial infection after an unsatisfied primary treatment in the local hospital and had to request a secondary operation in our department. Computed tomography including plain scan, three dimension reconstruction and computed tomographic angiography are used to determine the course and extent of head injury. A frontal craniotomy was performed. Three pieces of stick were found residual and removed with the comminuted orbit bone fragments. A pedicled temporalis muscle fascia graft was applied to repair the frontier skull base and a free temporalis muscle flap to seal the frontal sinus defect. Aggressive broad-spectrum antibiotics of vancomycin and meropenem were administrated for persistent fever after operation. CSF external drainage system continued for 12 days, and was removed 10 days after temperature returned to normal. The Glasgow coma scale score was improved to 15 at postoperative day 7 and the patient was discharged at day 22 uneventfully. We believe that appropriate preoperative surgical plan and thorough surgical exploration by microsurgery is essential for attaining a favorable outcome, especially in secondary operation. Good postoperative recovery depends on successfully management before and after operation for possible complications as well.

5984. Yucel, A., et al. (2018). "Transnasal Endoscopic Removal of a Knife Causing Penetrating Brain Injury in a Child." The Journal of craniofacial surgery **29**(7): e694-e695.

Transnasal penetrating brain injuries are rare and a medical emergency, which needs to be treated promptly. A 4-year-old male patient was brought to our emergency room with a knife sticking out of his nose. The patient was immediately taken to the operating room and the knife was removed under general anesthesia. No cerebrospinal fluid leakage or any bleeding was seen and so the operation was terminated. The authors herein report a penetrating brain trauma through to the cella turcica with a knife that improved without any sequelae at a child.

5985. Yue, J., et al. (2017). "Adult firearm-related traumatic brain injury in United States trauma centers." Journal of neurotrauma **34**(13): A23.

Firearm injuries cause an estimated 33,000 deaths annually in the United States. Management algorithms following gunshot wounds to the head (GSWH) have been static for two decades and outcomes remain in need of systematic characterization. Adult GSWH patients in the National Sample Program (NSP) of the National Trauma Data Bank (NTDB), years 2003-2012, were extracted. Multivariable regression identified predictors for hospital length of stay (HLOS), intensive care unit length of stay (ICU LOS), medical complications, mortality, and discharge disposition. Odds ratios (OR) and 95% confidence intervals (CI) were reported. Statistical significance was assessed at $p < 0.001$. In total, 8,148 patients were included extrapolating to 32,439 national incidents. Age was 36.6 - 16.4 years. Mean HLOS was 13.9 - 17.9 days and ICU LOS was 8.6 - 17.4 days. The mortality was 54.6%. Age, injury intent, Glasgow Coma Scale (GCS) score, Injury Severity Score (ISS), and hypotension were significant predictors as previously reported ($p < 0.001$). Compared to privately insured patients, Medicare/Medicaid patients had longer HLOS (mean increase 4.4 days, 95% CI [2.6-6.3 days], $p < 0.001$). Compared to the Midwest, the South had longer HLOS (mean increase 3.7 days [2.0-5.4 days], $p < 0.001$) and more complications (OR 1.7 [1.4-2.0], $p < 0.001$); the West had less complications (OR 0.6 [0.5-0.7], $p < 0.001$). Compared to handgun, injury from shotgun and hunting rifle had lower odds of death (OR 0.3 [0.2-0.4], $p < 0.001$; OR 0.5 [0.4-0.8], $p < 0.001$). Suicide had lower odds of discharge to home compared to accident (OR 0.5 [0.3-0.7], $p < 0.001$). Relative to Level I trauma centers, Level II trauma centers had lower odds of discharge to home (OR 0.7 [0.5-0.8], $p < 0.001$). In conclusion, firearm type, injury intent, insurance type, and geographic region are important prognosticators for acute recovery and outcome following GSWH, in addition to older age, hypotension, and injury severity. Improved understanding of civilian GSWH is critical to increasing awareness and reducing injury burden from firearm injuries.

5986. Yue, J. K., et al. (2022). "Management of migrating intracranial bullet fragments in a 13-year-old female after firearm brain injury: technical and surgical nuances." Brain injury **36**(3): 432-439.

INTRODUCTION: We present the challenges and nuances of management in a rare case of multiple migrating intracranial fragments after pediatric gunshot wound to the head (GSWH)., CASE PRESENTATION: A 13-year-old girl suffered left parietal GSWH, with new neurologic decline 3 days after initial debridement. Serial imaging showed the largest intracranial fragments had migrated into the left trigone, and descended further with head of bed (HOB) elevation. HOB was iteratively decreased, with concurrent intracranial pressure monitoring. After extubation, with an alert and stable neurologic exam, HOB was decreased to -15 degrees, allowing gravity-assisted migration of the

fragments to an anatomically favorable position within the left occipital horn. The patient underwent occipital craniotomy for fragment retrieval on hospital day 27. Two large and >20 smaller fragments were retrieved using neuronavigation and intraoperative ultrasound. Forensics showed these to be .45 caliber handgun bullet fragments. The patient recovered well after 2-months of intensive inpatient rehabilitation., DISCUSSION: During new neurologic decline after GSWH, bullet migration must be considered and serial cranial imaging is requisite. Surgical retrieval of deep fragments requires judicious planning to minimize further injury. Tightly controlled HOB adjustments with gravity assistance for repositioning of fragments may have utility in optimizing anatomic favorability prior to surgery.

5987. Yuen, E. C. P. (2004). "The use of prophylactic antibiotics in trauma." Hong Kong Journal of Emergency Medicine **11**(3): 161-168.

Infection is an important cause of morbidity and mortality in trauma. In this literature review, the microbiological profiles and the use of prophylactic antibiotics in various traumatic situations are discussed. This review includes abdominal and chest trauma, craniocerebral trauma, long bone fractures, open globe injuries and animal bite injuries.

5988. Yuh, S.-J. and A. Alaqeel (2015). "Ten self-inflicted intracranial penetrating nail gun injuries." Neurosciences (Riyadh, Saudi Arabia) **20**(3): 267-270.

Penetrating craniocerebral injuries from nail gun use are rare. We describe a case of 10 self-inflicted nail gun injuries with intracranial penetrations. We also review the literature and discuss management strategies of such craniocerebral trauma. A 33-year-old male with a long-standing history of severe depression took a nail gun and sustained 10 penetrating intracranial injuries. Initial neuroimaging revealed 10 penetrating nails, all sparing the major cerebral vasculature. Immediate surgical removal was undertaken in the surgical suite using a combination of craniotomies, craniectomies, and blind removal. Intracranial injuries from self-inflicted nail gun misuse is becoming increasingly more frequent. Initial appropriate clinical decision-making are critical in preventing further cortical or vascular damage.

5989. Yuksel, F., et al. (2004). "Management of maxillofacial problems in self-inflicted rifle wounds." Annals of plastic surgery **53**(2): 111-117.

Severe gunshot wounds to the face, produced by high-velocity rifles or shotgun blasts, present a formidable challenge to reconstructive surgeons. In this study, the results of 14 cases with gunshot wounded faces caused by fire from rifles are presented, and the principles of the management of those victims were determined. These patients had attempted to commit suicide and placed the muzzles of the rifles beneath their chins. The ages of the patients ranged from 20 to 24 years, with a mean age of 22 years. These wounds were caused by close-range gunshots (<10 cm), and the missiles had high velocity (more than 800 m/second). All patients had wounds in their submental triangle areas. The exit sites of the missiles differed among patients. All exit wounds were in the angle limited by the deviation from the gun-barrel axis. After clinical and radiologic evaluation and conservative debridement of all devitalized tissues, the fractures were reduced and stabilized appropriately. Large bony defects were treated by bone grafting, and all soft tissue lesions were closed in layers. The entrance and exit sites were covered primarily after thorough debridement except one case whose defect was reconstructed with bilateral sternocleidomastoid (SCM) flaps, one for submental skin and the other for the mouth floor. Intraoral soft tissues were then repaired by primary closure, tongue flaps, or SCM flaps in case they were necessary. Free tissue transfers were not required for treatment of secondary soft-tissue problems. Resolution of tissue edema, softening of scars in time, and insertion of bone graft may improve the deformity significantly. The initial anatomic reconstruction of the existing bone skeleton and the maximal use of regional tissue for cutaneous reconstruction provide an esthetic appearance that can never be duplicated by secondary reconstruction.

5990. Yun, J., et al. (2018). "YH25448, an irreversible 3r d generation EGFR TKI, exhibits superior anticancer effects with potent brain BBB penetration in NSCLC." Cancer Research **78**(13).

EGFR mutated lung cancer shows approximately 10-15% of non-small cell lung cancer (NSCLC). Although the best therapeutic EGFR tyrosine kinase inhibitors (TKIs) targeting mutant EGFR, such as gefitinib and erlotinib, are used in the first line treatment of patients with advanced EGFR mutated NSCLC, the acquired resistance to the drugs usually

appears in 10-12 months of therapy by the occurrence of a second EGFR mutation T790M. YH25448, a highly mutant-selective and irreversible 3rd generation EGFR TKI potently penetrating blood brain barrier (BBB) penetration, targets both activating EGFR mutations Del19, L858R and T790M mutation while sparing wild type. In NSCLC cell lines and primary cancer cells from patients harboring EGFR mutations, YH25448 showed more potent inhibition of cancer cell growth and significantly increased tumor cell apoptosis compared to osimertinibs, which is one of 3rd generation EGFR TKIs. In vivo mouse model implanted with H1975 cells, YH25448 treatment at the once-daily showed a dramatic dose-dependent tumor regression in both subcutaneous and intracranial lesions with no abnormal signs such as skin keratosis shown in osimertinib-treated mice. Plasma half life of YH25448 was 5.9-6.8 hr and tumor to plasma AUC0-last ratio was 3.0-5.1 in tumor bearing mice. YH25448 also showed excellent penetration of the BBB, achieving CSF concentrations exceeding the IC50 value for pEGFR inhibition in the tumor-bearing mice. Taken together, these findings suggest important role for the further development of YH25448 as a novel therapeutic for the treatment of EGFR mutant-positive NSCLC patients with brain metastases.

5991. Yurdakul, A. S., et al. (2005). "An interesting cause of recurrent haemoptysis: haemoptysis 7 years after a foreign body penetrated the lung parenchyma and aorta." Respirology (Carlton, Vic.) **10**(2): 229-232.

A 43-year-old man presented with a 12-month history of recurrent haemoptysis. Postero-anterior chest X-ray of a patient with a history of a penetrating thoracic trauma 8 years previously showed a long wedge-shaped opacity just above the left hemidiaphragm, representing the 'tip of the knife' appearance, and penetrating from the lateral chest wall deep to the thoracic aorta. After consultation with the cardiovascular surgeons, it was decided that the patient should have an operation to remove the foreign body penetrating the aorta. During the operation, a piece of glass was located in the posterior segment of the left lower lobe, and it had also penetrated the aorta through to the posterior wall. The glass had a pointed end, was wedge-shaped and measured 8 cm x 3 cm x 0.5 cm. It was removed, and a 5-cm segment of aorta was replaced with dacron graft. Patients with penetrating chest trauma require routine chest X-rays as many will have a haemothorax, pneumothorax or a penetrating foreign body in the chest in the absence of clinical findings. Postero-anterior chest X-rays as well as lateral X-rays must be carefully and systematically examined for foreign bodies.

5992. Yusuf, A. S., et al. (2017). "Clinical Presentation and Outcome of Impalement Craniocerebral Injuries - A CASE SERIES." Journal of the West African College of Surgeons **7**(2): 112-123.

Non-missile, low-velocity penetrating craniocerebral injuries are uncommon among civilians and unlike missile injuries, are associated with localized brain injury and subsequent good outcome if managed appropriately. Penetrating injuries to the brain caused by a retained, relatively blunt or sharp object that perforate the brain along its longitudinal axis producing a wound track corresponding to its length of penetration, are called impalement injuries. Most of the impalement craniocerebral injuries are accidental and varying objects have been reported. We report our experience with the management of seven cases of impalement craniocerebral injuries. Five of the patients were adult male while two female children were involved. One case was from assault, others resulted from accidental injury. Left side of the cranium was more commonly involved. The impaled objects in this study included a lead pencil, a screw driver, a branch of a tree, and other metallic objects. Most of the patients had craniectomy and water tight dura repair during remover of the impaled object. All patients made good recovery following surgical intervention. Management principles entail early recognition, deliberate and careful debridement, and judicious antibiotic therapy. The surgical approach to these injuries varies, depending on the route of entry.

5993. Yu-Wai-Man, P. (2015). "Traumatic optic neuropathy-Clinical features and management issues." Taiwan journal of ophthalmology **5**(1): 3-8.

Traumatic optic neuropathy (TON) is an uncommon cause of visual loss following blunt or penetrating head trauma, but the consequences can be devastating, especially in cases with bilateral optic nerve involvement. Although the majority of patients are young adult males, about 20% of cases occur during childhood. A diagnosis of TON is usually straightforward based on the clinical history and examination findings indicative of an optic neuropathy. However, the assessment can be difficult when the patient's mental status is impaired owing to severe trauma. TON frequently results in profound loss of central vision, and the final visual outcome is largely dictated by the patient's baseline visual acuities. Other poor prognostic factors include loss of consciousness, no improvement in vision after 48 hours, the absence of

visual evoked responses, and evidence of optic canal fractures on neuroimaging. The management of TON remains controversial. Some clinicians favor observation alone, whereas others opt to intervene with systemic steroids, surgical decompression of the optic canal, or both. The evidence base for these various treatment options is weak, and the routine use of high-dose steroids or surgery in TON is not without any attendant risks. There is a relatively high rate of spontaneous visual recovery among patients managed conservatively, and the possible adverse effects of intervention therefore need to be even more carefully considered in the balance.

5994. Yu-Wai-Man, P. and P. G. Griffiths "Steroids for traumatic optic neuropathy." (6).

Background, Traumatic optic neuropathy (TON) is an important cause of severe visual loss following blunt or penetrating head trauma. Following the initial injury, optic nerve swelling within the optic nerve canal can result in secondary retinal ganglion cell loss. Optic nerve decompression with steroids or surgical interventions or both has therefore been advocated as a means of improving visual prognosis in TON., Objectives, The aim of this review was to examine the effectiveness and safety of using steroids in TON., Search methods, We searched CENTRAL (which contains the Cochrane Eyes and Vision Group Trials Register) (The Cochrane Library 2013, Issue 4), Ovid MEDLINE, Ovid MEDLINE In-Process and Other Non-Indexed Citations, Ovid MEDLINE Daily, Ovid OLDMEDLINE, (January 1950 to May 2013), EMBASE (January 1980 to May 2013), Latin American and Caribbean Literature on Health Sciences (LILACS) (January 1982 to May 2013), Web of Science Conference Proceedings Citation Index- Science (CPCI-S) (January 1990 to May 2013), the metaRegister of Controlled Trials (mRCT) (), ClinicalTrials.gov (and the WHO International Clinical Trials Registry Platform (ICTRP) (). We did not use any date or language restrictions in the electronic searches for trials. We last searched the electronic databases on 21 May 2013. We also searched the reference lists of included studies, other reviews and book chapters on TON to find references to additional trials. The Science Citation Index was used to look for papers that cited the studies included in this review. We did not manually search any journals or conference proceedings. We contacted trial investigators and experts in the field to identify additional published and unpublished studies., Selection criteria, We planned to include only randomised controlled trials (RCTs) of TON in which any steroid regime, either on its own or in combination with surgical optic nerve decompression, was compared to surgery alone or no treatment., Data collection and analysis, Two review authors independently assessed the titles and abstracts identified from the electronic searches., Main results, We included one study that met our selection criteria; a double-masked, placebo-controlled, randomised trial of high dose intravenous steroids in patients with indirect TON diagnosed within seven days of the initial injury. A total of 31 eligible participants were randomised to receive either high dose intravenous steroids (n = 16) or placebo (n = 15), and they were all followed-up for three months. Mean final best corrected visual acuity (BCVA) was 1.78+/-1.23 Logarithm of the Minimum Angle of Resolution (LogMAR) in the placebo group, and 1.11+/-1.14 LogMAR in the steroid group. The mean difference in BCVA between the placebo and steroid groups was 0.67 LogMAR (95% confidence interval -1.54 to 0.20), and this difference was not statistically significant (P = 0.13). At three months follow-up, an improvement in BCVA of 0.40 LogMAR occurred in eight eyes (8/15, 53.3%) in the placebo group, and in 11 eyes (11/16, 68.8%) in the treatment group. This difference was not statistically significant (P = 0.38)., Authors' conclusions, There is a relatively high rate of spontaneous visual recovery in TON and there is no convincing data that steroids provide any additional visual benefit over observation alone. Recent evidence also suggests a possible detrimental effect of steroids in TON and further studies are urgently needed to clarify this important issue. Each case therefore needs to be assessed on an individual basis and proper informed consent is paramount.

5995. Yu-Wai-Man, P. and P. G. Griffiths (2007). "Steroids for traumatic optic neuropathy." Cochrane database of systematic reviews (Online)(4).

Background: Traumatic optic neuropathy (TON) is an important cause of severe visual loss following blunt or penetrating head trauma. Following the initial injury, optic nerve swelling within the optic nerve canal can result in secondary retinal ganglion cell loss. Optic nerve decompression with steroids or surgical interventions or both has therefore been advocated as a means of improving visual prognosis in TON. Objectives: The aim of this review was to examine the effectiveness and safety of using steroids in TON. Search strategy: We searched the Cochrane Central Register of Controlled Trials (CENTRAL) in The Cochrane Library (Issue 1, 2007), MEDLINE (1966 to February 2007), EMBASE (1980 to February 2007), LILACS (March 2007) and NRR (Issue 1, 2007). We also searched the reference lists of included studies, other reviews and book chapters on TON to find references to additional trials. The Science Citation Index was used to look for papers that cited the studies included in this review. We did not manually search any journals or conference proceedings. Trial investigators and experts in the field were contacted to identify additional published

and unpublished studies. There were no date or language restrictions in the electronic searches for trials. Selection criteria: We planned to include only randomised controlled trials (RCTs) of TON in which any steroid regime, either on its own or in combination with surgical optic nerve decompression, was compared to surgery alone or no treatment. Data collection and analysis: Two review authors independently assessed the titles and abstracts identified from the electronic searches. Main results: No studies were found that met our selection criteria and therefore none were included for analysis. Authors' conclusions: There is a relatively high rate of spontaneous visual recovery in TON and no convincing data that steroids provide any additional benefit over observation alone. Recent evidence also suggests a possible detrimental effect of steroids in TON and further studies are urgently needed to clarify this important issue. Based on the current literature, TON cases presenting more than eight hours after the initial injury should not be treated with steroids. The decision to initiate treatment for patients seen within the eight-hour window remains controversial and the supporting evidence is weak. Each case therefore needs to be assessed on an individual basis and proper informed consent is paramount. An adequately powered RCT of steroids in TON poses difficult challenges and is probably not feasible.

5996. Yu-Wai-Man, P. and P. G. Griffiths (2013). "Steroids for traumatic optic neuropathy." The Cochrane database of systematic reviews(6): CD006032.

BACKGROUND: Traumatic optic neuropathy (TON) is an important cause of severe visual loss following blunt or penetrating head trauma. Following the initial injury, optic nerve swelling within the optic nerve canal can result in secondary retinal ganglion cell loss. Optic nerve decompression with steroids or surgical interventions or both has therefore been advocated as a means of improving visual prognosis in TON., OBJECTIVES: The aim of this review was to examine the effectiveness and safety of using steroids in TON., SEARCH METHODS: We searched CENTRAL (which contains the Cochrane Eyes and Vision Group Trials Register) (The Cochrane Library 2013, Issue 4), Ovid MEDLINE, Ovid MEDLINE In-Process and Other Non-Indexed Citations, Ovid MEDLINE Daily, Ovid OLDMEDLINE, (January 1950 to May 2013), EMBASE (January 1980 to May 2013), Latin American and Caribbean Literature on Health Sciences (LILACS) (January 1982 to May 2013), Web of Science Conference Proceedings Citation Index- Science (CPCI-S) (January 1990 to May 2013), the metaRegister of Controlled Trials (mRCT) (www.controlled-trials.com), ClinicalTrials.gov (http://clinicaltrials.gov) and the WHO International Clinical Trials Registry Platform (ICTRP) (www.who.int/ictrp/search/en). At three months follow-up, an improvement in BCVA of 0.40 LogMAR occurred in eight eyes (8/15, 53.3%) in the placebo group, and in 11 eyes (11/16, 68.8%) in the treatment group. This difference was not statistically significant (P = 0.38)., AUTHORS' CONCLUSIONS: There is a relatively high rate of spontaneous visual recovery in TON and there is no convincing data that steroids provide any additional visual benefit over observation alone. Recent evidence also suggests a possible detrimental effect of steroids in TON and further studies are urgently needed to clarify this important issue. Each case therefore needs to be assessed on an individual basis and proper informed consent is paramount.

5997. Yu-Wai-Man, P. and P. G. Griffiths (2013). "Surgery for traumatic optic neuropathy." The Cochrane database of systematic reviews **6**: CD005024.

BACKGROUND: Traumatic optic neuropathy (TON) is an important cause of severe visual loss following blunt or penetrating head trauma. Following the initial insult optic nerve swelling within the optic nerve canal or compression by bone fragments are thought to result in secondary retinal ganglion cell loss. Optic nerve decompression with steroids or surgical interventions or both have therefore been advocated to improve visual prognosis in TON., OBJECTIVES: To examine the effects and safety of surgical interventions in the management of TON., SEARCH METHODS: We searched CENTRAL (which contains the Cochrane Eyes and Vision Group Trials Register) (The Cochrane Library 2013, Issue 4), Ovid MEDLINE, Ovid MEDLINE In-Process and Other Non-Indexed Citations, Ovid MEDLINE Daily, Ovid OLDMEDLINE, (January 1950 to May 2013), EMBASE (January 1980 to May 2013), Latin American and Caribbean Literature on Health Sciences (LILACS) (January 1982 to May 2013), the metaRegister of Controlled Trials (mRCT) (www.controlled-trials.com), ClinicalTrials.gov (http://clinicaltrials.gov) and the WHO International Clinical Trials Registry Platform (ICTRP) (www.who.int/ictrp/search/en). We did not use any date or language restrictions in the electronic searches for trials. We last searched the electronic databases on 28 May 2013. We also searched the reference lists of other reviews and book chapters on TON. We also contacted researchers in the field., SELECTION CRITERIA: We planned to include only randomised controlled trials (RCTs) of TON in which any form of surgical intervention either on its own or in combination with steroids was compared to steroids alone or no treatment., DATA COLLECTION AND ANALYSIS: Two authors independently assessed the titles and abstracts identified from the search strategy. No studies were found that met our inclusion criteria and therefore none were included for analysis., MAIN RESULTS: No studies were found that met our inclusion criteria., AUTHORS' CONCLUSIONS: The current body of evidence consists mostly of small, retrospective case series. Given the wide range of surgical interventions used in TON it is very difficult to compare these studies, even qualitatively. However, there is a relatively high rate of spontaneous visual recovery and no evidence that surgical decompression of the optic nerve provides any additional benefit. On the other hand, surgery carries a definite risk of complications such as postoperative cerebrospinal fluid leak and meningitis. The decision to proceed with surgery in TON therefore remains controversial and each case needs to be assessed on its own merits. Although there is an urgent need for an adequately powered, RCT of surgical intervention in TON, this will prove a difficult endeavour.

5998. Zaaroor, M., et al. (2008). "Administration off label of recombinant factor-VIIa (rFVIIa) to patients with blunt or penetrating brain injury without coagulopathy." Acta neurochirurgica **150**(7): 663-668.

Traumatic brain contusions may increase in size over time or may develop at a delay after injury. This may lead to neurological deterioration, long term morbidity or even death. Coagulation disorders after injury can contribute to progression of haemorrhage. Recombinant activated factor VII (rFVIIa) was used in 12 patients with a severe head injury who had no systemic coagulopathy but who were considered to be at risk of progression of their intracranial lesion. Twelve consecutive patients suffering from life-threatening acute head injuries from blunt (3 cases) and penetrating mechanisms were given with rFVIIa, either to prevent the expected development of brain contusion or to assist in bleeding control during surgery. In 11 patients, rFVIIa was given by the attending neurosurgeon. Two of the patients died of their severe penetrating injuries one of whom had severe vasospasm 2 days after administration of rFVIIa. The other 11 patients did not appear to suffer any treatment-related adverse effects. When the drug was given prophylactically to prevent brain resection (6 cases) or to limit the need for widening resection (5 cases), marked control was achieved in seven cases, and a lesser effect was observed in the other 4 cases. We conclude that, in a small and highly individually selected series of patients with severe head injury, the administration of rFVIIa did not lead to adverse effects. Although the majority of patients were considered to be at high risk of progression of their lesions, this occurred in only one. The early use of rFVIIa in head injured patients without systemic coagulopathy may reduce the occurrence of enlargement of contusions, the requirement of further operation, and adverse outcome. Prospective randomised controlled studies are required to investigate this.

5999. Zaba, C., et al. (2009). "[Diagnostic and organizational error in head injuries]." Blad diagnostyczny i organizacyjny w obrazeniach glowy. **59**(3): 259-262.

The study aimed at presenting a case of a diagnostic and organizational error involving lack of detection of foreign body presence in the soft tissues of the head. Head radiograms in two projections clearly demonstrated foreign bodies that resembled in shape flattened bullets, which could not have been missed upon evaluation of the X-rays. On the other hand, description of the radiograms entered by the attending physicians to the patient's medical record indicated an absence of traumatic injuries or foreign bodies. In the opinion of the authors, the case in question involved

a diagnostic error: the doctors failed to detect the presence of foreign bodies in the head. The organizational error involved the failure of radiogram evaluation performed by a radiologist.

6000. Zacharias, G., et al. (2002). "Foreign body in the base of skull." Indian Journal of Otology **8**(1): 37-39.

We would present a case of a young boy who accidently shot himself with an airgun and the pellets were lodged in the infraorbital region and the floor of the middle cranial fossa. With the help of the orbital ultrasound and x-ray lateral view of the skull, surgical exploration and removal of the pellets through an external modified Lynch Howarth approach was done successfully. Emphasis is being, laid on the intraoperative use of C-arm.

6002. Zacks, J. M., et al. (2016). "Effects of penetrating traumatic brain injury on event segmentation and memory." Cortex; a journal devoted to the study of the nervous system and behavior **74**: 233-246.

Penetrating traumatic brain injury (pTBI) is associated with deficits in cognitive tasks including comprehension and memory, and also with impairments in tasks of daily living. In naturalistic settings, one important component of cognitive task performance is event segmentation, the ability to parse the ongoing stream of behavior into meaningful units. Event segmentation ability is associated with memory performance and with action control, but is not well assessed by standard neuropsychological assessments or laboratory tasks. Here, we measured event segmentation and memory in a sample of 123 male military veterans aged 59-81 who had suffered a traumatic brain injury as young men, and 34 demographically similar controls. Participants watched movies of everyday activities and segmented them to identify fine-grained or coarse-grained events, and then completed tests of recognition memory for pictures from the movies and of memory for the temporal order of actions in the movies. Lesion location and volume were assessed with computed tomography (CT) imaging. Patients with traumatic brain injury were impaired on event segmentation. Those with larger lesions had larger impairments for fine segmentation and also impairments for both memory measures. Further, the degree of memory impairment was statistically mediated by the degree of event segmentation impairment. There was some evidence that lesions to the ventromedial prefrontal cortex (vmPFC) selectively impaired coarse segmentation; however, lesions outside of a priori regions of interest also were associated with impaired segmentation. One possibility is that the effect of vmPFC damage reflects the role of prefrontal event knowledge representations in ongoing comprehension. These results suggest that assessment of naturalistic event comprehension can be a valuable component of cognitive assessment in cases of traumatic brain injury, and that interventions aimed at event segmentation could be clinically helpful. 6003. Zafonte, R., et al. (2012). "Results of the citicoline brain injury treatment (COBRIT) trial." Brain injury **26**(4-5): 389.

Traumatic Brain Injury is a major cause of death and disability.Citicoline has a favorable side-effect profile and several met analysis have suggested a possible benefit in stroke and dementia. COBRIT is an NIH sponsored randomized double blind, placebo controlled, multi center trial of 1213 patients designed to evaluate the effects of 90 days of citicoline on functional outcome. Unique to this study is the enrollment of those with complicated mild, moderate and severe TBI. Participants: 1,213 patients with complicated mild (GCS 13-15 or motor score=6 with abnormal CT scan, moderate (GCS 9-12 and motor score<6,) or severe (GCS<9, -) TBI were randomized within 24 hours of injury. Subjects ranged from 18 to 69 years of age. Those with penetrating injuries or preexisting severe psychiatric or neurological problems were excluded.Interventions: Citicoline 1000mg twice daily (via feeding tube or orally) beginning within 24 hours and extending to 3 months after injury. Main Outcome Measures: Assessments at 1, 3, and 6 months after injury involving several functional and cognitive instruments combined to form a global statistic. Instruments included the Extended Glasgow Outcome Scale, California Verbal Learning Test-2, Controlled Oral Word Association Test, Digit Span subtest and Working Memory Index of the Wechsler Adult Intelligence Test-3, Stroop Test, and Trail Making Test. A databank of neuroimaging and genomic markers was established for enrolled subjects. Secondary outcomes also include, survival, toxicity and rate of recovery. Results: Enrollment has concluded and the dataset will be closed in

October. Final results will be analyzed and reported. Those attending will be able to describe the design and unique aspects of the COBRIT trialThose attending will be able to discuss the results and caveats of the COBRIT trial.

6004. Zafonte, R., et al. (1998). "Superior sagittal sinus thrombosis: a complication of gunshot wound injuries to the brain." NeuroRehabilitation **10**(1): 61-66.

Superior sagittal sinus thrombosis (SSST) is a rare complication of non-penetrating brain injuries. However, this is not an uncommon event in those patients who have suffered a gun shot wound (GSW) to the head. Disturbances in blood flow, lead to development of SST, endothelial injury and clotting abnormalities. Complications include increased weakness, mental status changes, seizures and potential mortality. The purpose of this paper is to illustrate three cases of SSST and the need to be alert for this entity. Our cases involve three young female patients each of whom suffered a GSW to the head, with resultant severe brain injury. In each case, severe disability ensued and imaging studies revealed the presence of the superior sagittal sinus syndrome. The cases demonstrate three different presentations and time courses of this entity, along with the appropriate treatment choices. This condition may appear in the immediate post-injury period, in the post-acute rehabilitation period or even at distant follow-up; therefore, patients with TBI secondary to GSW need to be monitored for an extended time interval for clinical signs which may be indicative of SSST.

6005. Zafonte, R. D., et al. (1997). "Functional outcome after violence related traumatic brain injury." Brain injury **11**(6): 403-407.

Violent injuries have become an increasingly prevalent cause of traumatic brain injury (TBI). These injuries can be classified as either penetrating or non-penetrating in nature. While much of the research on violence has been within a military population, there exists a marked difference between military and civilian injuries. Prior work has reported relatively poor outcomes for those individuals who have suffered penetrating TBIs, but little has been done to assess specific functional outcome parameters in survivors. We examined 25 subjects that had sustained blunt injuries and 25 cases with penetrating injuries as a result of a violent act. Cases were matched by initial Glasgow Coma Scale (GCS), age and educational level. Mean GCS for this study sample was 8.8. The following outcome variables were assessed at rehabilitation admission and discharge and at 1 year post injury: Disability Rating Scale (DRS), Rancho Los Amigos Scale (LCFS), Functional Independence Measure (FIM) (ambulation, expression items), length of stay, and cost of care. Student's t-tests were performed to assess for differences between the two groups. No significant differences were noted between the groups for any of the outcome variables. Although penetrating injuries may have a higher initial mortality, those who survive to come to rehabilitation appear to have similar outcomes to those patients with non-penetrating violence related injuries.

6006. Zafonte, R. D., et al. (1998). "Moving bullet syndrome: a complication of penetrating head injury." Archives of physical medicine and rehabilitation **79**(11): 1469-1472.

Penetrating injuries, by definition, result in retained bullets or fragments. Usually, these fragments are removed surgically during wound debridement. Occasionally, the position of the bullet may preclude removal if it is thought that surgery could exacerbate neurologic damage. Complications from retained fragments are uncommon. One rare complication is the spontaneous migration of the fragment. Two cases of spontaneous migration of retained bullets are presented. In both cases neurologic deterioration was noted and computed tomographic imaging was diagnostic. In one case, this complication delayed transfer from the acute care hospital to rehabilitation. In the other case, the migrating bullet was removed during the inpatient rehabilitation stay. Each person improved neurologically after the migrating bullet fragment was removed. Additionally, functional progress was marked in both persons and symptomatic relief noted. Rehabilitation physicians caring for survivors of penetrating brain injuries need to be aware of this potentially devastating phenomenon.

6007. Zafonte, R. D., et al. (2001). "Severe penetrating head injury: a study of outcomes." Archives of physical medicine and rehabilitation **82**(3): 306-310.

OBJECTIVE: To determine and describe the demographics and functional outcomes of persons who require inpatient rehabilitation for severe penetrating head injury resulting from a gunshot wound to the head., DESIGN: Data were collected prospectively from the time of admission to acute care through discharge from inpatient rehabilitation.,

SETTING: Two sites: an urban, level I, acute care, trauma center and an inpatient rehabilitation hospital with a specialized brain injury unit., PARTICIPANTS: Twenty-seven persons with severe penetrating head injury., MAIN OUTCOME MEASURES: The FIM instrument, the Disability Rating Scale (DRS), and the length of stay (LOS)., RESULTS: Demographic data showed our population to be similar to other groups of persons at high risk for violent injury. Eighty-five percent of the subjects were men with a mean age of 34 years. The majority were African American (93%), reflective of our general patient population. Average acute care LOS was 31 days and average rehabilitation LOS was 44 days. Average FIM gain was 40.2 and, on average, DRS scores improved 7.6 points from rehabilitation admission to discharge. All study participants made enough progress to be discharged to private residences., CONCLUSION: Although the mortality rate is high among patients with penetrating head injury, those who survive to receive inpatient rehabilitation can achieve functional improvement.

6008. Zafonte, R. D., et al. (2001). "Penetrating head injury: a prospective study of outcomes." Neurological research **23**(2-3): 219-226.

The purpose of our study was to describe the outcomes of persons with penetrating brain injury resulting from a gunshot wound to the head. It is a prospective study of 442 patients admitted with gunshot wounds to the head over a 7 year period to our University Trauma Center Emergency Department, an urban trauma center and an inpatient rehabilitation hospital with a specialized brain injury unit. Measures and factors described include initial Glasgow Coma Scale score, Revised Trauma Score, the Disability Rating Scale, Functional Independence Measure, levels of cognitive functioning, patient demographics, length of stay, hospital charges, and discharge disposition. Initially 36% of patients expired in or were dead upon arrival to the Emergency Department; 64% of patients survived to be admitted for inpatient care. Of those admitted, 41% expired within the first 48 h of admission. Fifty-two percent of those admitted had severe injuries, 7% moderate injuries, and 42% had mild head injuries. Sixty-two percent of the survivors were discharged from acute care to private residences. The remaining 38% were discharged to programs providing varying levels of care depending upon their level of functioning and care needs. Patients sustaining severe injuries following gunshot wound(s) to the head have high early mortality. Survivors able to participate in an inpatient rehabilitation program have good potential for functional improvement.

6009. Zaidel, D. W. and N. Edelstyn (1995). "Hemispheric semantics: effects on pictorial organization of patients with unilateral brain damage." The International journal of neuroscience **82**(3-4): 215-221.

Memory for incongruous scenes (violating "knowledge-of-the-world") versus unorganized (jumbled) arrays was tested in war veterans with unilateral penetrating missile wounds of the brain in order to assess hemispheric differences in semantic schemas in long-term memory. Left brain-damaged (LBD) patients were selectively impaired in remembering unorganized scenes compared to right brain-damage (RBD) patients. There was no significant LBD-RBD difference in remembering incongruous scenes. The results confirm the presence of hemispheric asymmetry for semantic schemas in long-term memory, even in pictorial material. However, some features in the organization of semantic schemas are common to both hemispheres and suggests presence of similar knowledge systems. The asymmetry is discussed in terms of intact left hemisphere specialization for assigning meaning to a visual scene when obvious meaning appears to be absent.

6010. Zaitsev, O. S., et al. (2000). "[An epileptic syndrome in patients with the sequelae of gunshot craniocerebral wounds]." Epilepticheskii sindrom u bol'nykh s posledstviiami ognestrel'nykh cherepno-mozgovykh ranenii.(2): 21-25.

To study the specific features of the epileptic syndrome after present-day gunshot cranial wounds (GCW), as well as risk factors of its occurrence, 56 victims were examined prospectively (within at least a year after their admission). The epileptic syndrome developed in 18 (32.1%) patients within 1 to 15 months following GCW; there were prevalent generalized convulsive (in 13 of the 18 patients) and focal (in 12 of the 18 ones) seizures. One type of seizures was noted in 7 patients, two or three ones were in 11. The polymorphism of seizures and a disparity of their psychopathological structure to the side of brain lesion were typical for left-handers. As compared to other patients, epileptics were more commonly found to have: 1) frontoparietal lesion; 2) multiple bony defects of the vault of the skull; 3) enlargement of the lateral ventricle of the brain on CT scans; 4) primary coma for > 2 hours and other depressed consciousness syndromes for > 1 day; 5) signs of left-handedness. The findings suggest that there is a need for studies of the functional asymmetry of the brain to gain a better insight into the problem.

6012. Zakrison, T. L., et al. (2022). "Review Paper on Penetrating Brain Injury: Ethical Quandaries in the Trauma Bay and Beyond." Annals of surgery.

OBJECTIVE: The aim of this review was to review the ethical and multidisciplinary clinical challenges facing trauma surgeons when resuscitating patients presenting with penetrating brain injury (PBI) and multicavitary trauma., BACKGROUND: While there is a significant gap in the literature on managing PBI in patients presenting with multisystem trauma, recent data demonstrate that resuscitation and prognostic features for such patients remains poorly described, with trauma guidelines out of date in this field., METHODS: We reviewed a combination of recent multidisciplinary evidence-informed guidelines for PBI and coupled this with expert opinion from trauma, neurosurgery, neurocritical care, pediatric and transplant surgery, surgical ethics and importantly our community partners., RESULTS: Traditional prognostic signs utilized in traumatic brain injury may not be applicable to PBI with a multidisciplinary team approach suggested on a case-by-case basis. Even with no role for neurosurgical intervention, neurocritical care, and neurointerventional support may be warranted, in parallel to multicavitary operative intervention. Special considerations should be afforded for pediatric PBI. Ethical considerations center on providing the patient with the best chance of survival. Consideration of organ donation should be considered as part of the continuum of patient, proxy and family-centric support and care. Community input is crucial in guiding decision making or protocol establishment on an institutional level., CONCLUSIONS: Support of the patient after multicavitary PBI can be complex and is best addressed in a multidisciplinary fashion with extensive community involvement.

6013. Zamani, A., et al. (2021). "White matter changes following experimental pediatric traumatic brain injury: an advanced diffusion-weighted imaging investigation." Brain imaging and behavior **15**(6): 2766-2774.

Pediatric traumatic brain injury (pTBI) is a major community health concern. Due to ongoing maturation, injury to the brain at a young age can have devastating consequences in later life. However, how pTBI affects brain development, including white matter maturation, is still poorly understood. Here, we used advanced diffusion weighted imaging (DWI) to assess chronic white matter changes after experimental pTBI. Mice at post-natal day 21 sustained a TBI using the controlled cortical impact model and magnetic resonance imaging (MRI) was performed at 6 months post-injury using a 4.7 T Bruker scanner. Four diffusion shells with 81 directions and b-values of 1000, 3000, 5000, and 7000s/mm2 were acquired and analyzed using MRtrix3 software. Advanced DWI metrics, including fiber density, fiber cross-section and a combined fiber density and cross-section measure, were investigated together with three track-weighted images (TWI): the average pathlength map, mean curvature and the track density image. These advanced metrics were compared to traditional diffusion tensor imaging (DTI) metrics which indicated that TBI injured mice had reduced fractional anisotropy and increased radial diffusivity in the white matter when compared to age-matched sham controls. Consistent with previous findings, fiber density and TWI metrics appeared to be more sensitive to white matter changes than DTI metrics, revealing widespread reductions in fiber density and TWI metrics in pTBI mice compared to sham controls. These results provide additional support for the use of advanced DWI metrics in assessing white matter degeneration following injury and highlight the chronic outcomes that can follow pTBI.

6014. Zamick, P. (1976). "Reconstruction of an orbito-facio-cranial gunshot wound." British journal of plastic surgery **29**(1): 92-96.

6015. Zamora, R., et al. (2016). "Dynamic networks and principal drivers of systemic inflammation in combat casualties." Shock **45**(6): 77.

Objective: After more than a decade of war in Iraq and Afghanistan, we observed an increase in combat-related injury survival, a paradoxical increase in injury severity, and extensive systemic inflammation all mainly due to blasts. In the civilian setting, we have begun to address the complexity of post-traumatic inflammation using computational

modeling. We hypothesized that computational assessment of dynamic networks and principal drivers following assessment of relevant systemic inflammatory mediators could provide insights into the role of inflammation in determining clinical outcomes in combat casualties. Methods: Two hundred combat wounded active-duty service members who sustained high-energy extremity injuries were enrolled prospectively between 2008 and 2012. In addition to injury-specific and demographic data, serum samples from those patients were collected and assayed for 24 inflammatory mediators during each debridement. Segregation of the patients based on the type of injury (Blast injury [Blast, n = 67] vs. Gunshot wound [GSW, n = 9]; magnitude of injury (number of wounds (1 [n = 16]; 2 [n = 13]; 3 [n = 14]; more than 3 [n = 33]), and the presence of traumatic brain injury (TBI [n = 27] vs. no TBI [n = 43]) was performed followed by analysis using multiple datadriven algorithms: Principal Component Analysis (PCA), Dynamic Network Analysis (DyNA), and Dynamic Bayesian Network (DBN). Results: Similar to civilian trauma, DBN defined a consensus network in all patient sub-groups involving MCP-1 and IP-10 upstream of multiple mediators including IL-6. PCA suggested both conserved and different principal drivers in each sub-group. DyNA suggested differences in dynamic networks between GSW and Blast. There was no apparent effect of number of wounds on inflammatory DyNA network complexity, although in general inflammatory complexity was higher with time post-injury in all sub-groups. DyNA complexity was overall greater in TBI vs no-TBI patients. Conclusions: This is the most comprehensive systems analysis to date of systemic inflammation following combat injury. We have defined key dynamic network signatures associated with different injury type, especially with regard to TBI, with core inflammation network features resembling those seen in civilian blunt trauma patients. These approaches may help better diagnose, and ultimately treat, combat casualties.

6016. Zarate-Méndez, A., et al. (2003). "Utility predicts of the Glasgow out come scale in severe head injury." Archivos de Neurociencias **8**(2): 70-74.

Severe head injury (SHI) is the fourth cause of general mortality on population and the first in the working population in our country. This work analyse the outcome of severe head injury don't yet clear. Material and Method: The present it is an observational, longitudinal and ambipective study, which analyzed demographic distribution from a population of 6844 patients with head injury, 364 patients with a SHI, this study was made at the emergency room of a General Hospital of Mexico City, since 1ts January 1997 to 1st January 2002. In a question table we had recorded the Initial Glasgow Coma 3Scale (IGCS) score's, head scan finding, medical or surgical initial treatment, Glasgow outcome scale (GOS) and a 6 month follow up. Results: From a total of 364 patient selected, 46.4% (n=169) were female and 53.6%(n=195) male, the media age was 39.1 (22.2 years and the Initial Glasgow Coma Scale score's was of 6.8 (1.4 points, the head scan finding were brain edema 47.3% (n=172), surgical intracerebral hematoma 29.4% (n=107), non-surgical intracerebral hematoma 12.6% (n=46), skull fracture 29.7% (n=108), epidural hematoma 13.5% (n=49), convexity subdural hematoma 10.2% (n=37), interhemispheric subdural hematoma 2.7% (n=10), intraventricular hemorrhage 12.6% (n=46).The treatments were: medical treatment was given only in 51.1% (n=186), medical and surgical treatment in 48.9% (n=178). Admission causes were the following: robbery 49.8% (n=167), games 10. 4% (n=38), falls 11.0% (n=40), firearm wound 6.3% (n=23), car accidents 26.4% (n=96). The result of the Glasgow outcome scale were: good recovery 49.7% (n=181), moderate disability 15.7% (n=57), severe disability 13.2% (n=48), persistent vegetative state 14.3% (n=52), death 7.1% (n=26). There was an strong correlation between poor prognosis for life in GCS of 4 and 5 points ($p<0.01$), and poor prognosis for function with score of 5 and 6 points ($p<0.01$), and good prognosis in score of 7 points ($p<0.01$), with a confidence interval of 95% (8.445- .9202) and a correlation index r= -0.9613. Conclusion: We recommended a quantitative and exact evaluation due to direct correlation for outcome, perhaps in a near future the developed of a new subscale it is a possibility.

6017. Zavaros, G., et al. (1991). "[A case of maxillofacial gunshot wound complicated by acute hemorrhage from the internal carotid artery and the internal jugular vein]." Maxillofacialis lovesi serules a. carotis interna es v. jugularis interna akut verzeses szovodmenyes esete. **84**(2): 53-56.

A complicated case of a big vein injury associated with a maxillofacial gun-shot injury and its successful treatment are reported on. The course of the vein injury is explained and the significance of team work is emphasized.

Multiple and self-inflicted penetrating brain injuries (PBI) rare. PBI are rare. We report the case of multiple self-inflicted PBI in a 45 year old man caused by a nail gun. He was admitted to after shooting four nails into his head and one into his thorax. We review the literature on the topic and describe how this case was successfully managed in our hospital.

6020. Zdetsis, A. D. (2009). "Rationalizing and functionalizing stannaspherene: Very stable stannaspherene "alloys"." The Journal of chemical physics **131**(22): 224310.

It is illustrated here by ab initio calculations based on density functional theory and other high level methods that the high stability of the icosahedral Sn(12) (2-) dianion known as stannaspherene, reflects stability toward ionization rather than cohesion. This could be also connected with novel fluxional rearrangements and paths of Sn(12) (1-) leading eventually to Sn(12) (2-) involving charge transfer. In view of the very similar structural and electronic properties with the corresponding isovalent borane (B(12)H(12))(2-), it is demonstrated that stannaspherene can be further rationalized and functionalized on the basis of an isolobal analogy between group 14 clusters and isovalent boranes, carboranes, and bisboranes. Such analogy is of the same nature with analogous isolobal and isovalent similarities between silicon, hydrogenated silicon-carbon clusters and deltahedral boranes and carboranes, which the present author, scoptically and synoptically, has described as the "boron connection." It is predicted and verified theoretically: First, that the isovalent Bi(2)Sn(10) and Sb(2)Sn(10) clusters, considered as the microscopic analogs of tin-bismuth alloys, are very stable (more stable than stannaspherene itself) very symmetric and isolobal to Sn(12) (2-); and second, that embedded clusters of the form M@Sn(12) (2-), M@Bi(2)Sn(10), M=Pt,Pd are very stable and highly symmetrical (I(h) and D(5d) respectively) with large highest occupied-lowest unoccupied molecular orbital gaps and very large embedding energies of the order of 5-6 eV. It is furthermore predicted that Pt@Sn(12) (2-) and Pt@Bi(2)Sn(10) can be synthesized in view of their higher stability compared to Pt@Pb(12) (2-) which has already been synthesized. The marginal energy difference of 0.03 eV between the meta- and the para-isomer of Bi(2)Sn(10) indicates a fluxional behavior with respect to Bi-Sn interchange which should be related with the Sn(12) (1-) fluxionality leading eventually to Sn(12) (2-). This rearrangement is also associated with a strange aromatic behavior. The same type of Bi-Sn fluxionality is also encountered in higher energy structures. Due to the "inert pair effect" in tin, the validity of the isolobal analogy is much stronger and fully valid compared to isovalent species based on germanium or silicon, such as Ge(12) (2-), Bi(2)Ge(10), and Ge(10)C(2)H(2) and Si(12) (2-), Bi(2)Si(10), and Si(10)C(2)H(2). The present ideas are in full agreement with available experiments and suggest even further functionalization of stannaspherene, analogous to metaloboranes, metalocarboranes, and stannaboranes with several potential applications.

6021. Zdravkovic, M., et al. (2009). "Three cases of death caused by shots from blank cartridge." The American journal of forensic medicine and pathology **30**(4): 403-406.

The authors describe 3 cases of lethal injuries caused by 7.62 mm blank cartridge shots from military automatic rifle of domestic origin (AK 47, 7.62 mm). In 1 case, the cartridge was fired from a weapon that had been leaned on the head, with subsequent destruction of brain, and in other 2 cases, the weapon had been leaned on the chests, which led to destruction of heart parts. The injuries were caused by the action of striking wave of gunpowder explosion, the air blast type. The cases demonstrate that the gas pressure from the exploding propellant of blank cartridge is powerful enough to penetrate the thoracic wall and the skull.

6022. Zechnich, A. D., et al. (1995). "Applying the trauma triage rule to blunt trauma patients." Academic emergency medicine : official journal of the Society for Academic Emergency Medicine **2**(12): 1043-1052.

OBJECTIVE: To determine the accuracy of the Baxt Trauma Triage Rule (TTR: systolic blood pressure < 85 mm Hg; Glasgow Coma Scale-motor score < 5; or penetrating trauma to head, neck, or trunk) for prediction of major trauma in an independent data set of blunt trauma patients., METHODS: Retrospective evaluation of the TTR in a cohort of patients identified by Oregon Trauma System entry criteria. Accuracy for prediction of "major trauma" victims was measured using resource-based definitions of major trauma. Participants included 626 adult, blunt trauma patients at a level-I trauma center serving a metropolitan center of more than one million people., RESULTS: Of 524 patients with

sufficient registry data to apply the TTR, 95 (18%) and 63 (12%) patients met the criteria for major trauma suggested by Baxt et al. and Emerman et al., respectively. Using the Baxt definition of major trauma, the TTR had a sensitivity of 74% (95% CI: 0.65-0.83) and a specificity of 84% (95% CI: 0.81-0.88). There were 25 significant false-negative results, including 12 patients requiring urgent laparotomy and four patients requiring emergency airway procedures. Using the Emerman definition of major trauma, sensitivity improved modestly to 76% (95% CI: 0.65-0.87) and specificity decreased slightly to 80% (95% CI: 0.77-0.84)., CONCLUSIONS: In this blunt trauma population, the Baxt TTR failed to identify a significant number of severely injured patients. Slight alterations in the definition of "major trauma" can significantly affect the performance characteristics of triage instruments.

6023. Zee, I. and K. A. Duncan (2012). "Regulation of estrogen receptors and CREB-binding protein (CBP) following traumatic brain injury." FASEB Journal **26**.

Following brain injury, estradiol is neuroprotective and promotes neuronal survival and cell proliferation. Transcription of estrogen-mediated targets occurs through the dimerization of the estrogen receptor alpha and beta (ERα, ERβ), to DNA following recruitment of coregulators and heat shock proteins. Coregulators (coactivators and corepressors) remodel chromatin via histone-DNA contact stabilization and allow for the binding of additional transcription factors and RNA polymerase II recruitment. The role of coregulators following traumatic brain injury (TBI), though, is unknown. In this study, we investigated the interaction between ERα, ERβ, and CREB-binding protein (CBP) following neurotrauma. CBP is a nuclear coactivator that interacts with both the amino-terminal domain (AF-1) and carboxy-terminal ligand-binding domain (AF-2) of ER. Adult male and female zebra finches (Taeniopygia guttata) were given a single penetrating injury and collected at 1 and 7 days post injury. Transcriptional activity and expression of ERα, ERβ, and CBP were examined using quantitative polymerase chain reaction and immunohistochemistry. Preliminary data suggest that CBP is upregulated following injury and play a role in estrogen receptor mediated neuroprotection following injury, and suggest a novel role for estrogen receptor coactivators.

6024. Zeiderman, M. R. and L. L. Q. Pu (2020). "Contemporary reconstruction after complex facial trauma." Burns and Trauma **8**.

Complex facial trauma requires complex repair and solutions. This process is challenging for the surgeon who seeks to manage the expectations of the patient and family while achieving the best possible result. Historically, the use of pedicled flaps, and then free tissue transfer, were the primary techniques utilized. Advancements in soft-tissue reconstruction, such as perforator flaps and pre-expanded and prefabricated flaps, allow refinement of the soft-tissue reconstruction process to create the best initial soft-tissue coverage. The advent of contemporary technologies, such as virtual surgical planning, stereolithography and customized implants and plates, facilitates a tailored approach to the patient’s reconstructive needs for precise bony reconstruction. When surgical and technological techniques are combined in complementary multistage reconstructions, better reconstructive and aesthetic outcomes are achievable than ever before. In this review, the authors present a summary of the management of complex facial trauma based on the senior author’s broad experience. Initial management and contemporary reconstructive techniques and technology to provide optimal outcomes are reviewed. A case series of complex facial traumas and their reconstructive process is also presented to demonstrate how complementary staged procedures can yield an optimal result. We believe the reconstructive surgeon managing complex facial trauma should strive to incorporate contemporary technologies and techniques into their armamentarium to provide the best patient care.

6025. Zeiler, F. A. and C. J. Kazina (2016). "Lateral plating of the temporal bone: Hemostatic technique for complex transverse fractures of the petrous temporal bone." Trauma case reports **3**: 12-17.

Background: Transverse petrous temporal bone fractures are commonly associated with significant intracranial trauma. Diastases of these fractures can lead to issues with hemostasis in the setting of venous sinus or petrous internal carotid artery (ICA) injuries. Objective: To describe a rare case of a severe displaced transverse petrous temporal bone fracture with impending intra-operative exsanguination, treated with fracture reduction and lateral plating in order to achieve hemostasis. Methods: We retrospectively reviewed the records of a patient admitted to the neurosurgical department with a hyperacute epidural hematoma (EDH) secondary to a transverse petrous temporal bone fracture with venous sinus and petrous ICA injuries. Results: A 22 year old male was admitted for a severe traumatic brain injury leading to a left displaced transverse petrous temporal bone fracture and a hyperacute EDH. Given the location of the

fractures, injury to the venous sinus (at the area of the transverse-sigmoid junction) and petrous ICA was suspected.Intra-operatively, significant blood loss from both the venous sinus and petrous ICA was encountered. Given the displaced temporal bone fracture, packing of the areas was impaired.We performed a manual reduction of the temporal fracture, followed by lateral plating in order to achieve hemostasis from the petrous ICA and aid with packing of the venous sinus injury. Conclusions: Reduction and lateral plating of displaced transverse petrous temporal bone fractures can aid significantly with intra-operative hemostasis in the extreme case of venous sinus and/or petrous ICA injuries.

6026. Zeilig, G., et al. (2010). "Civilian spinal cord injuries due to terror explosions." Spinal cord **48**(11): 814-818.

STUDY DESIGN: Retrospective analysis of civilians with spinal cord injuries (SCIs) due to terror explosions., OBJECTIVES: To analyze and describe the clinical characteristics and rehabilitation outcomes of civilians with SCI due to explosions admitted for in-patient rehabilitation from 2000-2004., SETTING: SCI rehabilitation service, Tel Hashomer, Israel., METHODS: Retrospective chart review. Civilians with SCI due to terror-related gunshot wounds (GSWs) served as a control group., RESULTS: Eleven civilians with SCI caused by penetrating atypical foreign objects (PAFOs) and eight with GSWs were identified. The male-to-female ratio was approximately 2:1. Foreign objects were present within the spinal canal in seven patients, causing bone injury without canal penetration in three, and one patient had both bone injury and canal penetration. The most common level of injury was thoracic. Seven had complete motor SCI. Three individuals improved in American Spinal Injury Association status: one individual improved from B to C (cervical); one from C to D (thoracic); and the third from D to E (lumbar). Despite the similar acute hospital length of stay and functional independence measure (FIM) scores on admission, the PAFO group had a shorter rehabilitation length of stay with higher FIM scores and higher FIM efficiency at discharge., CONCLUSIONS: Although the pathophysiology of PAFO blast injuries is similar to the high-velocity GSWs or the high-energy military munition injuries, better rehabilitation outcomes were seen, with slightly higher FIM efficiency and efficacy at discharge. This result is likely to be caused by less neurological tissue damage at impact.

6027. Zellem, R. T. (1985). "Wounded by bayonet, ball, and bacteria: medicine and neurosurgery in the American Civil War." Neurosurgery **17**(5): 850-860.

The American Civil War was a holocaust that illustrated the mid-19th century's unpreparedness for the delivery of medical care to the mass casualties due to both wounds and disease. Several major considerations are offered to explain the soldiers' morbidity. Incomplete understanding of pathophysiology and its management is exemplified by the treatment of the battlefield head injury. Accepting these concepts and the extent of the knowledge of the time, that higher mortality did not occur is in part testimony to the admirable care that was rendered and human resilience in an effort to survive.

6028. Zemla, J. and J. Brydak (1977). "[Gunshot wounds of facial cranium in radiological examination (author's transl)]." Polski przeglad radiologii i medycyny nuklearnej **40**(6): 468-470.

6029. Zentner, J., et al. (1991). "A wooden foreign body penetrating the superior orbital fissure." Neurochirurgia **34**(6): 188-190.

The case of a 12-year-old patient with a wooden foreign body which had penetrated the superior orbital fissure is presented. Using a transethmoidal approach, only some splinters lying in the periorbital soft tissue were removed. The patient became febrile, indicating an infectious complication due to a retained foreign body. This was confirmed by CT scan and MRI demonstrating a main splinter in the superior orbital fissure. Total removal of the wood was achieved via a pterional extradural approach. The difficulties of identifying wooden foreign bodies as well as the topographical problems involved with the approach to the superior orbital fissure are discussed.

6030. Zerbo, S., et al. (2021). "Preventable fatal injury during rally race: a multidisciplinary approach." International journal of legal medicine **135**(3): 893-901.

INTRODUCTION: The motor vehicle crash (MVC) constitutes an important challenge for forensic pathology in order to identify the manner and cause of death. Our study focuses on a fatal accident during a rally race corresponding to MVC sub-category., MATERIALS AND METHOD: Postmortem computed tomography (PMCT) was performed before the conventional autopsy. Autoptic and PMCT data were compared. Data collection allowed analyzing biomechanical dynamics of the incident and post-traumatic injuries through qualitative-statistics and solicitation quantitative indices., RESULTS: Photo and circumstantial evidence analysis showed a wrong installation of double shoulder belt system of head and neck support (HANS) collar. PMTC clearly highlighted multiple and bilateral fractures involving roof and base of skull; a displaced fracture of the right acetabulum was also encountered. Autopsy confirmed PMCT data and revealed a brainstem laceration. AIS (Abbreviated Injury Scale) achieved a maximum score in consideration of fatal injuries., DISCUSSION: The injuries analysis resulting from photographic surveys examination, conventional autopsy, and PMCT has led us to confirm a fatal front collision with a tree trunk. Head trauma represents a major injury in the present case. In this case, head injuries, related to whiplash trauma, are a consequence of a double shoulder belt system (HANS collar component) wrong installation., CONCLUSION: MVC and especially high-speed motor racing represent an important death cause. There was, for this reason, a marked development of cars and occupants' safety systems, such as HANS collar. PMCT improves the diagnostic performance of conventional autopsy and increases forensic medical knowledge related to traumatic injuries.

6031. Zerpa, E. (2022). "Traumatic Injuries From an Encounter With a North American Grizzly Bear." Air medical journal **41**(1): 23-24.

Introduction: Estimates of grizzly bear, Ursus arctos horribilis, populations in North America include 25,000 in Canada, 30,000 in Alaska, and 1,918 in the lower-48 states.1,2 Because of population growth due to wildlife conservation and increased outdoor recreation, bear encounters are more common in recent years, contributing to a greater incidence of human injuries.3,4,5 Encounters are classified as “sudden,” “provoked,” or “predatory,” with most human injuries being associated with “sudden” encounters in response to a perceived threat by the bear.3,6,7 These encounters are likely to occur in the remote wilderness leading to a significant delay in treatment and transport to definitive care.8 We report a patient with injuries sustained from a “sudden” grizzly bear encounter who was treated and transported via helicopter emergency medical services (HEMS) to a trauma center. Case Report: After a bear encounter in a remote wilderness area, a 41-year-old male patient sustained a scalp avulsion at the right occiput above the superior nuchal line and an approximately seven-inch laceration running contralaterally from the avulsion to the left occiput. Bleeding at both injury sites was self-limiting and successfully controlled with direct pressure. Substantial bruising and abrasions to the left anterior chest were noted, along with mild abrasions to the right hip and a puncture wound to the right posterior forearm. The patient's eyes also became irritated from capsaicin exposure when a bear spray canister deployed after being punctured during the encounter. The patient was alert and oriented without respiratory distress and displayed no signs of hemodynamic instability throughout the transport. Pain was managed with fentanyl and antibiotic prophylaxis was initiated with cefazolin. The patient was delivered to the trauma team at the receiving facility in a stable condition. Discussion: Bear encounter injury patterns that predominate in the literature are puncture, avulsion, and crush injuries, notably to the head, face, and scalp.3,6 These injuries stem from a combination of the bear's jaws, teeth, and claws. Infection risk is considerable due to aerobic and anaerobic species in the oral cavity as well as contamination with foreign material from the environment.4,9 These injuries require thorough debridement and broad-spectrum antibiotic therapy should be initiated early. Capsaicin spray has been shown to be an effective bear deterrent and its use in this case, though incidental, likely contributed to termination of the encounter.3,10 Conclusion: This case underscores the serious and potentially life-threatening injuries that can result from encounters with grizzly bears and is consistent with previously reported encounters. Patients may present with complex soft-tissue and musculoskeletal injuries and risk of infection, requiring acute trauma resuscitation and early antibiotic treatment. Additional research on bear encounter injuries and their management will help improve the care of these patients by HEMS crews that are likely to care for these patients on “scene” flights or hospital transports to higher levels of trauma care.

6032. Zhang, A. F., et al. (1997). "Mandibular fracture due to gunshot: A case report." Japanese Journal of Plastic and Reconstructive Surgery **40**(3): 299-302.

It is rather uncommon to sustain a gunshot wound in Japan. We report a case of mandibular fracture due to such. A 27-year-old male, who unintentionally shot himself in the mandible by a .38 caliber handgun, was transported to

our critical care center by ambulance and was treated immediately. X-rays upon admission showed the bullet and its fragments lodged in the subcutaneous tissue behind the fractured mandible with the inner table being severely crushed. Since intraoral and neck swelling were tremendous, only the bullet and the hematoma were removed via the wound in the initial operation. A week later, a second operation was performed to repair the bicortical fracture of the mandible. A follow-up four months after discharge confirmed that the postoperative course was uneventful and the operations left no occlusal or maceration problems.

6033. Zhang, B., et al. (2011). "Neurological, functional, and biomechanical characteristics after high-velocity behind armor blunt trauma of the spine." The Journal of trauma **71**(6): 1680-1688.

BACKGROUND: Behind armor blunt trauma (BABT) describes a nonpenetrating injury to the organs of an individual wearing body armor. The aim of this study was to investigate the neurologic and functional changes that occur in the central nervous system after high-velocity BABT of the spine as well as its biomechanical characteristics., METHODS: This study evaluated 28 healthy adult white pigs. Animals were randomly divided into three experimental groups: (1) 15 animals (9 in the exposed group and 6 in the control group) were tested for neurologic changes; (2) 10 animals (5 in the exposed group and 5 in the control group) were used for studies of cognitive function; (3) and 3 animals were used for examination of biomechanics. In the group tested for neurologic changes, 9 anesthetized pigs wearing body armor (including a ceramic plate and polyethylene body armor) on the back were shot on the eighth thoracic vertebrae (T8) with a 5.56-mm rifle bullet (velocity appropriately 910 m/s). As a control, six pigs were shot with blank ammunition. Ultrastructural changes of the spinal cord and brain tissue were observed with light and electron microscopy. Expression levels of myelin basic protein, neuron-specific enolase (NSE), and glial cytoplasmic protein (S-100B) were investigated in the serum and cerebrospinal fluid using enzyme-linked immunosorbent assays. Electroencephalograms (EEGs) were monitored before and 10 minutes after the shot. Pressures in the spine, common carotid artery, and brain were detected. Acceleration of the 10th vertebrae (T10) was tested. Finally, cognitive outcomes between exposed and control groups were compared., RESULTS: Neuronal degeneration and nerve fiber demyelination were seen in the spinal cord. The concentrations of neuron-specific enolase, myelin basic protein, and S-100B were significantly increased in the serum and cerebrospinal fluid 3 hours after trauma ($p < 0.05$). The electroencephalogram was suppressed within 3 to 6 minutes after trauma. The pressure detected in the brain was higher than that detected in the common carotid artery ($p < 0.01$). The trauma resulted in paralysis of two hind limbs and in cognitive dysfunction., CONCLUSION: The results from our animal model indicate that high-velocity BABT of the spine generates high pressure and acceleration in the spine, induces varying degrees of paralysis of hind limbs, and disturbs cerebral function. The neuronal degeneration caused by the pressure wave may be one of the important pathologic events involved in the development of trauma-related complications.

6034. Zhang, D., et al. (2017). "Management of Penetrating Skull Base Injury: A Single Institutional Experience and Review of the Literature." BioMed research international **2017**: 2838167.

BACKGROUND: Penetrating skull base injury (PSBI) is uncommon among head injuries, presenting unique diagnostic and therapeutic challenges. Although many cases of PSBIs have been reported, comprehensive understanding of its initial diagnosis, management, and outcome is still unavailable., MATERIALS AND METHODS: A retrospective review was performed for patients treated in neurosurgical department of Changzheng Hospital for PSBIs. Presurgical three-dimensional (3D) Slicer-assisted reconstructions were conducted for each patient. Then we reviewed previous literature about all the published cases of PSBIs worldwide and discussed their common features., RESULTS: A total of 5 patients suffering PSBIs were identified. Penetrating points as well as the surrounding neurovascular structures were clearly visualized, assisting in the presurgical planning of optimal surgical approach and avoiding unexpected vascular injury. Four patients underwent craniotomy with foreign bodies removed successfully and 1 patient received conservative treatment. All of them presented good outcomes after proper management., CONCLUSION: Careful physical examination and radiological evaluation are essential before operation, and angiography is recommended for those with suspected vascular injuries. 3D modeling with 3D Slicer is practicable and reliable, facilitating the diagnosis and presurgical planning. Treatment decision should be made upon the comprehensive evaluation of patient's clinicoradiological features and characteristics of foreign bodies.

6035. Zhang, J., et al. (2018). "WSD1227: A brain penetrable VEGFR2 inhibitor for the treatment of primary and metastatic brain tumors." Neuro-Oncology **20**: vi30.

The VEGF pathway has emerged as an important target for cancer therapy by blocking the development of malignant neovasculature, thus to reduce oxygen availability to the tumor and decrease its growth. Anti- VEGF agents have been approved for several malignancies, such as GBM, NSCLC, mBC, CRC, OC, etc with satisfactory performance to extracranial lesions, but not in intracranial lesions. Insufficient penetration across BBB is one of factors limiting intracranial anti-tumor activity for those anti- VEGF agents, due to either large molecule weight or being substrate of BBB efflux transporters. The incidence of BM is increasing, and surgery/ radiotherapy are the most common options for the management of BM. Patients with BM have a very poor prognosis and short survival. To address the role of anti-angiogenesis in the treatment of BM, a BBB penetrable, selective and potent VEGFR2 inhibitor WSD1227 is discovered with IC50 against VEGFR1/2/3 at 0.69/0.35/0.41nM versus against other targets such as PDGFRα IC50 22.9nM, PDGFRβ IC50 19.4nM, cKit IC50 383nM, FLT3 IC50 555 nM and CSF1R IC50 1062nM. In-vitro MDCKII transfected cell assays demonstrated WSD1227 is not a substrate of P-gp or BCRP, two main efflux transporters on human BBB. Preclinical CNS PK studies confirmed brain penetration of WSD1227 with Kp,uu,brain close to unity, thus not exacerbating VEGF related systemic toxicities. WSD1227 possessed superior PK profile with sufficient free PK exposure to achieve target engagement in mice. Treatment of tumor bearing mice in GBM, NSCLC, CRC and OC xenograft models with WSD1227 resulted in significant tumor growth inhibition. Predicted human PK properties are very promising to offer sufficient target engagement in clinic. Taken together, our data provide a good rationale for WSD1227 to be developed toward clinic to investigate antiangiogenetic therapies for management of patients with primary or metastatic brain tumors.

6036. Zhang, J., et al. (2019). "Wsd1227: A bbb penetrable vegfr small molecule for the treatment of primary and metastatic brain tumors." Cancer Research **79**(13).

Anti-angiogenesis has been proved to be a good strategy for cancer treatment (such as in GBM, NSCLC, mBC, CRC, OC, etc.) with satisfactory performance to extracranial lesions, but not in intracranial lesions. Insufficient penetration across BBB could be one of factors limiting intracranial activity for those approved anti-VEGF agents. There is a need to develop a BBB penetrable VEGFR inhibitor to clinic to assess the efficacy and safety. Here we report that WSD1227, a novel, selective VEGFR inhibitor, displays potent activity, excellent CNS penetration and preclinical safety and efficacy. The IC of WSD1227 against VEGFR1/2/3 at 0.69/0.35/0.41nM versus against other targets such as PDGFR IC 22.9nM, PDGFR IC 19.4nM, cKit IC 383nM, FLT3 IC 555 nM and CSF1R IC 1062nM. WSD1227 treatment resulted in significant anti-tumor activity in VEGF related extracranial and intracranial mice models, with superior efficacy than bevacizumab. There is no increased risk of CNS hemorrhage in intracranial tumor bearing mice treated with WSD1227. In addition, WSD1227 is predicted to be CNS penetrable with decent PK in human. Taken together, our data provide a good rationale for WSD1227 to be developed toward clinic to investigate anti-angiogenetic therapies for management of patients with primary or metastatic brain tumors.

6037. Zhang, J. L., et al. (2021). "Research progress in the systemic treatment for breast cancer with brain metastasis." Journal of Shanghai Jiaotong University (Medical Science) **41**(5): 671-677.

Breast cancer is one of the most common malignancies in women. Brain metastases occur in approximately 10%-20% of patients with advanced breast cancer. In recent years, with the rapid progress of systemic treatment, extracranial lesions have been effectively controlled and the survival time of patients with breast cancer have been prolonged. Thus the possibility of developing brain metastases has been increased. Moreover, advances in modern diagnostic imaging technology and the routine surveillance of cancer patients have increased the detection rate of brain lesions. Based on the above two aspects, the breast cancer brain metastases (BCBM) have become increasingly common in the clinical settings. Because many chemotherapeutic drugs can not penetrate the blood-brain barrier, the patients with brain metastases have less treatment options, worse survival outcomes and lower quality of life. This article focuses on the recent advances in systemic treatment for BCBM, aiming to provide reference for basic research and clinical practices of this disease.

6038. Zhang, L., et al. (2020). "Abdominal skin inflammation as an initial symptom of a perforating gastric foreign body: A case report." Medicine **99**(40): e22534.

RATIONALE: Foreign bodies are frequently ingested, but only approximately 1% of them cause perforation. Perforations in the lesser curvature of the stomach are exceedingly rare. Here, we report a case of gastric perforation in the lesser curvature caused by a foreign body. The patient presented to the clinic complaining of abdominal skin swelling and reddening with upper abdominal discomfort as the initial symptoms., PATIENT CONCERNS: An 83-year-old female presented with a mass in the middle of the epigastrium for 10 days. Physical examination found an apparent local tenderness and inflammatory mass in the upper abdominal wall. Her body temperature was normal (37.5degreeC) and the white blood cell count was elevated (8.12 x 10/L [reference value 3.5-9.5 x 10/L])., DIAGNOSES: The ultrasound examination of the abdomen revealed a 4 cm strip-like hyperechoic object entangled in the muscles of the abdominal wall. The computed tomography scan revealed a thin strip of bone-like hyperdense shadow. Intraoperative findings showed a sharp fishbone protruding from the lesser curvature of the stomach into the abdominal cavity, part of which remained in the gastric cavity. The postoperative pathological report revealed chronic suppurative inflammation with abscess and sinus canal formation., INTERVENTIONS & OUTCOMES: The patient underwent a gastric foreign body removal with partial gastrectomy. Anti-inflammatory treatment post-surgery rapidly relieved the patient's symptoms of discomfort in the upper abdomen. At the 1-month follow-up, the patient showed no discomfort in the upper abdomen and the inflammatory mass was no longer present., LESSONS: A foreign body had penetrated through the lesser curvature of the stomach, an area with a flat gastric wall, which occurs infrequently. In such cases, computed tomography is the gold standard for diagnosis of foreign bodies in the digestive tract. Ultrasound can also be used as a supplemental diagnostic technique. It is recommended that people who wear dentures should exercise caution while eating, especially when the food contains bones.

6039. Zhang, L., et al. (2017). "Development of crash induced injury criteria for predicting brain injuries using a human head computer model." Journal of neurotrauma **34**(13): A32-A33.

Finite element (FE) modelling can serve as a powerful tool to study biomechanical process of head and brain injuries that is difficult to investigate experimentally on living human subjects. Recently, a detailed human head model, GHBMC (Global Human Body Modelling Consortium) M50, representing a 50th percentile male adult head has been developed, validated and used to develop tissue level injury criteria for TBI. The objective of this study was to validate a detailed GHBMC 5th percentile female (F05) head model which accounts for gender related size, geometrical and anatomical differences in order to properly predict injury risk sustained by this population. A number of Crash Induced Injury (CII) criteria for injuries to the skull, face, and brain of various regions were developed to enable the prediction of the injury risk by the model. Thirty-one sets of published cadaveric head impact experimental data were simulated to validate the biomechanical response of the head model in terms of force-deflection for various facial and cranial bones, intracranial pressure and brain/skull relative displacement for brain of various regions. Then, Forty-four sets of head impact experiments with injurious and non-injurious conditions were simulated to develop CII values for skull fracture, facial fracture, acute subdural hematoma (ASDH), cerebral contusion, and diffuse axonal injury (DAI) at various white matter structures/regions and their associated severities. Model predicted biomechanical responses correlated well to the experimentally measured results with objective ratings greater than 0.7 (1 being perfect). The current GHBMC F05 head model has been rigorously validated against all exiting data head impact experiments and responses. The current model is capable of predicting six different head injury types affecting nine regions/locations with reasonable predictive capability. With further improvement and exercises, the human head model can enable assessment of possible real-world injury scenarios to understand the injury mechanisms and allow for engineering improvements to help prevent potential head/brain injury from traumatic events.

6040. Zhang, L., et al. (2019). "Validation of the strain response in the brain: Recent update of the ghbmc M50 head model." Journal of neurotrauma **36**(13): A38-A39.

A number of finite element (FE) head models have been developed to improve the prediction of traumatic brain injury. Development of brain injury criteria requires a FE head model that has detailed anatomical and material representation of a human head and robust performance under various impact conditions. The GHBMC M50 head model introduced in 2013 has been validated against various cadaveric impact data. The model has the capability of predicting skull and facial fractures, contusion, diffuse axonal injury and acute subdural hematoma. The current study reports the new validation study against available cadaveric brain strain data and optimized brain tissue properties for improving the biofidelity. In cadaver tests, the maximum principal strain (MPS) was calculated from 12-triads formed by a cluster of 7 radio-opaque targets implanted in the brain. All 8 cadaver impact tests were simulate. The head model

predicted node displacements at the NDT locations were used to calculate the model MPS results. The viscoelastic properties of brain tissues were optimized to improve the correlation. The head model predicted MPS in the brain was 0.05-0.10 while as the cadaver MPS was 0.04-0.09. The overall temporal responses of the model MPS matched to most of the cadaveric responses except for a couple of cases where presumably the deviation of the node locations in the FE model compared to the target locations in the cadaver brain could affect the displacement results, subsequently the strain calculation. The average objective CORA rating was 0.52. It exceeded the CORA results reported by another group using a different head model recently. The current GHBMC M50 head model version 5 has been validated against localized strain responses in the brain according to the newly available data obtained from cadaveric head impact tests. The material properties of the viscoelastic brain tissues defined for the model have been optimized to mimic the material behaviors under relevant impact conditions. This enhancement will add the improved capability to the current model in predicting tissue-strain mediated brain injury.

6041. Zhang, M., et al. (2019). "Combined penetrating trauma of the head, neck, chest, abdomen and scrotum caused by falling from a high altitude: A case report and literature review." International emergency nursing **44**: 1-7.

This report describes an extremely rare case of combined penetrating trauma that includes the head, neck, chest, abdomen and scrotum. A 46-year-old male construction worker fell from a 5-metre-high platform, and a rebar that was fixed vertically on the ground penetrated the scrotum into the pelvic and abdominal cavities, passing through the chest, neck, mouth, and nose to the outside of the body through the left side of the head. The rebar penetrated the oral cavity and was palpable on the anterior side of the neck and abdomen. The head, neck, chest and abdominal CT scan and reconstruction showed brain contusion, fractures of the skull and skull base, subarachnoid haemorrhage, palate injury, tongue injury, injury to the right lobe of the thyroid, pleural effusion, pulmonary contusion, cardiac contusion, injury to the left lobe of the lung, neck and mediastinal emphysema, and pneumothorax. Emergency green channels provide a rescue process for urgent and severe cases and smooth and timely diagnostic and treatment process to save patients' lives. The medical staff worked together as a team for the initial evaluation and rescue. Emergency nurses played an important role in communicating, cooperating, managing insulation and pain, and providing psychological counselling, which greatly enhanced the efficiency and quality of the nursing. After the patient underwent surgery, anti-infection treatment, sedatives, analgesics, nutritional therapy, psychological support, and other intensive treatment measures, he recovered well two months after the injury. Follow-up at 5 and 11months after discharge showed good recovery.

6043. Zhang, X.-Y. and Y.-M. Yang (2016). "Scissors stab wound to the cervical spinal cord at the craniocervical junction." The spine journal : official journal of the North American Spine Society **16**(6): e403-406.

BACKGROUND CONTEXT: Stab wounds resulting in spinal cord injury of the craniocervical junction are rare. A scissors stab wound to the cervical spinal cord has been reported only once in the literature., PURPOSE: This paper aimed to report a case of Brown-Sequard-plus syndrome in an 8-year-old boy secondary to a scissors stab wound at the craniocervical junction., STUDY DESIGN: Case report and review of the literature., PATIENT SAMPLE: Case report of an 8-year-old boy accidentally stabbed in the neck by scissors, which were thrown as a dart., METHODS: The case study of an 8-year-old boy who was hospitalized because of a scissors stab wound at the craniocervical junction. The patient developed Brown-Sequard-plus syndrome on the left side of the body. Magnetic resonance imaging revealed a laceration of the spinal cord at the craniocervical junction with cerebrospinal fluid leakage. Careful cleansing and interrupted sutures of the wounds were performed to prevent cerebrospinal fluid leakage. Rehabilitation therapy was performed 2 days later., RESULTS: A follow-up examination revealed complete recovery of the neurologic deficit 8 months post-injury., CONCLUSION: Treatment of scissors stab wounds to the cervical spinal cord, whether conservative management or thorough surgical exploration, should be individualized based on history, examination, and imaging. As shown in this case report, despite conservative management, complete recovery, which was unexpected, was attributed to the initial mild laceration of the spinal cord and ipsilateral spinal cord functional compensation.

6044. Zhang, Y. P., et al. (2014). "Traumatic brain injury using mouse models." Translational stroke research **5**(4): 454-471.

The use of mouse models in traumatic brain injury (TBI) has several advantages compared to other animal models including low cost of breeding, easy maintenance, and innovative technology to create genetically modified strains. Studies using knockout and transgenic mice demonstrating functional gain or loss of molecules provide insight into basic mechanisms of TBI. Mouse models provide powerful tools to screen for putative therapeutic targets in TBI. This article reviews currently available mouse models that replicate several clinical features of TBI such as closed head injuries (CHI), penetrating head injuries, and a combination of both. CHI may be caused by direct trauma creating cerebral concussion or contusion. Sudden acceleration-deceleration injuries of the head without direct trauma may also cause intracranial injury by the transmission of shock waves to the brain. Recapitulation of temporary cavities that are induced by high-velocity penetrating objects in the mouse brain are difficult to produce, but slow brain penetration injuries in mice are reviewed. Synergistic damaging effects on the brain following systemic complications are also described. Advantages and disadvantages of CHI mouse models induced by weight drop, fluid percussion, and controlled cortical impact injuries are compared. Differences in the anatomy, biomechanics, and behavioral evaluations between mice and humans are discussed. Although the use of mouse models for TBI research is promising, further development of these techniques is warranted.

6045. Zhao, Y. F., et al. (2011). "A rare case of a glass fragment impacted in the parapharyngeal space associated with neurovascular compromise." International journal of oral and maxillofacial surgery **40**(2): 209-211.

It is rare for foreign bodies to be found in the parapharyngeal space due to the protection of the mandibular ramus and zygomatic bone. The authors describe a rare case of a patient with an unusual penetrating neck injury caused by broken windshield glass in a traffic accident, which lodged in the parapharyngeal space and punctured the internal jugular vein and cranial nerves. 3 weeks later, a delayed exploration was performed on the patient after detailed evaluation of the relationship between the foreign body and the great vessels. The authors removed the glass fragment easily with no active bleeding because it had been surrounded by a fibrous envelope. This experience indicates that increasing the duration of foreign body retention in the parapharyngeal space may be helpful, allowing fibrosis to surround the foreign body, reducing the risk of active bleeding when it is removed.

6046. Zhdanova, D., et al. (2022). "Intranasal Administration of Microvesicles in the Brain of Mice with Induced Model of Alzheimer's Type of Neurodegeneration." BioNanoScience **12**(2): 685-692.

Despite significant advances in modern medicine, effective therapeutics for Alzheimer's disease (AD) treatment have not yet been found. Currently, the use of exosomes and microvesicles derived from mesenchymal stem cells (MSCs) has begun to be considered as one of the promising approaches to the therapy of this disease. Exosomes and microvesicles in comparison with MSCs have significant benefits such as nanometric size, inability to divide, lack of risks of immunogenicity, malignant transformation, and thrombosis. In this work, cytochalasin B–induced membrane vesicles (CIMVs) from MSCs isolated from the adipose tissue were obtained and characterized, and the possibility of their penetration into the brain after intranasal administration was studied. Preliminarily, MSCs were transduced with the recombinant replication-deficient lentivirus containing RFP gene. The study was carried out on a model of sporadic AD in olfactory bulbectomized (OBX) mice, demonstrating behavioral, biochemical, and morphological signs of neurodegenerative process of the Alzheimer's type. Four hours after intranasal administration, presence of vesicles containing the fluorescent protein RFP was observed in the hippocampus and neocortex of OBX mice, i.e., in the brain areas most vulnerable to AD. It is assumed that microvesicles administrated intranasally can act as nanocontainers for target delivery of biologically active compounds present in MSCs, or even drugs to the brain regions affected by neurodegeneration, and are a promising therapeutic agent for the treatment of AD.

6047. Zheng, H. X., et al. (2021). "Iatrogenic pseudoaneurysm of the superficial temporal artery following craniectomy from a scalp hook retractor penetrating injury: Case report and literature review." International journal of surgery case reports **84**.

Background: Iatrogenic pseudoaneurysms in scalp vessels are an uncommon complication after cranial surgery. This paper reports a case of scalp pseudoaneurysm in the superficial temporal artery (STA) after forceful hook retraction

in craniectomy and reviews the relevant literature. Case description: A 36-year-old man with history of hypertension and depression presented to the emergency department with head injury after using sedation medication. Brain computed tomography (CT) revealed a 2-cm-thick right parietal extradural hematoma (EDH) with parietal skull fracture, a bilateral lower frontotemporal contusional intracerebral hematoma, diffuse subarachnoid hemorrhage, and a right frontotemporoparietal subdural hematoma. To prevent EDH progression, frontotemporal emergency craniectomy to remove the EDH was performed. The next day, a firm, painful mass measuring 3 × 3.5 cm2 was discovered over the right frontal scalp. The mass was close to the site where the scalp hook retractor had been placed during surgery. Sonography revealed pulsatile blood flow with an arterial feeder inside the mass. CT angiography revealed a 1 × 1.2 × 0.7 cm3 pseudoaneurysm in the right frontal scalp from the frontal branch of the STA. We scheduled a resection of the pseudoaneurysm and combined cranioplasty on the 29th postoperative day. The pseudoaneurysm was resected en bloc. The patient was discharged with clear consciousness and intact muscle power. Conclusion: The complications of STA pseudoaneurysms caused by scalp hook retractors are rare and not yet well reported. Surgeons must avoid injuring the STA when using a scalp hook retractor.

6048. Zheng, M., et al. (2012). "Nature's pharmacy: Eburnamonine and its derivative as therapeutics against brain tumors." Cancer Research **72**(8).

Brain tumors are highly aggressive and often afflict younger patients. In 2011 there were 22,340 estimated new cases of brain tumors in the United States with 40% arising from metastatic lesions originating mostly from lung, breast, and melanoma tumors. Treatment options remain limited and include steroids, whole brain radiation, and surgery. Because of difficulty penetrating the blood-brain barrier (BBB), chemotherapy is usually not a viable option. Therefore, any intervention that can block the malignant colonization of the brain and/or eliminate symptomatic and occult brain lesions will significantly improve both quality of life and survival. To target brain tumors, a successful therapy has to meet the following criteria: 1) penetrate the BBB; 2) exhibit specificity for the tumor cells; and 3) have minimal off-target effects. Here we investigate a Periwinkle minor derived natural product, eburnamonine (EBN), and its structural analog, 15-methylene-(-)-eburnamonine (15-M-EBN), as therapeutic agents against brain lesions from glioblastoma multiforme and metastatic breast cancer. The two common subtypes of breast tumors giving rise to brain metastases are triple negative and Her2 positive primary tumors. Potency of EBN and 15-M-EBN was evaluated in cultures of chemosensitive (U87) and chemoresistant (SF767) glioma cell lines and 'brain-seeking' metastatic breast cancer cells, MDA-MB-231BR (triple negative) and MDA-MB-231BR-Her2 (Her2 positive). To test whether our compounds can overcome the environment-mediated drug resistance (EM-DR) cells were treated in the context of extracellular matrix (ECM) (hyaluronic acid, collagen IV/laminin, and collagens I and IV/laminin/fibronectin to reconstruct the brain, mammary gland, and bone marrow microenvironments respectively). The off-target toxicity of EBN and 15-M-EBN was tested on normal neuronal cells, bone marrow stromal cells, and non-malignant mammary epithelial cells. To evaluate the capacity of EBN and 15-M-EBN to penetrate the BBB, we utilized a transwell model with hCMEC/D3 cell monolayer mimicking the BBB. We demonstrate that EBN and 15-M-EBN are cytotoxic against glioma and 'brain-seeking' metastatic breast cancer cells (LC50=42 micromolar and 14 micromolar respectively) with minimal toxicity against non-malignant cells. Moreover, 15-M-EBN is active in the tumor environment and predicted to cross the BBB and have anti-cancer stem cell activity. Our preclinical data establish that 15-M-EBN meets the major criteria for a successful therapeutic agent to target brain lesions, both primary and metastatic, due to its ability to: 1) exhibit specificity for the tumor cells; 2) have minimal neurotoxicity and off-target effects; and 3) penetrate the BBB. In vivo studies are in progress to establish a pro-drug strategy to increase water solubility and bioavailability of 15-M-EBN for further clinical development.

6049. Zhong, W., et al. (2017). "Biological and cognitive underpinnings of religious fundamentalism." Neuropsychologia **100**: 18-25.

Beliefs profoundly affect people's lives, but their cognitive and neural pathways are poorly understood. Although previous research has identified the ventromedial prefrontal cortex (vmPFC) as critical to representing religious beliefs, the means by which vmPFC enables religious belief is uncertain. We hypothesized that the vmPFC represents diverse religious beliefs and that a vmPFC lesion would be associated with religious fundamentalism, or the narrowing of religious beliefs. To test this prediction, we assessed religious adherence with a widely-used religious fundamentalism scale in a large sample of 119 patients with penetrating traumatic brain injury (pTBI). If the vmPFC is crucial to modulating diverse personal religious beliefs, we predicted that pTBI patients with lesions to the vmPFC would exhibit greater fundamentalism, and that this would be modulated by cognitive flexibility and trait openness. Instead,

we found that participants with dorsolateral prefrontal cortex (dlPFC) lesions have fundamentalist beliefs similar to patients with vmPFC lesions and that the effect of a dlPFC lesion on fundamentalism was significantly mediated by decreased cognitive flexibility and openness. These findings indicate that cognitive flexibility and openness are necessary for flexible and adaptive religious commitment, and that such diversity of religious thought is dependent on dlPFC functionality.

6050. Zhou, J., et al. (2012). "Hydrogen-rich saline reverses oxidative stress, cognitive impairment, and mortality in rats submitted to sepsis by cecal ligation and puncture." The Journal of surgical research **178**(1): 390-400.

BACKGROUND: Sepsis is associated with high morbidity and mortality, and survivors can present with cognitive dysfunction. The present study was performed to investigate the effects of hydrogen-rich saline (HRS) on oxidative stress in the brain, cognitive dysfunction, and mortality in a rat model of sepsis., METHODS: A rat model of sepsis was induced by cecal ligation and puncture. Physiologic saline or HRS was administered intraperitoneally (2.5 mL/kg or 10 mL/kg) 10 min before the operation. The survival rate was recorded, and cognitive function was tested using the Morris water maze. The reactive oxygen species and malondialdehyde levels and superoxide dismutase activity in the hippocampus were observed to evaluate the oxidative stress levels. The caspase 3 levels were measured to detect apoptosis. The histopathologic changes in the hippocampus were evaluated by hematoxylin-eosin staining and the terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate nick end labeling assay., RESULTS: Cecal ligation and puncture resulted in a poor survival rate, evidence of brain injury, and cognitive dysfunction. The hippocampal reactive oxygen species and malondialdehyde levels increased significantly, and superoxide dismutase activity decreased significantly. HRS reversed these changes in a dose-dependent manner., CONCLUSIONS: These findings indicate that HRS could attenuate the consequences of sepsis induced by cecal ligation and puncture in rats, at least in part, by the inhibition of oxidative stress.

6051. Zhou, L., et al. (2014). "Phase 1 trial of icotinib combined with whole-brain radiation therapy for EGFR-mutated non-small cell lung cancer patients with brain metastases: Updated results." International Journal of Radiation Oncology Biology Physics **90**(5): S38-S39.

Purpose/Objective(s): Icotinib has been demonstrated to provide similar efficacy to gefitinib in non-small cell lung cancer (NSCLC) patients. This phase 1 trial (NCT01516983) evaluated the dose-escalation toxicities of icotinib combined with whole brain radiation therapy (WBRT) in EGFRmutated NSCLC patients with brain metastases, and cerebrospinal fluid (CSF) penetration rates of icotinib were assessed in the dose-escalation. Materials/Methods: The cohorts were constructed with a 3 + 3 design, and the dose-escalation schedule of icotinib was set as 125 mg tid, 250 mg tid, 375 mg tid, 500 mg tid, and 625 mg tid. Icotinib was started 7 days before and continued during WBRT (37.5 Gy/15 f/21 d), and maintained until disease progression or intolerable toxicities occurred. The blood and CSF samples were obtained on day 7 (before WBRT), day 29 (after WBRT), and day 57 of therapy. Neurocognitive function (NCF) was assessed with Mini-Mental Status Examination. Results: Fifteen patients were enrolled in this trial. The most frequent treatment-related toxicities were grade 1-2 alopecia (15/15), acne-like rash (14/15) and nausea (11/15). At dose level of 500 mg tid, 3 out of 6 patients experienced dose-limiting toxicity including 1 grade 3 alanine aminotransferase elevation and 2 grade 3 nausea. The mean CSF penetration rate of icotinib was 4.04% (range: 1.23%-9.71%), and there was a good correlation between plasma and CSF concentrations (R2=0.577, P<.001). There were no statistical differences in plasma concentrations, CSF concentrations, and penetration rates of icotinib between day 7, day 29, and day 57. However, CSF concentration (154.09 ng/mL, P<.001) and penetration rate (7.06%, P<.001) of icotinib were much higher at dose of 375 mg tid. After the median follow-up time of 56 weeks, the overall response rate (ORR), disease control rate (DCR) and median progress free survival (PFS) were 80%, 100%, and 46 weeks (95% CI: 43-49 weeks), corresponding to 80%, 100%, and 78 weeks (95% CI: 20.4-123.6 weeks) of intracranial lesions. There were no statistical differences in NCF of patients in low-dose group (125 mg tid-250 mg tid) and high-dose group (375 mg tid-500 mg tid) within 20 weeks of treatment. Moreover, compared to baseline, there were no significant differences in NCF of patients within 20 weeks either. Conclusions: WBRT with concurrent and maintenance icotinib (125 mg tid-375 mg tid) were tolerable and efficient in EGFR-mutated NSCLC patients with brain metastases. WBRT might not increase penetration rate of icotinib, and there were the highest CSF concentration and penetration rate at dose of 375 mg tid. Within 20 weeks of treatment, there was no neurocognitive function deterioration observed in this trail.

6052. Zhou, S., et al. (1998). "Experimental study on firearm wound in maxillofacial region." Chinese medical journal **111**(2): 114-117.

OBJECTIVE: To make clear the range of firearm wound in the maxillofacial region, the optical repair time and the characteristics of accompanied indirect brain damage, and to offer the principle of emergency treatment and the early repair of war wound., METHODS: With the aid of the standard Sweden model, 200 dogs were used in the experiment. Varies tissues around the primary canal were harvested chronologically, in different zone and different tissue, for histopathological examination., RESULTS: The necrotic range of various tissues in the maxillofacial region was less than that in the extremities. In the maxillofacial region, there was a significant temporary cavity following the passing of bullet, which caused indirect brain damages., CONCLUSION: These findings are helpful to the treatment of war wound in the maxillofacial region. Early bone transplantation using microvascular anastomosis in the treatment of gunshot wound in the maxillofacial region is recommendable.

6053. Zhou, S. W., et al. (2019). "Traumatic Globe Luxation With Chiasmal Avulsion." Journal of neuro-ophthalmology : the official journal of the North American Neuro-Ophthalmology Society **39**(1): 41-43.

BACKGROUND: To describe an unusual case of traumatic globe luxation with optic chiasmal avulsion and review the existing literature on this rare condition for further discussion of mechanisms, diagnosis, and management., METHODS: Case report and review of existing case reports and case series identified through literature search., RESULTS: A 28-year-old woman, with no previous medical history, had left globe luxation and optic chiasm avulsion after being stabbed directly into the left orbit with the use of the stiletto high heel of a shoe. Automated visual field testing detected a temporal hemianopia in the unaffected eye despite normal central visual acuity. Chiasmal avulsion was demonstrated by MRI., CONCLUSIONS: This case suggests that perimetry and MRI should always be considered in traumatic globe luxation to localize the site of injury. Temporal hemianopia in the fellow eye indicates a concomitant chiasmal injury.

6054. Zhou, X.-b., et al. (2013). "Vitreoretinal surgery combined with C-arm fluoroscopic-guided removal of intraorbital foreign body following ocular perforating injury." Chinese medical journal **126**(15): 2993-2995.

6055. Zhou, Z., et al. (2011). "Penetrating injury of rectum and vertebral body by steel bar causing cauda equina syndrome." Spine **36**(12): E803-807.

STUDY DESIGN: Case report., OBJECTIVE: To report an extremely rare case of combined penetrating injury to rectum and vertebral body by steel bar causing cauda equina syndrome., SUMMARY OF BACKGROUND DATA: Only one similar case has been reported. Our case was more severe and posed more challenges to physicians., METHODS: A 37-year-old male had a penetrating rectal injury by a long steel bar as a result of a falling accident. He was firstly treated with removal of the bar, debridement, and fecal diversion. Spine and cauda equina injuries were found the second day by lumbar and sacral CT. Because of infection after the first surgery, decompressive surgery was performed 2 months from injury. Cerebrospinal fluid fistula happened on the 12th day after surgery which was managed by debridement, irrigation and drainage, suture of the leaking skin and combined use of antibiotics., RESULTS: When being discharged, he could ambulate independently but could not control his voiding. The colostomy and urinary canal was preserved during the follow-up., CONCLUSION: Steel bar penetrating injury of rectum and vertebral body can be severe and cause complex injuries. Complications included infection and cerebrospinal fluid fistula. Thorough history and physical examination and CT and MRI inspection are very important for timely diagnosis and early treatment of spine and cauda equina injuries. Dural tear should be carefully inspected and repaired during posterior lumbar decompression surgery. Cooperation of experienced surgeons from orthopedics and gastrointestinal department is needed to give the patient the most appropriate treatment and improve prognosis.

6056. Zhu, H.-s., et al. (2004). "[Pathological changes of cat brain tissues after cranial gunshot wound in hot and humid environment]." Di 1 jun yi da xue xue bao = Academic journal of the first medical college of PLA **24**(7): 761-764.

OBJECTIVE: To investigate pathological changes in cat brain tissues after gunshot wound in the head in hot and humid environments., METHODS: Sixteen cats were randomly divided into 4 groups, namely the normal environment (group 1), gunshot in normal environment (group 2), hot and humid environment (group 3), and gunshot wound in hot

and humid environment (group 4) groups. Pathological changes of the cat brain tissues were observed with both optical and electron microscopes., RESULTS: The early-stage changes in group 2 were high-lighted by vasomotor dysfunction, with the coexistence of both vascular spasm and dilation. In group 3, vascular spasm was depressed while hemorrhagic changes increased. On the brain tissue sections in group 4 for optical microscopic observation and ultra-thin sections for electron microscopic examination, the number of viable neural cells was obviously reduced, and edema, degeneration of the organelle occurred; loosening of the capillary tight junction, rupture and bleeding of the blood vessels, as well as degeneration and loosening of the myelin sheath were observed by transmission and scanning electron microscopes, and such changes were more serious than those in group 2., CONCLUSION: The hot and humid environment can significantly affect the pathological changes in the brain tissues of cat with cranial gunshot wound.

6057. Zhu, R., et al. (2018). "Case report: Management of intracranial nail gun injury." Journal of neurotrauma **35**(16): A268-A269.

Background: Penetrating nail gun injury to the head is an extremely rare mechanism of neurotrauma with relatively low mortality and morbidity as compared to other high-velocity trauma modalities. Due to its rare occurrence, other concomitant injuries and clinical judgment of the neurosurgeon direct immediate and ongoing surgical/ medical management. Case Presentation: A 30-year-old man with recently initiated antidepressant therapy walked into the emergency department with his wife after an apparent suicide attempt. The mechanism of injury was firing a single nail from a pneumatic nail gun directed at his left temple, prompting trauma team activation. He denied the loss of consciousness or other trauma. He was hemodynamically stable and neurologically intact, able to recall all events preceding and following the injury, and moving all extremities with a Glasgow coma scale of 15. Secondary survey was significant for left frontal temporal penetrating head wound without an associated contralateral exit wound. Computed tomography of the brain shows a 6.3cm nail in the right frontal region without major intracerebral vessel disruption. The neurosurgery team took the patient to the operating room for left temporal wound washout, debridement of gross contamination, and closure with titanium cranial fixation plate. The foreign body was not accessible on initial surgical intervention; instead left in place to define the anatomy and plan for subsequent removal. The neurosurgery team used thin-slice computed tomography to create 3D reconstructions and stereotactic navigation techniques for subsequent right craniotomy and foreign body removal on hospital day two. The patient tolerated the procedures well and recovered with full neurologic function. Based on the extensive wound contamination on initial presentation, infectious disease recommended broad-spectrum antibiotics for 4 weeks postoperatively. Conclusion Limited guidance exists for management of low velocity penetrating cranial injuries. Care providers should direct attention to determining if there is a need for emergent surgery. Literature review suggests care teams pursue immediate surgical exploration for removal of gross contamination and control of hemorrhage. Foreign body removal is left to the clinical judgment of the neurosurgeon, and initiation of broad-spectrum antibiotic therapy is advisable as soon as possible after recognizing such injuries.

6058. Zhu, R. C., et al. (2021). "Treatment of a self-inflicted intracranial nail gun injury." BMJ case reports **14**(1).

A 30-year-old man walked into the emergency department after a suicide attempt by firing a nail from a pneumatic nail gun directed at his left temple. He was haemodynamically stable and neurologically intact, able to recall all events and moving all extremities with a Glascow Coma Scale of 15. CT of the brain showed a 6.3 cm nail in the right frontal region without major intracerebral vessel disruption. He was taken to the operating room for left temporal wound washout, debridement of gross contamination and closure with titanium cranial fixation plate. The foreign body was not accessible on initial surgical intervention and was left in place to define anatomy and plan for subsequent removal. Thin slice CT images were used to create 3D reconstructions to facilitate stereotactic navigation and foreign body removal via right craniotomy the following day. The patient tolerated the procedures well and recovered with full neurological function.

6059. Zhu, W., et al. (2003). "Different glial reactions to hippocampal stab wounds in young adult and aged rats." The journals of gerontology. Series A, Biological sciences and medical sciences **58**(2): 117-122.

Brain injury induces reactive gliosis. To examine the activation of glial cells after brain injury in young versus aged rats, we used a brain stab-wound model and examined the expression of cells positive for ED1 (ED1(+)) and glial

fibrillary acidic protein (GFAP(+)) in the hippocampus in young-mature (3 months) and aged (25 months) Wistar rats at various times following hippocampal stab injury. ED1(+) cells appeared more frequently in the aged rats than in the young-mature rats under control conditions, whereas the number of GFAP(+) cells was not different between two groups. Following the stab wound, there was an increase in ED1 expression that was delayed but stronger in the aged rats and that persisted longer; the increase of the number of GFAP(+) cells also persisted longer. We conclude that different glial reactivity in the aged brain suggests that aging is associated with increased glial responsiveness that may enhance susceptibility to injury and disease in the brain.

6060. Zhu, X., et al. (2003). "[The clinical study of 1,267 cases therapeutic keratoplasty using donor corneal grafts in long-time preservation with dehydrated]." Yan ke xue bao = Eye science **19**(2): 110-113.

PURPOSE: To evaluate its effects of 1,267 cases therapeutic keratoplasty using donor corneal grafts in long-time preservation with dehydrated., METHODS: The long-time preservated donor corneal grafts came from Xi'an Eye Bank, they accorded with the clinical demands. To select 1,267 cases therapeutic keratoplasty in August 1976 to December 1999, and make an analysis of preoperation and postoperation visual contrast, original focus controlling, donor corneal graft reviviscence., RESULT: The transparent rate of donor corneal grafts after preservation was 94.9%, the clinical cure rate: Infective corneal ulcer/perforation 88.8%, pannus totalis and corneal opacity 98.3%, chemical burn and heat burn (perforation corneoblepharon) 92.1%, keratoconus and acute keratoconus 99.5%, corneal degeneration(marginal shallow of stroma) 99.0%, other cases 88.9%, mean all effective rate 93.5%., CONCLUSION: 1. For the treatment of serious corneal infection, and cases which poorly respond to medicine, therapeutic keratoplasty may be the only effective method. 2.Long-time corneal dehydration in water-free calcium chloride-silica gel may provide clinical supply of corneal materials whenever necessary, so it is an easy and simple, highly applicable method.

6061. Zhuo, L., et al. (2009). "[Application of confocal laser scanning microscope in forensic pathology]." Fa yi xue za zhi **25**(6): 455-458.

Confocal laser scanning microscopy(CLSM) is a new technique for microscopic imaging, which can collect the transverse section image of the samples and produce three-dimensional reconstruction and present higher spatial resolution than the conventional light microscope. As a precision instrument for the microscopic image, it plays an important role in forensic pathology. The article reviews the recent research achievements from sudden cardiac death, bullet wound and nervous system damage, etc, and explores the potential applications of the forensic pathology research and forensic practice.

6062. Zide, M. F. and B. N. Epker (1979). "Short-range shotgun wounds to the face." Journal of oral surgery (American Dental Association : 1965) **37**(5): 319-330.

To efficiently treat short-range shotgun wounds to the face, it is imperative to have a basic understanding of the causes, pathogenesis, probable extent of initial injury, primary treatment principles, and secondary reconstruction problems associated with these injuries. This paper deals with these basic principles in an attempt to provide a guide to the treatment of these devastating injuries.

6063. Zilinskiene, L., et al. (2014). "Emergency radiology: Maxillofacial and skull-base trauma." Trauma (United Kingdom) **16**(4): 243-255.

Craniofacial trauma is common following road-traffic accidents, assaults and falls and may occur in isolation or associated with other body injuries. Due to the complexity of the maxillofacial and skull-base region, initial diagnosis may be inaccurate or delayed, leading to significant morbidity. Multidetector computed tomography is the modality of choice following high-energy blunt or penetrating trauma. It allows accurate evaluation of the fracture patterns and associated soft tissue complications and aids the appropriate medical and surgical treatment. In this article, we review and classify the most common traumatic injuries to the maxillofacial and skull-base region and outline the role of imaging in establishing complications and prognosis.

6064. Zimmer, J., et al. (1979). "Orbital gunshot wound causing a carotid-cavernous fistula and ipsilateral occlusion of the internal carotid artery: case report." Military medicine **144**(7): 485-486.

6065. Zingg, S., et al. (2021). "Evolving critical care air transport team operations within Afghanistan." Critical care medicine **49**(1 SUPPL 1): 676.

INTRODUCTION: The United States Air Force Critical Care Air Transport Teams (CCATTs) are flying more unregulated missions in Afghanistan as a result of military force drawdown. Due to situational urgency, an unregulated mission cannot undergo pre-flight validation by a flight surgeon, and initial patient data is incomplete. This hinders CCATTs' ability to formulate a specific pre-flight care plan. Understanding CCATT mission details within Afghanistan may inform CCATT readiness training and prepare providers for these ill-defined missions. METHODS: Data was obtained from all 2017-2019 patient records stored in the Tactical Critical Care Evacuation Team database, which is maintained by the United States Air Force 59th Medical Wing Pilot Unit. RESULTS: The database records included 148 patients transferred via 70 unregulated and 66 regulated missions. The median age was 30 years, and 97% of the patients were male. In total, 87.6% suffered a traumatic injury, the majority of which were caused by gunshot wounds (39.3%) and improvised explosive devices (35.1%). Common injuries included soft tissue (48.0%), orthopedic (36.5%), and traumatic brain (33.1%) injuries. In-flight interventions involved maintaining mechanical ventilation (57.4%), as well as the administration of blood products (16.2%), paralytics (17.6%), vasopressors (18.2%), and sedation (64.2%). En route complications including hypothermia (2.7%), hypotension (6.1%), and hypoxia (2.7%) were not common. Significant ($p<0.05$) differences between the treatments provided during regulated and unregulated missions were identified for vasopressors (26% vs. 7%), propofol (50% vs. 27%), fentanyl (59% vs. 37%), and mechanical ventilation (68% vs. 44%). The unregulated missions were shorter, lasting an average of 30 min vs. 60 min for regulated flights ($p<0.01$); the unregulated missions included two mass casualty events and one in-flight diversion. CONCLUSIONS: Logistical and clinical treatment differences were identified between unregulated and regulated CCATT missions in Afghanistan. Common treatments provided during the shorter unregulated missions included mechanical ventilation, blood transfusion, and administration of vasopressors, sedation, and analgesia. Although uncommon, CCATTs should be prepared for in-flight diversions and mass casualty events.

6066. Zito, E., et al. (2002). "[Amniotic membrane transplantation in severe corneal epithelial diseases. Preliminary results]." Greffe de membrane amniotique dans les pathologies severes de l'epithelium corneen. **25**(9): 879-888.

PURPOSE: To evaluate amniotic membrane transplantation (AMT) in severe corneal epithelial diseases., METHODS: Amniotic membrane transplantation was performed in 14 eyes of 14 patients from four groups: A, five severe ocular burns; B, four cases of cicatricial keratoconjunctivitis; C, three persistent epithelial defects after penetrating keratoplasty; D, two cases of pseudophakic bullous keratopathy. Five patients underwent AMT alone; two patients underwent AMT combined with limbal transplantation; the other three patients had limbal transplantation performed before AMT. Eight patients required combined penetrating keratoplasty. Patients with corneal stable reepithelialization, no corneal neovascularization, and no recurrence of the initial pathology were considered successful., RESULTS: The mean follow-up was 7+/-3 months. All but three patients underwent corneal reepithelialization within 6 weeks of AMT, with a mean healing time of 31+/-23 days. The success rate was 75% at 6 months (Kaplan-Meier method). Three of four procedures in group B failed. In eight patients, visual acuity improved, in one it worsened, and in the last five patients it remained unchanged. Visual acuity increased by an average of 7+/-9 lines., CONCLUSION: AMT is a useful technique for ocular surface reconstruction, especially in association with limbal transplantation. It could also improve the prognosis of penetrating keratoplasty in patients with severe corneal conditions.

6067. Zivkovic, V., et al. (2019). "Suicidal head impalement with a hydraulic press machine - occupation-related suicide in a psychiatric patient." Forensic science, medicine, and pathology **15**(1): 143-146.

A 63-year-old mechanic, diagnosed with schizophrenia, was found next to a hydraulic press used for removing car wheel bearings. He was in a sitting position, bent towards the machine, with his head placed between the piston and the pressing plate. His flexed left arm was resting on the lever beneath the machine pedestal, and on the right side there was a power switch that was still in the "on" position. His right arm was beside his body, but away from the machine. On the pressing plate, beneath the decedents head, was a piece of bloody cloth. Blood spatters were present on the left

hand and left trouser leg. At autopsy there was a gaping laceration in the right temporal area extending to the right ear lobe, where a piece of helix was missing. This missing tissue was found on the inner surface of the left temporal bone. The temporal lobes and brain-stem were destroyed along the wound trajectory but there were no brain contusions present. There was blood aspiration in both lungs, but all other findings were unremarkable. Death was attributed to the fatal head injury that resulted from the low-velocity penetration of the hydraulic press piston. While the cause of death was self-evident and undoubted, the manner of death required medico-legal investigation. The protective cloth that had been placed on the pressing plate, a medical history of schizophrenia, and the absence of any defensive injuries, all led to the conclusion that this was a case of a rather unusual suicide, which could be regarded as related to the decedents occupation.

6068. Zoltewicz, J. S., et al. (2013). "Biomarkers track damage after graded injury severity in a rat model of penetrating brain injury." Journal of neurotrauma **30**(13): 1161-1169.

The goal of this project was to determine whether biochemical markers of brain damage can be used to diagnose and assess the severity of injury in a rat model of penetrating ballistic-like brain injury (PBBI). To determine the relationship between injury magnitude and biomarker levels, rats underwent three discrete PBBI severity levels defined by the magnitude of the ballistic component of the injury, calibrated to equal 5%, 10%, or 12.5% of total rat brain volume. Cortex, cerebrospinal fluid (CSF), and blood were collected at multiple time points. Levels of three biomarkers (alphaII-spectrin breakdown product [SBDP150], glial fibrillary acidic protein [GFAP], and ubiquitin C-terminal hydrolase-L1 [UCH-L1]), were measured using quantitative immunoblotting and/or enzyme-linked immunosorbent assays. In injured cortex, SBDP150 and GFAP levels were increased significantly over controls. Cortical SBDP150 was elevated at 1 day but not 7 days, and GFAP at 7 days but not 1 day. At their respective time points, mean levels of SBDP150 and GFAP biomarkers in the cortex rose stepwise as injury magnitude increased. In the CSF, increasing severity of PBBI was associated with increasing concentrations of both neuronal and glial biomarkers acutely at 1 day after injury, but no trends were observed at 7 days. In plasma, SBDP150 was elevated at 5 min after 10% PBBI and at 6 h after 12.5% PBBI. UCH-L1 levels in plasma were elevated acutely at 5 min post-injury reflecting injury severity and rapidly decreased within 2 h. Overall, our results support the conclusion that biomarkers are effective indicators of brain damage after PBBI and may also aid in the assessment of injury magnitude.

6069. Zoltewicz, S., et al. (2011). "Biomarkers track injury severity in a rat model of penetrating ballistic brain injury." Journal of neurotrauma **28**(6): A39.

The goal of this project is to determine whether the severity of brain injuries resulting from bullets, shrapnel, or other penetrating objects can be tracked or diagnosed by measuring biomarker levels. We have used a rat model of penetrating ballistic-like brain injury (PBBI) for these studies. To assess the relationship between injury magnitude and biomarker levels, rats were subjected to one of three discreet PBBI severity levels operationally defined by the magnitude of the ballistic component of the injury (calibrated to equal 5%, 10%, or 12.5% of total rat brain volume; n = 5 per group). Brain tissue and cerebrospinal fluid (CSF) were collected from these rats at two time points (1 and 7 days post injury), and levels of two biomarkers (SBDP150 and GFAP; markers of axonal injury and gliosis, respectively) were measured using quantitative immunoblotting and ELISAs. We found that SBDP150 levels were significantly elevated 1 day after PBBI in the brain tissue compared to controls, but not at 7 days. SBDP150 levels in brain at 1 day showed clear stepwise increases as injury severity increased across all three injury magnitudes, although differences did not reach statistical significance at n = 5. In contrast, GFAP levels were observed to increase significantly over controls after 7 days in brain, but not at 1 day. However the increase in GFAP in brain 7 days post-PBBI was not correlated with injury magnitude. Regarding CSF, levels of both SBDP150 and GFAP were significantly elevated 1 day after injury compared to controls, and the level of GFAP correlated to the magnitude of brain injury. Therefore we have two promising biomarkers for early detection of PBBI which show promising changes associated with injury magnitude. Further studies are warranted to increase sample sizes.

6070. Zorman, D., et al. (1990). "Treatment of mandibular fractures by external fixation." Oral surgery, oral medicine, and oral pathology **69**(1): 15-19.

This series encompasses thirteen fractures of the mandible treated by external fixation. The indications were five fractures of edentulous mandible, four fractures through missile wounding, and four fractures without soft tissue

lesion treated in Africa. Twelve patients were found to show good or excellent results. In our indications, this method is a successful approach to the treatment of the fractured jaw.

6071. Zugibe, F. T. and J. T. Costello (1993). "The Iceman murder: one of a series of contract murders." Journal of forensic sciences **38**(6): 1404-1408.

A body with a gunshot wound to the head was discovered in a wooded area in mid September 1983 wrapped with about 20 consecutive layers of plastic garbage bags and rope. Examination of the body revealed a bullet hole in the occipital-parietal region and a peculiar decomposition of the body. Following a forensic reconstruction of our autopsy findings, microscopic studies and other ancillary factors, we concluded that the body had been frozen for about 2 and one-quarter years prior to its being dumped along a mountain road here in Rockland County. The means by which we concluded that the victim had been frozen for about 2 and one-quarter years and other important aspects of this case are fully discussed.

6072. Zuravleff, J. J. and M. H. Johnson (1997). "An ophthalmic surgeon's view of orbital imaging techniques." Seminars in ultrasound, CT, and MR **18**(6): 395-402.

Selection of an orbital imaging technique requires a thorough understanding of pertinent anatomy applied to relevant clinical history and detailed ophthalmic examination. The clinical finding should direct the clinician to the imaging study that provides maximum information and narrows diagnostic considerations for the individual patient. Clinical examples are provided to illustrate the rationale in ordering magnetic resonance images, computed tomography, ocular ultrasound, and color Doppler arteriography of orbital processes.

6073. Zwart, I., et al. (2009). "Umbilical cord blood mesenchymal stromal cells are neuroprotective and promote regeneration in a rat optic tract model." Experimental neurology **216**(2): 439-448.

Exploitation of the ability of stem cells to protect damaged neuronal tissue may be a more viable strategy than cell replacement for repair of the central nervous system (CNS). In this study we assessed the capacity of human umbilical cord blood (hUCB)-derived mesenchymal stromal cells (MSCs) to protect and promote regeneration of axotomised neurons within the rat optic system. The optic tract of neonatal rats was transected at the level of the lateral geniculate nucleus, and MSCs were introduced into the lesion site. MSCs survived well up to 2 weeks after grafting, and did not migrate significantly or differentiate. In the presence of MSC grafts, host axonal processes were found to be present in the lesion site, and there was stimulation of an endogenous neural precursor population. Four weeks after grafting, retrograde tracer experiments demonstrated that grafted MSCs, as well as cells of a human fibroblast line, exerted a neuroprotective effect, rescuing a significant percentage of axotomised retinal ganglion cells (RGCs). Further experiments with retrograde and anterograde tracers strongly indicated that MSCs could also promote re-growth of axotomised RGCs to their target, the superior colliculus (SC). Further analysis showed that hUCB-derived MSCs secreted several immunomodulatory and neurotrophic factors in vitro, including TGFbeta1, CNTF, NT-3 and BDNF, which are likely to play a role in neuroprotection. Our data indicate that hUCB-derived MSCs may be an easily accessible, widely available source of cells that can contribute towards neural repair through rescue and regeneration of injured neurons.

6075. Zwetyenga, N., et al. (2012). "Reconstruction of large mandibular and surrounding soft-tissue defects using distraction with bone transport." International journal of oral and maxillofacial surgery **41**(10): 1215-1222.

Reconstruction of large bone and soft-tissue defects of the inferior third of the face is possible using various surgical techniques. Patients who require these procedures need to be in good general health, may have sequelae linked to donor sites, and require several interventions to achieve good aesthetic and functional results. The aim of this study was to report outcomes in patients with large mandibular and soft-tissue defects treated using osteogenic distraction with bone transport. Between 2001 and 2008, 14 patients had distraction with bone transport. Most patients were men

(92.1%). The mean age was 43.1 years. The average mandibular bone reconstruction was 13.6 cm. The mean duration of distraction was 2.3 months. No infections occurred, and in all cases reconstruction of soft tissues was obtained. Two patients had non-union and underwent reconstruction using an iliac bone graft. Patients with sufficient bone height (57.1%) had dental implants. 44 implants were inserted, two of which were lost. 36 implants were activated. Six patients had satisfactory oral rehabilitation with implant-supported prostheses. Osteogenic distraction with bone transport allows total or partial restoration of oral function, provides an acceptable appearance, and enables patients to resume a reasonable quality of life.

6076. Zyck, S., et al. (2016). "Treatment of Penetrating Nonmissile Traumatic Brain Injury. Case Series and Review of the Literature." World neurosurgery **91**: 297-307.

INTRODUCTION: Penetrating traumatic brain injuries (TBIs), with the exception of gunshot wounds, are relatively rare occurrences and affect all ages. Clinical presentation varies depending on the mechanism of the injury. Prompt surgical treatment is often indicated and is influenced by patient clinical examination, anatomic trajectory, and the penetrating object's size, shape, and velocity., METHODS: We present 3 cases of penetrating TBI. Their similarities and differences affecting operative and medical management are compared. We relate our experience with management of penetrating intracranial foreign bodies in general and discuss the relevant literature., RESULTS: Our first case was a 12-year-old male who presented with a self-inflicted transfacial transcranial injury by a crossbow. The arrow passed through the left sphenoid and cavernous sinus and exited through the parietal calvarium. Our second case was a 37-year-old man with a transoral intracranial stab wound by a knife. In our third case, we present a 46-year-old male who accidentally fired a nail gun into his right ear. The nail traversed the posterior wall of the external auditory canal into the posterior fossa, ending in the cerebellar vermis. Each case was treated with craniotomy and foreign body removal. All resulted in good outcomes after surgical treatment., CONCLUSION: Surgery in penetrating TBI is the treatment of choice. Our cases demonstrate how certain principles applied to individual patient scenarios may optimize clinical results. Severity of the injury and operative approach are among the most important considerations to achieve the best patient outcomes.

Open Abstract
Penetrating traumatic brain injury (pTBI) affects civilian and military populations resulting in significant morbidity, mortality, and healthcare costs. No up-to-date and evidence-based guidelines exist to assist modern medical and surgical management of these complex injuries. A preliminary literature search revealed a need for updated guidelines, supported by the Brain Trauma Foundation. Methodologists experienced in TBI guidelines were recruited to support project development alongside two cochairs and a diverse steering committee. An expert multi-disciplinary workgroup was established and vetted to inform key clinical questions, to perform an evidence review and the development of recommendations relevant to pTBI. The methodological approach for the project was finalized. The development of up-to-date evidence- and consensus-based clinical care guidelines and algorithms for pTBI will provide critical guidance to care providers in the pre-hospital and emergent, medical, and surgical settings.

Keywords: blast injury; guidelines; head trauma; penetrating brain injury; traumatic brain injury

Introduction
Penetrating (pTBI) traumatic brain injury (TBI) is a catastrophic primary wounding mechanism encountered in military and civilian settings and is characterized by the violation of the skull and brain by a foreign body. For those who survive, the constellation of cerebral injuries in the setting of either pTBI or blast-related pTBI creates complex management scenarios for pre-hospital and in-hospital healthcare providers. Recovery and rehabilitation are often protracted and complicated for these patients. Civilian pTBI accounts for an estimated 20,000 deaths in the United States each year with mortality in up to 90% of victims.[1,2] The high lethality of civilian pTBI likely relates to the predominance of missile injury, including gunshot wounds, the absence of protective gear, and the violent circumstances that frequently surround the injury (i.e., attempted suicide, homicide, and other close-range mechanisms). From the military perspective, pTBI was prevalent in recent conflicts in Iraq and Afghanistan and most often results from a blast mechanism. pTBI outcomes in these modern conflicts are better than in past reports,3–10 most likely because of more aggressive clinical care.[6] Before the conflicts in Iraq and Afghanistan, management in those who survived to reach care included limited surgical debridement and wound closure.[11] In contrast, the new military model includes early cranial decompression and prevention of cerebrospinal fluid leak with skull base repair, causes of secondary brain injury are aggressively sought and mitigated (i.e., cerebrovascular injury), and a multidisciplinary approach to cranial reconstruction is used.mpTBI clinical practice guidelines were first published in 2001 by an independent group.12 Topics addressed included antibiotic prophylaxis, antiseizure prophylaxis, management of cerebrospinal fluid leaks, surgical management, vascular complications, intracranial pressure monitoring, and prognosis. The 2001 guideline has not, however, been updated to reflect modern militaryexperiences nor incorporate newer evidence- and consensus-based practices. There are no known published pTBI treatment algorithms informing patientmanagement, despite the tremendous popularity of blunt TBI management algorithms13–15 and despite important changes to medical and surgical care over the past two decades. In response, the Brain Trauma Foundation (BTF) in collaboration with military and civilian TBI experts in the field, and with funding from the American Department of Defense (US ArmyMedical Research and Acquisition Command, BA200139: The Development of Best Practice Penetrating TBI Guidelines for Military and Civilian Patients) will generate an updated, evidence- and consensus-based pTBI clinicalpractice guideline and new care algorithms. The BTF has published numerous clinical practice guidelines for TBI care over the past quarter century[16,17] and is undertaking this update with permission from the original pTBI guideline authors.

Methods
Key definitions
For this work, pTBI will be defined as a head injury with violation of, at minimum, the skull and likely dura and brain by a foreign body (Table 1). Linear non-displaced skull fractures alone, which result from a relevant wounding mechanism, will not be included. pTBI encompasses penetrating, tangential, and perforating injuries. pTBI has previously been subclassified as high-velocity missile, low-velocity missile, and non-missile injuries. However, because of the practical difficulty distinguishing high- and low-velocity missile injuries clinically, we will instead subclassify pTBI mechanistically as: 1) missile injuries (e.g., gunshot wounds); 2) blast fragment injuries (i.e., type II blast injury—blast overpressure plus fragment injury); and 3) low-velocity injuries (e.g., knives). Our working group ratified the latter classification scheme with a blinded consensus vote. Development of an expert workgroup BTF leadership, alongside civilian and military clinicians with topical expertise in pTBI, comprise the pTBI Expert Workgroup. The workgroup and its efforts are led by two co-chairs with guidance and governance provided by a core multi-disciplinary steering committee. Workgroup members were selected for diversity among disciplinary expertise relevant to the management of TBI,

scientific expertise, and demographic and geographical, representation. Represented medical disciplines include neurosurgery, plastic surgery, neurology, general/trauma surgery, orthopedic surgery, ENT (ear, nose, and throat) surgery as well as emergency medicine, physical medicine, pediatrics, pre-hospital care, and rehabilitation. A military medic and a patient (service member recovered from a pTBI) are included. Sex and ethnic diversity was also specifically sought.

Systematic review

Topic identification and refinement. Workgroup members were divided into three areas of clinical focus: pre-hospital and emergent management; surgical management; and medical management, led by A.L.B., B.A., and J.G., respectively. Each workgroup will update the topics included in the 2001 guidelines and will develop clinically relevant key questions as well as inclusion and exclusioncriteria using the Population, Interventions, Comparators, Outcomes, Timing, Setting and Study design (PICOTS) framework. The present effort will endeavor to only inform aspects of care in which pTBI care would be distinct from, orotherwise insufficiently informed by, the ‘‘umbrella’’ recommendations found in the fourth edition of the Severe Traumatic Brain Injury Guidelines, which largely focus on blunt head injury. Generated recommendations aim to be relevant to all patients with pTBI.However, evidence supporting distinct recommendations for key patient subgroups will be reported and may include differentiation by wounding mechanism (missile, blast fragment, or lowvelocity injuries), military versus civilian victims, and adult versus pediatric victims.

Literature search. We will search Ovid MEDLINE, EMBASE, and Cochrane CENTRAL without date limits. The search strategy will be developed and executed by a specialized medical research librarian with experience in systematic reviews with peer review by a second librarian. Study selection. Review of abstracts and full-text articles will be informed by pre-specified PICOTS and corresponding inclusion and exclusion criteria. All abstracts identified by the literature search will be assessed by one reviewer and excluded abstracts confirmed by a second reviewer. Independent, dual review of the full text of any potentially relevant article identified at abstract level will be conducted. Disagreements will be resolved by consensus or with the addition of a third reviewer. Included and excluded articles, and reasons for exclusion, at the full-text level will be provided to the Guideline Panel for review and will be included as an appendix in the full Evidence report. Studies meeting inclusion criteria will be in children, adolescents, and/or adults with traumatic injuries that violate the skull and that provide evidence for a key question. Included outcomes of intervention studies consist of mortality, morbidity, function, and selected intermediate outcomes (Table 2). We will not exclude studies based on sample size, location of study, or baseline Glasgow Coma Scale score. Data abstraction and risk ofbias assessment. We will abstract data from all studies that include population characteristics (e.g., age, sex, wounding mechanism, and military/civilian status), intervention and comparator characteristics (e.g., methods of resuscitation, prophylactic drug and dose, and type of surgery performed),

Table 1. Key Definitions

_ Penetrating traumatic brain injury (pTBI): a head injury with violation of, at minimum, the skull and likely dura and brain by a foreign body. Linear non-displaced skull fractures alone will NOT be included.

_ pTBI encompasses penetrating, tangential, and perforating injuries as follows:

- Penetrating: a foreign object penetrates skull and dura and remains within the skull. This wounding mechanism lacks an exit wound.
- Tangential: a foreign object glances off the skull, which often drives skull fracture fragments into the brain.
- Perforating: a ‘‘through-and through’’ injury, characterized by entry and exit wounds.

Of these three, perforating brain injuries are associated with a worse outcome.

_ pTBI will be subclassified as:

- Missile injuries (such as gunshot wounds)
- Blast fragment injuries (such as type II blast injury—blast overpressure plus fragment injury)
- Low-velocity injuries (such as knives) numbers enrolled and analyzed, relevant outcomes (i.e., mortality, neurological function, selected morbidities, and cost), and funding source.

All included studies will be assessed for risk of bias using criteria specific for the type of study design. Randomized trials will be assessed for risk of bias based on the randomization process, method for allocation concealment, similarity of baseline characteristics, blinding, missing data overall and differences between groups, whether intent-to-treat analysis was used, and possible reporting bias. Assessment of non-randomized studies with a comparison group will include selection of participants, whether differences in prognostic factors between groups were present, missing data, prespecification of outcomes, whether ascertainment of outcomes was unbiased, and adjustment for potential confounding.

Assessment of single-group trials will include selection of participants, pre-specification of outcomes, whether ascertainment of outcomes was unbiased, and assessment of missing data. Case series and case reports are studies with high risk of bias and will not be individually assessed. Study risk of bias will be assessed by two independent reviewers. Data synthesis and quality of the body of evidence. When there is more than one study of an intervention, data will be synthesized quantitatively if a meta-analysis is appropriate (i.e., when studies are clinically homogeneous enough to provide meaningful combined estimates). When statistical heterogeneity is present in a pooled analysis, we will explore the reasons for this using stratified analysis and sensitivity analysis, as appropriate. We will also consider the potential effects of various participant subgroups (e.g., based on demographic characteristics, severity of injury, and injury mechanism) on intervention effects. When data cannot be pooled, we will provide a qualitative summary and analysis of findings.

Table 2. Inclusion/Exclusion Criteria for Source Literature

PICOTS Inclusion / Exclusion Populations
All ages
Penetrating brain injury including blast, tangential, and perforating injury from missiles, blast fragments, or low velocity
_ All baseline GCS levels
_ Mixed types of brain injury with at least 85% penetrating if results not reported individually
_ Non-human studies
_ Injury limited to linear, non-displaced skull fracture or isolated face/neck injuries
_ Mixed types of brain injury and results not presented by injury type or <85% penetrating injury
Interventions Pre-hospital, prolonged field care, transport, ED, and trauma center evaluation:
_ Initial resuscitation and prevention/mitigation of secondary injury
_ On-scene wound management
_ Cervical spine immobilization
Surgical management:
_ Prevention and treatment of cerebrospinal fluid leaks
_ Vascular injuries
_ Foreign body removal and prerequisites
_ Cranial decompression
Medical management:
_ Intracranial pressure monitoring (if distinct from fourth edition)
_ Intracranial pressure treatment (hyperosmolar therapy, lumbar drainage,
CPP management including BP thresholds, ventilation therapies)
_ Seizure prophylaxis
_ Antibiotic prophylaxis
_ DVT prophylaxis
_ Chemoprophylaxis for stroke prevention
Comparators Placebo, no intervention, active control, waitlist control, delayed treatment,
head-to-head studies
None
Outcomes _ Mortality
_ Neurological function
_ Selected morbidity
_ Cost
_ Satisfaction
_ Quality of life
_ Sleep
Timing Outcomes up to 1 year post-injury Outcomes >1 year post-injury
Setting Pre-hospital, trauma center, medical, surgical setting in all countries.
Battlefield and mass causality as well as civilian
_ Rehabilitation setting
Study designs _ All experimental study designs, observational studies including case series and case report
_ Epidemiological studies for salvageability
_ Current, well-conducted systematic reviews (may also use systematic
reviews to identify studies searches may have missed)
_ Abstracts, comments letters

_ Non-English language
_ Narrative reviews
_ Systematic reviews not meeting inclusion
Criteria: BP, blood pressure; CPP, cerebral perfusion pressure; DVT, deep vein thrombosis; GCS, Glasgow Coma Scale.

We will assess the quality of the body of evidence by outcome using the GRADE (Grading of Recommendations Assessment, Development and Evaluation) approach with the following criteria: risk of bias of included studies,

, consistency of effect, precision of the estimate, directness of the evidence, and potential publication bias.[9] The quality of the body of evidence will be rated high, moderate, low, and very low. As an example, the highest-quality evidence (rated high) would come from multiple, well conducted randomized trials with consistent findings, a precise pooled estimate of effect of the intervention on an included outcome, and be absent other bias. The lowest-quality evidence (rated very low) would come from expert opinion in the absence of any study data. We will generate a summary of findings table that includes ratings for quality of the body of evidence.

Development of recommendations.

The development of recommendations is the next step after the evidence has been identified and synthesized and rated for risk of bias. Evidence-based recommendations are based on the quality of the body of evidence, applicability, and generalizability. For topics where there is little or no research, recommendations may be developed using rigorous Delphi consensus methodology. Recommendations will be assigned a level based on the quality of the body of evidence. We will recognize five levels of recommendation based on the quality of the body of evidence:

_ Level I recommendations are based on high quality of the body of evidence.
_ Level II recommendations are based on moderate quality of the body of evidence.
_ Level III recommendations are based on low quality of the body of evidence.
_ Level IV recommendations are based on very low quality of the body of evidence.
_ Level C: recommendations based on consensus in the absence of research evidence.

Delphi process for consensus

Blinded consensus voting will be conducted to establish consensus for key aspects of the project. This will be particularly important for consensus-based algorithm development. A vote of 80% will be required to declare consensus as having been achieved where at least 80% of the panel participates in the vote. This is the same threshold used for consensus in the recent Seattle International Severe Traumatic Brain Injury Consensus Conference (SIBICC) effort.[14,18] A week-long in-person meeting will be held 18 months into the 2-year project to finalize the recommendations and algorithm. A private company will facilitate electronic, blinded voting at this meeting to enable the Delphi methodology.

Discussion

Benefit from guideline and treatment algorithms

Clinical practice guidelines evaluate and consolidate available literature into evidence-based recommendations designed to inform best care. Guidelines for the management of TBI created by the BTF were the first surgical clinical practice guidelines published,[16] and their implementation has been credited with an*50% reduction in mortality.[19,20] Because of their demonstrated benefit, compliance with the BTF guidelines is mandated for U.S. trauma centers to maintain trauma accreditation. Because of the success of the BTF guidelines and their demonstrated benefit, multiple editions of the BTF adult guidelines have been published,[15,16,21,22] and TBI guidelines have been developed for numerous additional topics, including pediatrics,[23] combat, pre-hospital care,[24] and prognosis.[25] The BTF's infrastructure has been key for disseminating and updating these important documents, with the most recent fourth edition TBI guidelines largely addressing closed head injury published in 2017.[22]

Algorithms for care bridge published evidence and its gaps with the realities of practice. Such care pathways were included with the first and second editions of the BTF adult guidelines, and they were the most popular aspect of these documents. These algorithms are inherently and necessarily consensus based, and

Table 3. Proposed Topics for pTBI Evidence-Based Guidelines

Overview: definitions, scope, and methodology
Pre-hospital
_ Pre-hospital/emergent and prolonged field care, transport, and initial evaluation

_ Prognosis and outcome predictiona
_ Antibiotic prophylaxis: indications and agents
_ Invasive and non-invasive neuroimaging: role, timing, and techniques
Surgical
_ Indications, timing, and techniques for surgical management
_ Vascular injuries: screening and managementa
_ Prerequisites for foreign body removal
_ Cerebrospinal fluid leaks: prevention, diagnosis, and management Critical care

_ Delayed vascular complications: screening and management including chemoprophylaxis for stroke preventiona
_ Seizure prophylaxis: indications and agents
_ Intracranial pressure monitoring
A denotes a new topic NOT previously included in published guidelines.[12]

pTBI, penetrating traumatic brain injury.
their construction requires methodologies distinct from those for developing evidence-based clinical practice guidelines. To address the gap between evidence-based recommendations and patient care for severe blunt TBI patients, the SIBICC was recently convened, which led to two well-received and high-impact publications. [13–16, 26] In contrast, no such algorithms for the management of penetrating and blast-penetrating TBI have ever been published.

Penetrating traumatic brain injury guidelines
Guidelines for the management of pTBI were last published in the Journal of Trauma more than two decades ago[12, 27–33] and, of course, do not reflect important subsequent advances in the literature and clinical standards of care (see Literature Search below).[34] The combination of outdated pTBI guidelines and nonexistent treatment algorithms may negatively impact morbidity and mortality because of the lack of consolidated clinician guidance on best practices for the medical and surgical care of pTBI. Because BTF did not lead the 2001 guideline, the organization sought permission to update the pTBI guidelines from the leadership of the original effortand this was granted.

New penetrating traumatic brain injury literature
To estimate the volume of new studies to be screened and assist resource planning, a preliminary literature search was conducted (on April 8, 2020), using PubMed (https://www.ncbi.nlm.nih.gov/pubmed) and the basic search term ‘‘penetrating brain injury.’’ A total of 968 references were identified when limiting the search criteria to publication dates between January 1, 1933 andDecember 31, 2001. This search time frame includes the references that formed the foundation of the existing and outdated pTBI guidelines referenced above and specifically includes all periods of armed conflict from World War II to 2001.When using the same search term and limiting publication dates from January 1, 2002 to the present, 2413 candidate references were identified. This suggests that the overwhelming majority of the existing information on pTBI has been published after the last guidelines were generated in 2001 and, in large part, reflect the experiences and care provided during the conflicts in Iraq and Afghanistan. This affirms the strong need fo updated pTBI guidelines.

Contrasting civilian and military experiences
Although pTBI is problematic in both civilian and military populations, military neurosurgeons garner more experience managing these patients than most civilian neurosurgeons. Consequently, the military experience has led to important paradigm shifts in pTBI management over time. Such an important early advance for pTBI came from the Vietnam War. In the early days of the Vietnam War,neurosurgeons performed aggressive debridement of intracranial foreign bodies in an effort to prevent infection.[35–38] A paradigm shift emanated from this conflict because it was judged that the neurological damage resulting from this aggressive debridement di more harm than good. As a result, to this day neurosurgeons typically leave inaccessible fragments behind at the time of an initial craniotomy, retrieving them later only if they should become infected. The most recent conflicts in the Middle East have seen thelongest period of sustained conflict in America’s history. A return to more aggressive surgical and clinical approaches have seen outcomes in service members improve, beyond those typical of civilians despite more severe wounding mechanisms.[39] The modern military paradigm involves early cranial decompression, prevention of cerebrospinal fluid leak with skull base repair, and aggressive efforts to mitigate secondary insults. One important study supporting this new approach involved wounded American soldiers from 2003 to 2008.[4] Of the 408 head injuries studied, 228 were penetrating, with >80% resulting from primary and secondary blast injury. Of those who survived their initial trauma, field resuscitation, and transport to Walter Reed National Military Medical Center for definitive care, 154 received emergent decompressive craniectomy.

A remarkably high proportion of these persons survived with good clinical outcomes.[4] Increased attention to neurovascular injuries and vasospasms related to blast exposure has also been central to this new paradigm.[39–41] These advances in military pTBI care are the central impetus for updating the pTBI guidelines.

Blast as a factor complicating penetrating brain injury

The recent conflicts in Iraq and Afghanistan have created renewed interest in blast as a mechanism of TBI. The Centers for Disease Control and Prevention (CDC) has defined blast injuries as ''.characterized by the anatomic or physiologic changes from the direct or reflective over-pressurization force impacting the body's surface.''[42] Blast injuries are subdivided into four submechanisms: impact of body surfaces with the overpressure wave (primary blast injury); penetrating injury resulting from fragments propelled by blast (secondary blast injury); results of persons propelled or thrown by the blast wind (tertiary blast injury); and all explosion-related injuries (e.g., burns, crush injury, and quaternary blast injury). Given the importance of blast injury accompanying pTBI in the military, we have decided to include an analysis of such patients in this project. Given the risk of vasospasm inherent to blast-related pTBI, this patient subgroup mandates consideration of distinct management.[35]

Conclusion

A methodologically rigorous BTF effort, funded by the U.S. Department of Defense, is underway to update 2001 recommendations for the clinical care of pTBI. The vetted, multi-disciplinary workgroup will also develop the first treatment algorithms for pTBI to bridge gaps in published evidence with the practicalities of patient care.[17] Future work will strategize and examine dissemination and implementation of the finalized guideline and algorithm to assess impact.
